The attributable risk of HTLV-1 as a cause of leukemia/lymphoma is highest in the forties to fifties and thereafter declines. In Jamaica and Trinidad, over 70% of all lymphoid malignancies are attributable to HTLV-1 exposure.[117,135] In some instances, ATL occurs in the pediatric age group, with patients as young as 5 and 6 years of age reported, but these instances are extremely rare.[137] The lifetime risk of developing ATL among healthy carriers is approximately 1–5%, but this figure might underestimate the attack rate for those infected early in life. In comprehensive studies conducted over an 8-year period in Jamaica and Trinidad, all cases of non-Hodgkin's lymphoma (NHL) in the population were ascertained and blood collected for HTLV-1 determination. The world age-standardized NHL incidence rate in Jamaica was 1.9 ± 0.2 per 100,000 py and in Trinidad was 2.9 ± 0.4 per 100,000 py. Overall, the incidence of NHL increased with age and was higher in males than in females. In the HTLV-1-infected population, NHL incidence was inversely related to age, and age-specific rates were higher in males than in females. However, NHL incidence in those estimated to have acquired HTLV-1 infection in childhood showed no sex difference, and 1 in 1300 such carriers (95% CI, 1 in 1100

to 1 in 1600) per annum were estimated to be at such risk (Fig. 22-5). For T-cell NHL, as proxy for ATL, incidence was highest in those who were infected with HTLV-1 early in life (perinatally or via breast milk), with a high sustained risk from early adulthood in both sexes. Thus, while overall NHL incidence rates reveal that HTLV-1 endemicity does not impose an exaggerated lymphoma burden on these populations, the risk for lymphoma among carriers who acquire infection early in life is dramatic and consistent with the hypothesis that virus exposure early in life is critical for lymphomagenesis.[117]

ATL subtypes

Four major categories of ATL have been characterized: acute or prototypical type, lymphoma type, chronic type, and smoldering type[129] (Fig. 22-5). A feature of the natural history of this disease is for the more benign types, smoldering and chronic types to evolve into the more aggressive types. Acute ATL is an aggressive mature T-cell lymphoma with frequent leukemic involvement (80% of cases) with characteristic pleomorphic polylobulated cells, hypercalcemia (50% of cases), and cutaneous involvement (40% of cases ranging from maculopapular rashes to tumorous lesions). Organ and extranodal involvement is common. Lymphoma-type ATL shares many features with acute ATL, but it is distinguishable by the absence of peripheral leukemic involvement. Both acute and lymphoma types have the most aggressive clinical course and poor prognosis. Chronic ATL presents as T-cell chronic lymphocytic leukemia, and a substantial proportion of patients have cutaneous involvement; nodal or extranodal involvement is rare, and hypercalcemia is absent. Smoldering ATL resembles mycosis fungoides/Sézary syndrome, with cutaneous involvement presenting as erythema or as infiltrative plaques or tumors, and Pautrier's microabscesses may be

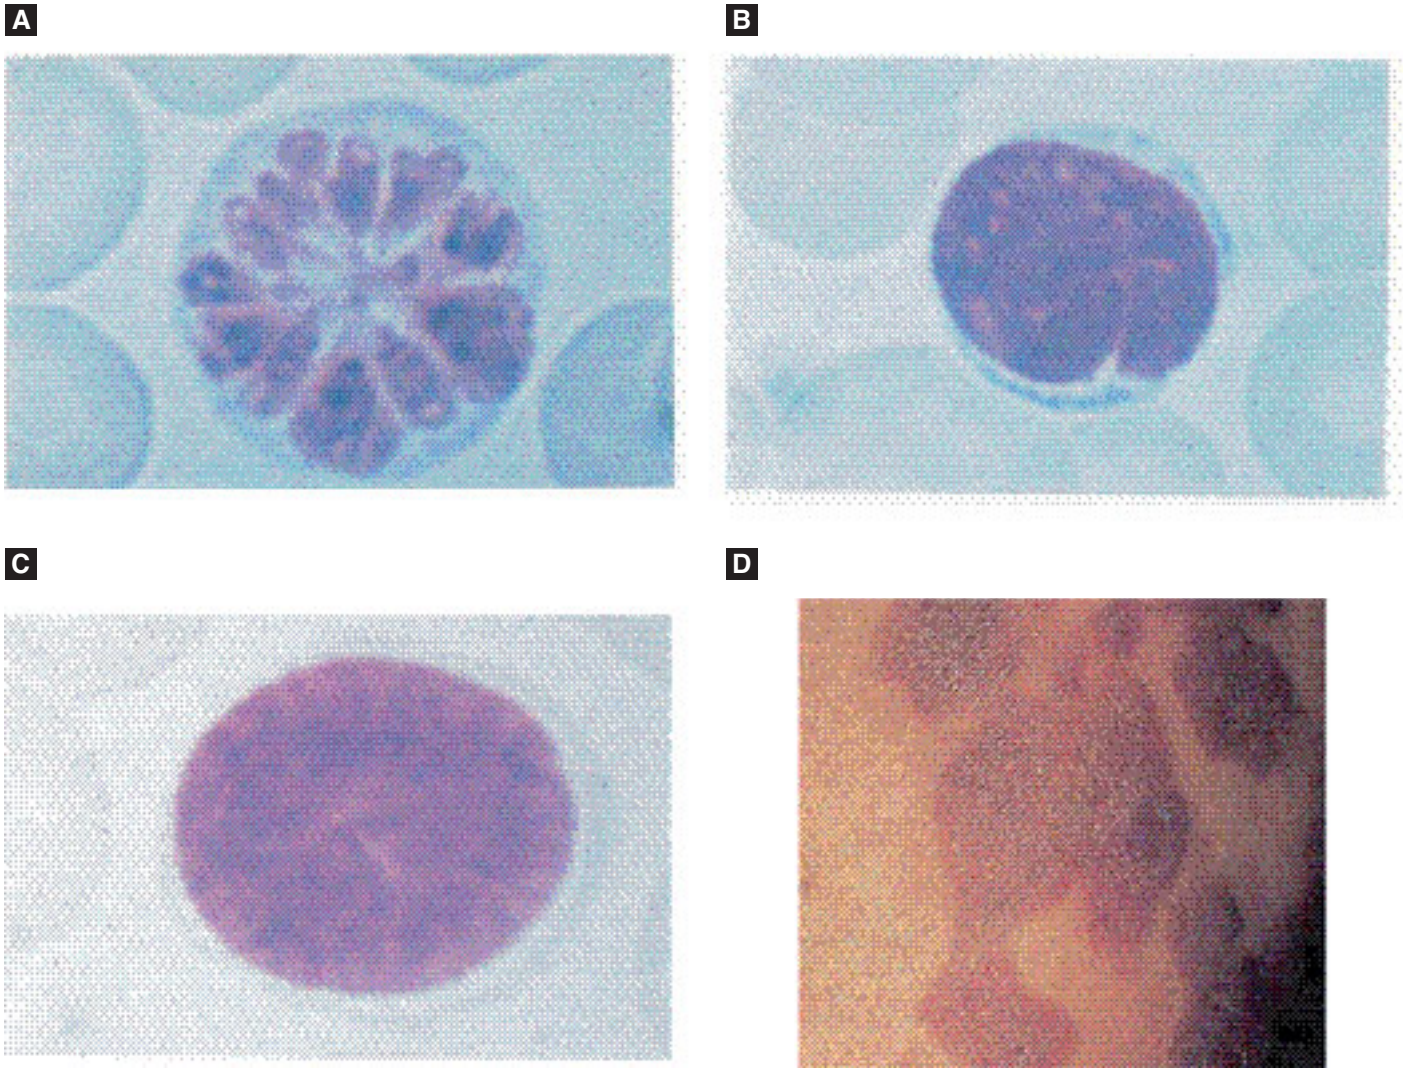

FIGURE 22-5. Features of adult T-cell leukemia: **A.** "flower cell" from acute ATL; **B.** buttock cell from chronic ATL; **C.** typical cell from smoldering ATL; **D.** cutaneous involvement details of the features are discussed in text. (With permission from Yamaguchi K, Kiyokawa T, Futami G, et al. Pathogenesis of adult T-cell leukemia from clinical pathologic features. In: Blattner WA, ed. *Human Retrovirology: HTLV*. Philadelphia, PA: Lippincott-Raven, 1990, p. 163.)

observed. Chronic and smoldering forms have a better prognosis than acute and lymphoma type. The distribution of clinical subtypes appears to vary by geography with acute forms more prominent in Japan than in Jamaica where the lymphoma type is more frequent.[136]

Pathogenesis

The etiology of ATL is well established by the virtually universal association of HTLV-1, either in the context of positive HTLV-1 antibodies in the vast majority of cases and the finding of monoclonally integrated HTLV-1 or, in some cases, defective virus that always includes viral genes critical for transformation, notably the HTLV *tax* gene whose integration sites vary markedly between individuals.[138,139] As summarized above, HTLV Tax has pleotrophic effects that along with some accessory genes have powerful impacts on fundamental cellular gene control mechanisms that contribute to malignant transformation.[140] However, by the time the multistage process involved in malignant transformation is complete, the *tax* genes of HTLV-1 are fully silenced as mutagenic mutations of the cell promoted by Tax become constitutively expressed and host-immune responses to Tax are made irrelevant to host-tumor responses.[141] Over the course of HTLV-1 infection leading to malignancy, Tax interacts with numerous cellular proteins to reprogram cellular processes to alter transcription, cell-cycle regulation, DNA repair, and apoptosis, resulting in proliferation of cells that increasingly accumulate carcinogenic mutations.[142] Among its targets, Tat upregulates CREB, NF-κB, and SRF signaling pathways, transactivates by *cis*-acting mechanisms cellular promoters including those of cytokines (IL-13, IL-15), cytokine receptors (IL-2R-α), and costimulatory surface receptors (OX40/OX40 L) leading to upregulated protein expression and activated signaling cascades (e.g., Jak/STAT, PI3Kinase, JNK), and stimulates cell growth by direct binding to cyclin-dependent kinase holenzymes and/or inactivating tumor suppressors such as p53 and DLG.[143–146] Tax also silences cellular checkpoints such as checkpoint kinase 2 (Chk2) that coordinate cell-cycle progression with DNA repair and cell survival or death which in turn guard against DNA structural damage and chromosomal missegregation. By inactivating these processes, cells with potential carcinogenic mutations survive, they do not undergo cell death, and they allow leukemia to emerge in a portion of HTLV-1 carriers.[147] Additionally, host genetic factors are implicated in the findings that show that HLA-A*26, -B*4002, -B*4006, and -B*4801 alleles predispose to ATL because of the limited recognition of HTLV-1 Tax peptide anchor motifs and epitopes capable of generating anti-HTLV-1 Tax $CD8^+$ cytotoxic T-lymphocytes (CTLs), thus predisposing such individuals to persistent and poorly regulated HTLV infection.[148] Thus as summarized in Fig. 22-6, Tax exerts pleotropic effects on cell growth by promoting uncontrolled cell growth, abrogating DNA repair mechanisms, and preventing cell-cycle arrest and apoptosis in promoting the development of the malignant T-cell phenotype.[140] Additionally, the gene products of the ORF I and II impact other cellular functions that promote cell growth and may also promote the carcinogenic process.

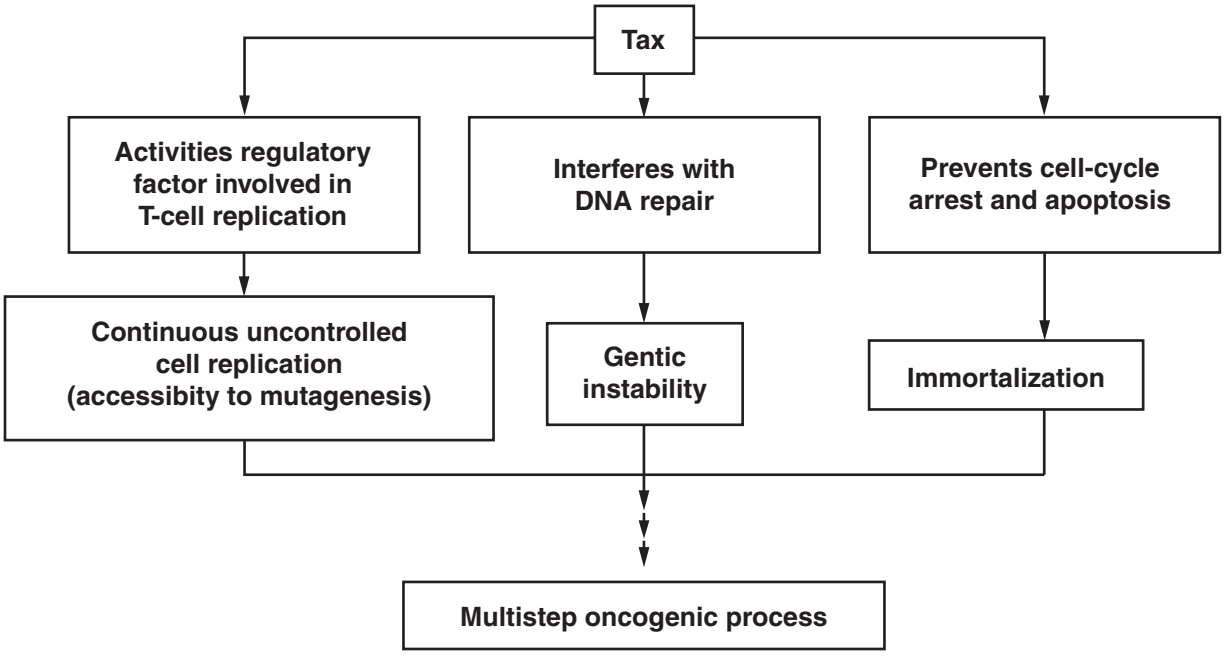

FIGURE 22-6. The role of Tax in ATL pathogenesis involves multiple pathways of cellular dysregulation and oncogenic mutation as detailed in the text. (With permission from Azran I, Schavinsky-Khrapunsky Y, Aboud M. Role of Tax protein in human T-cell leukemia virus type-I leukemogenicity. *Retrovirology* 2004; 1: 20.)

Prognosis

The prognosis of patients with acute and lymphoma-type ATL is poor.[149] Most patients with the acute and lymphoma types die within 6 months of diagnosis (Fig. 22-7[150]). Significant prognostic factors include poor performance status at diagnosis, age over 40, extensive disease, hypercalcemia, and high serum LDH level.[58] Death usually results from rapid growth of tumor cells, hypercalcemia, bacterial sepsis, opportunistic infections such as *Pneumocystis carinii* pneumonia, and other infectious complications seen in patients with lymphoma-associated immunodeficiency. In Jamaica and Trinidad, a major cause of death is bacterial sepsis.[134] Smoldering ATL has a relatively good prognosis with a 70% 5-year survival. The chronic subtype has a 20% 5-year survival that while dismal is better than the 5% 5-year survival observed in acute and lymphoma types.

Treatment

ATL carries a very poor prognosis because of the resistance of leukemic cells to conventional chemotherapy. With a 70% 5-year survival, many hematologists recommend watchful waiting in the case of smoldering and chronic ATL, although treatment with prednisone with or without cyclophosphamide is sometimes used. Treatment with aggressive therapy for these forms is associated with high rates of complicating infections resulting from the damaging effects of therapy on the bone marrow. The acute and lymphoma types of ATL are aggressive high-grade lymphomas with a generally poor prognosis, although some cases do respond with prolonged remission to multidrug regimens.[61,151,152] In Japan, large trials of vincristine, cyclophosphamide, prednisolone, and doxorubicin (VEPA) or VEPA-M (adding methotrexate) as well as more complex 9- and 10-drug regimens have shown some success but poor long-term survival.[152,153] While initial response rates, even for the poorest risk categories, are over 50% and complete remissions are achieved in 20%, these responses can be short-lived, with relapses occurring in weeks to months often involving the central nervous system.[152] Recent reports suggest a therapeutic role for allogeneic hematopoietic stem cell transplantation (allo-HSCT) for patients with ATL. An analysis of 40 patients receiving allo-HSCT for aggressive ATL cases in Japan reported that all evaluable cases entered complete remission with median survival time at 9.6 months for all patients. The estimated 3-year overall survival was 45.3%, relapse-free survival 33.8%, and disease relapse 39.3%. While not statistically significant among 10 who relapsed, 5 cases achieved a second complete remission including 3 by reduction or cessation of immunosuppression, suggesting a graft-versus-ATL effect.[154] Another approach that requires systematic evaluation builds on the observation that some patients respond to a combination of zidovudine and IFN-α, which induces a high rate of complete remission and lengthens survival when used in combination with conventional cytoreductive therapy.[155] A recent study of arsenic trioxide demonstrated responses in patients failing prior chemotherapy but involved high levels of toxicity.[156] Newer agents such as proteasome inhibitors, retinoids, and angiogenesis inhibitors, as well as cellular immunotherapy, are also being evaluated.[157]

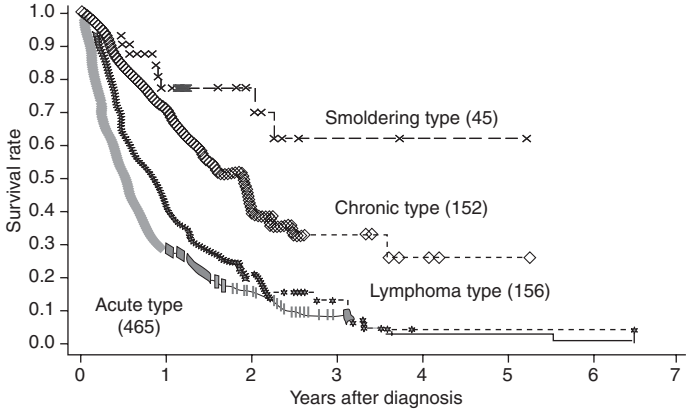

FIGURE 22-7. Survival patterns of different ATL subtypes after polychemotherapy. Acute and lymphoma-type ATL have the poorest prognosis after chemotherapy (see text). (With permission from Tsukasaki K, Ikeda S, Murata K, et al. Characteristics of chemotherapy-induced clinical remission in long survivors with aggressive adult T-cell leukemia/lymphoma. *Leuk Res* 1993; 17: 157–166.)

NEUROLOGIC DISEASE

A neurologic syndrome called HAM/TSP is etiologically linked to HTLV-1.[127] The syndrome results from demyelination of the long motor neurons of the spinal cord causing a variety of symptoms, sometimes acutely, including stiff gait, spasticity, lower extremity weakness, back pain, urinary incontinence and impotence, and rarely ataxia. Lesions of the central nervous system are detected in some cases. Transfusion transmission of HTLV-1 has been associated with dramatic examples of acutely progressive neurologic symptoms; in Japan, blood transfusion is a significant risk factor for HAM/TSP.[158] It is estimated that disease incidence among carriers is approximately half that of ATL.[159] Females are approximately two times more likely to develop HAM/TSP; in Jamaican cases, sexual transmission is a documented risk factor.[160] The majority of adult cases occur in the 30–50-year age group, but pediatric cases as young as 3 years of age do occur. These patterns suggest that the latency period for HAM/TSP is shorter than that for ATL and both early-life and adult exposures cause disease.

Pathogenesis

The pathogenesis of HAM/TSP results from a complex interaction of defective host-immune responses that fail to control viral overproduction despite very high levels of cytotoxic

T cells, an imbalance in the T-helper response, immunogenetic factors that signal increased susceptibility to disease, and recently identified molecular mimics of viral proteins to neurocellular structures. Following HTLV infection, CTLs that target viral antigens play an essential role in the regulation of viral expression and control[161] as seen by the fact that up to 1% of all $CD8^+$ CTL among carriers recognize at least one epitope of HTLV.[162–167] In the case of the healthy carrier, there appears to be a dynamic equilibrium between viral replication and immune CTL responses that target Tax expressed by infected CD4 target cells.[165–168] As a consequence of ongoing Tax proliferation, there is a cell-associated expansion of HTLV-1 genome-containing $CD4^+$ cells and a compensatory expansion of $CD8^+$ CTL. As the number of $CD4^+$ cells containing the HTLV-1 genome expands, HTLV-1 antigens are expressed on the cell surface and become targets for CD8-mediated cytotoxic killing, maintaining this equilibrium. In the case of HAM/TSP, there is an imbalance in immune response manifested by an overexpression of Tax, high numbers of Tax-specific CTL, and excessive elevations in viral load, reflecting an aberrant immune response. Recent studies have started to unravel the pathogenic basis of this response. For example, CXCL10/IP-10, a T-cell type 1 (Th1)-associated chemokine, is significantly elevated in the CSF of HAM/TSP patients compared with controls, and exceeding levels noted in multiple sclerosis where this chemokine has been shown to be elevated, in which CXCL10/IP-10 upregulation was previously reported.[169] Similarly, cytokine signaling molecules, including transcription factors T-bet and GATA-3, IL-12R-β2 and suppressors of cytokine signaling (SOCS), such as SOCS1, all markers of Th1 signaling, are significantly increased in HAM/TSP patients in comparison with HTLV-I-uninfected individuals; while SOCS3, a marker for Th2 cells, decreased in HTLV-I-infected individuals, pointing to an imbalance in Th1 immunity in HAM/TSP.[170] Immunogenetic factors play an important role as noted by the finding that the class I allele HLA-A*02 halves the odds of HAM/TSP and is associated with proviral load one-third that of HLA-A*02(-) HTLV-I carriers. Additionally, HLA-DRB1*0101 doubled the odds of HAM/TSP in the absence of the protective effect of HLA-A*02.[171] These data are consistent with the hypothesis that deficient immune recognition of Tax epitopes blunts a robust cell-mediated immune response, resulting in elevated HTLV viral load associated with HAM/TSP.[166,172–174] Additionally, $CD4^+$ lymphocytes from HAM/TSP patients express HTLV-I protein significantly more readily than lymphocytes from asymptomatic carriers of similar HTLV-1 proviral load high rate, a finding that—when coupled with prior observations of overexpression of Tax and low efficiency of CD8-mediated cytotoxic T-cell responses—supports a mechanisms of immune-mediated pathogenesis.[175] Employing a novel antibody that specifically recognizes Tax11–19 peptide-HLA-A*201 complexes, the level of Tax11–19-HLA-A*201 expression on $CD4^+$ $CD25^+$ T cells, the major reservoir of HTLV-I provirus, was demonstrated to be increased in HAM/TSP and correlated with HTLV-I proviral DNA load, HTLV-I tax mRNA load, and HTLV-I Tax-specific $CD8^+$ T-cell frequencies. Such $CD4^+$ $CD25^+$ T-cell subsets stimulate and expand HTLV-I Tax-specific $CD8^+$ T cells, which may play an important role in the pathogenesis of HTLV-I-associated neurological disease.[176] A viral component to this effect is suggested by recent phylogenetic data showing a higher incidence of 1 *tax* subgroup (*tax*A) in HAM/TSP than *tax*B subgroup.[177] Additional data point to an indirect mechanism of pathogenesis whereby HTLV-1 induces an autoimmune process through molecular mimicry between a viral and cellular antigen and/or through indirect cytopathic effects of infiltrating virus-negative CD8 cells in the central nervous system milieu.[178] This hypothesis is supported by the finding that HAM/TSP patients make antibodies to heterogeneous nuclear ribonuclear protein A1 (hnRNP A1), a neuron-specific autoantigen.[179] Monoclonal antibodies to Tax cross-reacted with hnRNP A1, indicating molecular mimicry between the two proteins and providing a pathogenic basis for autoimmune neurologic disease.[180] Additionally, the finding that there are oligoclonal immunoglobulin bands in the CSF of HAM/TSP patients that react to HTLV-1 antigens supports this hypothesis.[166]

Treatment

The mainstay of HAM/TSP treatment has been corticosteroids, which are reported in open-label trials to reduce symptoms in approximately 40% of cases, especially in the context of early disease or those with rapid progression.[181,182] Cyclophosphamide[182] has also shown benefit in some patients. More recently, a number of therapies have emerged that target some of the pathogenic pathways of HTLV infection that are known to be imbalanced in the context of HAM/TSP. One example is Pentoxifylline (PTX), a phosphodiesterase inhibitor that has been shown to decrease TNF-α levels and to downregulate neutrophil activation, likely because of increases in intracellular cyclic AMP. In 13 of the 15 patients studied, motor disability, especially spasticity, improved substantially. PTX suppressed spontaneous proliferation of peripheral blood mononuclear cells in 14 of the 15 patients at 4 weeks.[183] In another study, the mechanism of PTX upregulation of IL-4 and IL-10 in both sera and CSF were associated with clinical improvement in six patients. IFN-γ levels in the sera were decreased but not correlated with clinical improvement. These data suggest that correction of the overrepresentation of the Th1 cytokine response may impact clinical symptoms.[184] In a small open-label study, long-term, high-dose IFN-α therapy administered at a dose of $6 \times 10(6)$ international units daily for 2 weeks and thereafter three times a week for 22 weeks showed that five of seven patients experienced sustained improvement in motor

performance during and up to 6 months after the completion of IFN-α. Another responder developed depression and another deteriorated and thereafter dropped out. Viral load declined in the responders, and autoproliferation of $CD4^+$ T cells even after the cessation of IFN-α was noted. $CD8^+$ DR^+ T cells in the peripheral blood and soluble IL-2 receptor levels in the sera increased significantly during the therapy in all patients, suggesting that both the reduction of HTLV-I proviral DNA load and immunomodulation by long-term IFN-α therapy contributed to its sustained clinical benefits.[185–187] Other experimental approaches such as antiretroviral therapy with lamivudine, which shows reduction in viral load,[188] and treatment with humanized anti-Tac associated with downregulation of activated T cells and a decrease in the HTLV-I viral load[189] have not been advanced to formal trials to assess impacts on clinical symptoms. Treatment with danazol, an androgenic steroid, has resulted in improvement in urinary and fecal incontinence but not in the underlying neurologic deficit.[190]

OTHER DISEASES ASSOCIATED WITH HTLV-1

Most of the other conditions listed in Table 22-2 associated with HTLV-1 also appear to involve an autoimmune/inflammatory pathogenesis; most include elevated viral-load levels as seen for HAM/TSP, and often these conditions are coincident with the neurologic syndrome. These include polymyositis of skeletal muscle,[191] sporadic inclusion body myositis,[192] large joint polyarthropathy among elderly patients,[193,194] infiltrative pneumonitis,[195] and uveitis.[196] In viral-endemic areas, 30–40% of idiopathic uveitis may be caused by the virus.[197] Other evidence for an immunologic abnormality includes parasitic infestations such as *Strongyloides stercoralis* that are refractory to treatment[198] and skin test anergy.[199] Depressed hemoglobin and lymphopenia have been reported in healthy HTLV-1 carriers.[200] Infective dermatitis is an HTLV-1-associated syndrome in children; it also appears to involve HTLV-1-associated immunodeficiency that is manifested by refractory generalized eczema and saprophytic staphylococcal and streptococcal bacterial infections. In most cases, onset occurs in early life with persistence into adulthood[128] or even develop in adulthood[201]; some cases go on to develop ATL and HAM/TSP.[202] The finding of spontaneous neutrophil activation in HTLV-1 infected patients may provide a pathogenic basis for infective dermatitis, since a defect in granulocyte function may explain the impaired capacity of the immune system to clear sapropytic bacterial infections.[203]

IMPACT OF HTLV-1 INFECTION ON OTHER INFECTIOUS DISEASES

HTLV-1 infection may cause subclinical and clinical immunosuppressive effects that mediate increased susceptibility to certain bacterial and parasitic diseases, including *S. stercoralis*[198] and *Mycobacterium tuberculosis*.[204,205]. In Japan, AIDS-like illnesses have been reported in some HTLV-1 carriers.[206] Coinfection with HTLV-1 and HIV-1 has been thought to result in acceleration of clinical immunosuppression and shortened survival in cross-sectional studies.[207] However, published data are all cross-sectional and therefore subject to problems of interpretation. Thus HTLV-1 infection in these patients may have been a marker of greater sexual exposure through common modes of transmission, or HTLV-1 may have facilitated HIV-1 transmission in some way.[208]

DISEASE ASSOCIATIONS OF HTLV-2

The disease associations of HTLV-2 also remain to be defined (Table 22-3), but there are suggestive case reports of degenerative neurologic conditions, suggesting an emerging link to HAM/TSP. Rare hematologic manifestations such as

Table 22-3. HTLV-Associated Diseases

Disease	HTLV-1	HTLV-2
Childhood		
Infective dermatitis	++++	No
Persistent lymphadenopathy	++	No
Adult		
Adult T-cell leukemia/lymphoma	++++	No
HTLV-associated myelopathy	++++	+++
Infective dermatitis	+++	No
Polymyositis	++	No
Inclusion body myositis	+	Unknown
Uvetitis	+++	No
HTLV-associated arthritis	++	No
Sjogren syndrome	++	No
Strongyloidiasis	++	No
Pulmonary infiltrative pneumonitis	++	No
Invasive cervical cancer	+	Unknown
Small cell carcinoma of lung	+	Unknown

++++, very strong evidence; +++, strong evidence; ++, possible association; +, weak association; No, evidence does not support association. Unknown—no data to support association or lack of association.

atypical hairy-cell leukemia and large lymphocytic leukemia have also been reported, but consistent associations have not been found. One prospective study of HTLV-2 positive drug users showed an excess of asthma-related deaths and an increased frequency of skin and soft-tissue infections.[209,210] These are currently under investigation in a number of cohorts. The finding that HTLV-2 provirus load is lower than that in HTLV-1 carriers as well as the trophism for CD8 cells may explain differences in viral pathogenesis.[211] A recent cohort analysis from Italy suggests that HTLV-2 protects against progression to AIDS, a finding that might be confounded by survivor bias in the cohort.[212]

CONTROL OF HTLV INFECTIONS

PREVENTION

Guidelines for prevention and counseling have been developed for HTLV-1 and -2 by a Centers for Disease Control and Prevention Working Group.[213] Standard prevention approaches address each of the major avenues of transmission and are similar for both viruses: screen blood, eliminate breast-feeding by known infected mothers or where not feasible, limit breast-feeding to the first 6 months of life, and advise use of condoms by discordant couples.

The value of blood donor screening has been well documented in Japan, where up to 15% of HTLV-I infections have been eliminated. In nonendemic areas such as the United States, the cost-effectiveness of screening has been questioned, but because of the risk for HAM/TSP in the transfusion setting, all blood bank units in the United States are screened. However, because HTLV-I is transmitted only in blood units containing cells and not in plasma, plasma donations are not screened for HTLV-I.

Pregnant women who are HTLV-I positive should not breast-feed their infants, and this is official policy in the United States. However, in developing countries where safe alternatives to breast-feeding may not be available, limiting breast-feeding to the first 6 months may afford some protection via maternal antibodies.

The use of condoms is recommended for couples who are discordant for HTLV infection. Given the relatively low frequency of sexual transmission for each sexual encounter, couples who desire a pregnancy could plan to have unprotected sex during periods of maximal fertility. Such decisions require careful discussion between physician and patient, and there are no absolute guidelines in this particular area.

Counseling seropositive patients involves a clear discussion of the distinction of HTLV from HIV. In addition, HTLV virus type should be defined by serologic methods, and the distinctions in disease associations of the two virus types should be emphasized.

On a population level, prevention measures that have been developed for HIV infection also are applicable against HTLV. Since the populations at risk for HIV are also at risk for HTLV-I in viral endemic areas (e.g., persons at risk for STDs, persons with high rates of partner exchange, commercial sex workers, etc.), HIV prevention guidelines will also benefit those at risk for HTLV-I. Thus prevention measures that promote condom use, treatment of sexually transmitted infections, and decrease of high-risk exposures will also prevent HTLV-I infection. Nosocomial infection has only been reported in one instance involving a "microtransfusion" and thus HTLV-I is unlikely to be transmitted in this setting. There is no therapy for HTLV-I infection and thus no chemoprophylaxis. Passive immunoprophylaxis is hypothetically effective as noted in animal studies, but has no practical clinical application given the low risk for transmission except through sexual, breast-feeding, and transfusion exposure where other prevention methods are more applicable.

23 Biology of Herpesviruses

Peter E. Pertel and Patricia G. Spear

INTRODUCTION

Over 100 herpesviruses have been identified, with at least eight infecting humans. All human herpesviruses are well adapted to their natural host, being endemic in all human populations studied and carried by a significant fraction of persons in each population. The human herpesviruses include herpes simplex viruses types 1 and 2 (HSV-1 and HSV-2), varicella-zoster virus (VZV), Epstein-Barr virus (EBV), cytomegalovirus (CMV), human herpesvirus 6 (HHV-6), human herpesvirus 7 (HHV-7), and human herpesvirus 8 (HHV-8) or Kaposi's sarcoma (KS)-associated herpesvirus. Disease caused by human herpesviruses tends to be relatively mild and self-limited in immunocompetent persons, although severe and quite unusual disease can be seen with immunosuppression.

A few key characteristics differentiate the herpesviruses from other viruses. These include (1) a double-stranded linear DNA genome ranging in size from 125,000 to 250,000 base pairs, (2) an icosahedral capsid approximately 125 nm in diameter consisting of 162 capsomers, (3) an amorphous layer of viral proteins located between the capsid surface and outer envelope and called the *tegument*, and (4) a lipid bilayer envelope containing viral glycoproteins. In addition to these structural elements that define members of the Herpesviridae family, all herpesviruses share biologic traits. These include expression of a large number of viral enzymes, assembly of the nucleocapsid in the cell nucleus, cytopathic effects on the cell during productive infection, and ability to establish latent infections in an infected host.

The pathology and epidemiology of herpesvirus infections depend not only on viral replication and associated cytotoxicity but also on the capacity of herpesviruses to establish latent infections. The term *productive infection* will be used here to describe, at the cell level, an infection in which the invading virus replicates to yield progeny virus. *Latent infection* or *latency* means that the genome of the invading virus is stably maintained by the cell with only limited expression of viral genes, no production of progeny virus, and no evident virus-induced cytotoxicity. Latent infections can be converted to productive infections by factors and stimuli that have not yet been fully defined. This conversion results in activation of virus replication, possibly at levels sufficient to cause clinical symptoms. Recurrence of disease due to periodic or sporadic activation of viral replication is an important feature of the pathology caused by HSV. In addition, asymptomatic shedding of herpesviruses may play a significant role in transmission from person to person.

This chapter will focus on the sexually transmitted herpesviruses, HSV, CMV, EBV, and HHV-8, all of which can also be transmitted in other ways. HSV is a major cause of genital ulcers and also causes similar mucocutaneous lesions in and around the mouth and on any other part of the body surface where inoculated. Other disease manifestations include keratitis, encephalitis, and meningitis. CMV infections are mostly asymptomatic, but can be severe and disseminated to multiple organ systems in the immunodeficient. CMV can cause AIDS-associated retinitis. CMV is probably the only herpesvirus capable of infecting the fetus transplacentally, which can result in various developmental abnormalities including hearing loss and mental retardation. EBV causes infectious mononucleosis and is associated with a variety of benign and malignant lymphoproliferative diseases and carcinoma, particularly under conditions of immunodeficiency. HHV-8 is the cause of KS and AIDS-associated primary effusion lymphoma (PEL).

TAXONOMY AND GENOMIC ORGANIZATION

Members of the family Herpesviridae are diverse and have been isolated from mammals, birds, reptiles, boney fish, amphibians, and oysters. The herpesviruses from mammals, birds, and reptiles have been classified into three subfamilies based on biologic differences. The α-herpesviruses are neurotropic viruses that replicate relatively rapidly and infect a wide range of cells in cell culture. Examples include HSV-1, HSV-2, and VZV. The β-herpesviruses replicate slowly and are restricted in the types of cells productively infected in cell

culture. Cells infected by β-herpesviruses often become enlarged. Examples include CMV, HHV-6, and HHV-7. The γ-herpesviruses are lymphotropic viruses that also replicate relatively slowly and are restricted in the types of cells productively infected. Examples include EBV and HHV-8. Except for the close relationship between HSV-1 and HSV-2, each of the human herpesviruses appears to be more closely related to biologically similar animal herpesviruses than to each other. This classification scheme based on biologic differences is for the most part concordant with evolutionary inferences that can be drawn from nucleotide sequence analysis.[1] In this chapter, HSV, CMV, and EBV will be discussed as the prototypes of their respective subfamilies, with some attention also given to HHV-8.

The genomes of the various herpesviruses are clearly evolutionarily related but differ in size, in organization of unique and repeated sequences, and in gene content and order.[1] Although each virus encodes unique genes, a large fraction of the genes of herpesviruses is conserved among members of the family. These homologous genes are arranged in several colinear blocks (Fig. 23-1). The blocks are themselves arranged in the same order and orientation for members of any one subfamily of herpesviruses and in different orders and orientations for viruses from different subfamilies. Genes specific for a virus or subfamily tend to be at the genomic termini or in clusters between the blocks of homologous genes. Certain key regulatory proteins and genes expressed in latency tend to be different for members of the different subfamilies.

MOLECULAR BIOLOGY OF VIRAL REPLICATION

Herpesvirus genomes encode approximately 100 or more proteins. Although a relatively large percentage of viral genes may not be essential for viral propagation in cell culture, all are most likely required for efficient viral function during naturally occurring infections. Many of these genes encode proteins that modulate or prevent certain host immune responses or that permit each herpesvirus to establish and maintain long-term infections in their natural hosts in ways that are biologically distinct for each virus.

Despite the fact that HSV infections outside the laboratory are, for the most part, limited to humans, the virus has an extremely broad host range. Many animal species can be experimentally infected with HSV and many types and species of cultured cells will support HSV replication. On the other hand, the other human herpesviruses have a much more limited host range, are fastidious about the cell types in which they will replicate, and are often much more difficult to propagate in cell culture. Consequently, the molecular details of viral replication are much better understood for HSV than for the other human herpesviruses.

Herpesvirus infection is initiated by attachment of the virus to a susceptible cell. Viral glycoproteins in the virion envelope bind to components of the cell surface in a cascade of interactions that culminates in fusion between the viral envelope and a cell membrane, thereby delivering the nucleocapsid into the

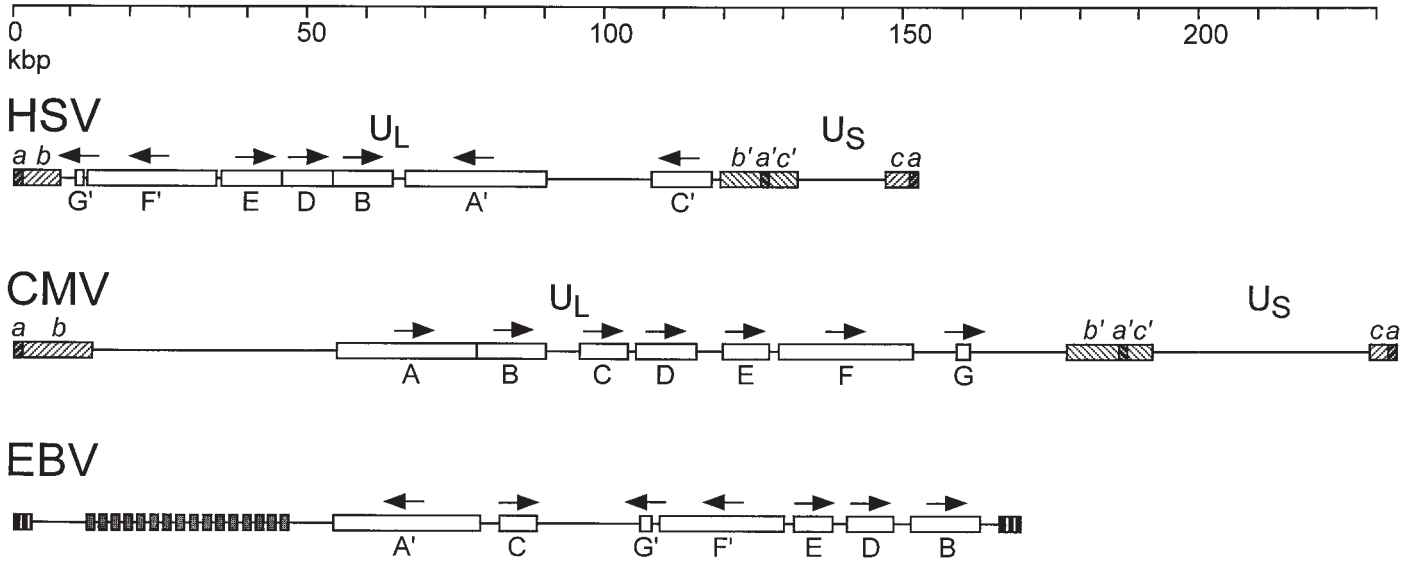

FIGURE 23-1. The genomes of three representative α, β, and γ herpesviruses (HSV, CMV, and EBV) showing the positions of repeated sequences and of conserved gene blocks. The scale of these maps is in thousands of base pairs (kbp). The hatched boxes on the CMV and HSV maps represent repeated sequences present in two copies with inverted orientations. These repeated sequences divide the CMV and HSV genomes into unique long (U_L) and unique short (U_S) segments. The small shaded boxes on the EBV genome represent multiple repeated sequences all in the same orientation. The open boxes and letter designations represent conserved blocks of genes. The arrows denote the orientation of the blocks relative to CMV. These maps were adapted from Mocarski[2] and are based largely on the nucleotide sequence analyses of Kouzarides et al.,[3] McGeoch et al.,[4] and Baer et al.[5]

cell cytoplasm. After penetration, the nucleocapsid is transported to the cell nucleus. In productively infected cells, herpesvirus gene expression proceeds in a well-coordinated cascade.[6] Expression of the immediate-early (α) regulatory genes is necessary for the subsequent transcriptional activation and expression of the delayed-early (β) and late (γ) genes of the lytic cascade required for viral replication. In latently infected cells, the immediate-early (and delayed-early and late genes) ordinarily will not be expressed. The factors that determine whether immediate-early genes will not be expressed, permitting the establishment of latency, or will be expressed, initiating the cascade of viral gene expression required for viral replication, have not been adequately defined for any herpesvirus.

Viral DNA replication and nucleocapsid assembly are in the cell nucleus. Subsequent steps in viral morphogenesis include envelopment of the nucleocapsid by budding through the inner nuclear membrane, de-envelopment of the virus particle by fusion of the primary envelope with the outer nuclear envelope, and secondary envelopment of the nucleocapsid by budding into the trans-Golgi network or an endosome. The virion is then transported out of the cell by exocytosis.

VIRION PROTEINS

Highly conserved among herpesviruses are the capsid proteins that comprise the icosahedral shell surrounding the viral genome and the scaffold and DNA packaging proteins that permit capsid assembly followed by insertion of the viral genome. Less well conserved are the proteins that lie between the capsid shell and the inner aspect of the lipid-containing outer envelope. These proteins, collectively called the tegument, serve a number of regulatory functions, including enhancement of transcription of immediate-early viral genes, shut-off of host protein synthesis, phosphorylation of host and viral proteins, etc. At least a dozen viral-encoded proteins and glycoproteins are integral components of the virion envelope and serve several functions. A subset of these membrane proteins mediates entry of virus into the host cell by inducing fusion between the virion envelope and a cell membrane. Another subset includes IgG Fc-binding proteins and complement-binding proteins that can modulate host immune effector functions. Others have the role of traffic control inside the infected cell, ensuring that the envelope proteins are targeted to the appropriate cytoplasmic membrane where envelopment takes place and that vesicles containing virions are targeted to the appropriate cell surface for exocytosis.

VIRAL ENTRY INTO CELLS

Depending on the host cell type, herpesvirus entry can occur by fusion of the virion envelope with the cell plasma membrane or with the membrane of an endocytic vesicle. The first step in entry is binding of the virus to the cell surface. For most herpesviruses studied to date, with the exception of EBV, the initial binding is to heparan sulfate chains on cell-surface proteoglycans.[7] The viral glycoproteins that mediate this binding to heparan sulfate include a highly conserved herpesvirus glycoprotein designated gB and less highly conserved or unique glycoproteins that have different names in different viruses. In general, the binding of virus to heparan sulfate is reversible. Virions retaining infectivity can often be released from cells by use of a soluble competitive inhibitor such as heparin, which is closely related to heparan sulfate.

Following initial virus binding to the cell, entry requires the activation of a viral-membrane-fusing complex of glycoproteins. For most or all herpesviruses, this complex is thought to include the conserved glycoproteins designated gB, gH, and gL.[8] For individual herpesviruses, membrane-fusing activity may require other glycoproteins in addition, glycoproteins that are generally not conserved among all herpesviruses. The entry of HSV, CMV, EBV, and HHV-8 will be discussed separately to illustrate how different cellular requirements for entry influence cellular tropism and pathogenesis.

HSV entry

HSV can infect a variety of cultured cell types, including epithelial cells, fibroblasts, neurons, and leukocytes. The binding of HSV to heparan sulfate on cells can be mediated either by gB or by gC, the latter of which is also able to bind to and inactivate the C3 component of complement and is conserved among α-herpesviruses but not other herpesviruses. The glycoproteins required for entry are the conserved glycoproteins, gB, gH, and gL, as well as gD, which is conserved among most α-herpesviruses (with the exception of VZV), but not among other herpesviruses.[9] The membrane fusion required for entry is triggered by the binding of gD to one of its cell-surface receptors. This binding somehow activates the fusogenic activity of gB, gH, and gL. The latter two glycoproteins form a stable heterodimer (gH/L), the functional unit, whereas gB forms a homo-oligomer, probably a trimer.

The gD-binding entry receptors include three classes of cell-surface molecules: herpesvirus entry mediator (HVEM), a member of the tumor necrosis factor receptor family; nectin-1 and nectin-2, cell-adhesion molecules belonging to the immunoglobulin superfamily; and specific sites in heparan sulfate generated by the action of particular 3-O-sulfotransferases.[10] All of the HSV entry receptors are expressed on a variety of differentiated cell types, although nectins are likely to be the receptors for entry of virus into neurons.[11,12] It remains to be determined which of these receptors is chiefly responsible for the entry of HSV into various cell types that are targets in disease, such as epithelial cells, neurons, cells of the immune system, etc.

Electron microscopy of HSV virions labeled with gold-tagged antibodies (Fig. 23–2) has permitted the demonstration that three of the glycoproteins involved in viral entry (gB, gC, and gD) constitute three morphologically distinct spikes projecting from the virion envelope.[13] X-ray structures of gD crystallized alone and in complex with HVEM have been determined.[14] These structures and mutagenic analyses of gD have shown that gD presents different interfaces for binding to its various cell surface receptors and can assume different conformations depending on the receptor.[11,15–17]

CMV entry

As with HSV, the initial attachment of CMV to cells is mediated by binding of viral glycoproteins to cell-surface heparan sulfate.[18] Glycoprotein complex II (gC-II), now known to be a disulfide-linked heterodimer of gM and gN, is the predominant component of the viral envelope that mediates virus binding to heparan sulfate.[19] By use of a cell fusion assay, it was shown that gH and gL are sufficient for the fusion of certain cell types but not others.[20] This indicates that gH and gL are probably also required for the membrane fusion leading to viral entry. It seems likely that gB is also required for viral entry although this has not been established. However, it has been shown that gB binds to cell surface heparan sulfate and other receptors[21–23] and has a role in signal transduction, including the induction of interferon-responsive genes.[24–26]

A variety of cell-surface molecules have been implicated in CMV entry into cells. The leading candidates as of this writing are the epidermal growth factor receptor (EGFR) and

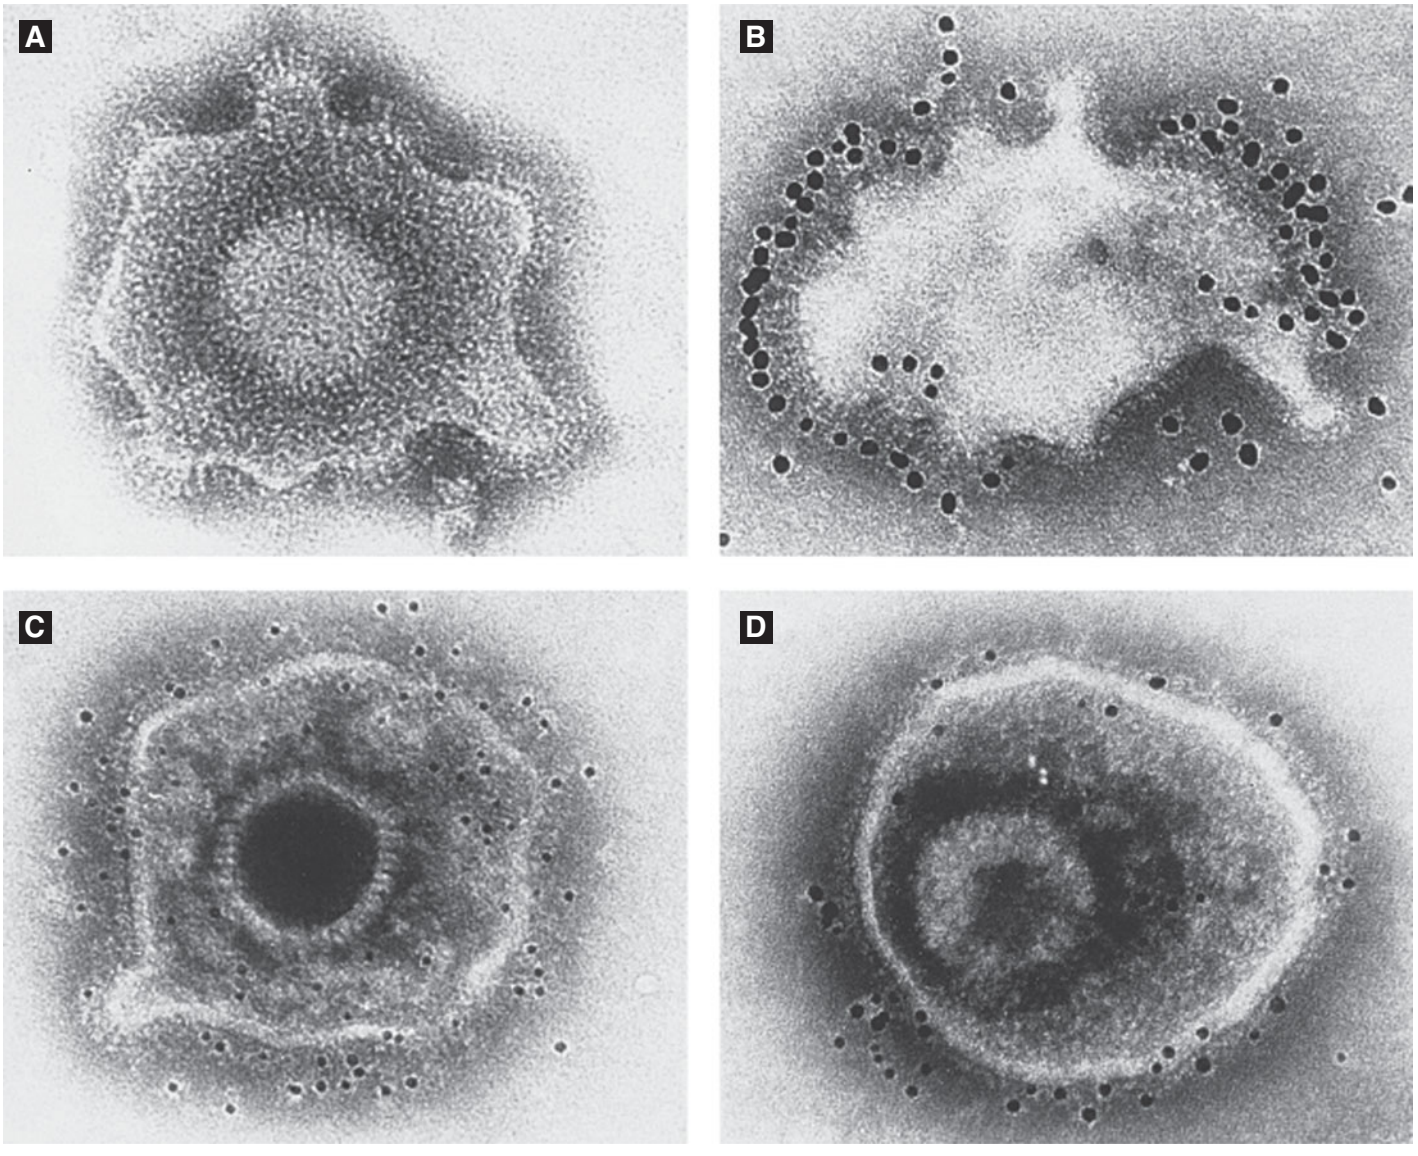

FIGURE 23-2. Electron micrographs of negatively stained HSV showing different kinds of spikes projecting from the virion envelope. The most prominent spikes are composed of gB, as shown by the decoration of these spikes with gold-labeled anti-gB, **B.** Similarly, long, slender structures, difficult to resolve, are gC, **C.,** and some of the short, fuzzlike structures are gD, **D.** No antibody was added in panel, **A.** Similar figures were published by Stannard et al.[13] (*Courtesy of L. M. Stannard.*)

integrins.[22,23] CMV gB is thought to bind to several different integrins via a disintegrin domain.[22]

EBV entry

EBV can infect both B lymphocytes and epithelial cells. The viral and cell requirements for entry into each cell type are different, however. The attachment of EBV to B cells is mediated by the binding of gp350/220 to CD21,[27] a receptor for the complement component C3d. Entry into B cells requires at least gH/L and gp42, which forms a tripartite complex with gH/L.[28] Entry is triggered by the binding of gp42 to major histocompatibility complex (MHC) class II molecules.[29,30] An x-ray structure of gp42 in complex with MHC class II has been determined.[31] The structure revealed a hydrophobic surface on gp42, which includes amino acid residues critical for entry and which probably interacts with gH/L or other viral or cell proteins required for entry.[32] The receptors required for entry into B cells are usually not expressed on epithelial cells, and EBV entry into epithelial cells does not require gp42.[28] The identities of epithelial cell receptors for EBV entry and the viral ligands for these receptors remain to be determined. It is thought that interaction of gH/L with an epithelial cell receptor may be critical. On the basis of cell fusion studies, it seems likely that EBV gB, in addition to the glycoproteins mentioned above, is required for viral entry into both B lymphocytes and epithelial cells.[33,34]

HHV-8 entry

As for HSV and CMV, the initial interaction of HHV-8 with cells can be the binding of virus to heparan sulfate.[35] For HHV-8, this binding is mediated by the virion glycoproteins gpK8.1A or gB.[36,37] HHV-8 gB can also bind to certain integrins on the cell surface and this interaction has a role in induction of signaling pathways that may be necessary to prepare the cell for viral entry.[38–40] Glycoproteins gB, gH, and gL are necessary and sufficient for HHV-8-induced cell fusion of two human cells lines.[41] However, the addition of glycoprotein K8.1A enhances cell fusion and the range of cell types that are permissive for HHV-8-induced cell fusion and entry.[41a] A cystine transporter has been identified as a fusion-entry receptor.[41b] HHV-8 is capable of infecting a variety of cultured cell type, but most of these infections lead to latent infection rather than to viral replication.

INTRACELLULAR SYNTHESIS OF VIRAL COMPONENTS

Once a herpesvirus nucleocapsid enters the cytoplasm of the cell, it is transported to the vicinity of a nuclear pore. Transport of the nucleocapsid to the nucleus is mediated by specific interactions of the nucleocapsid with components of the cellular cytoskeleton, especially microtubules. The nucleocapsid docks to a nuclear pore and the viral genome is delivered into the nucleus. There the viral genes are transcribed by cellular RNA polymerase II under control of viral regulatory components, some of which are tegument components. In productive infection, the immediate-early or α genes, which encode mostly regulatory proteins, are transcribed first. For HSV, optimal transcription of the α genes requires the activity of a viral regulatory protein called α *trans-inducing factor* (αTIF) or VP16. This viral regulatory protein is a component of the tegument and is delivered to the cell along with the viral genome. Homologous genes have been identified in EBV (BPLF-1) and in CMV (pp71).

Once the α genes have been transcribed and the α proteins translated, one or more of these proteins enables the transcription of the delayed-early or β genes. The β genes encode enzymes and other proteins required for viral DNA replication. Most herpesviruses encode enzymes that can phosphorylate nucleosides and therefore also can activate nucleoside analogue inhibitors of viral DNA replication. In addition, all herpesviruses encode a DNA polymerase, which is responsible for genomic replication during lytic infection and is the target of nucleoside analogue inhibitors. Following α and β gene expression and DNA replication, the late or γ genes are expressed. The γ genes encode most of the virion structural proteins and glycoproteins.

Herpesviruses and certain other DNA viruses have provided excellent experimental systems for the study of eukaryotic gene expression and its regulation, in part because these viruses use cellular machinery for transcription of viral DNA to RNA and subsequent transcript processing to yield functional mRNAs. The virus superimposes on this cell machinery its own regulatory factors that aid in targeting cell transcription factors to virus-specific nucleotide sequences. Interestingly, herpesviruses differ from other DNA viruses and from eukaryotic cells in that most viral genes expressed during productive infection are free of introns (intervening sequences that are removed from RNA transcripts by splicing to yield the functional mRNAs). In productively infected cells, RNA splicing can be inhibited by viral proteins; for example, by the HSV protein ICP27.[42] One can speculate that expression of ICP27 homologs and evolution toward intron-free genes facilitate the expression of viral genes in preference to cell genes during a productive infection. In contrast, herpesvirus genes expressed in latently infected cells are usually spliced.

After synthesis of herpesvirus proteins in the cytoplasm, most of the proteins are transported to the nucleus, where they serve as regulatory factors, enzymes involved in DNA replication, or structural components of the nucleocapsid. Viral glycoproteins and other integral membrane proteins are made on membrane-bound ribosomes and become distributed to most membranes of the cell.

ASSEMBLY AND EGRESS OF VIRIONS

Assembly and egress of herpesvirus virions begins in the cell nucleus and ends with exocytosis of virions from the cell.[43]

Herpesvirus nucleocapsids are assembled in the cell nucleus. The nucleocapsids then acquire an envelope by budding through patches of the inner nuclear membrane that have been modified to contain viral proteins. These enveloped virus particles can be observed in the perinuclear space. Subsequent events in virion assembly include de-envelopment of these particles by fusion with the outer nuclear membrane, followed by reenvelopment of the cytoplasmic nucleocapsids at membranes of the trans-Golgi network or endosomes. These mature virions, enclosed within cytoplasmic vesicles, are then transported to the cell surface and released from the cell by exocytosis.

FATE OF THE CELL THAT PRODUCES VIRUS

Herpesviruses kill the cells in which they replicate, at least in cell culture. For HSV, a viral gene product, virion host shutoff protein, a tegument component introduced into the cell during viral entry, causes degradation of preexisting cytoplasmic mRNAs such that cell protein synthesis is immediately inhibited. Other viral factors produced after infection inhibit or alter various host functions, including DNA replication and RNA processing. In contrast, CMV initially stimulates host cell DNA, RNA, and protein synthesis, and effective CMV replication is dependent on this stimulation. Later in the replicative cycle, host macromolecule synthesis is inhibited.

A hallmark of α-herpesvirus infections in vivo is the presence of polykaryocytes, at least in infected epithelia. Herpesvirus-induced cell–cell fusion may function as an alternative method for spreading virus from cell to cell and could facilitate evasion of host immune responses.

LATENCY

The ability of herpesviruses to persist for the life of their natural hosts depends in large part on their ability to establish latent infections. Latency occurs when the viral genome is stably maintained in the cell nucleus with expression of only a limited subset of viral genes. The latently infected cell is not killed by the virus, and viral gene products expressed may actually stimulate cell division or other cell activities. Virions or infectious virus cannot be recovered from latently infected tissue immediately after its removal from an experimental animal or human cadaver. However, activation of latent virus to the replicating state, yielding infectious virus, often can be achieved by in vitro cultivation of the explanted latently infected tissue.

EBV and HHV-8 can induce the proliferation of latently infected cells, causing cell division even in the absence of antigenic or other mitogenic stimuli. HSV is not known to induce the proliferation of latently infected cells. This apparent difference may be related to properties of the cells that harbor latent viral genomes. EBV and HHV-8 genomes are latent in premitotic cells whereas HSV genomes are latent in postmitotic neurons. Thus, the observed differences in viral gene expression during latency, as described below, may in part reflect the need for EBV and HHV-8 to regulate cell proliferation and to partition their genomes to daughter cells when cell division does occur.

HSV LATENCY

A major site of latency for HSV is sensory ganglia of nerves innervating the site of initial infection.[44] Infection of the sensory neurons occurs during initial HSV infection when the nerve endings are exposed to the virus. Virus is subsequently transported up the axons to the cell bodies. The HSV genomes present in ganglia of latently infected animals and humans are probably episomal and circular, in contrast to virion-associated genomes, which are linear.

Although gene expression by HSV is apparently not required during a latent infection, analyses of latently infected animal and human cells reveal the presence of transcripts (Fig. 23-3) from one specific region of the viral genome.[47] These latency-associated transcripts (LATs) are transcribed from the DNA strand opposite that encoding one of the immediate-early proteins ICP0 or IE110. A relatively large transcript gives rise to a stable intron, from which two different spliced forms are derived. Expression of HSV proteins from LAT transcripts has not been reproducibly demonstrated.

The expression of LATs is not absolutely essential for the establishment of latency or for the reactivation of latent virus in animal models, and LATs can be detected during productive infections. However, the significance of LATs in latency is suggested by observations that LAT expression is a good marker for the latent state induced by wild-type virus and that LAT-negative mutants may be somewhat impaired in their ability to reactivate from latency.

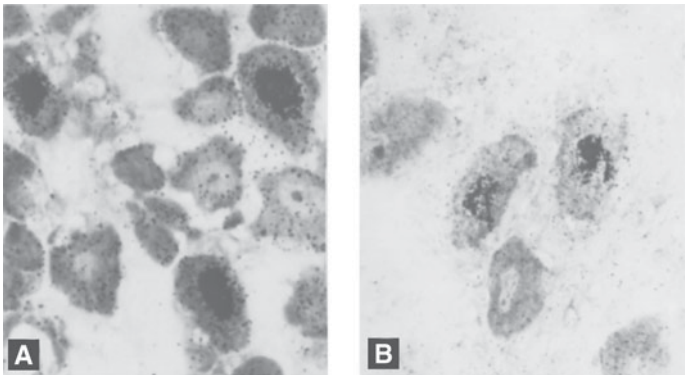

FIGURE 23-3. Detection of HSV-1 LAT in neurons of peripheral ganglia by in situ hybridization and autoradiography. The black autoradiographic grains are localized over nuclei of some of the neurons in mouse tissue, **A.,** and human tissue, **B.,** taken from latently infected subjects. Experimental details are given in publications by Stevens et al.[45,46] (*Courtesy of J. G. Stevens.*)

Reactivation of latent HSV can result after exposure to a variety of stimuli, including stress, fever, colds, sunlight, menstruation, etc. The mechanism by which virus is reactivated is unknown. Virus is subsequently transported down the axon to the site of initial infection or nearby. The frequency and clinical severity of reactivation depends on several factors, including immunocompetence of the infected host and severity of the initial infection. Presumably, a larger number of peripheral cells infected during a severe initial outbreak will result in a larger number of infected sensory neurons. Interestingly, HSV-1 reactivates more readily from trigeminal and cervical sensory ganglia, whereas HSV-2 reactivates more readily from sacral ganglia.[48,49] This correlates with the tendency for HSV-1 to cause recurrent orolabial disease and for HSV-2 to cause recurrent genital disease. The reasons for this are not known but may be secondary to differences in the cell or viral proteins needed for reactivation and lytic growth in each cell type.

CMV LATENCY

Epidemiologic studies first implicated leukocytes as a possible site of CMV latency. CMV can be transmitted by blood transfusions, and the risk of infection can be decreased substantially by using leukocyte-depleted blood.[50,51] Tissue-resident macrophages or dendritic cells have also been implicated as sites of latency because any organ or tissue can transmit CMV from a seropositive to a seronegative individual. CMV DNA-positive cells are rarely detected in peripheral blood monocytes from healthy seropositive individuals. However, bone-marrow-derived myelomonocytic progenitors of monocytes, macrophages, dendritic cells, and neutrophils are routinely viral DNA positive at a frequency of 1/100,000 cells.[52] CMV gene expression in myeloid precursors is restricted. Transcripts derived from both strands of the CMV genome at the region encoding the immediate-early proteins IE1 and IE2 can be detected but these differ from the transcripts produced during productive infection. One unspliced and two spliced transcripts have been characterized, and their expression appears to correlate with latent infections.[53] These transcripts may function to downregulate expression of IE1 and IE2. Differentiation of monocytes into macrophages[54] or dendritic cells[55] can result in reactivation of natural latent infection. Mature cells support productive infection.

In immunocompromised individuals, CMV infection is associated with production of immediate-early antigens in many cell types, including endothelial and epithelial cells, sometimes without evidence of productive viral infection. These infected cell types may be important in viral dissemination and transmission. Cell-to-cell spread of CMV from endothelial cells to monocytes and macrophages[56] can contribute to viral dissemination within a host. CMV replication in epithelial cells lining the ducts of the salivary glands and kidneys can contribute to viral transmission to new hosts.

EBV LATENCY

EBV establishes latent infections in B lymphocytes. In latently infected B cells, the viral genomes usually persist as closed circular episomes that are not integrated into the cellular DNA. At least 11 viral proteins that can be expressed during latency have been identified in cultures of lymphoblastoid cells immortalized by EBV.[57] These include EBV nuclear antigens (EBNAs) and viral latent membrane proteins (LMPs). Maintenance and controlled replication of the EBV episome require EBNA-1.[58] This protein interacts with the origin of DNA replication for latent EBV (ori-p) and also interacts with chromosomal proteins for the partitioning of EBV episomes to the progeny of dividing cells. The protein LMP-2 inhibits the switch from latent to lytic EBV infection by influencing transmembrane signal transduction, including blocking of signaling through the B-cell receptor.[59]

The proteins EBNA-2, EBNA-3A, EBNA-3C, EBNA-LP, and LMP-1 all appear to have roles in growth transformation of B lymphocytes.[60] These proteins function by interacting with cell signaling pathways. For example, LMP-1 interacts with human proteins (TRAFs) that are involved in tumor necrosis factor receptor family signaling, whereas EBNA-2 transactivates several cell and viral genes. Expression of all these viral latency proteins in vivo, however, will usually induce cytotoxic responses by natural killer (NK) cells and T cells.

Two additional EBV products that may have a role in latency include small nonpolyadenylated virus-encoded RNAs (EBERs), which are expressed in both lytic and latent infections, and the protein BHRF-1, which is an EBV homolog of the human oncogene *Bcl-2* and can protect B cells from apoptosis. EBERs are not absolutely required for EBV immortalization of B cells but significantly contribute to efficient growth transformation.[61]

It has been proposed that EBV infects naïve B cells in vivo and directs their antigen-independent differentiation to memory B cells, with different sets of EBV gene products expressed at the various stages of this differentiation.[57] In naïve B cells, the full set of EBV latency-associated genes, as described above, can be expressed, resulting in cell proliferation (and the induction of potent anti-EBV T cell responses). EBV-driven differentiation of the naïve B cells to cells with properties of germinal-center cells is thought to be accompanied by expression of EBNA-1, LMP-1, and LMP-2A. As the germinal-center cells differentiate to memory B cells, expression of most or all EBV genes is extinguished. If these resting memory cells are induced to divide, they may express EBNA-1, which is required for the partitioning of EBV genomes to daughter cells. Terminal differentiation of the B cells into plasma cells can initiate viral replication.[62]

HHV-8 LATENCY

Most of the cells in lesions of KS and in primary effusion (B cell) lymphoma are latently infected. Many of the cultured cell types that are susceptible to HHV-8 entry also become latently infected. Similar to EBV, HHV-8 can express several (at least seven) genes in latently infected cells.[63] The best studied of the gene products is LANA-1, a multifunctional protein that is a reliable marker of HHV-8 infection. This protein both activates and represses transcription, blocks apoptosis, and has roles in cell transformation. In addition, LANA-1 is able to tether the viral genome to cell chromosomes, as does EBNA-1 of EBV, to ensure partitioning of viral genomes to daughter cells. Other HHV-8 proteins expressed in latency have a variety of activities, including enhancement of cell proliferation, blockage of apoptosis, transformation of cells to a tumorigenic phenotype, and immunomodulation. These viral proteins expressed in latency can explain many aspects of the pathology characteristic of KS and PEL.

VIRAL AND HOST DETERMINANTS OF DISEASE

Herpesviruses are well adapted to their natural hosts. Many more people become infected than ever show overt signs of disease. This is particularly true for EBV and CMV. The specific manifestations of disease for each virus are determined by the types of cells targeted for entry, the ability of these cells to support viral replication or latent infections, effects of viral gene products on latently infected cells, the tendency for reactivations to occur, the nature of immune responses, ability of each virus to subvert particular immune responses, and, undoubtedly, genetic variations of virus and host that influence susceptibility or resistance to disease. The manifestations of disease described below can be explained, at least in part, by information presented in the preceding sections on the properties of each virus.

HSV DISEASE

HSV can cause gingivostomatitis, herpes labialis, keratoconjunctivitis, cutaneous herpes, genital herpes (see Figs. 23-4 to 23-7), encephalitis, meningitis, and neonatal herpes (see Fig. 23-8). Infection with HSV is initiated by contact of virus with mucosa or abraded skin. Replication of HSV in cells of the epidermis follows, resulting in cellular destruction and inflammation. Clinically, vesicles on an inflammatory base are noted. Microscopically, multinucleated giant cells (see Fig. 23-9), focal cellular necrosis, and ballooning of infected cells are noted. During an initial infection, virus gains access to sensory neurons, allowing establishment of latent infection. Further spread of virus is limited primarily by innate responses of the host. In animal models, HSV can be detected in sensory nerve ganglia within 2 days of infection. Limited viral replication follows in neural tissue, allowing virus to migrate back down axons to sites near the incoculation site. This phenomenon, called zosteriform spread, along with contiguous spread of virus in the cells of the epidermis, may explain the large surface area affected during a primary HSV infection. Ultimately, the host immune response in immunocompetent persons will control viral replication and allow healing of lesions.

Reactivation of latent HSV and recurrent lesions can be induced by multiple stimuli, including ultraviolet light, immunosuppression, fever, pneumococcal pneumonia, and trauma to the latently infected neuron. The severity of symptoms associated with reactivation can vary substantially and may be related to the amount of replicating virus, the virulence of the HSV strain, and the integrity of the host immune system. Virus reactivation and replication occur periodically in asymptomatic persons, allowing apparently healthy people to spread infection to others.[64]

The location of recurrent HSV lesions depends on the anatomical structure of the nervous system, providing an explanation for apparently anomalous recurrent lesions.[65] For example, recurrent HSV lesions following a primary genital herpes infection can involve other lower body sites, such as the

FIGURE 23-4. Severe primary HSV infection with extensive vesicles, ulcerations, and penile edema.

FIGURE 23-5. Less severe primary genital HSV infection showing intact vesicles and pustules with surrounding erythema together with an earlier lesion, which is crusted and healing.

FIGURE 23-6. Recurrent HSV infection, showing grouped vesicles of the glans penis.

FIGURE 23-7. Primary genital herpes of the vulva.

FIGURE 23-8. Neonatal HSV infection. Ulcers and crusted lesions on the buttocks.

buttocks and perianal region, because sensory nerves that arise from the lumbosacral ganglia innervate diverse areas.

HSV-1 can cause sporadic cases of encephalitis. It has been proposed that virus spreads via neurons from peripheral ganglia to the brain. This can occur either after primary infection or recurrent disease in adults with no known immunological or developmental abnormalities. It remains unclear what determines the ability of HSV to spread from peripheral ganglia to the brain, which occurs more rarely in humans than in animal models of disease. In severe primary HSV-2 genital infection, meningitis may occur.

Despite the ability of HSV to infect many cell types, HSV disease is usually localized to the body surface at the site of inoculation and to the sensory and autonomic ganglia of nerves communicating with this site. Undoubtedly, an effective immune response is responsible in part for limiting the spread of infection. The possibility exists, however, that there are nonimmunologic barriers to the spread of infection in the normal adult. For example, certain cell types in fully differentiated tissues may not be able to support HSV replication, due either to inaccessibility or lack of required cell-surface receptors or to lack of other factors needed for biosynthesis of viral components. In addition, the basement membrane underlying epithelial surfaces contains high concentrations of heparan sulfate proteoglycans, which could trap virus and impede its spread to the dermis.[66]

Infections of many cell types can be seen, however, in cases of HSV disease in infants. Perinatal infections with HSV can

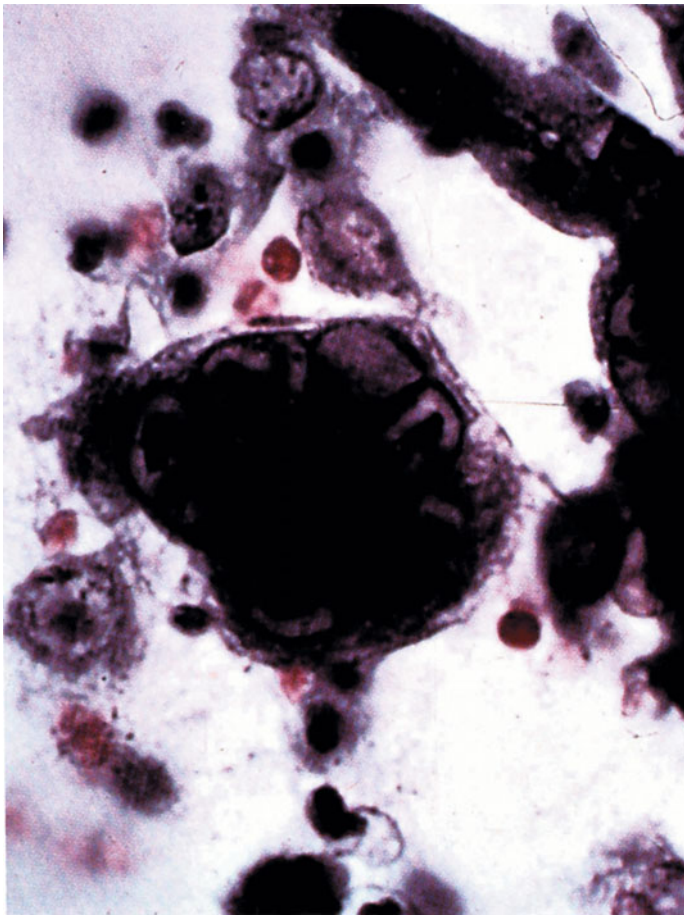

FIGURE 23-9. Wright Giemsa stain of scrapings from a herpetic lesion (Tzanck smear) showing multinuclear giant cell and ground-glass appearance of nuclei with nuclear inclusions.

occur by delivery of the infant through an infected birth canal or by postnatal exposure. HSV disease in newborn infants can be disseminated, involving many organ systems, including the central nervous system.[67] Treatment can reduce lethality but neurological sequelae might not be avoided. These manifestations of disease in newborns are clearly distinct from the more localized disease seen in children and adults. It is unclear whether the susceptibility of infants to disseminated disease is due to an immature immune system and/or to enhanced susceptibilities of newborn cells and tissues to HSV infection and spread.

HSV rarely causes severe or disseminated disease in adults, except when cell-mediated immunity is compromised. It seems likely that both innate and adaptive cell-mediated mechanisms are critical for limiting the spread of HSV infection and controlling viral replication.[68–70] Cell-mediated immunity directed against HSV-infected cells involves NK cells, activated T cells, and macrophages. Both MHC class I and class II restricted T cells have direct cytotoxic effects against HSV-infected cells. Cytokines released by lymphocytes may have direct antiviral activity or may act to regulate other components of the host immune response.

Humoral immune mechanisms also appear to play important roles in controlling infection.[71] HSV glycoproteins expressed on the surface of the viral envelope or infected cells are targets for neutralizing antibodies and antibody-dependent cell-mediated cytotoxicity, respectively. In addition, monoclonal antibodies against viral glycoproteins have been shown to protect against neurologic disease and to prevent the establishment of latency in animal models.[72,73] The role of these antibodies in human infections is not clear, but the quantity of maternally derived neutralizing and antibody-dependent cell-mediated cytotoxic antibodies does correlate inversely with disseminated disease in newborns.[74–76] Interestingly, high titers of antibodies correlate with high frequency and severity of recurrent disease in adults.[49,77] The reason is not clear, but the high titers of antibodies appear to reflect a more severe primary infection. More severe primary infections correlate with an increase in frequency and severity of recurrent disease and, therefore, with repeated antigenic stimuli.

CMV DISEASE

CMV can cause mononucleosis, hepatitis, chorioretinitis (see Fig. 23–10), pneumonitis, colitis, and congenital cytomegalic inclusion disease. Infection with CMV usually is initiated by contact of virus with cells of the oropharynx or the genital tract or by transfusion of contaminated blood. CMV infections are typically subclinical. The most common clinical manifestation is a self-limited mononucleosis, although disease can be quite severe and life-threatening in immunosuppressed persons. Clinical disease most likely results from viral cytolysis and the host's inflammatory response. However, additional pathology may result from abortively infected cells. The hallmark of CMV disease on histology is the cytomegalic inclusion-bearing cell.

Neutralizing antibodies directed against CMV can decrease the efficiency of viral transmission and can attenuate clinical

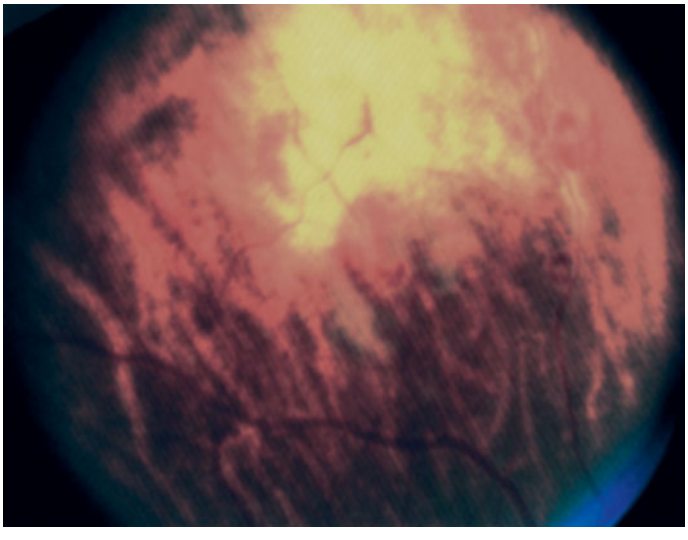

FIGURE 23-10. CMV chorioretinitis in a patient with AIDS.

disease. However, cell-mediated immunity appears to be much more important in controlling CMV replication. The incidence of severe CMV disease is markedly increased in persons with suppressed cell-mediated immunity, and the risk of CMV disease correlates with the degree of immunosuppression.[78–80] Cell-mediated immunity against CMV involves activated T cells, NK cells, and macrophages. The cytotoxic T-cell response can be both MHC class I and class II restricted. Transfer of $CD8^+$ cytotoxic T-cell clones to immunodeficient bone marrow transplant recipients may be able to restore protective immunity.[81] The immunosuppressive agents used to prevent graft rejection by transplant recipients can have profound and specific effects on CMV reactivation and replication.[82] Allogeneic transplantation itself can provide stimuli that reactivate CMV replication in leukocytes resident in the organ, and immunosuppression can facilitate replication and spread of virus. CMV is a significant cause of morbidity and organ failure in transplant patients.

CMV infection itself is immunosuppressive, consistent with the fact that leukocytes are targeted by the virus. Normal monocyte, T-cell, and NK cell function can all be inhibited.[83–85] CMV infection of monocytes or lymphocytes reduces interleukin-1 and interleukin-2 production and responsiveness. Thus, there are global effects of CMV infection on immune responses due to viral infection of cells of the immune system. More specific effects of particular CMV proteins are outlined in a later section.

EBV DISEASE

Diseases caused by EBV include mononucleosis, hepatitis, encephalitis, and lymphoproliferative syndromes. EBV initially infects epithelial cells and/or B cells in lymphoid tissues in the oropharynx. The virus disseminates throughout the lymphoreticular system. Clinical symptoms typically are not seen in young children but are seen in adolescents and adults. Symptoms and signs of infection in large part result from the inflammatory and immune responses directed against EBV.

The humoral immune response to an EBV infection consists of specific antibodies directed against viral antigens and heterophile antibodies.[86] Heterophile antibodies probably result from polyclonal stimulation of immunoglobulin synthesis in EBV-infected B cells and consist mostly of immunoglobulin M (IgM) molecules, some of which can bind to animal red blood cell antigens. Heterophile antibodies are detected in approximately 90% of persons with infectious mononucleosis due to EBV, and their presence can be used to confirm the diagnosis. Antibodies directed against platelets, neutrophils, nuclear antigens, and ampicillin have all been reported. These antibodies may have a role in mediating some of the complications of infectious mononucleosis, such as the rash that develops in over 70% of infectious mononucleosis patients treated with ampicillin.

Early in an EBV infection a mononuclear lymphocytosis consisting mostly of NK and T cells specific for EBV is noted. Cytotoxic T cells can destroy EBV-infected B cells that express viral antigens.[87] The importance of cytotoxic T cells in controlling EBV replication in vivo is indicated by the abnormally high levels of EBV-infected B cells in persons with diseases associated with suppressed cell-mediated immunity, such as persons with AIDS and those receiving immunosuppressive medications. The cytotoxic T cells are directed against epitopes on LMP-1, LMP-2, and several EBNAs, but not EBNA-1. This is consistent with the expression of EBV proteins known to be required for B-cell immortalization and proliferation, which in the appropriate environment results in differentiation to memory B cells. Early in infectious mononucleosis most of the circulating latently infected B cells have properties of resting B cells.[88]

Ultimately, the immune response generated in immunocompetent persons controls viral replication and B-cell proliferation, and the number of infected B cells circulating in the body drops about 100- to 10,000-fold. This drop correlates with the development of EBV-specific cytotoxic T cells. These cytotoxic T cells persist for the lifetime of the infected host, probably because of the continued presence of latently infected B cells that periodically reactivate or express additional proteins that can be recognized by the immune system. In addition, EBV can be isolated from the oropharynx for 12–18 months after the resolution of clinical disease and then intermittently in both immunocompetent and immunosuppressed persons.[89]

Many of the symptoms and signs of infectious mononucleosis, including pharyngitis, fever, lymphadenopathy, and splenomegaly, may in part be a direct consequence of the host immune response. The systemic symptoms, including fever, malaise, and headaches, may result from the immune response directed against the infected B cells. Treatment of infectious mononucleosis with high doses of acyclovir stops viral replication in infected cells but does little to attenuate clinical symptoms.[90]

In persons with congenital or acquired immunodeficiencies, virus-induced B-cell proliferation may occur relatively unchecked and can result in polyclonal or monoclonal lymphomas. Monoclonality probably results from mutations during EBV-induced cell proliferation that confer a selective advantage to the mutated cell. EBV also has been implicated as a causal factor in Burkitt's lymphoma, Hodgkin's lymphoma, lymphoproliferative syndromes, and nasopharyngeal carcinoma, along with the hyperproliferative disorder oral hairy leukoplakia in persons with AIDS.

HHV-8 DISEASE

Primary HHV-8 infection in immunocompetent persons can be associated with mild nonspecific symptoms and signs, including fever, fatigue, rash, diarrhea, and lymphadenopathy.[91]

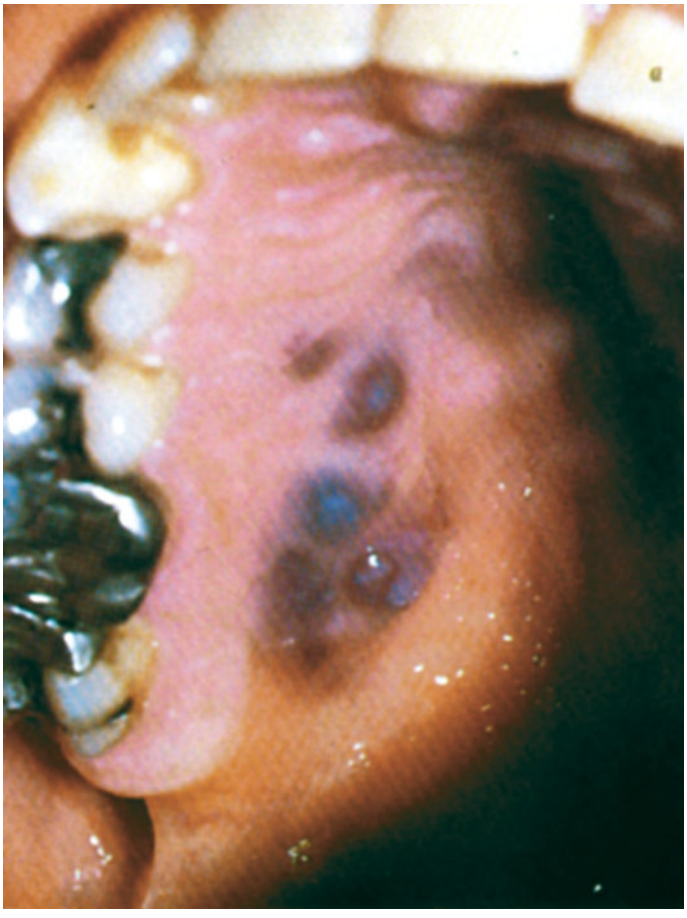

FIGURE 23-11. Kaposi's sarcoma in the palate as a manifestation of AIDS.

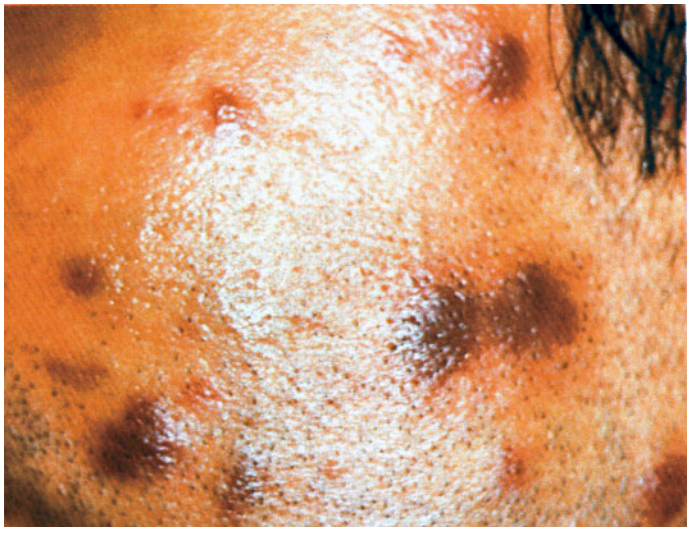

FIGURE 23-12. Kaposi's sarcoma on the face of a homosexually active man with AIDS.

Proliferative forms of disease are usually, but not always, associated with immunodeficiency. It is now clear that HHV-8 infection is causally associated with all four epidemiologic forms of KS: classic KS occurring in elderly Mediterranean men; endemic KS in young men and children in Africa; iatrogenic KS in organ and tissue transplant recipients; and AIDS-associated KS (see Figs. 23-11 and 23-12). HHV-8 DNA is invariably detected in diseased but not healthy tissues of KS patients. HHV-8 infection is also associated with AIDS-associated PEL and multicentric Castleman disease.

It is unclear whether KS is a true malignancy or a reactive proliferation.[63] Nevertheless, the HHV-8 proteins expressed in latently infected cells can explain the cellular proliferations characteristic of KS lesions, which are composed of various cell types including endothelial cells, extravasated inflammatory cells and erythrocytes, and the characteristic "spindle" cells. Whereas most of the cells in KS lesions and cells of PEL are latently infected, a small fraction undergo lytic replication with the production of virus.

VIRAL IMMUNOMODULATORY PROTEINS

As mentioned above, most infections by the herpesviruses described here are asymptomatic or subclinical. With the exception of primary and recurrent HSV lesions, HSV encephalitis, CMV congenital disease, and infectious mononucleosis, most diseases caused by these viruses occur in the context of immunodeficiency. Virus–host interactions have evolved to a point of fine balance, wherein the virus can maintain itself for the life of the host, with periodic shedding to enable transmission, but very little morbidity or mortality. This balance has apparently required that these viruses block or modulate certain kinds of immune responses. To this end, all herpesviruses, particularly those in the β- and γ-herpesvirus subfamilies, express proteins that modulate both innate and adaptive immune responses. Most, but not all, of these immunomodulatory proteins are expressed during productive infections, which provoke the most brisk innate and adaptive responses. In many cases, the genes encoding these immunomodulatory proteins appear to have been acquired from the host genome, with each subfamily of herpesviruses acquiring different sets of genes that are interspersed among the blocks of genes encoding core viral functions.

Type I interferons are key mediators of innate resistance to viruses. Herpesviruses, as well as most other viruses, express products capable of blocking the production of interferon itself or the protective cell products made in response to interferon or preventing the action of these cell products. HSV, CMV, EBV, and HHV-8 all encode several proteins and small RNAs that have these activities. Those targeting just one of the interferon-induced proteins will be described. This protein is the dsRNA-dependent protein kinase PKR, a key factor in rendering cells incapable of replicating viruses. When PKR is activated by the binding of dsRNA, it phosphorylates eIF2α, a translation factor, thereby shutting down protein synthesis. Several herpesvirus proteins can inhibit the activation of PKR or phosphorylation of eIF2α, including HSV US11,[92] CMV TRS1 and IRS1,[93] EBV SM,[94] and HHV-8

vIRF2.[95] A small RNA encoded by the EBV genome (an EBER) can also inhibit activation of PKR.[96] Finally, HSV ICP34.5 directs a cellular phosphatase to dephosphorylate eIF2α.[97]

NK cells also play important roles in the innate responses to viruses. The ability of herpesviruses to control interferon induction serves to reduce interferon-induced activation of NK cells. There are more specific strategies to evade NK cells, however. The binding of NK cells to receptors on other cells can result in inhibition or stimulation of NK cytotoxic activities, dependent on whether the potential target cell is recognized as unaltered by virus infection or other assaults or as altered, respectively. When HLA-E on potential target cells presents a leader peptide from other MHC class I proteins, it can bind to the inhibitory receptor, CD94/NKG2A, on NK cells. CMV-infected cells can sustain this inhibition of NK activity by presentation of a leader peptide derived from the viral protein gpUL40.[98]

There are a variety of ways in which herpesviruses subvert adaptive cell-mediated responses, including downregulation of MHC antigen expression and presentation on cell surfaces, blockade of antigen processing and peptide transport to sites for loading onto MHC antigens, and direct inhibition of T-cell function. Recent examples of the latter have been reported for HSV and CMV. HSV-infected cells in direct contact with primed cytolytic T cells can inhibit their cytolytic activity by an unknown mechanism.[99] HVEM, one of the entry receptors for HSV, is a ligand for the B and T lymphocyte attenuator (BTLA)[100–102] and also for LIGHT,[103] a member of the TNF family. By binding to BTLA, HVEM can inhibit T-cell activation whereas its binding to LIGHT can provide a second signal for T-cell activation. It is not yet known whether the interaction of HSV itself or HSV gD with HVEM can influence either the inhibitory or stimulatory activities of HVEM. CMV encodes a homolog of HVEM that is able to bind to BTLA and to inhibit T-cell activation.[102]

Although humoral immunity may not be as important for protection against herpesviruses as cell-mediated immunity, both HSV and CMV encode Fc-binding proteins that can block the effector functions of antibodies.[104,105] Also, HSV gC is a complement control protein that can protect virus from complement-mediated neutralization.[104] The HSV Fc-binding glycoprotein complex gE/I and complement-binding glycoprotein gC have been shown to have relevance to pathogenesis in a mouse model of disease. HSV mutants defective for these activities have reduced virulence.[106]

ANTIVIRAL AGENTS

Most of the drugs now in use for therapy of herpesvirus infections are nucleoside analogs or other agents that interfere with viral DNA replication. One of these medications is acyclovir.[107] Acyclovir is highly selective against cells infected with HSV or other herpesviruses that encode thymidine kinases. This selectivity is based on properties of two of the viral enzymes involved in DNA replication. First, acyclovir is initially phosphorylated to the monophosphate form by a viral-encoded thymidine kinase (TK) but not by cellular kinases. Subsequent phosphorylation to the active triphosphate form is by cellular kinases. Second, viral DNA polymerase is more sensitive to inhibition by phosphorylated acyclovir than are cell DNA polymerases. Unfortunately, mutations in either of these viral enzymes can render virus resistant to acyclovir. For the most part, clinically significant disease caused by resistant viral mutants is limited to immunosuppressed patients. Most acyclovir-resistant isolates are deficient in TK production, although missense mutations in the viral TK or in the viral DNA polymerase gene also can confer resistance.[108] Although resistant HSV isolates can be selected for after prolonged therapy with acyclovir, reactivated virus causing subsequent recurrences often retains susceptibility to the medication.[109] Valaciclovir is a prodrug of acyclovir that has increased oral bioavailability and is rapidly metabolized to acyclovir.[110]

Acyclovir is less effective against CMV, apparently because CMV does not encode a TK. Ganciclovir is more effective against CMV than is acyclovir. Although generation of ganciclovir monophosphate requires HSV TK in HSV-infected cells,[111] initial phosphorylation in CMV-infected cells is by a CMV protein kinase (UL97).[112,113] Resistance to ganciclovir can result from mutations in this protein kinase.

Newer nucleoside analogs include penciclovir and famciclovir. Penciclovir, like acyclovir, also requires initial phosphorylation by viral TK. Although penciclovir inhibits viral DNA polymerase less effectively than does acyclovir, high intracellular levels of the phosphorylated drug and its longer intracellular half-life result in viral inhibition similar to that achieved with acyclovir.[114] Famciclovir is itself inactive, but it is converted to penciclovir following absorption through the intestinal wall.[115] Ganciclovir, penciclovir, or famciclovir cannot be used to treat TK-deficient strains of HSV. In contrast, strains resistant to acyclovir because of mutations in the HSV DNA polymerase may still be sensitive to one or more of these medications. However, most resistant strains are deficient in TK production. For these strains, foscarnet therapy can be an alternative. Foscarnet is a pyrophosphate analog that noncompetitively inhibits the viral DNA polymerase.[116] Isolates of HSV, CMV, and VZV that are resistant to foscarnet because of mutations in the viral DNA polymerase have been described. Because foscarnet requires intravenous administration, topical application of trifluridine may be considered in select patients.[117] Both cellular and viral-encoded TK can initiate phosphorylation of trifluridine.[118] As a result, trifluridine is too toxic to be used systemically but can be used topically to treat TK-deficient strains of herpesviruses.

Vidarabine is an analog of adenosine that is highly effective at inhibiting HSV and VZV replication.[119] The mechanism by this inhibition is not known. Although vidarabine inhibits viral DNA synthesis, it is not an absolute chain terminator. Vidarabine can be used to treat TK-deficient viral strains, but foscarnet is more efficacious and is currently recommended.[120]

Cidofovir is an acyclic phosphonate analog of cytosine that is phosphorylated to the active form by cellular enzymes.[121] Because initial phosphorylation by viral enzymes is not required, cidofovir can be active against resistant herpesvirus strains. The antiviral activity of cidofovir is prolonged, allowing for infrequent dosing of drug.

Other drugs, mostly still under development, target other processes in herpesvirus replication. Fomivirsen is a 21-base antisense oligonucleotide complementary to CMV immediate-early 2 mRNA.[122] Fomivirsen is available for the treatment of CMV retinitis. Inhibitors of a serine protease that is essential for viral capsid maturation and is unique to herpesviruses (encoded by UL26 in HSV) may prove effective for the treatment of a wide range of herpesvirus infections.[123] Additional agents include those that inhibit HSV helicase and HSV ribonucleotide reductase.[124,125]

As more is learned about the molecular interactions essential for herpesvirus replication and for the establishment of latency, attention is likely to be focused on developing new drugs or agents that can block interactions specifically required by the virus. Known inhibitory agents, even if not therapeutically useful, can provide structural information needed to design clinically acceptable drugs with antiviral activity. For example, analogs of heparin might bind to HSV, CMV, or HHV-8 and block their adsorption to cells without possessing all the other pharmacologic activities of heparin. In fact, several sulfated or sulfonated polymers, or unrelated compounds that can also block the binding of HSV and HIV to cells, are being advanced to clinical trials for testing as intravaginal topical microbicides.[126] Similarly, finding compounds that can block the interaction between a herpesvirus and its entry receptor(s) may lead to the development of medications that can prevent viral entry into cells.

VACCINES

Many viral vaccines in current use prevent or attenuate clinical disease but do not necessarily prevent infection. The goal in vaccination has been to induce immunity that is equivalent to that induced during recovery from natural disease and which often confers long-lasting protection against another episode of the disease. However, even vaccines with limited efficacy may have a substantial impact on the prevalence of infection in a population by reducing the risk of acquiring the virus. Vaccine development poses great challenges in the case of herpesviruses because recovery from natural disease is not associated with elimination of virus and does not always protect against another episode of disease.

Live-attenuated, killed, and recombinant subunit herpesvirus vaccines have all been studied. Whole-virus vaccines have the advantage of exposing the immune system to all viral antigens. Live-attenuated vaccines have tended to produce longer-lasting immunity than killed preparations. However, live-attenuated herpesvirus vaccines may be capable of establishing latent infections. The risks are not clear and there is concern that vaccine recipients who subsequently become immunosuppressed may develop disease caused by reactivated virus. Two avirulent HSV strains have been shown to generate lethal recombinants in mice.[127] Thus, recombination between an attenuated vaccine strain and a superinfecting wild-type strain could occur. Because several herpesviruses have been associated with malignancies in humans, the long-term safety of any live-attenuated vaccine needs careful study. The establishment of a latent infection is not a concern with subunit vaccines. However, effective subunit vaccines require knowledge as to which viral proteins are the best immunogens for protective immunity.

Although there are no licensed vaccines currently available for HSV, CMV, EBV, or HHV-8, research in this area is ongoing. For HSV, several different recombinant subunit vaccines have been tested successfully in animal models.[128] In persons seronegative for HSV-2, immunization with a subunit vaccine containing both HSV-2 gB and gD has resulted in humoral and cellular immune responses equivalent to or greater than those typically seen with natural infections.[129] However, vaccination with both gB and gD in two large randomized and controlled trials failed to protect seronegative persons from the acquisition of HSV-2, despite high levels of HSV-2-specific neutralizing antibodies.[130] In two other large randomized and controlled trials, vaccination with gD reduced the acquisition of genital herpes among seronegative women but not among women seropositive for HSV-1 and seronegative for HSV-2 and not among men.[131]

In addition to preventing initial disease, another goal of vaccination may be to bolster the natural immunity of persons already infected and therefore prevent recurrent disease. In a study of persons with recurrent genital herpes, recipients of a HSV-2 gD subunit vaccine had fewer and less severe recurrences than placebo recipients.[132] The vaccine recipients in this study had higher titers of neutralizing antibodies.

A variety of vaccines against CMV (subunit, DNA-based, peptides, CMV antigens in viral vectors, and live-attenuated viruses) are also in various stages of testing and investigational use.[133]

SUMMARY

Despite the remarkable diversity of the human herpesviruses with respect to the diseases they cause, latent infection and subsequent reactivation of viral replication are key aspects of

their biology and pathology. The prevalence and epidemiology of herpesvirus-induced diseases are determined in large part by the fact that latently infected persons experience periodic reactivation and production of transmissable virus, whether or not clinical symptoms accompany the virus production. The management of immunocompromised patients is complicated by the facts that most of us carry one or more latent herpesviruses and that reactivation of these viruses can be devastating in the absence of normal immune responses. In immunocompetent persons, however, it is principally HSV that causes recurrent disease through reactivation of latent virus. This kind of disease poses difficult but interesting challenges for prevention and treatment.

24 Genital Herpes

Lawrence Corey and Anna Wald

Genital herpes simplex virus (HSV) infection is a disease of major public health importance, with markedly increased prevalence throughout the world during the last four decades. The morbidity of the illness, its high recurrence rates, its complications such as aseptic meningitis and neonatal transmission, have made this disease of great concern to patients and health-care providers. Multiple interactions between HSV and HIV, both on epidemiologic and clinical levels, further highlight the importance of this infection.

HISTORY

The word herpes (from the Greek, "to creep") has been used in medicine for at least 25 centuries. Cold sores (herpes febrilis, fever blisters) were described by the Roman physician Herodotus in 100 AD.[1] Genital herpes was first described by the French physician John Astruc in 1736, and the first English translation appeared in his treatise on venereal disease in 1754.[2] The disease also appeared to be well recognized by the venereologists of nineteenth century. In 1893 Unna diagnosed genital herpes in 9.1% of 846 prostitutes visiting his infirmary.[3] In 1886 Diday and Doyon published the monograph *Les Herpes genitaux* in which they observed that genital herpes often appeared after a venereal infection such as syphilis, chancroid, or gonorrhea. They also described cases of recurrent genital herpes.[4]

Fluid from oral–labial infection was shown to be infectious to other humans in the late nineteenth century. The disease was successfully transferred to rabbits in the early twentieth century, and HSV was grown in vitro in 1925.[5–7] In 1921, Lipshultz inoculated material from genital herpetic lesions into the skin of humans, eliciting clinical infection within 48–72 hours in six persons and within 24 days in one case. In other experiments, he observed that rabbits developed corneal infection more readily with strains originating from genital sites than oral–labial sites. While he surmised that there were epidemiologic and clinical differences between oral and genital herpes,[8] most workers felt that the viruses of genital and labial herpes were identical. In the early 1960s, Schneeweiss in Germany and Dowdle and Nahmias in the United States reported that HSV could be divided by neutralization tests into two antigenic types and that there was an association between the antigenic type and the site of viral recovery.[9–12]

EPIDEMIOLOGY

SEROEPIDEMIOLOGY OF HSV INFECTION

The development of accurate serologic assays for HSV-1 and HSV-2 has markedly enhanced our understanding of HSV-1 and HSV-2 epidemiology. In both infections, most people have subclinical disease and can be identified only by antibody status. The type-specific serologic assays allow the detection of HSV-2 in the presence of HSV-1 antibodies and vice versa.[13,14] Most of these assays utilize purified type-specific proteins such as glycoprotein gG1, and glycoprotein gG2, which are antigenically distinct between the two subtypes. The gG1 and gG2 assays accurately evaluate persons with long-standing HSV infections, regardless of clinical symptoms.[15] In the last 5 years, several of these assays, either in an ELISA or immunoblot format, have become commercially available, allowing for large-scale seroepidemiologic studies in various populations. Another approach for defining type-specific antibodies to HSV-1 and HSV-2 has been the use of Western blot assays to prototype antigens that has undergone extensive evaluation in defining subtype-specific antibody patterns.[14] The Western blot remains the most accurate test for serologic diagnosis of HSV-1 and HSV-2 infection, with a sensitivity of >98% and a specificity of >98% for distinguishing HSV-1 specific and HSV-2 specific antibodies. Commercially available HSV antibody assays have specificity and sensitivity (>95%) that are sufficient for clinical use,[16–19] although many of them have lower sensitivity for detection of incident and prevalent HSV-1 infection. ELISA and IFA assays which utilize prototype viral antigens are inaccurate and should not be utilized for clinical diagnosis or seroepidemiologic studies.[20,21]

Prevalence of antibody to HSV increases with age and correlates inversely with socioeconomic status.[12,22–26] Serosurveys of western populations in the post-World War II era found that 80–100% of middle-aged adults of lower socioeconomic status had antibodies to HSV, as compared with 30–50% of adults of higher socioeconomic groups.[27–29] In the United States in the 1970s, HSV-1 antibodies were detected in about 50% of high and 80% of lower socioeconomic class persons by age 30.[29] In the most recent data from NHANES, the prevalence of HSV-1 appears to have fallen slightly from 62% in the years 1988–1994 to 57.7% in the years 1999–2004 in the general population.[30] In Western Europe, the prevalence of HSV-1 infection in young adults remains 10–20% higher than that in the United States.[31] In STD clinics in the United States, about 60% of attendees have HSV-1 antibodies. In Asia and Africa, HSV-1 infection remains almost universal with the infection acquired in early childhood, although the HSV-1 prevalence in Japan is considerably lower.[32]

Antibodies to HSV-2 are not routinely detected in sera until puberty, and antibody prevalence with rates correlate with indices of sexual activity. The wider availability of serologic tests for HSV-2 has allowed for extensive characterization of HSV-2 infection worldwide (Fig. 24-1). Consistently, HSV-2 seroprevalence is higher among women than men. In the United States, the rates of HSV-2 have been assessed in consecutive nationwide surveys of adults. These studies showed that the HSV-2 seroprevalence has increased from 16.4% to 21.7% of adults in the United States between 1979 and 1991.[33] However, the most recent data that spans the 1999–2004 years suggest that the overall prevalence has decreased somewhat to 17%, reflecting a lower rate of infection among teenagers and young adults.[30] The cumulative lifetime incidence of HSV-2 reaches 25% in white women, 20% in white men, 80% in African American women and 60% in African American men (Fig. 24-2). Higher rates of HSV-2 among African American have been observed, which reflect higher rates of infection in the African American community as well as patterns of sexual networking rather than higher individual sexual behavior.

Worldwide, the HSV-2 seroprevalence appears lower in Europe, including Great Britain (9.7%) and Eastern Europe (6–25%),[34–36] and Australia (16% in women, 8% in men).[37,38] In Africa, population-based studies indicate very high level of infection, with teenagers becoming infected at the onset of sexual activity. For example, in South Africa, HSV-2 infection rates reach 80% in women and 40% in men by age 24.[39] In Latin America, HSV-2 infection rates range from 20% in women in Peru to 43% in female blood donors in Brazil to over 60% among men in STD clinic.[35,40] Fewer population-based studies have been conducted in Asian countries; among pregnant women the prevalence was 27% in Saudi Arabia, 8% in India, and 30% in the South Pacific Island Nation of Vanuatu.[35,41,42]

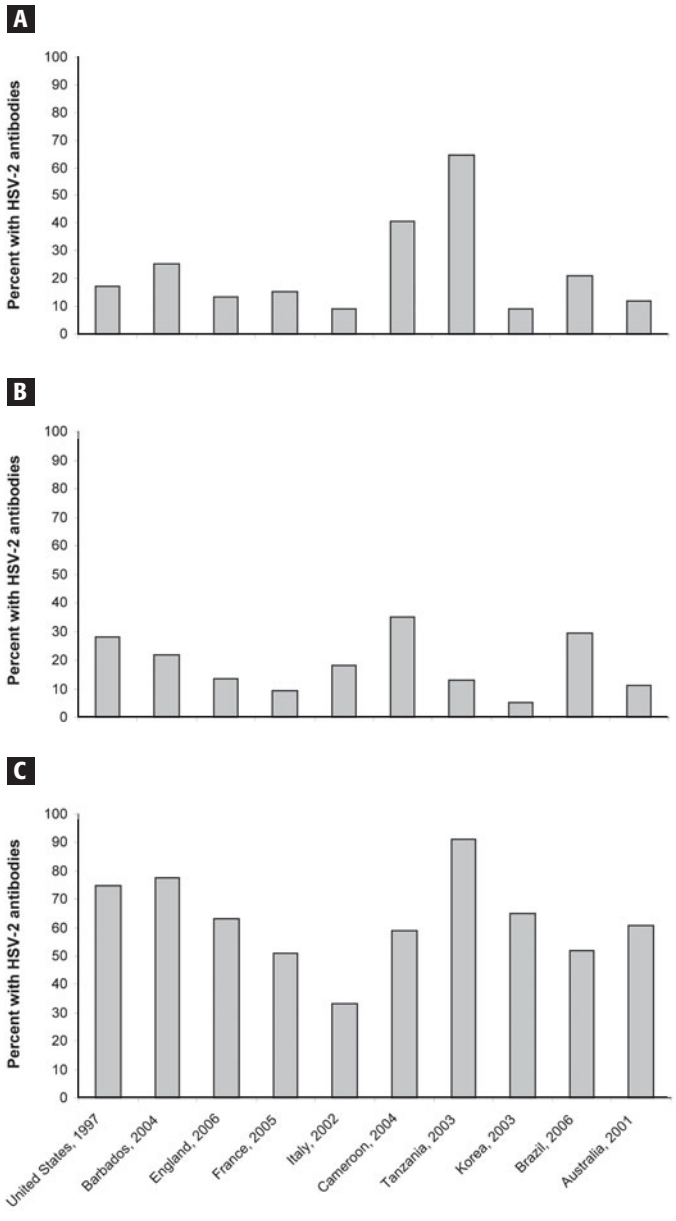

FIGURE 24-1. Seroprevalence of HSV-2 in population-based studies, and among pregnant women, and HIV-1 seropositive persons.

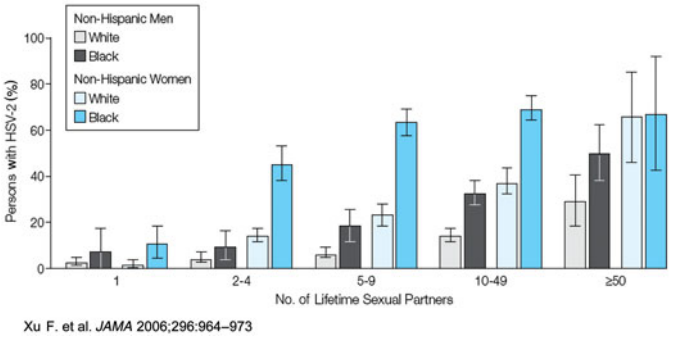

FIGURE 24-2. Age-adjusted herpes simplex virus type-2 seroprevalence according to the lifetime number of sex partners, by race/ethnicity and sex on NHANES in 1999–2004.

Not surprisingly, the frequency of HSV-2 antibody is higher among persons recruited from STD clinics and among men who have sex with men (MSM).[43,44] In both general population and high-risk groups, HSV-2 antibody is closely related to the lifetime number of sexual partners, age of sexual debut, and a history of other STDs. As such, it can serve as a serologic marker for sexual behavior in different populations.[45] HSV-2 infection rates are also higher among people with HIV infection; the complex interactions between HSV-2 and HIV are summarized below.

Incidence rates for HSV infections are difficult to estimate as most infections are acquired subclinically. A 15-year study of 839 adolescent women in Sweden showed that 50% of the cohort has acquired HSV-1 and 22% acquired HSV-2 by the end of the study.[46] Studies of candidate vaccines have shown that the risk of HSV-2 varies with gender, sexual orientation, and risk behavior.[47] Among HSV-2 seronegative women with partners who have documented genital HSV-2 infection, the rates of infection were 8.6% per 100 patient years.[48] Conversely, the rate of HSV-2 acquisition among men partnered with HSV-2 infected women was 1.5%. However, the rates of HSV-2 acquisition were higher among men recruited from STD clinics.[49] In Project RESPECT, a behavioral intervention study of high-risk urban youth, the incidence of HSV-2 was 9.9 per 100 person years for men and 14.8 for women.[50] In prospective studies of HIV seronegative MSM, the rates of acquisition of HSV-2 were 1.9 per 100 patient years and 1.0 per 100 patient years in two studies of HIV prevention.[51,52] HSV-2 acquisition is also common among persons with HIV. In a study from Zimbabwe, the risk of HSV-2 acquisition was 4.7-fold higher among HIV-positive versus HIV-negative persons; in a Ugandan study, the risk was 2.7-fold higher.[53,54] In a study of Ethiopian women with HSV-2 seropositive spouses, the rate of HSV-2 acquisition was 25% per 100 person years and in Tanzanian bar workers, 14.2 cases per 100 person years.[55,56] This high rate of HSV-2 acquisition in HIV seropositive person may reflect high-risk behavior, increased susceptibility, and/or exposure of HIV/HSV-2 infected person who are likely to be more infectious for HSV-2 than those without HIV (see below).

PREVALENCE OF GENITAL HSV INFECTIONS

The reported prevalence of genital herpes depends upon the demographic and clinical characteristics of the patient population studied and whether clinical and/or laboratory techniques are used for diagnoses. Seroepidemiologic studies have shown a wide disparity between antibody prevalence and clinical infections, indicating that many persons acquire subclinical infection.[12,57] Reasons for lack of recognition of the infection include mild disease in most persons, attenuation of symptoms in those with prior HSV-1 infection, location of lesions in difficult-to-examine areas, e.g., perianal region, and differential access to health care and availability of diagnostics in various populations. As such, there are great differences in the prevalence of HSV-1 and HSV-2 infection versus the frequency of symptomatic genital and oral–labial herpes seen by medical practitioners. HSV has been isolated from 0.3% to 5.4% of men and 1.6% to 10% of women attending STD clinics.[58–60] In non-STD clinic patient populations, HSV has been isolated from the genital tract in from 0.25% to 5.0% of patients. Most of these patients are asymptomatic.[61–64] HSV-2 has been shown to be the dominant cause of genital ulcer disease both in developing and developed countries. In Africa, the Far East and the United States, genital herpes is from 2 to 10 times more common than other infections in genital ulcers. The shift from syphilis and chancroid to genital herpes as the etiologic cause of genital ulcer disease can primarily be attributed to the use of HSV DNA PCR for detection of viral genome, in combination with the relative decrease in syphilis and chancroid caused by improved control methods and wider use of antibiotics. Etiologies of genital ulcer disease as defined by molecular diagnostics from diverse locations are shown in Table 24-1.

In the United States, HSV predominates as the most common cause of genital ulcers at all locations, and remains stable, unlike the rates of detection of *T. pallidum* and chancroid that have marked temporal and geographic variations.[65] The lack of detection of HSV in studies historically from developing countries based on clinical diagnosis or viral culture reflects the insensitivity of both methods. Overwhelmingly, the predominant cause of genital ulcers worldwide is HSV-2, accounting for 40–80% of diagnosed etiologies of genital ulcers. Of note, ~25% of genital ulcers continue to be undiagnosed.[67,68,73] This may partly reflect imperfect sensitivity of the multiplex assay often used. Detailed studies that employ both sensitive molecular techniques and serologic assays that characterize the natural history of such ulcers have rarely been performed. Additionally, the long duration of ulcers prior to seeking health care in developing countries skews the presentations observed in STD clinics toward more chronic etiologies. Consistent with this, HIV epidemic has resulted in greater proportion of persons presenting with genital herpes as the ulcers persist and are more extensive.[69,76]

The prevalence of genital herpes has increased markedly between the early 1960s and 1990s. In Britain, reports of patients with genital herpes in STD clinics increased sixfold between 1972 and 1994.[77] Initial visits to physicians in the United States for first-episode genital HSV increased 15-fold, from 16,986 in 1970 to over 240,000 in 2004,[78,79] and continue to increase, in marked contrast to the leveling off of HSV-2 seroprevalence results.

In the last decade, an increase in genital HSV-1 infections has been reported from Europe, North America, and Australia.[80,81,82,83] Several laboratory-based studies reported a shift in the relative proportion of HSV-1 and HSV-2 isolated

Percent may not add to 100%, as more than a single pathogen were found in some lesions.

from genital lesions, often with predominance of HSV-1 isolates from young people, women, and MSM.[84,85] The relative proportion of HSV-1 approximates 50% in some studies of college students.[86] While laboratory-based reporting is perhaps not a good indicator of overall incidence of genital herpes, the shift in the type of HSV found has been consistent. The reasons are not clear: both decrease in oral acquisition of HSV-1 during childhood and frequent oral–genital contact, especially among teenagers, have been postulated as a cause. Confirming this observation has been a change in the proportion of neonatal HSV-1 versus HSV-2 infection, with HSV-1 causing most infections in some series.[87]

SEXUAL TRANSMISSION OF HSV

The frequency of transmission of HSV-2 is influenced by gender, past HSV-1 infection, and frequency of sexual activity with a person with known infection. Transmission of HSV between sexual partners has been addressed most often in prospective studies of serologically discordant couples, i.e., in couples in whom one partner has and the other does not have HSV-2. Longitudinal studies of such couples have shown that the transmission rate varies from 3% to 12% per year.[47,88–90] Several studies have described couples in which HSV-2 has not been transmitted despite frequent sexual activity. Whether this is due to genetic or acquired resistance is unclear. Unlike other STDs, persons usually acquire genital HSV-1 and genital HSV-2 in the context of a steady rather than casual relationship.[91] Women have higher rates of acquisition than men; in one study the attack rate among seronegative women approached 30% per year.[88] This increased risk for acquisition among women compared with men is evident in the 5–20% higher seroprevalence of HSV-2 antibodies among women than men.[30] The reasons probably include anatomic differences which lead to greater mucosal surface area exposed in the genital area of women compared with men and possibly a lower perception of discomfort in men with active lesions than in women.[92,93] This latter feature may lead to increased sexual activity when lesions are present and hence higher transmission rates. Patterns of sexual behavior probably also play a role, with older men serving as a source of infections for younger women.

Sexual contact with persons with undiagnosed genital herpes may lead to higher acquisition rates. In a study of

66 source partners who were interviewed and examined, a third had a history of recurrent genital herpes, a third had a clinical history of recurrent genital lesions consistent with herpes, and a third denied a history of such lesions.[94] Median time of the relationship before transmission occurred was 3 months and the median number of sexual encounters was 24, suggesting that HSV is transmitted rather easily. These data have recently been confirmed in a study that showed the potential source partners' awareness of having genital herpes and disclosing it to the sexual partner is associated with a 50% decrease in the risk of HSV-2 transmission.[91] Thus, the diagnosis of genital herpes in the potential source partner and awareness of both partners as to the existence of a transmissible sexually transmitted infection (STI) may help reduce the risk of transmission. Most transmission events occur during episodes of subclinical shedding (discussed below). In prospective studies of HSV acquisition, only 40% of newly acquired cases of genital HSV-2 develop genitourinary complaints around the time of acquisition; prior HSV-1 infection protects against symptomatic acquisition of HSV-2. The disease pattern in the person who acquired the disease does not reflect the disease pattern of the source partner, suggesting that host factors rather than viral factors determine the severity of disease. Fifty-eight percent of patients with newly acquired genital herpes presented within 5 days of last sexual contact and 95% within 14 days of sexual intercourse, confirming the short incubation period noted in experimental human and animal studies.[8,95] There is conflicting data on whether past HSV-1 infection protects against HSV-2 acquisition, with the protection being marginal in most studies.[96]

PATHOGENESIS OF INFECTION

Transmission of HSV infections most frequently occurs through close contact with a person who is shedding (excreting) virus at a peripheral site, mucosal surface, and in genital or oral secretions. Since HSV is readily inactivated at room temperature and by drying, aerosol and fomitic spread are unusual means of transmission.[97–100] Infection occurs via inoculation of virus onto susceptible mucosal surfaces (e.g., the oropharynx, cervix, conjunctivae) or through abrasions on the skin. HSV infection is associated with focal necrosis and ballooning degeneration of cells, production of mononucleated giant cells, and eosinophilic intranuclear inclusions (Cowdry type-A bodies).[101] The initial cellular response is predominantly polymorphonuclear, followed by lymphocytic response. When viral replication is restricted, lesions reepithelialize.

Concomitant with initial infection, HSV ascends peripheral sensory nerves and enters sensory or autonomic nerve root ganglia where latency is established.[102–105] Using cocultivation techniques HSV-2, and rarely, HSV-1 have been isolated from sacral nerve root ganglia.[104] The biological mechanism by which latency is established and the nature of the virus–cell interaction that results in latency is incompletely understood. Latency can be established after both symptomatic and asymptomatic initial infection. Available evidence suggests that all HSV seropositive persons have latent virus in nerve ganglia and possibly all HSV-2 seropositive persons intermittently reactivate infection with HSV shedding occurring at least briefly on mucosal surfaces. Reactivation of disease may be clinically symptomatic or asymptomatic. Reinfection with different strains of virus has also been demonstrated; however, this appears to be an infrequent event and recurrences are usually due to reactivation of the initial strain of virus from latently infected ganglia.[106,107]

The molecular mechanisms by which HSV establishes latency and intermittently reactivates are unknown. Moreover, little is known about the molecular mechanisms of reactivation; largely because there are few accurate experimental systems to study these issues in vitro. In animal models, many HSV genes influence neuroinvasion and spread. When the region containing the latency-associated transcripts of HSV-2 is inserted into an HSV-1 virus, increasing reactivation in sacral nerve root ganglia has occurred, indicating that viral factors influence reactivation.[108]

Host factors also appear operative in influencing reactivation. Immunocompromised patients have both more frequent and more severe reactivations. Both HSV-1 and HSV-2 encode for proteins that are directed at subverting host T cell responses. The HSV protein, ICP-47 (infected cell protein no. 47), interacts with the transporter activity protein to prevent the interaction between HSV-specific peptides to HLA class I molecules. This downregulates certain HSV-1 peptides with HLA class I antigen on the cell surface and subverts the host $CD8^+$ CTL response to HSV.[109–111] Similarly, HSV infection can "stun" cytotoxic T lymphocytes and impair both their signaling and cytokine secretion.[112,113] This CTL inactivation appears unique to HSV-1 and HSV-2 and is associated with viral-cell entry.

Biopsies of herpetic lesions have shown that initially the predominant infiltrating cell is the $CD4^+$ lymphocyte.[114] Staining of such lesions shows the presence of activation markers on these CD4-bearing cells. These include IL-2 receptor, DR+, and ICAM-1+ within 2–4 days. These early $CD4^+$ infiltrating T cells produce γIFN and other cytokines in response to HSV antigen. γ-IFN in particular upregulates cellular HLA class I expression, which can then overcome the virus's ability to downregulate this response.[111] Infiltration of $CD8^+$ T cells into the lesion then occurs and helps clear virus. Clearance of HSV-2 from genital lesions is associated with detection of cytolytic killing of HSV-2 in lesional T cells.[115] Most of this CTL activity appears to be in the $CD8^+$ T lymphocytes. HSV-2 specific $CD8^+$ T cells appear to persist after healing resolution in the dermal epidermal junction and are

juxtaposed to the neural endings that innervate the region (Fig. 24-3).[116] These data imply that such cells participate in immune surveillance.

There is evidence that CD8+ T cells can be found in dorsal nerve root ganglia and such T cells appear to secrete γ-IFN, and removal of such cells is associated with viral reactivation.[117–120] These host responses may be important in controlling HSV at a ganglion level.

CLINICAL MANIFESTATIONS OF GENITAL HERPES

The severity of clinical manifestations and recurrence rate of genital herpes are influenced by viral and host factors such as viral type, prior immunity to autologous or heterologous virus, gender, and immune status of the host. The influence of other host factors such as age, race, and site of inoculation on the acquisition of infection or expression of disease are poorly understood. Host genetic background is likely to influence the natural history of HSV infections, but with exception of few well-characterized genetic mutations that are associated with severe outcomes,[121–125] the genetic determinants of severity of mucosal HSV infections are unknown. Many HSV infections (both HSV-1 and HSV-2) are subclinical and the differences in persons with symptomatic versus clinically silent disease have not been defined. Moreover, identical strain of virus may have markedly different patterns of reactivation between persons.

FIRST EPISODE OF GENITAL HERPES

The clinical manifestations of genital herpes differ greatly between first versus recurrent episode of HSV. First episodes of genital herpes often are associated with systemic symptoms, a prolonged duration of lesions, and viral shedding, and involve multiple genital and extragenital sites.[126] Patients who are experiencing true primary infection (i.e., the first infection with either HSV-1 or HSV-2) have more severe illness than patients who have clinical or serological evidence of prior HSV-1 infection.[127–129] In most surveys, about 50% of persons who present with their first episode of symptomatic genital herpes have primary infection with either HSV-1 or HSV-2.[61] Most persons with nonprimary first episodes of genital HSV infection have serological evidence of past HSV-1 infection;[130] acquisition of HSV-1 infection in persons with prior HSV-2 infection is rare. About 25% of persons with their first clinical episode of symptomatic genital herpes already have antibody to HSV-2 at presentation, indicative of past asymptomatic acquisition of HSV-2.[131] Thus, their initial clinical episode is their first recognized episode of past infection and does not indicate recent acquisition. Isolates recovered from sequential recurrences almost invariably have identical restriction enzyme patterns. Most genital HSV-1 infections are primary infections, as genital HSV-1 acquisition is rare after HSV-2 infection.[93,126,132,133]

Prior oral–labial HSV-1 infection appears to protect against the acquisition of genital HSV-1 disease,[130] although this has not been rigorously studied and the degree of this protection is not quantified. Genital HSV-1 disease does not protect completely against acquisition of genital HSV-2 infection, as sequential genital infections have been described.[134,135] Persons with first-episode nonprimary genital HSV-2 infection (i.e., prior HSV-1 infection) are less likely to have systemic symptoms and have a shorter duration of symptoms and signs than persons with primary genital herpes due to either HSV-1 or HSV-2.[61,126] However, prior HSV-1 infection does not appear to alter the subsequent rate of recurrences of genital HSV-2 disease.[93]

Primary genital herpes

Primary genital HSV-2 and primary genital HSV-1 infections are characterized by frequent and prolonged systemic and local symptoms (Fig. 24-4). Fever, headache, malaise, and myalgias are reported in nearly 40% of men and 70% of women with primary HSV-2 disease ($p < 0.05$). Systemic symptoms appear early in the course of the disease, usually reach a peak within the first 3–4 days after onset of lesions, and gradually recede over the subsequent 3–4 days.

Pain, itching, dysuria, vaginal or urethral discharge, and tender inguinal adenopathy are the predominant local symptoms of disease. The severity of local symptoms, duration of

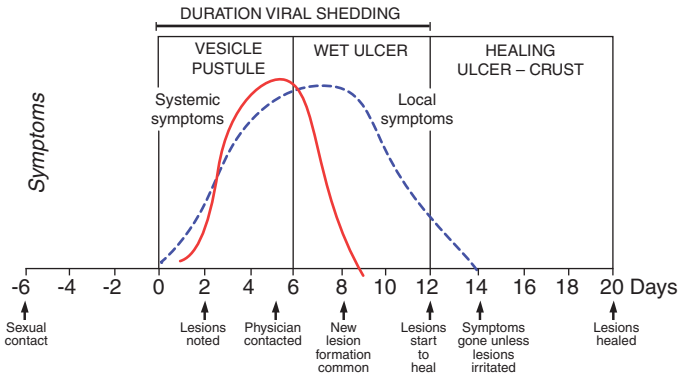

FIGURE 24-4. Clinical course of primary genital herpes.

lesions, and viral shedding appear similar in patients with primary HSV-1 and primary HSV-2 disease. Painful lesions are reported in 95% of men (mean duration 10.9 days) and 99% of women (mean duration 12.2 days) with primary HSV infection. Dysuria, both external and internal, appears more frequently in women (83%) than in men (44%). The isolation of HSV from the urethra and urine of both men and women with primary genital herpes suggests that, in addition to external dysuria resulting from urine touching active genital HSV lesion, HSV urethritis and/or cystitis may account for the higher frequency and longer duration of dysuria in women.

Urethral discharge and dysuria are noted in about one-third of men with primary HSV-2 infection. HSV can be isolated from a urethral swab or from first-voided urine of these men. The urethral discharge is usually clear and mucoid, and the severity of dysuria is often out of proportion to the amount of urethral discharge elicited on genital exams. Gram stain of the urethral discharge reveals between 5 and 15 polymorphonuclear leukocytes per oil-immersion field. Occasionally, a mononuclear cell response is seen.

The clinical symptoms of pain and discomfort from lesions gradually increase over the first 6–7 days of illness, reach their maximum intensity between days 7 and 11 of disease, and gradually recede over the second week of illness. Tender inguinal adenopathy usually appears during the second and third week of disease and often is the last symptom to resolve. Inguinal and femoral lymph nodes are generally firm, nonfluctuant, and extremely tender to palpation. Suppurative lymphadenopathy is a very uncommon manifestation of genital herpes.

Clinical signs and duration of viral shedding in primary genital herpes. In both men and women with primary genital HSV infection, widely spaced bilateral vesicopustular or ulcerative lesions on the external genitalia are the most frequent presenting sign (Figs. 24-5 and 24-6). Lesions are characteristically described as starting as papules or vesicles which rapidly spread over the genital area. At the time of the first clinic visit, multiple small vesicular lesions that coalesce into large areas of ulcerations are usually present, especially in women. The number, size, and shape of the ulcerative lesions vary greatly between patients. Edema of the labia or penis is common. These ulcerative lesions persist from between 4 and 15 days until crusting and/or reepithelialization occurs. In general, lesions in the penile and mons areas crust over before complete reepithelialization ensues. Crusting does not occur on mucosal surfaces. Residual scarring from lesions is uncommon. New

FIGURE 24-5. Primary HSV in a man.

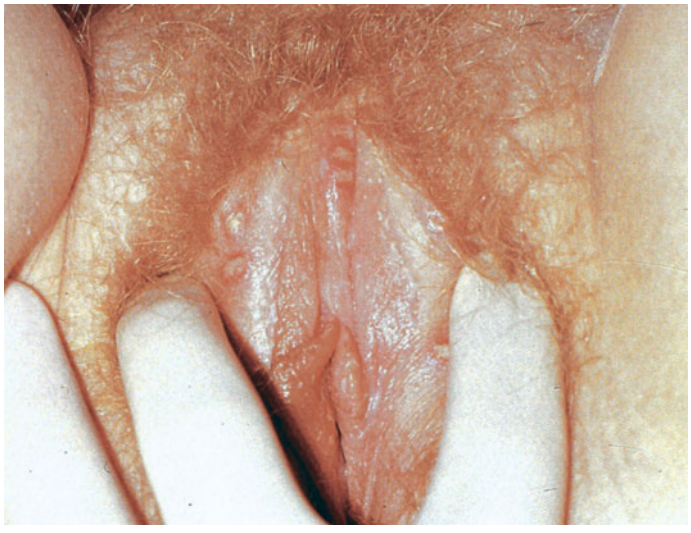

FIGURE 24-6. Primary Vulvar HSV.

lesion formation (the development of new areas of vesiculation or ulceration during the course of infection) occurs in over 75% of patients with primary genital herpes. New lesions usually form between days 4 to 10 of disease and one of the most obvious clinical effects of early systemic antiviral therapy of primary genital herpes is the reduction in new lesion formation. The median duration of viral shedding, as defined from onset of lesions to the last positive culture, is 12 days. The mean time from the onset of lesions to complete reepithelialization of all lesions appears slightly longer in women (19.5 days) than in men (16.5 days).

HSV cervicitis in first episodes of genital herpes. From 70% to 90% of women with first-episode HSV-2 infection have HSV cervicitis.[126,136] This compares to a 15–20% isolation rate of HSV-2 from the cervix among women who present with recurrent external genital lesions.[126,137] Primary genital HSV cervicitis may be symptomatic (purulent or bloody vaginal discharge) or asymptomatic.[61,138] Areas of diffuse or focal friability and redness, extensive ulcerative lesions of the exocervix, or severe necrotic cervicitis (Fig. 24-7) may be seen, occasionally in the absence of external herpetic lesions. HSV infection of the cervix usually involves the squamous epithelium of the exocervix in contrast to the mucopurulent cervicitis of *C. trachomatis* and *N. gonorrhoeae* infection. Clinical differentiation may be difficult, although cervical ulceration and necrosis is highly correlated with HSV cervicitis.

Pharyngeal infection. HSV of the pharynx is commonly seen in association with primary genital herpes and may be the presenting complaint in about 20% of patients with either primary HSV-1 or primary HSV-2 infections. Both HSV-1 and HSV-2 may cause pharyngitis and may be associated with oral–genital exposure to the source contact.[139,140] In children, autoinoculation of the genital area during the course of primary HSV-1 gingivostomatitis may be seen occasionally. HSV pharyngitis is seen much less frequently in patients with nonprimary first-episode genital herpes or patients with recurrent genital herpes (1%). Among persons with primary genital herpes who complained of sore throat during the acute episode of the disease, HSV was isolated from the pharynx in 70%. Viral cultures of the pharynx from 20 patients with primary HSV-2 who did not complain of sore throat did not yield HSV, indicating that HSV pharyngitis is usually symptomatic. Clinical signs of HSV pharyngitis may vary from mild erythema to a diffuse ulcerative pharyngitis.[139–142] The inflammatory response to these large areas of ulceration may produce a whitish exudate; when wiped away the extensive ulceration may be visualized. In rare cases severe swelling of the posterior pharynx resulting in obstruction of the airway may occur.[143] Extension of the ulcerative posterior pharyngeal lesions into the anterior gingival area may occur. Most patients with HSV pharyngitis have tender cervical nodes, and constitutional symptoms, such as fever, malaise, myalgia, and headache, are common. Many are misdiagnosed as having streptococcal pharyngitis, or infectious mononucleosis, and tonsillectomies in such patients have been reported.

HSV-1 pharyngitis is common in teenagers and college students and is often due to primary oral HSV-1 infection. The mode of transmission often is kissing during subclinical oral shedding. Reactivation of HSV in the pharynx rarely leads to symptomatic pharyngitis. Instead, recurrent oral–labial lesions or asymptomatic oral shedding are seen. Reactivation of HSV-2 in the trigeminal ganglia occurs less frequently than reactivation of trigeminal nerve root latent HSV-1 infection.[140,144]

COMPLICATIONS OF GENITAL HERPES

The complications of genital herpes are related both to local extension and to spread of virus to extragenital sites. Central nervous system involvement and fungal superinfection are also frequently encountered. Complications of primary genital herpes occur more frequently in women than in men.

Central nervous system complications

Aseptic meningitis. Central nervous system involvement may occur in several forms, including aseptic meningitis, transverse myelitis, or sacral radiculopathy.[145–147] In one series of patients with primary genital HSV-2 infection, stiff neck, headache, and photophobia on two consecutive examinations was reported in 36% of women and 13% of men ($p < 0.001$). Hospitalization was required for clinically overt aseptic meningitis in 6.4% of women and 1.6% of men with primary HSV-2 infections.[126] A study of primary genital herpes in the early 1900s reported a high frequency of CSF pleocytosis in patients without overt clinical evidence of meningeal irritation, suggesting that meningeal involvement may be frequent during primary genital herpes.[148]

Both HSV-1 and HSV-2 have been isolated from CSF, although nuchal rigidity and isolation of HSV-2 are much more common.[149,150] HSV aseptic meningitis is more frequently associated with genital HSV-2 infection, while HSV encephalitis in older children or adults is usually associated with oral HSV-1 infection.[93,151–153] Fever, headache, vomiting, photophobia, and nuchal rigidity are the predominant symptoms of HSV aseptic meningitis. Meningeal symptoms usually start from 3 to 12 days after onset of genital lesions. Symptoms generally reach a maximum 2–4 days into the illness and gradually recede over 2–3 days. The CSF in HSV aseptic meningitis is usually clear and the opening pressures may be elevated. White blood cell counts in CSF may range from 10 to over 1000 cells per cubic millimeter (mean 550). The pleocytosis is predominantly lymphocytic in adults, although early in the course of disease and in neonates, a predominantly polymorphonuclear response may be seen. The CSF glucose is usually more than 50% of the blood glucose, although hypoglycorrhachia has been reported, and the CSF protein is slightly elevated.[154] HSV is rarely isolated from the CSF, but HSV DNA detection with PCR assay is a sensitive diagnostic test (see section on diagnosis). The differential diagnosis of HSV aseptic meningitis includes diseases that result in neurological involvement and genital ulcerations: sacral herpes zoster, Behcet's syndrome (Fig. 24-8), collagen vascular disease, inflammatory bowel disease, and porphyria. Occasionally, patients will present with aseptic meningitis as the sole presenting sign of new HSV-2 acquisition; HSV detection in the spinal fluid in a patient lacking antibodies to autologous type virus is diagnostic.

Aseptic meningitis associated with genital herpes appears to be a benign, albeit uncomfortable, disease in immunocompetent persons. Signs and symptoms of encephalitis are unusual and persistent neurological sequelae are rare. Use of systemic antiviral chemotherapy of primary genital herpes decreases the subsequent development of aseptic meningitis.[155] Controlled trials of IV acyclovir (ACV) for established HSV meningitis have not been conducted. However, we recommend that IV ACV 5 mg/kg q 8 hours be given for hospitalized symptomatic patients. Once symptoms are resolved, oral antiviral therapy, preferably with valacyclovir, can be resumed. Oral antiviral agents should not, however, be utilized for patients with HSV-1 encephalitis.

FIGURE 24-8. Behcet's syndrome.

Other neurological complications. Both autonomic nervous system dysfunction and transverse myelitis have been described in association with genital HSV infection.[146–148] Symptoms of autonomic nervous system dysfunction include hyperesthesia or anesthesia of the perineal, lower back, and sacral regions and urinary retention and constipation. This complication occurs more frequently among women and men with HSV proctitis.[156,157] Physical examination reveals a large bladder, decreased sacral sensation, and poor rectal and perineal sphincter tone. In men, impotence and absent bulbocavernous reflexes may occur. CSF pleocytosis may be present in some patients. Electromyography usually reveals slowed nerve conduction velocities and fibrillation potentials in the affected area, and urinary cystometric examination shows a large atonic bladder. Most cases gradually resolve over 4–8 weeks.[158–161]

Transverse myelitis occasionally occurs in association with primary genital HSV infection.[158,162,163] Decreased deep-tendon reflexes and muscle strength in the lower extremities, as well as the above-described autonomic nervous system signs and symptoms, are present. In one reported case, significant residual dysfunction was present years later.[162] Whether autonomic nervous system dysfunction results from viral invasion of the central nervous system or an unusual immunologic response to infection is unknown.

EXTRAGENITAL LESIONS

The development of extragenital lesions during the course of infection is a common complication of first-episode primary genital herpes and is seen more commonly in women than in men. Extragenital lesions are most frequently located in the buttock, groin, or thigh area, although finger and eye can also be involved. Among patients with primary HSV-2, 9% develop extragenital lesions, most commonly on the buttocks.[164] Among patients with primary genital HSV-1, 25% develop extragenital lesions, usually in or around the mouth. Characteristically, the extragenital lesions develop after the onset of genital lesions, often during the second week of disease. The distribution of lesions on the extremities and/or areas near the genital lesions and their occurrence later in the course of disease suggests that the majority of extragenital lesions develop by viral reactivation in another

part of the affected dermatome rather than viremic spread.[165] However, the recent demonstration of HSV DNA in plasma of patients with primary HSV suggests that viremic spread may also be a factor in these lesions. Prior to universal use of gloves in health-care settings, HSV-1 was commonly isolated from herpetic infections of the hand.[97] Currently, herpetic infections of the hand are more likely to be caused by HSV-2 than HSV-1.[166]

DISSEMINATED INFECTION

Blood-borne dissemination evidenced by the appearance of multiple vesicles over widespread areas of the thorax and extremities occurs rarely in persons with primary mucocutaneous herpes.[167,168] Cutaneous dissemination usually occurs early in the disease and is often associated with aseptic meningitis, hepatitis, pneumonitis, or arthritis.[169,170] Other complications of primary genital HSV-2 infection include monoarticular arthritis,[171,172] hepatitis,[173,174] thrombocytopenia,[175] and myoglobinuria.[176] Pregnancy predisposes to severe visceral dissemination in primary genital HSV disease.[177–179] Diagnosis of disseminated HSV or HSV hepatitis is often delayed as skin lesions may be subtle or absent. Mortality is high, even in patients treated with IV ACV; liver transplant following HSV hepatitis has been reported. Severe mucocutaneous and occasionally visceral dissemination of disease may occur in patients with atopic eczema.[180–182] In immunosuppressed patients, especially those with impaired cellular immune responses, reactivation of genital HSV infection can be associated with viremic spread to multiple organs.[183–187] Such patients may develop interstitial pneumonia, hepatitis, and pneumonitis, similar to the manifestations of disseminated infection of the neonate. Disseminated visceral infections in the immunosuppressed and pregnant patient have high mortality and should be treated presumptively with systemic antiviral chemotherapy.

LOCAL EXTENSION OF DISEASE

Both HSV-1 and HSV-2 have been shown to be rare causes of pelvic inflammatory disease.[188] Some patients with primary cervical HSV infection may manifest lower abdominal pain and adnexal uterine tenderness, and extension of HSV infection into the uterine cavity has been reported, as well as laparoscopic evidence of vesicular lesions on the fallopian tube from which HSV has been isolated.[188]

Superinfection

Bacterial superinfection of genital herpes in immunocompetent patients is uncommon. In rare cases, pelvic cellulitis presenting as an advancing erythema and swelling of the perineal area is encountered. In such patients, systemic antimicrobial therapy should be administered.

In contrast, fungal vaginitis is frequently encountered during the course of initial genital herpes. In one series, yeast vaginitis was reported in 14% of women with first episodes of genital disease.[126] In another study of women attending an STD clinic, concurrent yeast infection was reported significantly more frequently in women with genital herpes than those without.[61] Characteristically, vaginal fungal infection develops during the second week of disease and is associated with a change in character of the vaginal discharge, and reemergence of local symptoms such as vulvar itching and irritation. Typical hyphal yeast forms can be demonstrated on potassium hydroxide examination of vaginal secretions. If symptomatic, appropriate treatment is recommended.

SUMMARY OF THE CLINICAL COURSE OF INITIAL GENITAL HERPES

First-episode genital HSV infection is a disease with both systemic and local manifestations. Over one-half of the patients with primary genital herpes suffer from constitutional complaints and one-third complain of headache, stiff neck, and mild photophobia during the first week of disease.

Patients with serological evidence of prior HSV-1 infection are less apt to have systemic symptoms and have a lower rate of complications and a shorter duration of disease than persons with true primary genital herpes. Neutralizing antibody to herpes simplex virus has been shown to inactivate extracellular virus and interrupt the spread of HSV infection.[189] In addition, a cellular immune response to HSV antigens appears earlier in persons with nonprimary genital HSV than in persons with true primary infection.[137] It is likely that both of these immune mechanisms account for the clinical differences between primary and nonprimary first episodes of genital infection.

Untreated primary genital herpes is a disease of significant morbidity warranting prompt diagnosis and treatment. We recommend initiation of oral antiviral therapy of all persons with a presumptive clinical diagnosis of first-episode genital herpes. Confirmation of the diagnosis with laboratory tests should be sought in all case, but therapy should not be delayed. Early use of therapy will abrogate the frequency of systemic manifestations of disease and prevent local extension of lesions into the upper genital tract. Moreover, early use of oral antivirals prevents the frequent development of new lesions that occur during the latter part of episode. In general, patients tend to note the resolution of headache, fever, and fatigue within 48 hours of initiating therapy with ACV, famciclovir, or valacyclovir. Lesions will continue to extend for the initial 48 hours, but the frequency of new lesions will decrease. Healing may take 7–10 days. We prefer to use at least 10 days of therapy with first-episode infection, as reactivation of virus with a new crop of vesicles is quite common in the initial 30 days posthealing of primary genital HSV-2. In our experience, early discontinuation of therapy tends to exacerbate this phenomenon. Besides

initiation of therapy, laboratory diagnosis and subsequent counseling about the nearly universal likelihood of reactivation and the potential for transmission of infection are the most important messages the treating clinician must convey to the patient with first-episode genital herpes. These latter issues are best discussed after symptoms and signs of disease abate at a later visit and are discussed more fully later in the chapter.

RECURRENT GENITAL HERPES: CLINICAL SIGNS AND SYMPTOMS

In contrast to first episodes of genital infection, the symptoms, signs, and anatomic sites of infection of recurrent genital herpes are localized to the genital region.[126,137,190] Local symptoms such as pain and itching are mild to moderate compared to initial genital infection, and the duration of the episode usually ranges from 6 to 12 days (Table 24-2). About 90% of persons with recurrent genital herpes develop prodromal symptoms in some episodes; the development of symptoms prior to appearance of lesions occurs in about 60% of the episodes.[191] Prodromal symptoms vary from a mild tingling sensation, occurring 0.5–48 hour prior to the eruption, to shooting pains in the buttocks, legs, or hips 1–5 days prior to the episode. In many patients, the symptoms of sacral neuralgia are the most bothersome part of the episode. In about 20% of episodes, patients experience prodromal symptoms without subsequent lesions. The risk of viral shedding is high during prodromal symptoms, even in the absence of lesions.

As with initial genital disease, symptoms of recurrent genital herpes tend to be more severe in women (Table 24-2). In several studies, painful genital lesions are reported more frequently (60–90%) in women (mean duration 5.9 days), compared with men (30–70%, 3.9 days, respectively). In addition, pain is more frequent and more severe in women compared with men.[92] Dysuria occurs in only 17% of women with recurrent disease. Most report only external dysuria, and isolation of HSV from the urethra is uncommon in both sexes (3–9%).

Lesions of recurrent genital HSV are usually confined to one side, with an area of involvement approximately one-tenth that of primary genital infection (Fig. 24-5). Untreated, the average duration of viral shedding from the onset of lesions is about 4 days; and the mean time from the onset of lesions to crusting of lesions averages between 4 and 5 days for both men and women (Table 24-2). The mean time from the onset of vesicles to complete reepithelialization of lesions is about 6–10 days. Considerable variability exists in the severity and duration of disease both among patients and in a patient between episodes. Some recurrences have only 1–2 lesions lasting 2–3 days, while others may be associated with 15–20 lesions lasting 12–16 days. Although symptoms of recurrent genital disease are more severe in women, objective signs of disease are relatively similar in the two sexes. Only about 15–30% of women who present with recurrent genital lesions experience concomitant cervical infection. When present, the duration of cervical viral shedding is short, occurs early in the episode, and is often without visible cervical lesions, unless routine colposcopy is performed (see "HSV cervicitis" section below).

Table 24-2. Selected Clinical Signs of Recurrent Genital Herpes in Patients Followed at the University of Washington Genital HSV Clinic

	Men *N = 218*	Women *N = 144*
Percent experiencing prodromal symptoms	53	43
Percent with pain	67[a]	88
Mean duration pain, days (range)	3.9 (1–14)[b]	5.9 (1–13)
Mean duration itching, days (range)	4.6 (1–16)	5.2 (1–15)
Percent with dysuria	9	27
Percent with tender lymph nodes	23	31
Mean duration tender nodes, days (range)	9.2 (1–25)[b]	5.9 (1–15)

"ATYPICAL" HSV REACTIVATION

Whereas the classical clinical findings of genital HSV are described above, recent studies have illustrated the diverse clinical spectrum of genital HSV infection. For example, among randomly selected women in an STD clinic, HSV was isolated from 33% of the women with genital lesions which lacked the characteristic appearance of vulvar ulcers; many of these lesions were small linear ulcerations, thought to be due to trauma or yeast vaginitis.[61] HSV was also isolated from cervical ulcerations, some of which could be seen only with colposcopy. HSV can often be identified from nonconcentric genital ulcers without an erythematous base (Figs. 24-9 and 24-10). Perhaps these findings illustrate that when an infection is as prevalent as HSV-2, varied clinical signs and symptoms are to be "expected." These observations, in concert with the epidemiological data indicating HSV as the most common cause of GUD, indicate that all genital lesions, regardless of appearance, should be evaluated for herpes. Laboratory diagnostic tests to detect HSV in the lesional area using either HSV PCR or the use of viral type-specific serologic assays can be employed by the clinicians to aid in the diagnosis. The detection of HSV-2 antibodies increases the likelihood of the ulcer in HSV, but coinfection with *T. pallidum* and *H. ducreyi* should be considered, depending on local epidemiology.

RECURRENCE RATE OF GENITAL HSV INFECTION

The major morbidity of recurrent genital herpes is its frequent reactivation rate. Most likely, all HSV-2 seropositive persons reactivate HSV-2 in the genital region. Moreover, because of the extensive area enervated by the sacral nerve root ganglia, reactivation of HSV-2 is widespread over a large anatomic area.

A prospective study of 457 patients with documented first-episode genital herpes infection has shown that 90% of patients with genital HSV-2 developed recurrences in the first 12 months of infection.[93] The median recurrence rate was 0.33 recurrences/month. Most patients experienced multiple clinical reactivations. After primary HSV-2 infection, 38% of patients had at least 6 recurrences and 20% had more than 10 recurrences in the first year of infection. Men had slightly more frequent recurrences than women, median 5 per year compared with 4 recurrences per year (Fig. 24-11). Also, patients whose primary infection lasted more than 34 days had more frequent recurrences than those who healed faster, median 8 compared with 4.3 recurrences per year, respectively. This echoes the finding in the guinea pig model in which the number of ganglia which express the HSV latency transcripts correlates with subsequent recurrences.[192] Patients

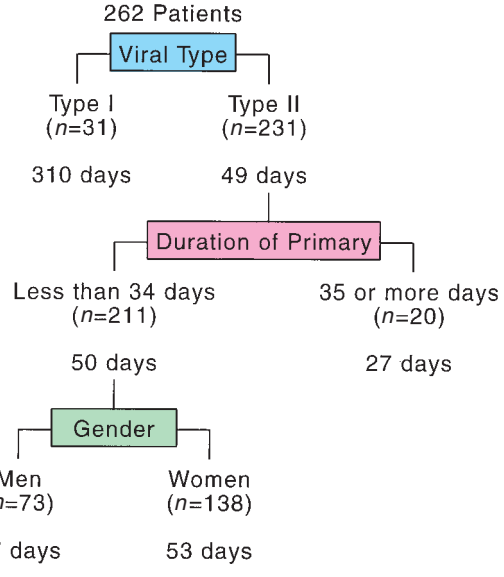

FIGURE 24-11. Determinants of median time to first recurrence after documented initial HSV infection.

with primary genital HSV-2 infection who have a more prolonged initial episode develop high titers of HSV-2 complement-independent neutralizing antibody in convalescent sera and are more likely to develop recurrences than those who do not develop anti-HSV neutralizing antibody.[130,193] Development of high titers of complement-independent neutralizing antibody in convalescent-phase sera after primary infection may reflect a high degree of antigenic exposure and/or a large number of latently infected cells in sacral nerve root ganglia. In the mouse model of mucocutaneous HSV infection, high levels of neutralizing antibody in convalescent sera have been associated with increased numbers of latently infected ganglionic cells.[194]

Recently, long-term cohort studies indicate that the frequency of symptomatic recurrences gradually decreases over time. In the initial years of infection, reported recurrence rate decreases by a median of 1 recurrence per year. As discussed below, almost all patients studied with recurrent symptomatic genital HSV also experience episodes of subclinical shedding. In general, these subclinical shedding episodes account for one-third to one-half of the total episodes of HSV reactivation as measured by viral isolation and for 50–75% of reactivations as measured by PCR.

Reactivation, both symptomatic and subclinical, is less frequent with genital HSV-1 versus genital HSV-2 infection. Overall, 57% of patients with genital HSV-1 will recur clinically in the first year of follow-up, and only 34% in the second year. In addition, the rate of recurrences is 1.3 recurrences per year in the first year and only <5% will have 4 or more recurrences.[195] In fact, frequent recurrences of genital herpes in persons with past genital HSV-1 suggest recent acquisition of genital HSV-2.[196]

■ OTHER CLINICAL SYNDROMES ASSOCIATED WITH GENITAL HSV INFECTION

HSV cervicitis

HSV may involve the cervix alone, without involvement of the external genitalia. Cervical HSV infection may be asymptomatic or may present as a mucopurulent cervicitis (Fig. 24-7). In a recent survey of women attending an STD clinic, HSV was isolated from the cervix of 4% of randomly selected women attendees.[61] Of these women with HSV cervicitis, half had concomitant first-episode genital lesions, 15% had evidence of recurrent genital lesions as well as HSV cervicitis infection, and 35% had only HSV cervicitis. Evidence of cervical lesions on routine speculum examination was present in 50% of these women, and an additional 15% of women had HSV lesions present on colposcopy. Overall, colposcopy detected 65% of women with HSV cervicitis. Papanicolaou smear revealed evidence of HSV cervicitis in 60% of women from whom HSV was isolated. Thus, even the most detailed clinical examination and cytologic testing will pick up only 65–70% of cervical HSV infection. Cervical HSV shedding is an occult site of reactivation of importance in transmission of HSV to infants and sexual partners.

Herpes simplex proctitis

HSV has been isolated from rectal mucosal and rectal biopsies in men and women with symptoms of rectal pain and discharge.[157,197–200] In the early 1980s, among 100 consecutive homosexual men who presented to an STD clinic with symptoms of rectal discharge and pain, HSV was isolated from rectal swabs and/or biopsies in 23%.[200] In men with nongonococcal proctitis, HSV was the most frequent pathogen isolated.

Unlike gonococcal proctitis, HSV proctitis is commonly associated with fever, systemic symptoms, severe rectal pain, discharge, tenesmus, and evidence of sacral autonomic nervous system dysfunction.[157,163,197–199,201–204] Patients usually present with acute onset of rectal pain, discharge, tenesmus, constipation, and bloody and/or mucoid rectal discharge. Fever, malaise, and myalgia are common and urinary retention, dysesthesia of the perineal region, and impotence may be reported. External perianal lesions are seen in about one-half of the cases. Anoscopy and/or sigmoidoscopy generally reveal a diffuse, friable rectal mucosa, although occasionally discrete ulcerations of the rectal mucosa may be present (Figs. 24-12 and 24-13). In most cases, the pathology is limited to the lower 10 cm of the rectum. Rectal biopsies of involved mucosa generally reveal diffuse ulcerations and lymphocytic infiltration. If multiple histological sections are performed, intranuclear inclusions may be demonstrated in rectal biopsies in about 40% of cases.[157] Both HSV-1 and HSV-2 have been isolated from patients with HSV proctitis.[157,199] Systemic ACV ameliorates the signs and symptoms of herpetic proctitis.[204] Most episodes of HSV proctitis are associated with the initial acquisition of HSV-1 or HSV-2, as overt proctitis is

FIGURE 24-12. Primary anorectal–sigmoidoscopic view (early).

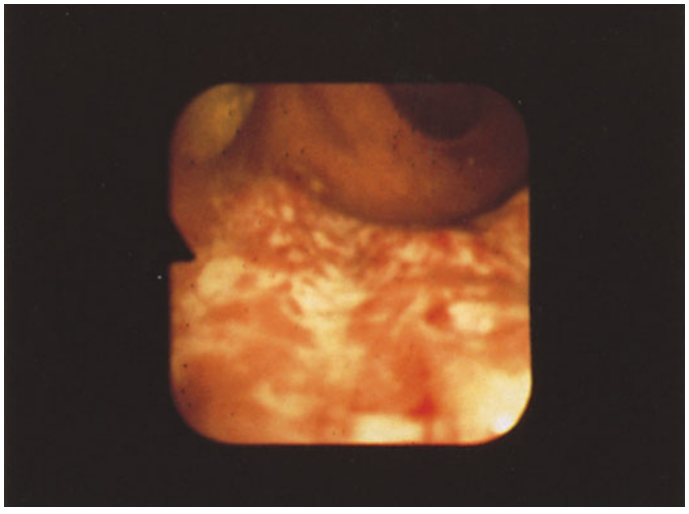

FIGURE 24-13. Primary anorectal–sigmoidoscopic view (late).

uncommon with HSV-1 or HSV-2 reactivations. Symptomatic anorectal HSV infection may also be seen in women with primary genital herpes.

HSV proctitis should be distinguished from subclinical reactivation of HSV in the perianal/perirectal region. Perianal reactivation of HSV as measured by the detection of HSV DNA in a perianal swab or by viral isolation is common in MSM as well as heterosexual men and women. Natural history studies suggest that perianal reactivation in men is especially common in MSM, reflecting perhaps the site of initial infection.[205] This subclinical perianal shedding is likely due to reactivation in latent sacral ganglionic reservoirs and occurs without any recent or past anal intercourse.

Recurrent aseptic meningitis

Benign recurrent lymphocytic meningitis, or Mollaret's meningitis, is a syndrome characterized by recurrent episodes of aseptic meningitis lasting 3–7 days and resolving without neurologic sequelae.[206] The CSF shows protein elevation and predominantly mononuclear pleocytosis. Recent studies have demonstrated HSV (usually HSV-2) DNA and the intrathecal persistence of HSV antibodies in the spinal fluid of patients with benign recurrent lymphocytic meningitis, indicating that HSV-2 is the etiologic agent for many, if not most, cases of this disease.[207–210]

Recurrent episodes of aseptic meningitis following initial episodes of genital HSV-2 infection complicated by aseptic meningitis have been described.[211] In one series of 27 patients with HSV-2 meningitis associated with first-episode genital HSV-2, recurrent meningitis was noted in 5 patients, headache in association with genital recurrences in 4, and possible recurrent meningitis in 7. Thus, 16 (27%) patients appeared to have recurrent HSV reactivation in the CNS. The advent of PCR assay and methods to detect HSV-specific intrathecal antibodies helped define the spectrum of HSV infections in the CNS. In a series of 13 patients who met strict diagnostic criteria for benign recurrent lymphocytic meningitis, 11 had HSV DNA and HSV-specific antibodies recovered from the CSF and the remaining 2 patients had intrathecal HSV-2 antibodies.[209] HSV-2 appears to be more frequently involved than HSV-1 and only a fraction of patients have a history of genital herpes.[209,210,212] Anecdotal reports and the our experience support the use of antiviral therapy to shorten or prevent the episodes.[212]

Subclinical Reactivation of HSV

Subclinical or asymptomatic viral shedding is an important aspect of the clinical and epidemiologic understanding of genital herpes, as most episodes of sexual and vertical transmission appear to occur during such shedding.[88,213,214] HSV has been cultured from the lower genitourinary tract of women and men in the absence of genital ulcerations or other lesions. Transmission of genital herpes usually occurs by sexual contact with a person who is shedding HSV subclinically.[94,214–216]

Longitudinal studies of persons with HSV-2 antibodies suggest that >90% of persons reactivate HSV intermittently in the genital tract.[217] The frequency of detection of reactivation varies with frequency of swabbing of the genital mucosa, the anatomic sites sampled, and the technique used to detect HSV. Women reactivate HSV in the cervicovaginal and vulvar as well as perianal area; men reactivate HSV on the penile skin and the perianal area.[218] The increasing recognition of perianal reactivation of HSV, which relates to the overlapping dermatomal innervation of this area with the vulvar area in women and the penile/scrotal area of men, has increased the rate of HSV detection on genital mucosa. Development of PCR assays for HSV DNA has markedly broadened our understanding of the pathogenesis of subclinical HSV-2 infection and many laboratories have developed very sensitive and specific PCR assays. The use of PCR assays to detect HSV on mucosal surfaces has increased the rate of HSV detection up to fourfold.[219] Subclinical episodes of HSV reactivation share several characteristics with clinical episodes: (1) 25% episodes last more than 1 day, (2) 17% of subclinical versus 22% of clinical episodes involve more than one anatomic site, (3) subclinical shedding is most likely to occur in temporal proximity to recurrences, and (4) women with frequent recurrences have frequent subclinical shedding.

Figure 24-14 depicts the pattern and frequency of subclinical shedding in a man and a woman with genital HSV-2 infection. As shown in the diagram, shedding occurs in "clusters" of time, and subclinical shedding often occurs prior to episodes of genital lesions or culture positivity. The frequency of subclinical HSV-2 shedding in both the oral and genital area is high, even in persons with no reported clinical lesions (Fig. 24-15). Quantitative HSV DNA PCR assays show that the number of viral copies in subclinical reactivation often is as high as that found during clinically recurrent HSV

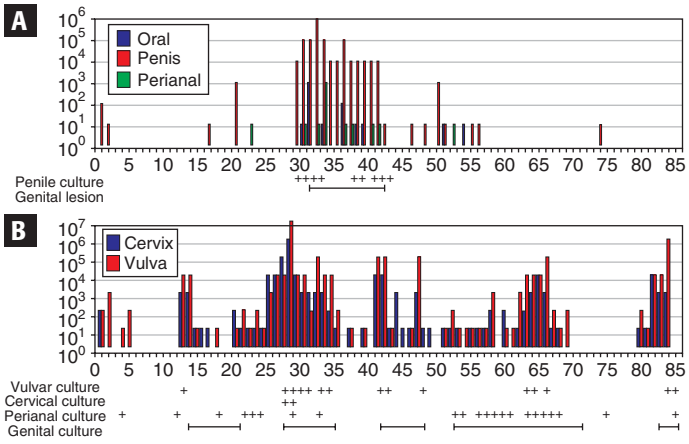

FIGURE 24-14. Clinical and virologic shedding pattern as detected by viral culture and HSV DNA polymerase chain reaction in, **A.,** a man and, **B.,** a woman. The man began obtaining daily viral cultures around day 30 after acquisition of genital HSV-2 infection. The woman was within 6 months of genital HSV-2 acquisition when she was enrolled into the study.

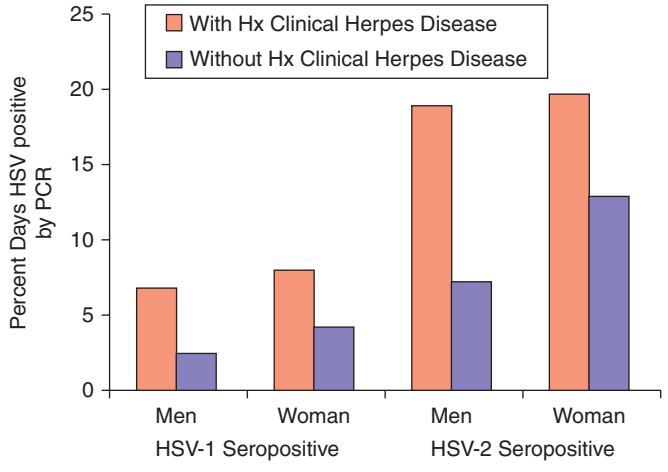

FIGURE 24-15. The frequency of subclinical shedding in both the oral and genital area; HSV-2 reactivation is frequent even in persons with no reported clinical lesions.

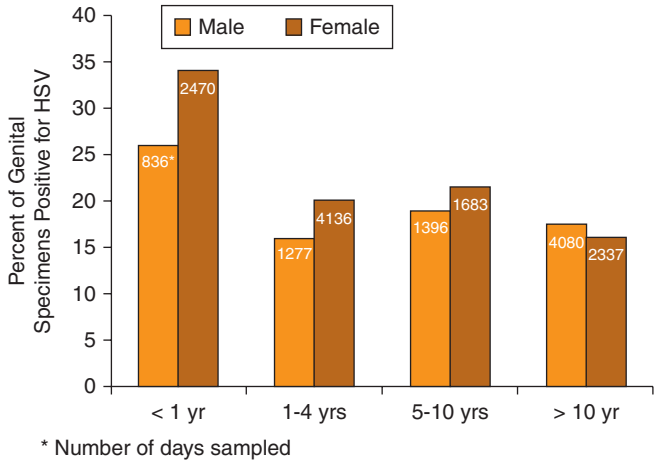

FIGURE 24-16. Frequency of HSV-2 reactivation by time since acquisition of HSV-2.

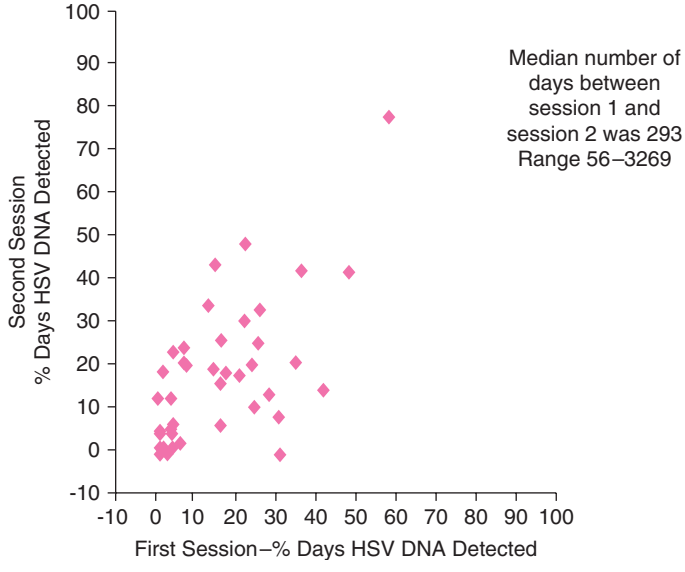

FIGURE 24-17. Percent days PCR positive during session: Comparison of shedding rates over time among 43 patients with HSV-2 infection.

episodes. Thus, the risk of HSV transmission is likely similar regardless of the presence of lesions, supporting the epidemiologic observation that most HSV is acquired from asymptomatic partners. Of note, the amount of HSV required for sexual or perinatal HSV transmission is not known.

Subclinical HSV reactivation is highest in the first year after acquisition of infection. During this time period, HSV can be detected from genital sites by PCR on a mean of 25–30% of days (Fig. 24-16). This is about 1.5 times higher than patients sampled later in their disease course. While longitudinal studies of sampling by PCR are limited, it appears that rates of shedding are relatively stable within individuals over a 1- to 2-year period (Fig. 24-17). These estimates represent averages, as individual variability is great.

Among men, the most common site of shedding is penile skin, followed by the perianal area, although among MSM the opposite pattern is observed.[220] Shedding can also occur from the urethra and from the semen, especially close to the time of acquisition, and transmission of HSV via infected semen has been documented.[221] However, semen viral cultures or PCR assays rarely yield virus[222] despite an early report of high rate of HSV isolation from seminal secretions in men undergoing vasectomy.[223] It is likely that penile skin shedding is the most important source of transmission from men to women, and perianal shedding is important in transmission of HSV among MSM.

The existence of frequent subclinical shedding implies that the control of genital herpes will not be achieved by the prevention of sexual encounters during recurrences of lesions, as transmission can occur at times when no lesions are noted. Counseling of patients with genital herpes needs to emphasize this potential for infectivity and provide appropriate strategies to decrease risk to patients' sexual partners.

THE PROBLEM OF UNRECOGNIZED RECURRENT GENITAL HERPES

Several recent studies have suggested that the vast majority of HSV-2 seropositive persons who deny having genital lesions are not truly asymptomatic, but have genital lesions that they do not recognize as herpetic. This observation has been demonstrated in several studies in different clinical settings. The initial study was conducted by Langenberg et al. in a gynecology clinic in a public hospital.[224] In this study, HSV-2 seropositive women unaware of genital herpes were instructed on the clinical signs and symptoms of genital disease. Pictures of genital HSV lesions were shown to them and the nature of HSV transmission and reactivation explained. The women were then asked to attend the clinic for any subsequent genitourinary complaints. Of 62 such women, 48% presented with recognizable genital lesions of HSV. Symptomatic genital herpes was the most common genitourinary complaint in this group of women during follow-up. Similar findings were reported by Frenkel et al. in a group of pregnant women.[225] Most recently, in a cohort recruited in a family practice clinic, we have followed 53 persons identified as HSV-2 seropositive without a history of genital herpes. During a median of 3-month follow-up, 62% of patients developed a typical recurrent HSV lesion, another 25% developed other localized genital complaints, and 83% had HSV detected in swabs of genital secretions. Only 1 person lacked either clinical and virologic evidence of genital herpes.[217] In comparison with a previously observed cohort of men and women with a clinical history of genital HSV-2 infection, the rate of subclinical viral shedding was similar (3.0 vs. 2.7) but the frequency of clinical recurrences and their duration was shorter in those who previously denied genital lesions. These findings help explain the unrecognized nature of lesions that tend to be mild and infrequent, and have shown that many people can be identified as having typical recurrences but they are not aware of having a lesion until they receive education about genital herpes (Table 24-3).

The studies showing the high rate of genital reactivation provide a framework for defining clinical and virologic manifestations of genital HSV infection. Rather than regarding HSV-2 as a predominantly silent infection with occasional clinical outbreaks with marked viral shedding, HSV is a dynamic infection, with very frequent reactivation, mostly subclinical, and active effort on the part of the immune system of the host is required to control mucosal viral replication. Thus, accurate serologic testing with an appropriate counseling session can effectively identify persons with unrecognized but virologically active genital HSV-2. As sexual contact with such persons is an important factor in HSV transmission, such an approach may be useful in containing the epidemic spread of this infection.

Table 24-3. Correlation Between the Recognition of Genital Herpes Lesions and Viral Shedding in 53 HSV-2 Seropositive Subjects with No Reported History of Genital Herpes

Variable	Herpes Simplex Virus Recovered[a]		
	Yes	No	Total Number of Subjects
Genital ulcers, blisters, or crusts	28 (85%)	5	33
Localized genital itching or soreness	10 (77%)	3	13
No clinical evidence of genital herpes	6 (86%)	1	7
Total	44 (83%)	9	53

Reactivation of genital herpes simplex virus type 2 infection in asymptomatic seropositive persons. *N Engl J Med* 2000; 342(12): 844–850.)

GENITAL HERPES VIRUS INFECTION IN THE IMMUNOCOMPROMISED PATIENT

Although initial literature on HSV infections in the immunosuppressed patient has concentrated on oral–labial disease, the increasing prevalence of genital herpes has resulted in an improved awareness of the consequences of genital herpes in this population. Immunocompromised patients have frequent and prolonged mucocutaneous HSV infections.[226–228] Over 70% of renal and bone marrow transplant recipients who have serologic evidence of HSV infection reactivate HSV infection clinically within the first month after transplantation.[229,230] Patients receiving chemotherapy often reactivate HSV at the time of neutropenia. While low neutrophil count by itself is unlikely to account for HSV reactivation, the epithelial destruction results in clinical and subclinical reactivation, further worsening the mucositis. In some trials, prophylactic-ACV-reduced bacteremia with oral pathogens in patients after chemotherapy.[231,232] Mucocutaneous HSV infections in the immunocompromised host may be associated with systemic complaints, prolonged local symptoms, and durations of viral shedding for greater than 30 days.

Recurrent genital herpes in immunosuppressed patients often results in the development of large numbers of vesicles which coalesce into extensive deep, often necrotic, ulcerative lesions.[228] Dissemination of virus may occur, although visceral involvement is relatively uncommon.[233] The routine administration of prophylactic ACV prior to

bone marrow transplantation has decreased the reactivation of HSV.[234,235] Several studies have demonstrated the benefit of ACV in shortening the clinical and virologic course of mucocutaneous HSV infection in the immunocompromised patients.[236] Residual host immunity is important, as the severity of infection is greater and response to antivirals is less in HSV seropositive persons who received stem cell transplant from HSV seronegative donor. Clinically, the optimal approach to serologically identified HSV infection in the immunosuppressed patient is suppressive antiviral medication initiated at the time immunosuppressive agents are administered and continued for the duration of immunosuppression. While breakthrough infection with ACV-resistant HSV has been reported,[237] our experience is that institution of acyclovir prophylaxis for the duration of immunosuppression in bone marrow transplant patients leads to lower incidence of ACV-resistant episodes.[238] Recurrent episodes of mucocutaneous lesions should be treated, usually with oral or IV ACV until resolution, and suppressive therapy is advised until host immunity recovers.

HSV IN PATIENTS WITH HIV INFECTION

Chronic, persistent genital herpes was noted as a sentinel feature of acquired immunodeficiency syndrome in 1981. Since that time, our understanding of the interactions between HIV and HSV-2 has increased, and trials of potential interventions are in progress. The interactions between these two viruses are examples of "epidemiologic synergy": both on a population level, and clinically, the two infections influence each other.[239]

IMPACT OF HSV-2 ON HIV INFECTION

HSV-2 is among the most common infection in HIV seropositive persons, as about 70% of HIV-infected persons in the developed world and 95% in the developing world have HSV-2 antibody. In the early 1980s, reports describing the increased risk of HIV infection, both prevalent and incident, among HSV-2 seropositive MSM were described.[240] Several recent reviews and metaanalyses of these studies have documented that HSV-2 infection preceded HIV acquisition and also showed that HSV-2 increases the risk of HIV infection among women (threefold), men (twofold), and MSM (1.7-fold).[241] Another study of couples in Africa showed that HSV-2 infection in one or both partners was the strongest risk factor for HIV concordance.[242] In Rakai, HSV-2 antibody in susceptible partner in HIV-discordant couples was associated with a fourfold increased risk of HIV acquisition; the magnitude of the increased risk was comparable with the increased risk conferred by higher systemic HIV RNA in the source partner (Table 24-4).

The role of HSV-2 in HIV transmission has been more difficult to define for methodological reasons. However, a study of 121 HIV-discordant heterosexual couples found a fivefold elevated risk for HIV transmission in the presence of an ulcerative STD in the source partner and the presence of newly acquired GUD was associated with new HIV infection.[243,244] This observation is biologically supported by potential of epithelial breaks to allow entry to HIV and the recruitment of $CD4^+$ lymphocytes to HSV lesions that allow for HIV initial attachment. Trials to define the ability of antiviral therapy for HSV-2 to decrease the risk of HIV acquisition among HSV-2 seropositive persons are currently in progress. Unlike HSV-2, HSV-1 infection does not appear to increase the risk of HIV acquisition. However, most persons who acquire HIV have prior HSV-1 infection, making it difficult to observe HIV acquisition in HSV seronegative persons. As noted above, HSV-1 reactivation in the genital tract is infrequent, perhaps also accounting for its lack for association with HIV acquisition.

The epidemiologic interactions between HIV and HSV-2 have led to calculation of potential population-level impact of these intersecting epidemics. If the risk of HIV infection is doubled in HSV-2 seropositive people, 50% of HIV infections among these persons are attributable to HSV-2 infection. The population attributable risk will depend on the prevalence of HSV-2 in the population at risk; at 50% HSV-2 prevalence, common among MSM, or African Americans in the United States, or general population in sub-Saharan Africa, 35% of HIV infections will be attributable to HSV-2. More complex modeling demonstrates the potential for "telescoping" of HIV epidemics in the presence of HSV-2—a much more rapid spread of HIV in HSV-2 seropositive populations.[245]

Several studies have shown that HIV-infected persons are at increased risk for HSV-2 acquisition. Potential reasons include increased susceptibility to infection or increased risk of contact with partners who are shedding HSV-2 in the context of HIV infection.

Table 24-4. Per-Contact Probability of HIV-1 Acquisition. Stratified by Plasma HIV-1 RNA in HIV-1 Seropositive Partner and HSV Serostatus in the Susceptible Partner[a]

HIV-1 plasma RNA in source partner (copies/mL)	Per-Contact Probability in the HIV-1 Susceptible Partner	
	HSV-2	HSV-2
<1700	0.0001	0.00004
1700–12,499	0.0023	0.0005
12,500–38,499	0.0018	0.0002
≥38,500	0.0036	0.0007

[a]None of the source partners were treated with antiretroviral therapy.

The frequent genital HSV-2 reactivation in HIV seropositive persons results in chronic antigenic stimulation. Schacker et al. showed that HIV strains initially in herpes ulcers subsequently appear in plasma.[246] A transient increase in plasma HIV RNA has been noted during recurrent genital herpes.[247] This increase of –½ log in HIV RNA has been noted in acute, chronic, and advanced HIV disease.[248] In studies among HIV-infected women, the risk of HIV detection in genital secretions is higher if HSV is also present.[249]

Antiviral therapy for HSV has been used as a probe to define the effect of HSV reactivation on systemic and mucosal HIV replication. In a study among HIV-infected women in Burkina-Faso, treatment with daily valacyclovir decreased plasma HIV ½ log and genital secretions HIV ¼ log.[250] Preliminary analysis of study among MSM in Peru showed a similar decrease in plasma HIV of about ½ of a log with a stronger effect among men with higher CD4 count. Both studies were done among persons not treated with antiretroviral therapy. The reductions in HIV plasma RNA take 6–12 weeks to demonstrate and are not seen with episodic use of the anti-HSV antivirals. These findings suggest that more attention to the treatment of HSV-2 infection in the HIV-infected persons is needed. For patient management, suppressive antiviral therapy could reduce viral load and potentially delay the time to initiation of antiretrovirals, or delay the time to emergence of HIV resistance in patients who responded to antiretroviral medication. Whether the smaller reductions in mucosal HIV observed during ACV therapy decrease the risk of sexual and perhaps perinatal HIV transmission is unclear. Studies to define these potential benefits are needed.

Laboratory studies have provided supportive evidence that HSV may be an important cofactor for HIV expression. The HSV regulatory proteins ICPO and ICP4 can upregulate the rate of HIV replication in vitro.[251] Both replicating and heat-inactivated HSV induces TNF-αβ activity and HIV expression in macrophages.[252,253] Herpetic lesions are associated with an influx of activated CD4-bearing lymphocytes,[254] which may result in increased expression of HIV on mucosal surfaces. In vivo, HSV-1 and HIV coinfection of epithelial cells results in higher copy number of HSV virions.[255]

HSV-1 AND HSV-2 IN HIV-INFECTED PERSONS

HSV infections are one of the most common clinical presentations and manifestations of HIV infection. However, the most significant impact of HIV on HSV disease is in the marked increase in the rate of viral reactivation, most of which is subclinical. Recent studies demonstrate that this subclinical reactivation persists even with effective HAART therapy.[256]

Chronic persistent genital ulcers caused by HSV were among opportunistic infections included in the definition of AIDS, and a small fraction of HIV- and HSV-infected patients present with persistent chronic mucocutaneous ulcerations often involving large areas of perianal, vulvar, or penile areas.[257] While most HIV-infected MSM have HSV-1 and 70% have HSV-2 infection, usually reactivation of HSV-2 causes severe clinical disease. Pain and lesions may present for months and can be disabling. Systematic evaluation of clinical genital herpes among HIV-positive MSM showed that rate of recurrences is increased and the episode is prolonged compared with HIV-negative MSM.[258] Interestingly, HSV-2 does not appear to disseminate even in persons with advanced HIV disease, and visceral disease is rare. HSV-2 meningoencephalitis has been reported occasionally in HIV-infected persons.

Recent studies of genital HSV-2 reactivation have shown that the risk of viral shedding is increased among HIV-infected persons, especially the risk of subclinical shedding. Table 24-5 compares HSV reactivation rates among a cohort of HIV-positive persons versus HIV-negative MSM and within HIV-positive and HIV-negative women. An inverse correlation between $CD4^+$ count and rate of genital HSV-2 shedding and a direct correlation between plasma HIV RNA and HSV-2 shedding exist. However, as with the HIV-negative persons, great individual variability in HSV-2 reactivation rates is observed, and even those with high CD4 count may shed HSV-2 frequently in the genital tract. Effective antiretroviral therapy (HAART) has led to an improvement in the clinical manifestations of HSV-2 infection; however, the impact on HSV genital shedding has been minimal. Thus, HSV-2 seropositive persons on HAART with low plasma RNA continue to shed HSV in the genital area frequently, and often at high copy number.

Most HSV infections in persons with HIV infection will respond to antiviral therapy, and ACV, valaciclovir, and famciclovir have all been shown to be useful in reducing clinical and subclinical reactivation of HSV in HIV-positive persons.[259–261] Suppressive therapy with ACV increases the daily pill burden, but prevents most clinical episodes, reduces the

Table 24-5. Frequency of HSV-2 Reactivation by HIV Status and Gender

	HIV Negative	HIV Positive
Women	*N* = 329	*N* = 83

% days positive for HSV	14.1	23.4

risk of HSV-2 shedding, and may have indirect effects on HIV, as noted above. Some patients who initially respond to ACV may develop thymidine kinase deficient mutants for which standard antiviral therapy is ineffective (see below).

An additional complication of HSV in HIV seropositive pregnant women is the potential impact of HSV-2 on the risk of maternal–fetal HIV transmission, as studies have observed an increased risk of HIV transmission to infants among women who are HSV-2 seropositive compared with HSV-2 negative or those who have genital ulcers in late pregnancy.[262,263] Whether the mechanism is mediated by a breach in epithelial barrier or higher systemic or local HIV RNA is unknown. Further studies are warranted to delineate the potential of HSV-2 to directly, or indirectly (though increase in HIV in the genital tract), affect vertical HIV transmission, both among women treated with potent complex antiretroviral regimens as well as those receiving single-dose nevirapine to reduce maternal to child HIV transmission.

GENITAL HSV INFECTIONS IN PREGNANCY

One of the major concerns to patients with genital herpes is the effect of disease on pregnancy and the neonate. Both congenital and intrapartum transmission of HSV infection have been described.[264,265] Neonatal herpes is a disease of high mortality and morbidity.[266–268] Transmitting this STD to a newborn also has devastating effects on the parents.

EPIDEMIOLOGY OF HERPES IN PREGNANCY

The prevalence of genital HSV infection during pregnancy as well as the relative incidence of neonatal HSV infection is influenced by the socioeconomic status, age, and past sexual activity of the patient population studied. In the United States, serologic evidence of HSV-2 infection is present in about 30% of middle class women attending prenatal clinics; the percentage is 50–70% in nonwhite lower socioeconomic obstetrical populations. Despite this high serologic prevalence, clinical evidence of HSV is much less. In Seattle, where an obstetric population has a 30% prevalence of HSV-2, a past or current history of genital HSV is present in 8% of women.

Neonatal HSV infection is a reportable disease in only few states in the United States. Estimates of the incidence of neonatal herpes have varied from 1 in 3000 to 1 in 20,000 live births.[267] The overall estimated frequency of neonatal HSV infection in the United States has been estimated to be approximately 1 in 7500 live births or about 400–1200 cases yearly nationally.[269] A recent survey in Canada reported an incidence of 5.9 per 100,000 live births.[87]

The highest risk for transmitting HSV in the perinatal period occurs during the acquisition of HSV in the woman at or near the time of labor.[270] This helps explain the wide variability in frequency of neonatal herpes worldwide. Obstetrical populations with high HSV-2 prevalence have low incidence of neonatal HSV infection. Populations with high risk of acquiring HSV in pregnancy have the highest neonatal HSV infection rates. Thus, contraceptive and behavioral practices markedly influence the epidemiology of neonatal HSV infection. Scandinavia and the west coast of the United States appear to have the highest neonatal HSV rates (about 1 in 3000 live births). As with genital HSV infections, recent data have shown a shift toward neonatal HSV-1 infection.

Among 7046 women followed with serologic evaluation during pregnancy, 94 seroconverted to HSV (64 to HSV-2 and 30 to HSV-1) during pregnancy, for an overall rate of 2.1%.[271] Of those with known time of seroconversion, 30% seroconverted in the first trimester, 35% in the second, and 40% during the third trimester. Overall, only 34 (36%) women presented with clinical signs of infection. None of the women who acquired antibody to HSV during pregnancy transmitted HSV to the neonate. However, 9 women in the cohort were found to acquire HSV in late third trimester and 4 of these 9 women transmitted HSV to the neonate. In this cohort, the risk of neonatal transmission was confined to the women who acquired HSV close to the time of labor. A subset of women were evaluated together with their sexual partners.[272] Among women who were seronegative for HSV-1 whose partners had HSV-1 antibody, the rate of HSV-1 acquisition during pregnancy was 3.5% (adjusted for the length of gestation). The rate of HSV-2 acquisition among susceptible women who had HSV-2 infected partners was 20%. Thus, the rate of HSV-2 acquisition among pregnant women appears very high, perhaps modified by high progesterone milieu that has been shown to shift susceptibility to HSV by 100-fold in a mouse model.[273] Despite the studies showing that the risk of HSV is highest among women who acquire HSV in late pregnancy, 30–50% of infants with neonatal HSV are born to women who have established, although often unrecognized, genital herpes.

CLINICAL COURSE OF GENITAL HERPES IN PREGNANCY

Most of the clinical manifestations of recurrent genital herpes, including the frequency of subclinical versus clinical infection and the duration of lesions, pain and constitutional symptoms are similar in pregnant and nonpregnant women.[274,275] The frequency and severity of recurrences appears to increase over the course of pregnancy.[275] Visceral dissemination of HSV in pregnant women acquiring primary genital disease has been described, especially if infection is acquired in the third trimester.[177–179] Routine antiviral therapy for first-episode HSV is not required in pregnancy but may be given for severe disease. IV ACV should be initiated in pregnant women who have evidence of disseminated infection, especially hepatitis, pneumonitis, or coagulopathy.

EFFECTS OF HSV ON PREGNANCY OUTCOME

Studies in the 1960s suggested that genital HSV infection was associated with an increased frequency of spontaneous abortion and premature delivery.[276,277] These studies also suggested that primary HSV cervicitis had a higher risk of complications than other aspects of disease. Brown et al. accumulated 28 cases of women who acquired first-episode genital HSV in pregnancy.[278] Pregnancy morbidity was only seen in the 15 women with clinical primary infection; that is, those with fever, constitutional symptoms, and severe lesions. Serologic and clinical evidence of nonprimary infection was not associated with pregnancy morbidity. Neonatal HSV and prematurity was most frequently seen in women who acquired primary genital infection during the third trimester.[278]

Several potential explanations may account for these differences in neonatal morbidity among women with primary versus recurrent genital HSV infection. With primary disease, both hematogenous spread of HSV as well as ascending chorioamnionitis may result in neonatal infection and disease.[279] Recurrent vulvar genital herpes is usually not associated with cervicitis or viremia. Several clinical series and a recent population-based study of women with recurrent genital HSV in pregnancy suggested no effect of clinical recurrent infection on neonatal outcome, including birth weight and gestational age.[274,275,280]

TRANSMISSION OF HSV TO THE NEONATE

Almost all cases of neonatal herpes are perinatally acquired: The infant acquires infection at the time of delivery through contact with HSV-infected genital secretions.[266,267,270,280–284] Over 70% of infants with neonatal HSV infection are born to mothers who lack symptoms or signs of HSV lesions at delivery. Table 24-6 describes the frequency of viral shedding and serologic status at the time of labor and its relationship to neonatal HSV from studies conducted at the University of Washington. As shown in Table 24-6, neonatal HSV can occur in women regardless of serologic status. However, the risk varies according to the serostatus: 1/1900 in HSV seronegative, 1/3900 in HSV-1 seropositive, and 1/4600 in HSV-2 seropositive women. An alternative calculation that may provide more relevant clinical risk is that the risk of transmitting HSV to the neonate is 30–50% in women with newly acquired HSV versus <1% in women with established infection. The low risk among HSV-2 seropositive women reflects low efficiency of transmission from women with reactivation HSV-2. This low risk may be mediated by the passage of maternal antibodies, or by limited viral replication in the genital tract during shedding in established disease, or both. HSV isolation is the strongest risk factor for intrapartum HSV transmission to the neonate with a relative risk of 346 compared with women in whom virus was not isolated.[270] However, HSV transmission from women who are culture negative can also occur; we have detected HSV DNA in swabs of 2 women who transmitted the infection to their neonates, indicating limited sensitivity of viral culture. Among women who have HSV isolated in the genital tract, new acquisition of HSV versus reactivation (OR = 49), isolation of HSV-1 versus HSV-2 (OR = 35), isolation of cervical versus vulvar HISV (OR = 15), and young maternal age are risk factors for neonatal herpes. In addition, cesarean delivery was protective against HSV transmission (OR = 0.14) and obstetrical manipulations such as scalp electrodes were associated with increased risk of HSV (OR = 3.5). This was the first study to demonstrate a protective effect of abdominal deliveries, although the practice has been endorsed for many decades, based on the goal of

Table 24-6. Frequency of HSV Isolation from Cervix and Vulva of Women in Labor in Relation to the Type of HSV Infection and to Transmission of Infection to the Neonate

	Culture (+)	Culture (–)	Note Done	Total Delivered
Mothers & cultures	202	39,821	18,339	58,362
Mothers with serology	177	22,630	11,928	34,735
Maternal disease	*Cases of neonatal herpes*			
Primary HSV-1	3	0	1	4
Primary HSV-2	1	1	0	2
Non-Primary FE	4	1	0	5
Recurrent HSV-1	2	1	1	4
Recurrent HSV-2	0	3	0	3
Total neonatal HSV	10	6[a]	1	18 cases

[a]HSV DNA by PCR positive in 2 of 5 specimens recovered. (With permission from Brown ZA, Wald A, Morrow RA, Selke S, Zeh J, Corey L. Effect of serologic status and cesarean delivery on transmission rates of herpes simplex virus from mother to infant. *JAMA* 2003; 289(2): 203–209.)

avoiding contact of the neonate with infected genital secretions. The benefits of C-section after rupture of membranes are uncertain.

These studies have also illustrated that the risk of viral shedding is assessed inaccurately by clinical examination that uses the presence of genital lesions as a proxy for viral reactivation. Among women who received abdominal deliveries for genital herpes, HSV DNA was detected from genital secretions among 46% of women.[285] Thus, the use of virologic rather than clinical approach to assess the presence of the virus at the time of delivery may potentially target surgical intervention at women who are at greatest risk for HSV transmission to the neonate.

MANAGEMENT OF PREGNANT WOMEN WITH GENITAL HERPES

The management of the pregnant women with genital HSV must be individualized and based on the clinical course of disease in the mother as well as the availability of virological and serologic methods of diagnosis. The acquisition of primary disease in pregnancy carries the risk of potential transplacental transmission of virus to the neonate. In some women, primary infection will result in spontaneous abortion; albeit this appears to be relatively uncommon. One common question raised by patients with first episodes of genital herpes during pregnancy who do not abort is the use of amniocentesis to determine if intrauterine infection, and hence a congenitally infected child, is present. The vast majority of pregnant women with recurrent genital herpes deliver normal infants, and routine amniocentesis is not recommended in these women.

Criteria for laboratory testing and surveillance, as well as delivery procedures for women with recurrent genital HSV infection, are the most frequently encountered questions of obstetricians handling pregnant women with HSV-2. The high prevalence rate of HSV-2 infection in pregnancy (antibody prevalence 30–60% depending on the population studied) and the low incidence of neonatal disease (1:6000 to 1:20,000 live births) indicates that only a few infants are at risk of acquiring disease. Cesarean section is therefore not routinely warranted for all women with recurrent genital disease. As intrapartum transmission of infection accounts for the vast majority of cases, only those women who shed HSV at the time of delivery need be considered for abdominal delivery. The presence of viral shedding at term is not predicted by shedding in weeks prior, and as such, weekly cytologic and virologic monitoring is not advocated.[274,275,280] Unfortunately, a rapid, reliable diagnostic method to detect asymptomatic cervical viral shedding of HSV is not currently available. This diagnostic gap is likely to be filled by a sensitive, rapid PCR that can be done at the time of labor to guide the delivery approach. Such an assay may be most useful in identifying women who acquired HSV in late pregnancy and are still seronegative but are shedding large amounts of HSV in the genital tract and are at high risk for HSV transmission to the neonate. In such women, the ~30–50% risk of HSV transmission justifies an operative delivery.

The risk of transmitting neonatal HSV among women who are HSV-2 seropositive is low, <1%. Patients with recurrent genital herpes should be encouraged to come to the delivery room early at the time of delivery. At this time, careful examination of the external genitalia and the cervix should be performed. Women who have no clinical evidence of lesions should be delivered vaginally; a swab for detection of HSV by viral isolation or HSV DNA PCR helps with subsequent infant management. The presence of active lesions of the cervix or external genitalia, or prodrome, i.e., clinical evidence of herpes virus infection of the lower genital tract, are indications for abdominal delivery.[286] This policy will result in the exposure of some infants to episodes of cervical and/or vulvar shedding. Only a few infants exposed to maternal excretions containing HSV-2 develop neonatal herpes.[284] Identification of such infants to communicate the HSV exposure to the attending pediatrician is necessary.[287,288] Currently, experts advise obtaining samples for HSV detection from the throat, nasopharynx, eyes, and rectum of these infants immediately and then at 5–10 day intervals. Any clinical evidence of lethargy, skin lesions, or other symptoms of neonatal HSV should be evaluated promptly. All infants from whom HSV is isolated after 24 hours of delivery should be treated with systemic antiviral chemotherapy.

Definitive studies on the relationship between the duration of ruptured membranes in the women with clinically apparent lesions and transmission of HSV to the infant are lacking but prolonged contact with infected secretions may increase the risk of acquisition. Delivery of infants by cesarean section, even from women with intact membranes, will occasionally result in neonatal herpes.[287] Many authorities recommend that if membranes have been ruptured for over 4–6 hours, cesarean section should no longer be considered for protection against HSV transmission. However, studies of neonatal HSV infection in Seattle have shown that transmission can occur from exposure to only external genital lesions, i.e., from women who are culture positive only on vulvar and not cervicovaginal swabs.

Infants born by cesarean section to women prior to the rupture of membranes or by vaginal delivery to women with no evidence of recent HSV infection are at minimal risk of developing HSV infection. Infants born of women at risk of transmitting disease to the neonate (i.e., women with active lesions)[289] should be observed closely for the first month of life and some experts recommend virologic evaluation throughout that time (see above). Any symptoms of neonatal disease (e.g., poor feeding, fever, hypothermia, skin lesions, or central nervous system signs such as seizures) should be

investigated expeditiously for evidence of neonatal HSV infection.[288,290] Management of contact between infant and mother should also be handled on an individual basis. In women who acquire primary genital herpes late in pregnancy, the high incidence of developing extragenital lesions and the potential of viremia suggest that a brief separation between mother and infant is warranted until therapy has produced a clinical and virological response. As recurrent genital herpes is rarely associated with disseminated disease or the development of extragenital lesions in exposed extremities, protection of the infant from exposure to infected genital secretion is adequate. When handling the infant in the hospital, education of the mother about handwashing techniques is appropriate, but rooming in should be allowed. Oral–labial herpes is a greater risk of postnatal acquisition of HSV infections to the newborn than genital herpes.[291] Thus, nursery personnel and other adults with external labial lesions caused by HSV should also be excluded for intimate contact with the newborn infant.[292]

Recent increase in genital HSV-1 has resulted in increase in neonatal HSV-1 infection. While HSV-1 reactivates in the genital tract less frequently than genital HSV-2, the risk of transmission to the neonate is much higher when HSV-1 rather than HSV-2 is isolated from genital secretions. This poses a question about management of women with HSV-1 during pregnancy. Women with known genital HSV-1 can be managed in the same way as women with genital HSV-2. All HSV-1 infected women should be carefully examined to rule out genital lesion at the time of labor. If such women are known to be shedding HSV-1 at the time of delivery, cesarean section prior to rupture of membranes should be considered.

Antivirals in pregnancy

Controversy exists regarding the use of antiviral therapy during pregnancy. The incidence of neonatal HSV-2 is low among women with recurrent genital herpes so that the efficacy of this approach for prevention of neonatal disease is very difficult. However, the incidence of cesarean delivery among women with genital HSV-2 is much higher and several studies have evaluated routine antiviral suppression in reducing HSV shedding at delivery and the frequency of abdominal delivery. In general, the studies have used daily therapy with ACV 400 mg tid or valacyclovir 500 mg bid starting at 36-week gestation for women with recurrent genital herpes. A systematic review of five of these studies has shown that this approach reduces the risk of recurrences, the risk of viral shedding, and the risk of abdominal delivery.[293] As such, this approach is listed as a management option in both the ACOG and the CDC guidelines and is widely used in the community. While this approach may decrease the risk of HSV-related cesarean sections, it is unlikely to have an impact on neonatal HSV, as most women who transmit HSV to their neonate have subclinical (new or recurrent) disease. The safety of ACV in late pregnancy has not undergone an extensive evaluation and concerns about the potential for neutropenia or renal impairment in the newborn remain. These potential issues are greater with the use of prodrugs (valacyclovir) as they achieve higher drug levels in the neonate. Thus, while a useful patient management approach, widespread use of antivirals to prevent neonatal HSV among women who are HSV-2 seropositive is of unproven benefit.

Prevention of HSV acquisition in pregnancy

The key to prevention of neonatal HSV is the prevention of acquisition of genital HSV-1 or HSV-2 infection late in pregnancy. As 30% of pregnant women are HSV-2 seropositive, identification of women at risk requires the use of type-specific serologic assays and testing for antibody during pregnancy. Women who are HSV-2 seronegative should be counseled about abstinence or at least avoiding unprotected coital activity in the last trimester. Some have advocated testing of the sexual partner to identify "discordant couples." Testing of the partner may present logistic difficulties, but allows for more precise definition of the risk of HSV acquisition in the pregnant women, as only about 20% of women have discordant strategies, with women being at risk for HSV acquisition.[272,294]

DIAGNOSIS OF GENITAL HERPES

■ CLINICAL DIFAGNOSIS

The differentiation between genital HSV infection and other infectious or noninfectious etiologies of genital ulceration is difficult and laboratory confirmation of the infection should always be sought. Epidemiologically, HSV is the most common cause of genital ulcerations both in the developed and in the developing world, especially with the decline of *T. pallidum* and *H. ducreyi* infections. While the characteristics described below can lead the clinician on a diagnostic pathway, the overlap in the clinical presentation is substantial, and the etiologic diagnosis based on clinical appearance is often inaccurate. This is especially true in HIV-infected persons, who may be at increased risk for several different STDs. In a prospective study where persons at risk for HSV-2 infection returned to clinic for evaluation of genitourinary symptoms, only 39% of those with newly acquired HSV-2 were diagnosed on clinical grounds.[295] Thus, the sensitivity for diagnosis of HSV-2 is low, even in a carefully monitored population. In addition, 20% of those who were given a clinical diagnosis of genital herpes were not infected, suggesting that false positive diagnosis of clinical grounds occur frequently. Given the gravity of diagnosing a lifelong viral STI, we feel that appropriate management of the patient should include laboratory confirmation.

In a patient with multiple grouped vesicles or a history of lesions of similar size, duration, and character, HSV infection is the most likely etiology of the ulceration. Lesions of genital herpes are often painful when touched and this clinical sign may be useful in differentiating coalesced genital herpetic ulcers from other etiologies such as *T. pallidum*. It should, however, be remembered that occasionally both organisms may coexist in the same lesion.[296] A persistent, tender, large ulcerative lesion in a patient at risk of *T. pallidum* infection, especially one in whom nontender, rubbery bilateral inguinal adenopathy is present, should raise the suspicion that both pathogens may be present.

Both primary and recurrent HSV infection can be accompanied by tender lymphadenopathy. The inguinal nodes upon palpation are usually nonfixed, and only slightly firm. Suppuration, commonly seen with *H. ducreyi* and/or lymphogranuloma venereum, is only rarely seen in genital HSV infection. Nontender, rubbery, firm lymph nodes are more commonly seen with *T. pallidum* infection. Because of the diversity of the signs and symptoms of HSV infections, laboratory confirmation of the etiology of genital ulcers should be sought in nearly all cases.[156]

Noninfectious causes of genital ulcerations, such as inflammatory bowel disease (Crohn's disease), mucosal ulcerations associated with Behcet's syndrome, or fixed drug eruption, may also be confused with genital herpes. These noninfectious causes are usually associated with ulcers that persist for much longer periods of time than those associated with recurrent genital herpes. In addition, the lesions themselves appear larger and deeper than those typically seen in genital HSV infection. The history of persistent lesions waxing and waning with the symptoms of bowel disease is usually elicited in those who have genital ulcerations as mucocutaneous manifestation of Crohn's disease. Persistent oral lesions, conjunctivitis, and/or central nervous system disease may help differentiate Behcet's syndrome from recurrent genital herpes. The overlap between primary genital HSV infection with conjunctivitis and aseptic meningitis and Behcet's syndrome may, however, cause diagnostic confusion (Fig. 24-8). In patients with a fixed drug eruption, a history of recent medication (e.g., trimethoprim–sulfamethoxazole) can be elicited. Excoriations resulting from scratching due to scabies infestation of the penile shaft can also mimic genital herpes, although these lesions lack the evolution seen in HSV. Persistent lack of laboratory evidence of HSV infection is often useful in establishing the clinical diagnosis of these noninfectious entities.

LABORATORY DIAGNOSIS

Laboratory confirmation of genital herpes should be performed on all persons. Knowledge of the diagnosis is useful in (1) explaining the potential infectivity during episodes of lesions, (2) identifying persons at risk for transmitting infection subclinically, (3) selecting women at future risk for transmitting the infection to the neonate, and (4) confirming the diagnosis in those in whom antiviral therapy is prescribed. Viral isolation, HSV DNA detection by PCR, HSV antigen detection by EIA or FA are all useful assays. In the last 5 years, HSV DNA PCR has emerged as the best test to be utilized on patients who present with genital herpes ulcers. The PCR assay is up to 4 times more sensitive than viral culture, can be done in high throughput system, within a short timeframe and with type-specific primers. HSV DNA is stable and thus the yield is not sensitive to transport time or condition. Historically, viral isolation has been considered a gold standard, followed by subtyping of the isolate.

Serodiagnosis is useful for documenting newly acquired infections and for diagnosis in persons who present without lesions or with atypical lesions. The commercial development of type-specific serologic methods provides the opportunity to identify person with undiagnosed HSV-2 infection. As most HSV appears to be transmitted from persons who have undiagnosed disease or asymptomatic infection, more active serologic testing for HSV-2 infection should be initiated in high-prevalence populations. The presence of HSV-2 antibodies in serum identifies HSV-2 infection that is nearly always genital, and is likely to reactivate intermittently, potentially resulting in transmission. Thus, the counseling provided for persons who are HSV-2 seropositive should parallel that of persons with clinical diagnosis of genital herpes.

COUNSELING/PREVENTION

Because of its chronicity, for many persons the diagnosis of genital herpes brings with it significant long-term complications. Many patients diagnosed with genital herpes report feelings of depression and isolation and fear of rejection and discovery.[297,298] These feelings tend to subside, although not completely, with time. A survey of members of the American Social Health Association support groups showed that 50% of respondents experienced depression and feelings of rejection,[298] even after many years of living with the disease. The distress associated with the diagnosis of HSV is exacerbated by the frequent difficulties in obtaining an accurate diagnosis and the difficulties of health-care providers in dealing with the emotional and sexual issues that surround the diagnosis. During the acute illness, the patient is often too concerned with the physical illness and with having the diagnosis of an STD to comprehend the chronic nature of the infection. Thus, the best strategy for counseling is to ask the patients to return after the primary illness resolves to deal with the long-term issues posed by having an incurable STD. At the first visit, palliation of symptoms is the most important

objective. In addition to antiviral therapy, local measures such as sitz baths or drying the genital area with a hair dryer can decrease the discomfort of lesions.

Clinicians should emphasize the recurrent and highly variable natural history of herpes infection and explain the potential for transmission during subclinical shedding. However, it is also important to reassure the patients that they will be able to continue to have intimate relationships, despite the infection. Women are often concerned regarding the potential for having healthy children and need reassurance that the risk of transmission during delivery is minimal for women with recurrent genital herpes. Patients need to be encouraged to tell the potential sexual partners of their infection, to abstain during recurrences, and to use condoms consistently at other times. It is useful to reinforce these issues over several visits and to see patients at their first recurrence to confirm their ability to recognize recurrences. Many patients are dismayed at their first recurrence because they realize that this infection will recur, while others are relieved that the symptoms are much milder than those during the primary episode. Most patients resent the lack of predictability of the disease as much as the discomfort. Attempts at controlling the recurrences include avoidance of certain foods, vitamin supplements, and stress reduction. Scientific evaluation of the benefit of these methods is lacking and fraught with difficulties. Despite the common perception that stress causes recurrences, a prospective study suggested that stress follows recurrences.[299]

In many settings, including pregnant women, STD clinic attendees, and persons seen in primary care, the interest in HSV-2 serologic testing among patients is high and both acceptability and acceptance exceed 50%.[300–303] Since most persons with HSV-2 infection do not have a history of genital herpes, serologic testing to identify those who are infected is also an important part of control of genital herpes. The settings in which serologic screening is useful for patient management are prenatal clinics, STD clinics, and settings that care for HIV-infected patients. Type-specific serologic tests should be available as part of general evaluation for STDs.

The frequent psychosocial distress that accompanies the diagnosis of symptomatic first-episode genital herpes has been used to obstruct wider use of serologic tests to identify persons with undiagnosed HSV-2.[304] However, several studies have shown that the distress that accompanies a serologic diagnosis of genital herpes is mild and transient.[305–307] In addition, such diagnosis often provides an explanation for previously undiagnosed genital symptoms. Knowledge of HSV-2 status and disclosure to partners is associated with lower risk of HSV-2 transmission. Thus, the potential individual and the public health benefit of serologic testing likely outweigh the understandable upset that follows being told of an HSV-2 infection.

Strategies for the control of genital herpes have not been well defined, although the tools to test such strategies are now available. A combination of methods is likely to be needed to contain the current epidemic of genital herpes. For persons with diagnosed HSV infection, disclosure of infection to partners results in ~50% decrease in the risk of HSV-2 transmission.[91] Avoiding sex during a recurrence or prodrome is also important, as viral shedding is most likely to occur at those times. Condoms decrease the risk of HSV-2 transmission from men to women and from women to men.[49,50] The protection offered by a condom is incomplete (~50%), given the wide distribution of HSV reactivation. Antiviral therapy has been shown to effectively suppress subclinical shedding.[308] An international, randomized, clinical trial demonstrated that daily valacyclovir given to source partners in HSV-2 discordant partnerships results in a 50% decrease in HSV-2 transmission to susceptible sexual partners.[309] Thus, chronic suppression of viral reactivation may become one of the strategies for HSV control in selected settings. Given that most people with HSV-2 infection have mild symptoms and unrecognized disease, the public health impact of suppressive therapy in discordant couples is likely to be limited. The interaction of the three control modalities—disclosure to partners, condom use, and suppressive therapy—has not been studied. Behavioral disinhibition may potentially offset the benefit of suppressive therapy if it leads to lower condom use, as has been observed in some patients with HIV receiving antiretroviral therapy. While nonoxynol-9 and other microbicides have been shown protective in animal models of HSV infection, human data are lacking,[310] and at this time microbicides are not recommended. Other microbicides with antiviral activity are understudy.

THERAPY OF GENITAL HERPES

The therapy of genital herpes includes the following goals: (1) preventing infection; (2) shortening the clinical course of disease, including the frequency of complications of primary infection such as aseptic meningitis and urinary retention; (3) preventing the development of latency and subsequent clinical recurrences after initial genital infection; (4) preventing subsequent recurrences of disease in those with established latency; (5) decreasing the transmission of disease; and (6) eradicating established latent infection. Despite major inroads in the therapy of genital herpes in the last 25 years, only some of the goals described above have been achieved by the available therapeutic interventions.

NUCLEOSIDE ANALOGS

Acyclovir

The mainstay of the therapy of genital HSV infection are formulations of nucleoside analogs, most often used in an oral form. ACV is the first antiviral developed and used for the

therapy of genital herpes. ACV is an acyclic nucleoside analog that is a substrate for HSV-specified thymidine kinase (TK).[311,312] ACV is selectively phosphorylated by HSV-infected cells to ACV-monophosphate (ACV-MP). Cellular enzymes then phosphorylate ACV-MP to ACV-triphosphate, a competitive inhibitor of viral DNA polymerase.[313–315] ACV-TP is incorporated into the growing DNA chain of the virus and causes chain termination.

ACV has potent in vitro activity against both HSV-1 and HSV-2.[316] In animal models, topical or systemic ACV markedly reduces the severity of mucocutaneous HSV infections and, if administered within 96 hours after inoculation of virus, prevents ganglionic latency.[315] Numerous trials of ACV in primary and recurrent genital herpes have been conducted. In primary genital HSV infection, IV ACV (5 mg/kg q 8 h for 5 days), oral ACV 200 mg (5 times/day for 10–14 days) and topical ACV (5% in polyethylene glycol ointment) all reduce the duration of symptoms, viral shedding, and speed lesion healing.[132,155,317,318] Systemic therapy prevents new lesion formation and abrogates systemic symptoms. As such, oral ACV is preferable to topical which has limited efficacy and its use is not recommended. The clinical effect of ACV on first-episode infection is considerable, reducing fever and constitutional symptoms within 48 hours of initiating therapy and rapidly relieving symptoms. As such, therapy should be initiated in all patients with presumptive first-episode genital HSV who present with active lesions. Our personal recommendation is to initiate therapy with 400 mg tid per day (Table 24-7). Higher dose of ACV (800 mg 5×/day) does not offer additional benefit nor does the addition of topical to oral medication.[319] We initiate therapy with a presumptive clinical diagnosis. If an alternative diagnosis is made, then therapy can be discontinued. Because the natural history of disease is for symptoms to progressively increase over the first week, early initiation of therapy is recommended even in patients who present with few lesions. Oral ACV is also effective for treatment of first episode of HSV proctitis in homosexual men[204] and of HSV stomatitis. While treatment of first-episode infection markedly shortens the course of first episode, it has no discernible effect on the long-term natural history of recurrences.[318,320] As such, all patients need to be counseled about the natural history, high rate of recurrences, especially among those with HSV-2 infection, potential complications (including neonatal herpes), and risk of transmission to sexual partners. As shown in Table 24-7, ACV has also been studied for therapy of recurrent episodes of genital herpes and daily suppressive therapy in those with clinical recurrences. Daily ACV markedly decreases the rate of HSV detection on genital mucosa by viral culture and HSV DNA PCR.

Valacyclovir

A major limitation of ACV has been poor oral availability, as only small fraction—10–20% of the dose—is absorbed.[321] As such, an effort has been made to manufacture a compound which would result in higher blood level of ACV. Valacyclovir, an ester of ACV, is rapidly and almost completely converted to ACV by intestinal and hepatic enzymes[322] and increases the bioavailability of ACV to 54%. Therefore, an oral dose of valacyclovir 1000 mg results in a similar area under the curve to IV ACV.[323] In general, studies comparing valacyclovir to ACV in genital HSV infection have shown the drugs to be comparable in the immunocompetent host. Valacyclovir offers potential convenience through reduced dosing frequency. Valacyclovir has been evaluated for the treatment of genital herpes in several studies[324,325] and is recommended by the FDA and CDC STD guidelines for treatment of first-episode genital herpes, suppressive daily therapy, and recurrent outbreaks.

Valacyclovir has been evaluated for suppression of herpes recurrences.[326] Valacyclovir 500 mg once daily was compared to placebo in 382 patients with a history of at least 8 recurrences per year. The study continued until first recurrence or for 16 weeks. At that time, 69% of valacyclovir recipients were recurrence free, compared to 9.5% of placebo recipients. Studies comparing valacyclovir 500 mg once daily to other doses and to ACV for 1 year of suppression of recurrent genital herpes indicate that valacyclovir 500 mg PO once daily is effective for patients with 9 or fewer recurrences per year. However, in patients with 10 or more recurrences per year, valacyclovir 250 mg PO bid or 1000 mg once daily is more effective.[327]

Valacyclovir 1000 mg bid has been compared to ACV 200 mg five times a day for 10 days for therapy of first-episode genital herpes.[328] No significant differences were noted between ACV and valacyclovir and both were well tolerated. Another study of 739 patients with recurrent genital herpes which compared valacyclovir 500 mg bid with ACV 200 mg five times a day for 5 days did not find any significant differences between the two regimens. A comparative trial showed that the efficacy of ACV 400 mg bid and valacyclovir 500 mg bid for suppression of clinical recurrences and viral reactivation is very similar.[325,218] Both drugs decrease the rate of viral isolation by 95% and the rate of HSV DNA detection by ~75%. The remaining shedding episodes are short and with low copy numbers; however, the amount of HSV required for transmission is unknown. Valacyclovir is the only anti-HSV drug that has been evaluated for reducing transmission of HSV-2 between sexual partners; 500 mg once daily reduced transmission of HSV-2 by 48%.[309]

Adverse effects during therapy with valacyclovir are rare and do not occur at a different rate in placebo or valacyclovir recipients. As expected from clinical experience with ACV, headache and nausea are the most frequent complaints. Dose adjustment is needed in persons with severe renal impairment disease.

Valacyclovir 8 g/day has been evaluated in clinical trials for the prevention of cytomegalovirus disease in immunocompromised patients. A syndrome of thrombotic microangiopathy has been described in about 3% of patients with HIV

Table 24-7. Recommended Regimens of Antiviral Chemotherapy of Mucocutaneous HSV Infections

Indication	Drug	Dose	Duration	Comments
First-episode genital herpes	Acyclovir	400mg p.o. 3×/day	10–14 days	Therapy has substantial benefit on all clinical and virologic aspects of the infection.Patients who have not healed after 2 weeks of therapy should be treated for additional 7 days.
	Acyclovir	200 mg p.o. 5×/day		
	Valacyclovir	500 mg–1000 mg p.o. 2×/day		
	Famciclovir	250 mg p.o. 3×/day		
First episode of herpes proctitis	Acyclovir	400 mg p.o. 5×/day	10–14 days	
Suppressive therapy	Acyclovir	400 mg p.o. 2×/day		Benefits of suppressive therapy are usually evident after 3–6 months of daily antiviral treatment. However, unless contraindications develop, it is preferable to continue therapy for at least 1 year.
	Valacyclovir[a]	500 mg p.o. 1×/day		
	Famciclovir	250 mg p.o. 2×/day		
Recurrent genital herpes				
	Short duration			Therapy shortens episode by 1–2 days. May be useful in patients with prolonged recurrences or significant distress during recurrences. Short course therapy is more convenient and economical
	Acyclovir	800 mg tid for 2 days		
	Valacyclovir	500 mg bid for 3 days or 1000 mg bid for 1 day		
	Famciclovir	1000 mg bid for 1 day		
	Standard duration		5 days	
	Acyclovir	400 mg p.o. 3×/day		
	Acyclovir	200 mg p.o. 5×/day		
	Valacyclovir	500 mg p.o. 2×/day or 1000 mg p.o. once daily		
	Famciclovir	125 mg p.o. 2×/day		
Aseptic meningitis	Acyclovir, intravenous	5 mg/kg q 8 h		After clinical improvement, oral administration of valacyclovir is recommended for a total of 10–145 days of treatment.

[a]Patient with very frequent recurrences (≥10 per year) benefit from valacyclovir 250 mg p.o. bid or 1000 mg qid.

infection, bone marrow and renal transplant recipients who received this high dose of valacyclovir for a median of 53 days (range 8–100 days). The relationship between valacyclovir and the syndrome is uncertain at this time; thrombotic microangiopathy has not been described in immunocompetent persons receiving up to 3 g of valacyclovir per day.[329]

Famciclovir

Famciclovir is a prodrug of penciclovir, a nucleoside analog that effectively inhibits HSV-1 and HSV-2. Similar to ACV, penciclovir requires viral TK for phosphorylation to monophosphate[330] and cross resistance with ACV is common. Penciclovir triphosphate inhibits viral DNA synthesis with a similar in-vitro activity to ACV.[331] The intracellular half-life of penciclovir appears longer than ACV (>10 hours). Oral famciclovir is 77% bioavailable.[332] The safety of famciclovir has been evaluated in several clinical trials, and the drug appears to be well-tolerated.[333] The most common reported adverse effects were nausea, headache, and diarrhea, occurring in similar proportion of famciclovir and placebo recipients. Although laboratory evaluation of famciclovir recipients did not indicate any deleterious effects, a lower dose is advised for patients with impaired creatinine clearance.

The efficacy of oral famciclovir for the treatment of recurrent genital herpes has been evaluated in several trials. In one trial involving 467 subjects with recurrent genital herpes, famciclovir recipients compared to placebo recipients had significantly reduced healing time (median 3.8 days for famciclovir recipients vs. 4.8 days for placebo recipients), viral shedding (1.7 days vs. 3.3 days), and duration of all symptoms (3.2 days vs. 3.7 days).[334] Famciclovir 125 mg twice daily was effective; higher doses did not confer additional benefit for immunocompetent patients with recurrent genital herpes.

In clinical trials comparing famciclovir with ACV 200 mg 5 times daily for the treatment of first-episode genital herpes, the two drugs appeared comparable in their ability to effect viral shedding, lesion healing, and resolution of symptoms.[335] Famciclovir is also effective for suppression of genital herpes when compared with placebo. It is not clear why a lower dose of famciclovir is effective for episodic treatment (125 mg bid) compared with suppressive treatment (250 mg bid). In comparative studies of daily suppressive famciclovir versus valacyclovir, the time to first recurrence was shorter among famciclovir recipients, and HSV was detected on 3.2% of days among famciclovir recipients vs. 1.3% of days among valacyclovir recipients ($p = 0.014$).[336] These data suggest that famciclovir may not be as effective as ACV or valacyclovir for HSV suppression and might be less effective if used to reduce the risk of sexual HSV-2 transmission.

Oral ACV, famciclovir, and valacyclovir have all been shown to be of benefit in reducing the duration of recurrent genital herpes.[337,338] A series of studies have demonstrated that both physician and patient initiated therapy reduces the duration of lesions and shortens the time in which virus can be isolated from lesions. Patient-initiated therapy tends to offer greater benefit due to earlier initiation of drug than physician-initiated therapy.[337] Recent studies of episodic therapy of genital herpes show that the clinical benefit of treatment of recurrences is substantial and that prompt administration of antiviral drugs is associated with increased rate of aborted lesions (recurrences that do not progress beyond prodrome). Regardless of the agent chosen, therapy should be initiated by the patient at the first sign or symptom of a recurrence. Such management requires education of patients regarding the manifestations of genital herpes and provision of appropriate supply of the antiviral drug for use at home. The currently recommended doses are shown in Table 24-7. Short courses of therapy (1–2 or 3 days) offer similar efficacy, more convenience, and reduced expense over the more standard 5-day treatment regimens. The success of very short courses of antiviral therapy reflects the importance of viral replication at the initiation of the recurrence, after which the immune system contains the infection. Not all episodes or patients with recurrent HSV require antiviral therapy, as the episodes will self-heal in immunocompetent patients with supportive care. In persons with severe symptomatic episodes, episodic antiviral therapy may be useful but suppressive therapy is more effective. Most immunosuppressed patients require therapy, in such patients short courses of therapy should not be used.

Topical antiviral therapy also has minimal benefit in recurrent genital HSV. Both the antiviral and the delivery base affect the outcome. In the United States, a 5% topical preparation in polyethylene glycol produced an antiviral effect but little clinical benefit.[132] In Europe where the preparation is a 5% ACV preparation in an aqueous cream, more consistent therapeutic benefit has been achieved.[339] We do not recommend topical therapy for genital HSV alone, or in addition to oral therapy.[340]

SUPPRESSIVE ANTIVIRAL THERAPY

Recurrence rates of genital herpes vary in individuals over time. Most patients who seek medical attention for symptomatic genital HSV report from 5 to 8 recurrences per year. Several studies have shown that daily oral ACV therapy among patients with frequently recurring genital HSV (4–12 episodes per year) is effective in preventing clinical recurrences of genital herpes.[341–345] ACV in doses of 200 mg two to five times daily for up to 6 years will prevent recurrences in 65–85% of patients as long as therapy is continued. In a 5-year study of suppressive ACV, the mean number of breakthrough recurrences declined from 1.7 during the first year to 0.8 during the fifth year.[346] Suppressive therapy in persons with frequently recurring disease produces considerable relief of symptoms and can provide major medical and psychosocial benefit.[297] Isolates recovered from patients who have received

long-term ACV therapy do not differ in their susceptibility to pretreatment isolates.[347]

For long-term therapy, simple and convenient dosage regimens are required to achieve maximum compliance. ACV 400 mg bid or valacyclovir 500 mg qid are the best initial starting dosage in the immunocompetent patients.[344] More than 90% of persons with frequently recurring genital herpes who are immunocompetent have a significant reduction in the number of clinical recurrences on suppressive therapy. Even among those on suppressive therapy, breakthrough recurrence will, however, still occur. About 25% of persons on suppressive therapy will develop a breakthrough recurrence each 3-month period.[344] Thus, it is likely that most patients on chronic suppressive therapy will, at some time, develop a breakthrough. Compared with untreated recurrences, breakthrough recurrences are associated with milder symptoms, shorter duration of viral shedding, and shorter duration of lesions.[341,348] Most patients prefer suppressive therapy to episodic therapy and rate their quality of life on herpes-related scales higher while on suppressive therapy.[349,350]

Because frequently recurring genital herpes may plague a patient for years, many patients desire to take oral ACV for prolonged periods. Preclinical animal studies of ACV showed no drug-related carcinogenicity, effect on fertility, or abnormal fetal development.[351] Chronic suppressive therapy taken at doses of 200 mg 5 times a day or 200 mg 2 times a day have had no effect on spermatic function in men.[222] Side effects of daily suppressive oral ACV are uncommon. Data from a multicenter trial and trials of smaller number of patients treated for up to 10 years do not show any clinical or laboratory toxicity.[346,347] Allergic reactions to ACV are rare and successful desensitization has been reported.[352,353]

One of the major issues facing the clinician with a patient with genital herpes is the use of intermittent versus chronic suppressive ACV therapy. We believe all patients should be informed about the option of episodic and suppressive antiviral therapy. Patients with frequently recurring genital herpes who have considerable physical discomfort, emotional upset, and potential for transmission of infection to sexual partners are all candidates for chronic suppressive therapy.[354] In addition, natural history of HSV-2 shows that the risk of viral shedding is highest within the first year of acquisition and such persons may be excellent candidates for suppressive therapy.[355] Early suppressive therapy may prevent further transmission at a time of potentially greatest risk, assist in adjustment to having genital herpes, and improve quality of life. Studies indicate that it takes from 5 to 7 days of therapy before clinical effect can be seen.[341] The decision to initiate suppressive therapy should be made with regard to patient preferences, objective severity of disease, psychological distress at having recurrences, and the potential for infection in susceptible partners. The cost of chronic therapy is concerning for many persons, although the price of generic ACV in the United States is relatively low (~$60 per year for ACV 400 mg bid).

HSV THERAPY IN PERSONS WITH HIV INFECTION

Relatively few clinical trials have been performed in this population, despite wide clinical use of these medications. The lack of clinical trials reflects underestimating of the importance of HSV in HIV infection as well as the perception that the market for antivirals in that setting is small. Recent studies, detailed above, showing an effect of drugs for HSV on plasma HIV are likely to lead to wider use of nucleoside analogs in this population. ACV, valacyclovir, and famciclovir have been studied as therapy for HSV in HIV-infected persons and appear effective.[356] Suppressive therapy is preferred for HIV-infected persons rather than episodic, and the dosing should be twice a day, even for valacyclovir.

TREATMENT OF RECURRENT GENITAL HERPES

ACV in pregnancy

Although ACV is not teratogenic in animals, until studies defining its role and safety in pregnancy are available, the routine use of oral ACV in pregnancy cannot be advocated. A pharmacokinetic evaluation of ACV in third trimester of pregnancy showed that the disposition of ACV appears similar in pregnant women to other adults.[235] A potential concern is the development of obstructive uropathy in the newborns secondary to ACV crystals. However, no such abnormalities have been observed in this study, or in a much larger number of infants with neonatal herpes treated with prolonged, and often high-dose, IV ACV.[357,358] However, neutropenia does occur in infants treated with prolonged ACV therapy and such infants need to be monitored.[359] While a recent study showing no laboratory abnormalities in infants of mothers treated with daily valacyclovir at the end of pregnancy is somewhat reassuring, the numbers are small and rare events have not been ruled out.[360]

Glaxo-Wellcome, in collaboration with the Centers for Disease Control, maintained a voluntary registry of women who received ACV (and few that received valacyclovir) during pregnancy. As of 1999, 756 women who received ACV in the first trimester were reported. A total of 3.2% of the children had birth defects compared to a background rate of 3%.[361] No consistent pattern of abnormalities has been noted. Although the number of women evaluated is insufficient to exclude a small increase in the rate of congenital abnormalities, lack of statistically significant increase in the incidence of defects and lack of pattern of abnormalities is reassuring. The safety of valacyclovir and famciclovir in early pregnancy has not been established. The use of ACV and valacyclovir in late pregnancy to prevent abdominal deliveries is discussed above; no data on famciclovir have been published in pregnancy.

EMERGENCE OF RESISTANCE

In vitro resistance to ACV can result from TK-deficient, TK-altered, or DNA-polymerase-resistant strains of HSV. TK deficiency is the most common mechanism of resistance of HSV to ACV.[362–365] Animal studies have suggested that TK-deficient mutants are less virulent and less able to establish neural latency.[366] However, some ACV-resistant strains appear to make enough TK to establish ganglionic latency and reactivate especially in immunocompromised patients.[367] Disease caused by strains with DNA polymerase mutation has also been reported.[368] ACV-resistant strains of HSV have been recovered from patients who have never been treated with ACV.[363,365] About 3% of isolates obtained from immunocompetent patients demonstrate in vitro resistance to ACV. The frequency of in vitro resistance has not changed from the time prior to availability of ACV and does not appear increased among patients who received several years of daily suppressive ACV.[347] Among women followed longitudinally with daily viral cultures, about 3% of isolates were ACV resistant in vitro.[369] The resistant strains were isolated on same day as sensitive strains from other genital sites and were followed on subsequent days with ACV-sensitive strains. As such, the demonstration of ACV resistance in vitro in immunocompetent population has not been associated with clinical failure of ACV therapy and routine testing for sensitivity is not recommended. Rare isolation of ACV-resistant strain likely represents a random mutation that is rapidly cleared by the immune system in a healthy host. An exception is a report of genital herpes with an HSV-2 strain characterized by an altered TK.[367,370] In this person, all isolates recovered from multiple recurrences had an altered TK and ACV did not offer clinical benefit. Additional cases of ACV-resistant HSV infection have been reported from immunocompetent patients, often with nongenital HSV infection.

The vast majority of ACV-resistant isolates have been from immunocompromised patients undergoing multiple courses of ACV for established infection.[313] However, the frequency of ACV resistance in HIV-infected patients appears low and the risk factors for the development of resistance have not been well-defined. In a surveillance study for ACV-resistant herpes, 5% of isolates were ACV resistant.[371] The risk for ACV resistance included low CD4 count and topical ACV therapy. Thus, continued surveillance of HSV strains associated with breakthrough recurrences and/or persistent mucocutaneous HSV is needed. At present, routine in vitro testing of HSV isolates for ACV sensitivity is not recommended. However, isolates from patients with persistent HSV infections unresponsive to ACV, especially those with advanced HIV disease, should have testing for ACV resistance. In this setting, in vitro resistance correlates well with ACV failure.[372] Most ACV-resistant HSV infections require therapy with alternative agents. As famciclovir has a similar mechanism of action, most ACV-resistant strains are also famciclovir resistant. Treatment with high-dose continuous infusion of ACV has also been reported as successful.[373] Recent observation that suppressive therapy with ACV compared with episodic therapy is associated with lower incidence of ACV-resistant HSV among bone marrow recipients implies that withholding of suppressive antiviral therapy in HIV-infected patients because of concerns for ACV resistance may result in increased rate of ACV resistance.[238]

The introduction of antiretroviral therapy has decreased the rate of ACV-resistant HSV among HIV-infected persons. However, severe and prolonged episodes of genital herpes recalcitrant to antiviral therapy have been noted as part of immune reconstitution syndrome in patients initiating retroviral therapy.[374,375] In some cases, in vitro studies show ACV susceptibility of the isolates and suggest that brisk immune response is responsible for the clinically severe lesions.

THERAPY OF ACV-RESISTANT HSV

Foscarnet

Foscarnet is a viral DNA polymerase inhibitor similar in structure to phosphonoacetic acid. In vitro, it has potent antiviral activity and has been effective in speeding the healing of lesions in animal models.[376] It is an insoluble compound and can be effectively administered only intravenously or topically. One study demonstrated in men a reduction in healing with 0.3% foscarnet cream as compared with placebo.[377] However, a collaborative Canadian trial of foscarnet cream 0.3% in men and 1% in women demonstrated little overall effect on reducing symptoms or lesions.[378]

Systemic toxicity during IV administration limits the use of foscarnet to patients who fail ACV therapy because of development of resistance. In this population, however, foscarnet has become the preferred agent. Foscarnet infusion healed 81% of 26 patients with ACV-resistant HSV infection.[379] A comparative study of foscarnet 40 mg/kg IV q 8 hours and vidarabine 15 mg/kg q day showed that foscarnet therapy led to healing of all 8 patients while all patients assigned to vidarabine failed therapy.[380] Adverse reactions are frequent but only rarely require discontinuation of therapy. The most common toxicities are renal insufficiency and metabolic disturbances, especially hypophosphatemia. Recurrences of HSV after foscarnet therapy can be either ACV-sensitive or ACV-resistant. HSV resistance to foscarnet has also been reported, usually in the setting of prolonged foscarnet therapy.[381] In that setting, the addition of ACV can be beneficial.

Cidofovir

Another nucleotide analog with good activity against herpes viruses is cidofovir, an acyclic nucleoside phosphonate.

Unlike ACV, which requires phosphorylation by HSV-specified enzymes, cidofovir is phosphorylated only by cellular enzymes. Therefore, cidofovir is active against HSV strains with a deficient or altered TK and, in fact, its appears more active against these isolates than against wild-type strains.[382] Topical and IV cidofovir has been used successfully to heal ACV-resistant lesions in some patients with AIDS and after marrow transplant,[383,384] although cidofovir resistance associated with polymerase mutations in immunocompromised patients has also been reported. A randomized, double-blind, placebo-controlled trial of topical cidofovir gel 0.3% or 1.0% in 30 patients with AIDS who did not respond to ACV therapy showed that 10 of 20 cidofovir recipients healed by at least 50% compared with none of the placebo recipients.[385] Most patients treated with topical cidofovir ceased viral shedding. No systemic reactions were noted; however, 23% of cidofovir recipients had mild or moderate local cutaneous adverse effects. However, as long-term toxicity studies of cidofovir showed tumors in animals, further development of the drug for immunocompetent persons has been slowed. Because of the potential for renal toxicity with IV administration, use of topical cidofovir is preferred for treatment of genital herpes. Availability of safer agents for therapy of herpes in healthy persons suggests that cidofovir will be an important therapeutic alternative only in the immunocompromised population.

Trifluridine

Trifluridine is a potent antiviral agent; toxicity precludes systemic administration. However, trifluridine is frequently used for treatment of ophthalmic herpes infections. A series of 26 patients with AIDS and herpes unresponsive to ACV demonstrated complete healing in 7 patients and partial healing in 14 patients.[386] Anecdotal reports also suggest that the use of IFN-α may potentiate the antiviral effects of trifluridine.[387] Topical imiquimod, a TLR-7 and 8 agonist used for treatment of warts, has also been effective in some patients

Resiquimod and Imiquimod

Resiquimod and imiquimod have been evaluated in clinical trials for genital herpes; both work in the animal model, although resiquimod has greater anti-HSV activity. These agents are applied topically during a recurrence to stimulate local immune response while the antigen is present, and delay time to subsequent recurrence. However, imiquimod was not effective in delaying time to next genital HSV recurrence in a clinical trial.[388] Resiquimod has been tested more thoroughly but the results have been inconsistent. A pilot efficacy trial showed a substantial delay to the time of next recurrence compared to vehicle administration, 169 versus 57 days ($p = 0.006$).[389] However, three-phase studies yielded negative results and patients who received resiquimod had a prolonged time healing of their initial recurrence. In contrast, a study to evaluate viral shedding after resiquimod application showed that participants receiving resiquimod had a lower subclinical shedding rate, lower rate of days with lesions, as well as a longer time to first recurrence.[390] Further commercial development of this compound has ceased, in our view, prematurely.

OTHER ANTIVIRALS

Several other therapies for genital HSV have been attempted with a variety of topical medications. Medication in which no therapeutic benefit can be demonstrated are listed in Table 24-8 below. Helicase inhibitors have been shown to have potent in vitro antiviral activity but their clinical development is still in early phases.

The following agents have been tested for genital herpes and the results demonstrate lack of efficacy: vidarabine, idoxuridine, edoxuridine, isoprinosine, ether, 2-deoxy-D-glucose, BCG vaccine, chloroform, povodine iodine, topical surfactants, photodynamic dyes, topical IFN-α transfer factor, and lysine.

IMMUNOTHERAPY

The use of HSV antigens to boost host immune responses has been a longstanding area of HSV research. In animal models, administration of HSV vaccines with varying adjuvants has been associated with reduction in the frequency of reactivation. In people, a double-blind, placebo-controlled trial of a recombinant gD2 vaccine in alum was shown to reduce the recurrence rate of genital HSV by 25%.[342] In a follow-up study, a recombinant gD2 gB2 vaccine (10 μg) in MF-59 reduced the severity of the HSV recurrence after immunization but did not reduce recurrence rates.[391] These effects are clinically modest but demonstrate the principle that immunotherapy offers promise as therapy for genital herpes. Several new approaches to immunotherapy are under investigation. Several immune modulators, especially those involving enhancing the toll-like receptor 7 and 8 pathways have shown in vivo activity in both small animals and humans.

Table 24-8. Ineffective Therapies for Genital Herpes

Vidarabine	Povodine iodine	Isoprinosine
Idoxuridine	Topical surfactants	2-deoxy-D-glucose
Edoxuridine	Photodynamic dyes	BCG vaccine
Ether	Topical interferon α	Lysine
Chloroform	Transfer factor	Nonoxynol 9

The ability to reduce disease severity for a prolonged time period is an attractive therapeutic alternative for many patients, but an effective product has proven elusive.

PREVENTION OF INFECTION

Several partly effective modalities have been established for HSV-2 prevention; disclosure to partners, suppressive antivirals, and condoms are discussed above. However, transmission of disease may still occur despite the use of condoms when viral shedding occurs in areas of genital tract not covered by a condom. Spermicides contain the topical surfactant nonoxynol 9, which inactivates HSV in vitro. Nonoxynol 9 has been shown to be ineffective in the treatment of established genital HSV infection.[129] Other microbicides that are currently in development include Carraguard and PRO2000. Human efficacy data for prevention of transmission or acquisition of HSV-2 with these products are not available.

The high prevalence of asymptomatic and atypical HSV infection implies that development of an effective HSV vaccine is the best approach to the prevention of HSV. Prophylactic subunit protein vaccines have been tested and shown effective in a variety of animal models.[392] The effort has concentrated on glycoprotein D and B, as the immune response to these glycoproteins appears to induce high levels of neutralizing antibodies. A trial of HSV vaccine composed of glycoprotein mixture elicited low levels of antibody titers and did not protect against infection.[393] A recombinant HSV-2 gD and gB vaccine in a novel MF-59 adjuvant emulsion induced humoral and cellular immunity comparable to that observed in natural infection.[394] However, in an efficacy trial of partners discordant for HSV-2 infection and persons attending STD clinics, the vaccine did not afford clinically useful protection from infection.[47] A similar subunit vaccine consisting of HSV-2 gD has shown partial efficacy against HSV-2 infection in women seronegative for HSV-1 and HSV-2.[90] The vaccine decreased the risk of developing clinical genital herpes by 75% and the risk of acquiring HSV-2 infection by 40%. The vaccine did not protect men or HSV-1 seropositive women. Another trial is evaluating this vaccine in a large cohort of HSV seronegative women. Protection against clinical disease but not against infection may not be of benefit from a public health standpoint, if the infected persons continue to shed virus subclinically and can transmit the virus to sexual partners.[395] Other vaccines under development include attenuated live vaccines, replication-defective viral mutants, live virus vectors expressing subunit protein, recombinant-vector-based vaccines and DNA vaccines.[192,392,394,396–400] These products are currently in preclinical or early clinical stages of development.

SUMMARY

Genital HSV infection is a disease of major public health importance. In the last 4 decades, genital herpes infection has increased in prevalence in many population groups, is widespread in the general population in the developing countries, and has emerged as the predominant cause of genital ulcer disease worldwide. First-episode genital HSV infection is a disease of multiple anatomic sites, lasts 3–4 weeks, and has a high rate of complications. In contrast, episodes of recurrent genital disease are of much milder intensity and duration. The major morbidity of recurrent genital herpes is its frequency of recurrences, its chronicity, and its effects on the patient's personal relationships and sexuality. The transmission of disease to the neonate is a major concern to women. Studies have shown effectiveness and safety of ACV and related compounds in reducing many of the clinical manifestations of genital herpes. Greater attention to the diagnosis of the unrecognized HSV-2 infection is needed as such persons are the major source of new infections. The cellular, mucosal, clinical, and epidemiological interactions between HSV-2 and HIV have become clearer in the last decade and the role of HSV-2 in fueling the HIV epidemic has been elucidated. Further investigations on the mechanism of HSV reactivation will hopefully provide additional tools to attempt to control this disease. In the meantime, knowledge of the natural history of the disease will aid the physician in providing the patient with the information necessary to understand this complex entity, decrease the transmission to sexual partners and neonates through education, and explain the long-term complication of the illness. In this way, the physician may do much toward allowing the patient to cope with the psychological and physical components of this illness.

25 Cytomegalovirus

Morgan Hakki and Adam P. Geballe

INTRODUCTION

Human cytomegalovirus (CMV) infections were first described at the beginning of the twentieth century based on the distinct histologic appearance of enlarged cells with viral inclusions associated with fatal infections in newborns.[1] Successful cultivation of the virus, initially in the mid-1950s, enabled a steady accumulation of knowledge about the epidemiology, molecular biology, immunology, and pathogenesis of CMV. While the introduction of effective antiviral drugs in the early 1990s led to significant improvements in the treatment of CMV, numerous questions about the biology and pathogenesis of CMV have not yet been answered and there remains an urgent need for improved therapeutic and preventative measures.

CMV shares many characteristics with other herpesviruses.[2] Its general structure, genetic organization, and ability to persist in a latent state for the lifetime of the infected individual are common to herpesviruses. Based on biological properties including slow growth, salivary gland tropism, and species specificity, CMV has been classified as a member of the beta subfamily of the herpesviridae. The beta subfamily also includes human herpesvirus (HHV)-6, HHV-7, as well as CMVs that infect many other mammalian species such as mice, rats, guinea pigs, and nonhuman primates. During the past few years, the grouping of these viruses into the betaherpesvirus subfamily has been well supported by phylogenetic analyses of nucleotide sequence data.[3–5]

More than 50% of individuals in most populations throughout the world demonstrate serological evidence of prior CMV infection.[6] The coevolution with and adaptation to its human host over millions of years may account for the observation that in most cases, CMV infection causes few if any symptoms.[5] However, in immunocompromised individuals, primary infection or reactivation of latent virus can be life-threatening. As well, congenital infections are common and can result in serious lifelong sequelae. The possibility that subclinical CMV infection contributes to chronic diseases such as atherosclerosis remains a hypothesis under active investigation.[7–9] Although CMV does not typically come to medical attention as a result of genital tract lesions or disease, it can be transmitted sexually and has important consequences for the sexually active, child-bearing population.

VIRUS STRUCTURE

VIRION ORGANIZATION

The CMV virion, like those of other herpesviruses, is approximately 200 nm in size and contains a large double-stranded DNA genome encased in an icosahedral capsid (Fig. 25-1). Surrounding the capsid is an unstructured region known as the tegument (or matrix) and an outermost lipid membrane containing viral glycoproteins. In addition to infectious virions, CMV infections produce at least two other types of particles, dense bodies, and noninfectious enveloped particles.[10] Although these particles cannot establish productive infections, they can bind and fuse to cell membranes and therefore have the potential to alter cellular activities.

CMV virions contain over 70 viral proteins as well as many cellular proteins and even some viral and cellular RNAs.[11,12] Viral glycoproteins on the virion surface are key determinants in mediating binding to and entry of the virus into the cell.[13,14] These proteins are also the major targets of anti-CMV neutralizing antibodies. Several internal proteins form structural elements of the virion and others serve regulatory roles in activating transcription of the first (immediate early, or α) kinetic class of viral genes to be expressed after infection.[15,16] Despite these functions, preformed virion proteins are not essential for viral replication following entry since the experimental introduction of naked viral DNA into permissive cells can yield infectious virus. The roles of many of the other virion proteins and RNAs in the infectious process are unknown, and some of these may be only incidentally acquired during virion assembly.

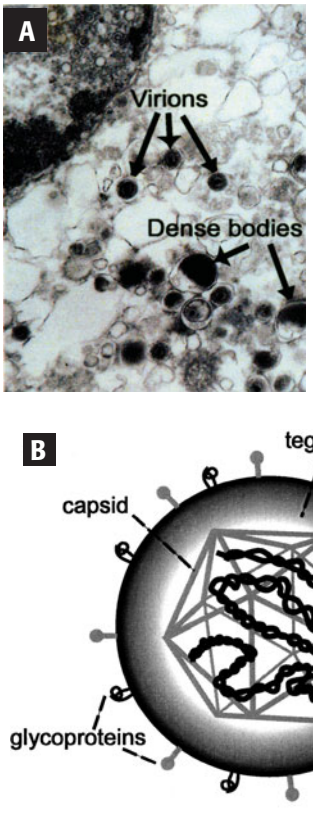

FIGURE 25-1. A. CMV infected cells as viewed by transmission electron microscopy. Cytoplasmic virions and dense bodies are indicated (55,000×, provided by Julie Randolph-Habecker, Fred Hutchinson Cancer Research Center). **B.** Diagram of a CMV virion. The lipid envelope contains glycoproteins and surrounds the unstructured tegument. The dsDNA genome is packaged within an icosahedral capsid.

GENOME

The CMV genome contains approximately 230 thousand base pairs of duplex DNA organized into long and short unique segments (Fig. 25-2). The short segment is flanked by inverted repeats. Although the long unique region is also flanked by inverted repeats in laboratory-adapted strains, these repeats are minimal or absent in clinical isolates that have not been passaged many times in cell culture.[3,17,18] For example, in place a portion of these repeats, the low-passage clinical isolate CMV (Toledo) contains 15 kilobase base pairs of unique DNA encoding 19 genes that are missing from the laboratory-adapted strain CMV (AD169).[19]

Computer analyses of the sequences of several CMV isolates suggest the presence of approximately 200 protein-coding open reading frames (ORFs).[4] In addition, several genes that produce noncoding RNAs, including microRNAs, have been identified.[20,21] By convention, CMV genes are named based on their position within each segment of the genome, although some genes have additional common names based on historical usage or homologies to genes of other herpesviruses. For example, UL55 is the 55th ORF in the unique long segment of the genome and is also known as the

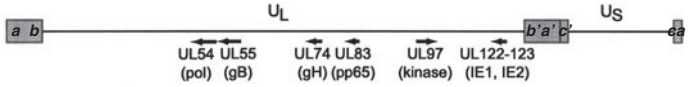

FIGURE 25-2. The CMV genome. Long unique (U_L) and short unique (U_S) segments are flanked by repeats of varying sizes ([*ab*], [*b'a'c'*], [*ca*]). The example shown here represents the laboratory adapted strain CMV (AD169). Arrows show the positions and orientations of several of the approximately 200 ORFs encoded by the genome.

glycoprotein B (gB) gene. While many genes are highly conserved among strains, others are surprisingly variable; the DNA polymerase varies at only 4% of amino acids, while UL144, which encodes a tumor necrosis factor-like protein, varies at as many as 21% of positions.[22,23]

CMV genes can be grouped into three phylogenetic classes.[24] One set of approximately 40 genes, including UL54 (DNA polymerase), UL55 (gB), and UL57 (ssDNA-binding protein), are located primarily in the central portion of the U_L region of the genome and have homologues in most other herpesviruses. Flanking this region are an additional approximately 40 genes that have homologues in other betaherpesvirus subfamily members. Finally, much of the U_S region and the ends of the U_L region contain genes specific to human or primate CMVs.

The functions of many CMV genes have not been evaluated in detail, but recent advances in engineering of the genome have provided some insights. As with other well-studied herpesviruses, only approximately half of all CMV genes are essential for the virus to replicate in cell culture.[25,26] These include genes involved in regulating the expression of other viral genes, those needed to replicate the viral DNA, and those which play an integral role in the formation of new virions. Genes nonessential for growth in cell culture are likely important for viral replication and spread in nature. These include genes involved in evading the host cellular immune response, determining cell tropism, and participating in the establishment and maintenance of latency.

DNA sequence polymorphisms between the genomes of distinct CMV isolates have been useful in tracking transmission. Many more differences are found when comparing isolates from epidemiologically unrelated cases than from isolates obtained from related cases such as mother–infant pairs, sexual partners, and transplant recipients following transplantation of organs from a common infected donor.[6,27,28] Studies attempting to correlate genetic sequence polymorphisms, most commonly in the gB gene, with different disease manifestations have been inconclusive.[29] Nonetheless, genetic variation among strains may account for some of the differing pathogenic manifestations of CMV infections. Interestingly, polymorphisms in one gene have generally been found to be unlinked to those in other genes, suggesting that genetic recombination between isolates occurs frequently in nature.

REPLICATION

LYTIC CYCLE

A common property of betaherpesviruses is their species specificity.[2] CMV causes disease only in humans, and the virus replicates only in cells of human origin. With a few exceptions, other mammalian CMVs display similarly limited species tropism. In cell culture, the virus grows well in diploid human fibroblasts and some, but not all, strains will grow in other cell types including endothelial cells and macrophages. In infected patients, evidence of CMV has been found in a wide range of cells, including fibroblasts, endothelial cells, epithelial cells, blood cells, smooth muscle cells, and macrophages.[30] However, it is not certain in which of these cell types the virus can complete its replication cycle and produce new virus.

CMV receptors are expressed on many cell types and, in fact, CMV can enter most human cells.[2] The virus initially binds to target cells through low-affinity interactions with cell surface heparan sulfate proteoglycans. More specific interactions between viral envelope proteins and cellular receptors then mediate the entry process resulting in fusion of the viral and cellular envelope. Studies aimed at identifying cellular receptors have implicated the integral membrane protein heterodimers $\alpha 2\beta 1$, $\alpha 6\beta 1$, and $\alpha V\beta 3$, and the epidermal growth factor receptor.[14,31] The ubiquity of these receptors may explain the ability of CMV to enter many cell types.

Binding of the virus to the cell surface activates signaling pathways, resulting in a large number of changes in the target cells.[32,33] Part of this cellular response appears to be mediated by sensing of the incoming virus by Toll-like receptor 2.[34] Thus, in addition to activating pathways that the virus uses for its replicative cycle, CMV binding to and entry into the cell may also initiate host innate immune responses.

After envelope fusion, the viral capsid and associated tegument translocate to the cell nucleus where transcription of immediate early genes commences, stimulated in part by preformed tegument proteins.[15,16] Potent transcriptional control elements that direct the expression of the major immediate early gene (UL122/UL123) have led to its widespread application for expression of foreign genes in many other experimental systems. The protein products of immediate early genes generally function to activate expression of early and late classes of proteins as well as to thwart apoptotic and other antiviral cellular responses.[2,35–37]

Early (or β,) genes are, by definition, those genes whose transcription requires prior immediate-early viral gene expression but not viral DNA replication, while late (or γ) gene transcription is dependent on viral DNA replication. In fact, many CMV genes are expressed at low levels at early times and at much higher levels at late times, after viral DNA replication has begun. DNA replication is thought to occur by a rolling circle mechanism.[38] Newly replicated genome length segments are cleaved from the rolling circle and packaged into viral particles. Egress of the virus from the cell is not well understood but, by analogy to other herpesviruses, is likely a complex process involving budding through the nuclear membrane followed by deenvelopment, reenvelopment, and eventual budding through the plasma membrane.

LATENCY

The ability to persist in a latent state in which no infectious virus is present but from which reactivation of viral production can occur is a hallmark of herpesviruses. In the case of CMV, little is known about the sites or mechanisms of latency. After recovery from acute CMV infection, individuals may continue to produce infectious virus for months, indicating that symptomatic resolution is not a reliable indicator of the transition from productive infection to latency.

Viral transmission from healthy seropositive blood donors suggests that a blood component is one site of latency. The fact that reducing the number of leukocytes in blood greatly reduces the risk of transmission suggests that these cells represent a latently infected population. A variety of laboratory studies support the hypothesis that cells of the granulocyte–monocyte lineage harbor latent CMV.[39]

CMV may persist in a latent state at sites other than blood leukocytes. Transplantation of solid organs clearly can transmit the virus and murine CMV resides latently in organs including the lung and spleen.[40] However, whether the latently infected cell type in these organs is transitory blood cells, temporary residents such as monocytes or macrophages, or permanent cells in these organs is not yet certain.

HOST IMMUNE RESPONSES

As with many viruses that cause chronic infection, CMV seems to have coevolved with humans to a balanced state in which the virus persists but generally causes little clinical illness. The host's innate and adaptive immune responses are usually successful at limiting CMV infection as is evident by the clear association of immune system dysfunction with CMV disease. In the absence of prophylactic antiviral treatment, CMV often reactivates in seropositive individuals who undergo hematopoietic stem cell transplantation (HSCT).[41] Immunosuppression resulting from drugs used to treat cancer and autoimmune disorders, and from impaired T-cell function that occurs with advanced AIDS, is also associated with reactivation of CMV.

A key component of the host immune response is the HLA class I-restricted $CD8^+$ T cell. Among the viral antigens recognized by these cells is the virion tegument protein pp65, the product of the UL83 gene. Using tetramer and intracellular cytokine staining techniques, many groups have reported that 5% or more of circulating $CD8^+$ T cells in normal

individuals can be specific for this one protein.[42] CD8 responses to IE1, gB, and other largely uncharacterized proteins are also detectable.[43] It is possible that the remarkably high number of CMV-specific CD8$^+$ cells is linked to frequent subclinical reactivations or to the endothelial cell tropism of the virus, causing repeated stimulation of CD8$^+$ T cells.

CD4 helper T cells also play an important role in controlling CMV. In a recent study of AIDS patients, loss of CMV-specific CD4$^+$ cells preceded the development of CMV disease even though CMV-specific CD8$^+$ cells were present.[44] In HSCT recipients, undetectable CMV-specific CD4$^+$ cells were significantly associated with late CMV disease and death.[45] CMV-specific CD4$^+$ cells likely function in part by helping to maintain robust CMV-specific CD8$^+$ cell responses.[46]

Infected individuals develop antibodies to multiple different CMV proteins. Many of the antigenic targets are present internally within the cell or virion and are unlikely to have roles in immune protection. However, antibodies to gB and gH, two envelope glycoproteins, can neutralize the virus in cell culture assays.[13] Although high titer CMV immune globulin may have some antiviral utility in conjunction with antivirals, passive immunity by itself has not been convincingly shown to be effective in preventing or treating established infection.[47]

VIRAL EVASIVE MECHANISMS

CMV has evolved a variety of mechanisms to avoid elimination by host's multifaceted antiviral responses (Fig. 25-3). Several CMV genes have been found to block intracellular response pathways as well as antiviral responses mediated by cells of the innate and adaptive immune systems.[24,48]

Autonomous cellular responses to viruses include ones that shut down basic processes necessary for viral replication, even at the risk to the health and viability of the cell. For example, viral infections often trigger apoptotic pathways, and CMV has several genes that block steps in this response.[48] CMV contains at least two genes, *IRS1* and *TRS1*, that bind double-stranded RNA (dsRNA) and can prevent activation of interferon-induced, dsRNA-activated enzymes that inhibit overall protein synthesis.[37,49] CMV counters the interferon system in part by preventing translocation of interferon regulatory factor 3 from the cytoplasm to the nucleus, one of the key steps in Toll-like receptor signaling and activation of the interferon response.[50]

Several viral genes including *US2, US3, US6, US8,* and *US11* act at different stages in the HLA class I and class II pathways to prevent presentation of viral peptides to T cells.[24] Cells lacking surface HLA class I are frequent targets for NK cells, but CMV has other genes that help it avoid these cells as well.

CMV also encodes several chemokines and chemokine receptors that mediate interactions with the host immune system. Chemokine receptors have been hypothesized to bind and sequester host cell chemokines, thereby inhibiting the influx of inflammatory cells. Conversely, viral chemokines may promote viral dissemination by attracting inflammatory cells, which then serve as vehicles for viral spread to distant sites.[48]

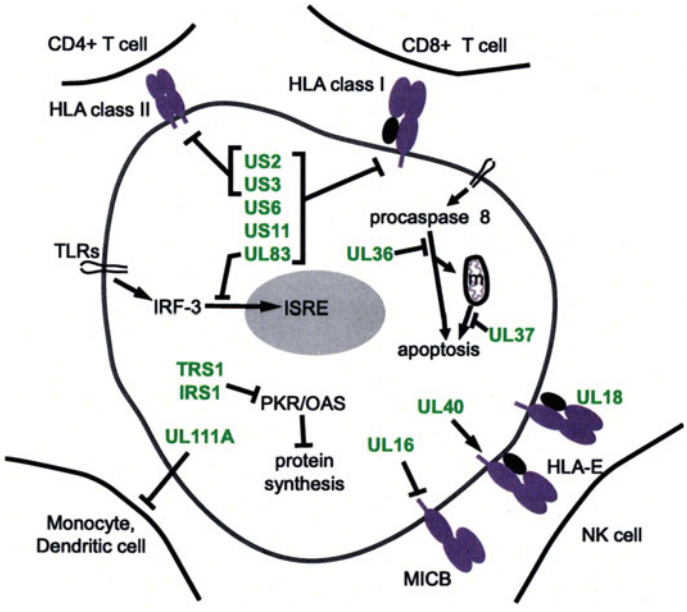

FIGURE 25-3. Immune evasion strategies. CMV encodes multiple genes (green) that interfere with cellular anti-viral responses. Among the targets of these CMV genes are cell autonomous responses (e.g., induction of apoptosis, stimulation of interferon gene expression, and shut off of protein synthesis) as well as responses mediated by various cells of the innate and adaptive immune system. (Abbreviations: IRF-3, interferon regulatory factor 3; ISRE, interferon-stimulated response element; m, mitochondrion; MICB, major histocompatibility complex class I chain-related B; OAS, oligoadenylate synthetase; PKR, protein kinase R; TLRs, toll-like receptors.)

EPIDEMIOLOGY

CMV is a ubiquitous virus, as evidence of infection has been found in persons of all ages, socioeconomic groups, and geographic locales. In the United States and Western Europe, 5–30% of children will be CMV seropositive by 5 or 6 years of age; this number reaches 40% by adolescence and increases by roughly 1% per year thereafter.[1,51] CMV infection is usually acquired earlier in life among persons living in developing countries and among those in lower socioeconomic strata in developed nations. As discussed below, the mode of acquisition and precise seroprevalence rate in the United States vary significantly among different populations.

CMV IN HETEROSEXUALS

CMV has long been thought of as a sexually transmissible infection based on several lines of evidence. CMV seroprevalance was found to be significantly higher among male partners of CMV seropositive women than of CMV seronegative women (74% vs. 31%).[28] The prevalence of CMV

seropositivity in sexually active women between the ages of 15 and 30 years was greater than that in celibate women of the same age.[52–55] Among women, predictors of CMV seropositivity included young age at the time of first sexual intercourse, greater number of lifetime sexual partners, and the presence of other STDs.[56–58] Seroconversion, presumably a marker for primary infection, occurred at a rate of 37% per year in women attending STD clinics compared to 2–7% in the general population, and correlated with having multiple sex partners in the preceding month and a prior history of any STD.[56] Additionally, an outbreak of CMV-associated mononucleosis was documented among sex partners but did not affect nonsexually active persons living in the same quarters.[59]

Consistent with these clinical observations, in adults CMV was isolated most frequently and in greater titers from cervical secretions and semen than from other sources.[54,60–62] Using molecular strain-typing techniques, it has been demonstrated that in the majority of cases, seroconcordant couples shared a similar CMV isolate, indicating spread from one partner to another.[28] In sum, evidence from clinical and molecular studies supports the role of sexual transmission as a major mechanism of CMV spread among heterosexuals.

CMV IN HOMOSEXUAL MEN

In the era before highly active antiretroviral therapy (HAART), CMV was a significant cause of morbidity and mortality in the HIV/AIDS population. The first documentation of the high prevalence of CMV in homosexual men originated from studies performed in San Francisco in the late 1970s and early 1980s.[63] The rate of CMV seropositivity in homosexual men attending an STD clinic was 93.5% compared to 54.3% in heterosexual men attending the same clinic and 42.7% in heterosexual men randomly selected from a pool of blood donors. Urinary excretion of CMV was found to be significantly more common in homosexual men compared to heterosexual men (7.4% vs. 0%). A similarly high rate of CMV seropositivity (86.9%) was found in homosexual men enrolled in a hepatitis vaccine trial.[64] Of the CMV seronegative participants enrolled in this study, 71% experienced primary infection during the 9 months of follow-up. Passive anal–genital contact was the only identifiable sexual practice associated with CMV seropositivity. Excretion of CMV was found more commonly in semen (34.6%) than in urine (7.7%) and semen-harbored virus for longer periods of time than urine (22 months vs. 9 months). Thus, it appears that the main route of transmission of CMV among homosexual men involves exposure of anal mucosa to semen that contains CMV. Finally, it should be noted that infection with multiple strains of CMV has been documented in homosexual men, with and without HIV/AIDS.[65] Therefore, the presence of CMV IgG does not seem to confer immunity to reinfection in an individual engaging in high-risk sexual practices.

CONGENITAL AND NEONATAL INFECTION

Transmission of CMV from the mother to her fetus or newborn represents an important mechanism by which CMV is spread within a population. Infants who acquire CMV from a maternal source will typically shed CMV for months to years, thereby serving as a source of viral transmission to others. Contact with body fluids from infected children in day-care centers is a common means of transmission of CMV from child to child and from child to day-care workers as well as to the parents of children of other attendees.[66–71] One pattern of transmission is for a first child to acquire CMV at day care and transmit the infection to his or her pregnant seronegative mother, resulting in a congenitally infected second child. Therefore, preventing infection of the newborn and infection in day-care centers could have a major impact on interrupting transmission of CMV in the general population.

CMV is transmitted from mother to child by three different routes: transplacental, intrapartum, and breast milk. Transplacental transmission can occur after primary maternal CMV infection during pregnancy, by reactivation of endogenous virus, or, less commonly by reinfection with a new strain of CMV.[72] While the rate of primary maternal infection during pregnancy is only 0.7–4.1%, the risk of transmission to the fetus in this setting is considerably higher (20–40%) than when the mother is seropositive prior to conception (2.2%).[73–75]

Intrapartum CMV transmission is directly related to local viral shedding during delivery. Close to 50% of infants born to the 2–28% of women who shed CMV from the vagina or cervix at the time of delivery will become infected.[60,75]

Finally, transmission via breast milk depends on the presence of CMV in the breast milk and on the duration of nursing. CMV can be recovered from breast milk in 30–70% of seropositive women, depending on the method of detection and the frequency of sampling.[76–79] Infants who nurse for less than 1 month are at low risk of becoming infected compared to those who nurse for a longer time.[76]

TRANSMISSION VIA BLOOD PRODUCTS AND TRANSPLANTED ORGANS

First described among patients receiving transfusions during cardiopulmonary bypass for open heart surgery,[80,81] CMV transmission can occur with transfusion of whole blood, red blood cells, and platelets. Transmission of CMV from seronegative donors occurs rarely and is likely due to inaccuracies with the CMV serology result or to the donor having being infected so recently that detectable antibodies have not yet been generated. Infection of an immunocompetent, seronegative recipient of blood products from a seropositive donor typically does not lead to clinical disease.[82] The incidence of CMV transmission from seropositive donors to seronegative recipients is estimated to be about 1%, this risk

being directly proportional to the number of blood units transfused.[83,84] Transfusion-transmitted CMV poses the greatest risk for morbidity and mortality among low-birth weight infants born to seronegative mothers and to seronegative HSCT or solid organ transplant (SOT) recipients.[82] For example, between 28% and 57% of CMV seronegative HSCT recipients of unscreened, unmanipulated blood products will seroconvert and a significant proportion of these individuals will develop CMV disease in the absence of prophylactic or preemptive therapy.[85]

The leukocyte is believed to be the primary vehicle of CMV transmission.[86,87] Two methods for reducing the risk of CMV transmission include the use of blood products from CMV seronegative donors and leukocyte reduction of blood products by filtering. The use of CMV-seronegative screened blood products dramatically reduces the incidence of infection in high-risk populations, such as transplant recipients and infants born to CMV seronegative mothers.[88–92] Leukocyte reduction has been shown to be as effective as the use of screened CMV-seronegative blood products in reducing the risk of CMV transmission.[93–97] One caveat to this approach is that although the CMV infection rate is similar using CMV-seronegative products or leukodepletion, the incidence of invasive CMV disease with leukodepletion was found to be higher in one study.[93] The reason for this is unclear, and overall leukodepletion remains an effective and safe method for reducing the risk of CMV infection and disease resulting from transmission in blood products.

Transmission of CMV through a transplanted organ is a well-known occurrence after SOT. A CMV seronegative recipients of a kidney or liver from CMV seropositive donors has a 70–80% chance of developing primary infection.[98–100] Using molecular typing methods, several studies have demonstrated that the CMV strain present in the recipient is identical to the strain from the donor.[27,101] In part due to the immunosuppression associated with organ transplantation, CMV seropositive recipients of organs from seropositive donors can also experience reinfection despite the presence of natural immunity pretransplant.[102]

CLINICAL MANIFESTATIONS

INFECTION IN IMMUNOCOMPETENT HOSTS

Symptomatic disease in otherwise healthy individuals is uncommon. Primary infection can result in a mononucleosis-like syndrome manifested by fever, lymphadenopathy, and peripheral blood lymphocytosis. While most cases of mononucleosis are due to infection with Epstein-Barr virus (EBV), CMV accounts for about 50% of EBV-negative cases.[103] Contrasting with EBV infection, pharyngitis and tonsillar exudates are less common in CMV mononucleosis.[103] Other manifestations of symptomatic CMV infection include abnormal liver function tests, malaise, sweats, and jaundice.[104] Rare manifestations include colitis,[105,106] pneumonitis,[103] hepatitis,[107,108] Guillain-Barre Syndrome,[109,110] meningoencephalitis,[111] myocarditis,[112,113] and blood dyscrasias such as thrombocytopenia and hemolysis.[114,115] The fact that CMV has endothelial cell tropism and has been linked to vasculopathy in cardiac transplant recipients has raised the possibility that CMV may be a factor in the development of atherosclerosis in the immunocompetent host.[7–9] However, this hypothesis remains controversial.

CONGENITAL INFECTION

Approximately 1% of newborns in the United States are infected with CMV in utero.[116] Of these, 7% will have symptomatic disease, or "cytomegalic inclusion disease."[117] It has been generally believed that fetal infection occurring from a previously immune mother is less severe than fetal infection occurring during primary maternal infection.[118–120] However, reports documenting severe fetal disease in newborns born to seropositive mothers indicate that preexisting maternal natural immunity does not always protect the fetus from the disease.[72,121–123] Manifestations of CMV inclusion disease include jaundice, hepatosplenomegaly, thrombocytopenia, and CNS involvement, such as microcephaly, chorioretinitis, hearing loss, and cerebral calcifications. In up to 20% of infants, cytomegalic inclusion disease is fatal. Among infants who do survive, many will have serious lifelong CNS sequelae, such as mental retardation, blindness due to optic atrophy, and sensorineural hearing loss. Most of the extra-CNS manifestations of inclusion disease resolve spontaneously.

Of the infants who are congenitally infected but do appear asymptomatic at birth, up to 15% will still manifest delayed sequelae such as mild developmental delay and hearing loss that may be bilateral and complete[124,125] The presence of CMV in the organ of Corti and in the neurons of the spiral ganglia as well as occasional CMV nuclear inclusions in cochlear cells point to CMV cytotoxicity as a plausible pathogenic mechanism for this syndrome.[124,125]

CMV infection that occurs in the peri- or postnatal period differs significantly from congenital infection. Urinary titers of CMV in these infants are typically lower than that in congenitally infected infants, and the vast majority do not develop symptomatic disease.[126] Symptomatic infection, although rare in this setting, may resemble that of mononucleosis.[127] However, infants of CMV seronegative mothers who acquire CMV from blood transfusion from seropositive donors are at high risk for developing multisystem CMV infections with a high fatality rate.[92] The use of CMV-seronegative blood products in this population dramatically reduced the morbidity and mortality associated with posttransfusion CMV.

INFECTION IN THE IMMUNOCOMPROMISED HOST

CMV disease is most commonly encountered in the immunocompromised host, particularly those who have undergone HSCT or SOT, or in those who have AIDS. While some manifestations of CMV disease are common to both the transplant population and the HIV-infected population, there are several significant differences in disease manifestations between these two groups (Table 25-1).

More than 90% of HIV-1-infected men are coinfected with CMV.[128] Individuals with $CD4^+$ counts less than 100 cells/mm^3 are at the greatest risk for CMV disease, which in the majority of cases represents reactivation of latent virus. In the era prior to the routine use of HAART, CMV was the most common viral opportunistic infection in persons with AIDS.[129] Since the introduction of HAART in the 1990s, the incidence of CMV disease has fallen by more than 80%.[130] Retinitis was the most common form of CMV disease and typically occurred when $CD4^+$ counts dropped below 50 cells/mm^3.[131] Less common manifestations of CMV disease in this population include polyradiculopathy characterized by ascending lower-extremity weakness, meningoencephalitis, esophageal ulcerations, colitis, and sclerosing cholangitis.

Several factors influence the development of CMV infection and disease after HSCT and SOT. Perhaps most important is the CMV serostatus of the donor and recipient. Primary infection in the seronegative SOT recipient is generally associated with higher rates of symptomatic infection and disseminated disease than reactivation of latent virus in a seropositive recipient, presumably due to the lack of any preexisting immunity in the seronegative recipient.[132,133] The development of primary CMV infection has been noted in up to 79% of liver transplants and 58% of kidney or heart transplants in which the donor is seropositive and the recipient is seronegative.[134,135] In the setting of HSCT, several studies have documented that CMV seropositivity of the recipient results in significantly increased overall posttransplant mortality compared to CMV seronegative recipients with a seronegative donor.[136] When the recipient is CMV seronegative, overall mortality is increased when the donor is seropositive compared to the situation where the donor is seronegative.[137] However, when the recipient is CMV seropositive, the effect of donor serostatus is uncertain. One large study failed to show an effect of donor serostatus on overall mortality,[138] while another showed increased mortality among unrelated transplants when the donor was CMV seronegative.[139] In this study, there was a trend toward a higher rate of death due to infectious complications among patients who received grafts from CMV seronegative donors ($P = 0.07$). This finding was hypothesized to be due to the potential protective effect of transferring CMV-specific immune cells in the seropositive graft.

Also critical to the development of CMV disease is the degree of immunosuppression. Among SOT recipients, the highest rates of CMV disease have been reported in lung and heart–lung recipients, and a higher rate of CMV disease is found in recipients of T-cell-depleted HSCT than in recipients of nondepleted stem cell product.[140,141] Additionally, the transplant recipient is at particularly high risk of CMV reactivation during periods of potent immunosuppression that accompany graft rejection or graft-versus-host disease.

Almost any organ can be involved in CMV disease after SOT or bone marrow transplant. Manifestations of CMV disease common to both SOT and stem cell transplantation include pneumonitis, hepatitis, and colitis. Even in patients who do not develop any of these overt manifestations of CMV infection, seropositivity has been associated with an increased incidence of serious bacterial and fungal infections after bone marrow transplant.[137] These observations suggest that "indirect effects" of subclinical CMV infections may include immune suppression, a plausible hypothesis in light of the frequent reactivation in transplant recipients, and the large number of immune modulatory molecules expressed by CMV.

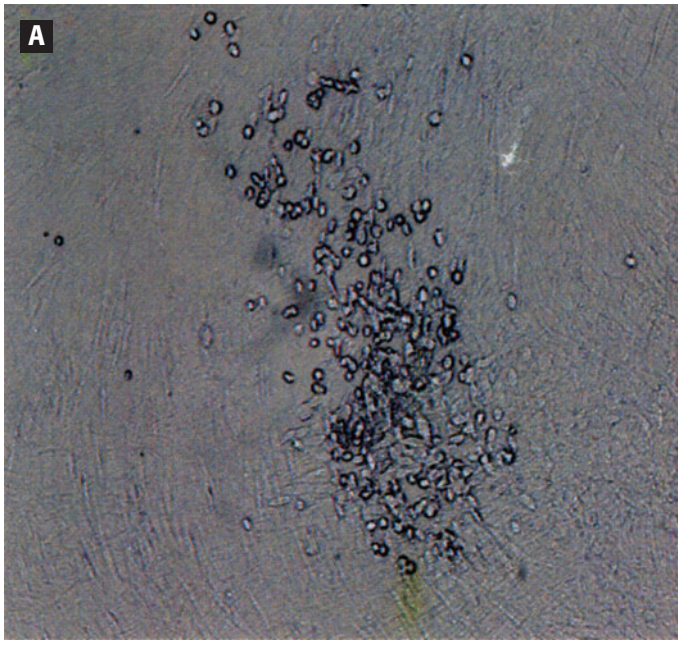
Table 25-1. Common Manifestations of CMV Infection

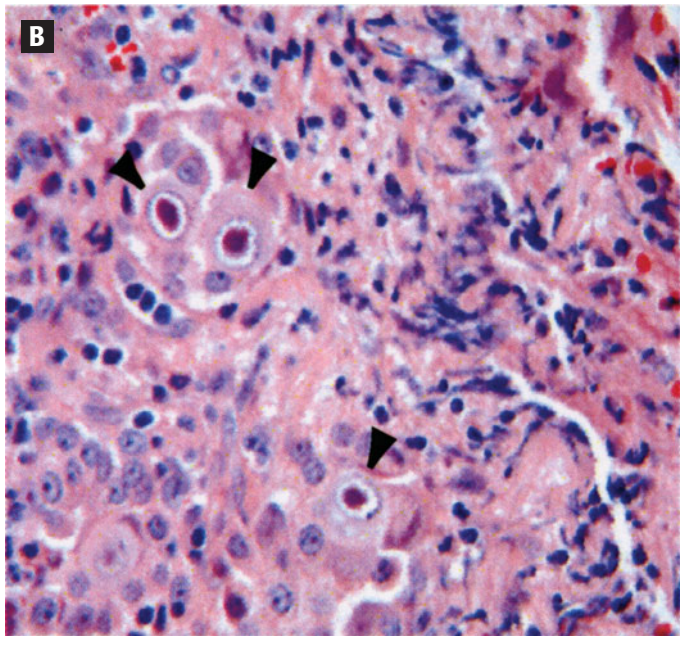
Neonates
• Cytomegalic inclusion disease
• Sensorineural hearing loss
Immunocompetent adults
• Mononucleosis-like syndrome
Solid organ transplant recipients
• Mononucleosis-like syndrome
• Allograft rejection/dysfunction in the transplanted organ (hepatitis, pneumonitis, coronary stenosis/allograft vasculopathy, renal impairment)
• Gastrointestinal disease (esophagitis, colitis)
Hematopoietic stem cell transplant recipients
• Pneumonitis
• Gastroenteritis
HIV/AIDS
• Retinitis
• Gastrointestinal (esophagitis, colitis, biliary tract disease)
• Neurological (encephalitis, polyradiculopathy)

DIAGNOSIS

CULTURE

Growth of CMV in the diagnostic laboratory, usually in primary human fibroblast cells, takes several weeks and is laborious (Fig. 25-4A). The shell vial technique, in which monoclonal





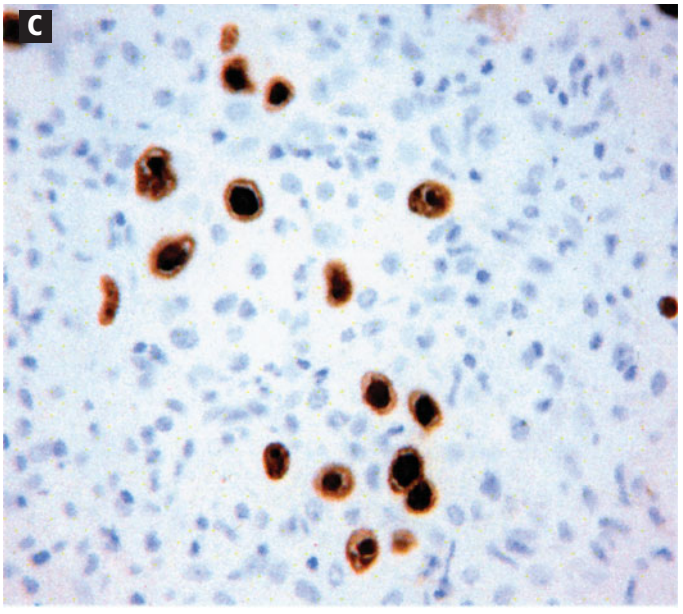


FIGURE 25-4. Cytopathology and histology of CMV infection. **A.** A CMV plaque appears by phase contrast microscopy as a cluster of rounded refractile cells surrounded by normal spindle-shaped fibroblasts 1 week after infection (10×). **B.** Hematoxylin and eosin (H&E) staining of a lung biopsy from a CMV-infected AIDS patient shows inflammatory infiltrates. Several cells display the characteristic "owls eyes" nuclear inclusions (arrowheads, 40×). **C.** Immunohistochemistry of the same lung biopsy shows many infected cells detected using a mixture of monoclonal antibodies directed against the IE1 and ppUL44 proteins (40×). (B and C were provided by Julie Randolph-Habecker and Robert Hackman, Fred Hutchinson Cancer Research Center.)

antibodies are used to detect CMV immediate-early proteins in cultured cells, can be performed within 18–24 hours after inoculation and is now widely used for rapid diagnosis of CMV in samples such as bronchoalveolar lavage (BAL) fluid.

ANTIGEN DETECTION

The detection of the CMV pp65 tegument protein in peripheral blood leukocytes using a monoclonal antibody offers a rapid, sensitive, and specific method of diagnosing CMV viremia. In this assay, peripheral leukocytes are spread on a glass slide and stained with a fluorescent antibody directed against pp65. The number of positive cells provides a rough estimate of the circulating viral load. When used in the transplant setting, a positive CMV pp65 assay has been shown to predict the development of invasive disease. False negatives can occur in up to 10% of cases of CMV pneumonia and colitis. Additionally, since the assay relies on the detection of pp65 in circulating leukocytes, it is not reliable in patients with profound leukopenia. The predictive value of this assay has not been validated when performed on other clinical samples such as BAL fluid.

POLYMERASE CHAIN REACTION

The polymerase chain reaction (PCR) relies on the amplification of CMV DNA from blood or other tissue specimens. While the assay characteristics vary from center to center, this

method is the most sensitive method for detecting CMV, and it maintains a good degree of specificity. In addition, it is rapid, with results usually available within 24 hours, and can provide a quantitative measurement of CMV viral load in a sample. PCR has been shown to be an accurate predictor of CMV disease in transplantation, HIV, and fetal infection.[142]

HISTOPATHOLOGY

The detection of CMV by shell vial, pp65 antigen, or PCR does not necessarily confirm CMV as the causative agent of a disease process. Thus, histopathology of biopsy samples is an important tool for diagnosing CMV invasive disease in situations where the diagnosis is otherwise unclear (Fig. 25-4). The presence of characteristic CMV "owl's eye" nuclear inclusions in, for example, a tissue biopsy specimen strongly implicates CMV as an etiologic factor. The sensitivity of this approach can be enhanced by the use of immunohistochemical techniques to identify CMV antigens even when classic inclusions may not be evident.

TREATMENT AND PREVENTION

ANTIVIRAL AGENTS

Ganciclovir is a nucleoside analogue of guanosine that acts as a competitive inhibitor of deoxyguanosine triphosphate incorporation into viral DNA. A CMV gene, *UL97*, encodes a phosphotransferase that converts ganciclovir to ganciclovir monophosphate. Cellular enzymes then convert the monophosphate to the triphosphate form. The major toxicity of ganciclovir is myelosuppression, with neutropenia occurring in up to 16% of all patients receiving ganciclovir, and 30% of HSCT recipients.[143] Neutropenia often responds to dose reduction, and sometimes support with granulocyte-colony stimulating factor is required. Less common side effects include confusion, dizziness, headaches, nausea, vomiting, and diarrhea. Resistance to ganciclovir can arise as a result of mutations in the *UL97* gene or less commonly in the DNA polymerase *(UL54)* gene.

Valganciclovir is the valine ester of ganciclovir. After oral administration, valganciclovir is quickly absorbed and hydrolyzed to ganciclovir by intestinal and hepatic cells. The advantage of valganciclovir is that it has much greater bioavailability compared to oral ganciclovir (almost 70% compared to 6–8%), and pharmacokinetic studies have demonstrated that a daily 900-mg oral dose of valganciclovir results in blood levels equivalent to 5 mg/kg of intravenous ganciclovir.[144] Based on controlled trials,[145,146] valganciclovir has been approved for induction and maintenance therapy of CMV retinitis in people with AIDS, and for the prevention of CMV disease in adult recipients of heart, kidney, and kidney–pancreas transplants. Side effects of valganciclovir are similar to those of intravenous ganciclovir, namely leukopenia, neutropenia, diarrhea, fever, among others.[147]

Foscarnet is a pyrophosphate analogue that binds directly to, and competitively inhibits, the CMV DNA polymerase. Unlike ganciclovir, foscarnet activity is not dependent on phosphorylation by the UL97 gene product; thus, CMV that has acquired ganciclovir resistance due to UL97 mutations will still be susceptible to foscarnet. Foscarnet has been used successfully for the treatment of most manifestations of CMV disease. Foscarnet has been shown to be equivalent to ganciclovir for the treatment of CMV retinitis and gastrointestinal disease in AIDS patients.[148,149] Resistance to foscarnet can occur and is due to mutations in the CMV DNA polymerase (UL54) gene. Renal failure, hypocalcemia, hypomagnesemia, and hypophosphatemia are all common and potentially life-threatening consequences of foscarnet therapy. Thus, close monitoring of the patient on foscarnet is required.

Cidofovir is a cytosine nucleotide analogue that does not require phosphorylation by viral enzymes for antiviral activity. Cellular enzymes convert cidofovir to cidofovir triphosphate, which then inhibits the CMV DNA polymerase. Since cidofovir is not phosphorylated by the CMV *UL97* gene product, it is active against ganciclovir-resistant UL97 mutants. However, some mutations in the DNA polymerase gene confer resistance to both ganciclovir and cidofovir.[150] The long half-life of cidofovir allows a once-per-week dosing schedule. The major toxicity with cidofovir is renal—uptake of the drug by the proximal renal tubular cells results in degeneration and necrosis of these cells. Since this effect is often irreversible and can lead to serious morbidity, cidofovir should be coadministered with probenecid, which reduces the uptake of cidofovir by renal tubular cells.

There is limited evidence for a role of high-titer CMV-immune globulin (Cytogam) in treating or preventing CMV infections.[47] In one trial, the combination of CMV-immune globulin and ganciclovir did reduce mortality in marrow transplant recipients with CMV pneumonitis compared to historical controls.[151] Whether high titer immune globulin is superior to standard intravenous immunoglobulin (IVIG) for this indication is not known.

Fomivirsen is an antisense RNA compound that inhibits CMV replication by hybridizing with the CMV immediate early 2 (IE2) mRNA and consequently blocking its translation. Although approved for the treatment of CMV retinitis in patients with AIDS, it is not commonly used because of the availability of implantable ganciclovir and oral valganciclovir.

TREATMENT OF THE NEWBORN

Due to the potential long-term effects of congenital CMV infection, there has been considerable interest in determining whether treatment of CMV has a role in this setting.[152] Intravenous ganciclovir, when administered to infants with

symptomatic CMV disease within 1 month of birth, was shown to reduce CMV viral load and possibly has a beneficial impact on auditory abilities in one study that was not placebo-controlled.[153] More recently, the effect of ganciclovir was evaluated in infants born with CMV CNS disease in a randomized trial.[154] Intravenous ganciclovir (6 mg/kg every 12 hours for 6 weeks) or no treatment was given to infants less than 1 month old who were born with symptomatic CMV CNS disease. Significantly fewer ganciclovir recipients had hearing deterioration at 6 months and 1 year compared to control patients. Additionally, ganciclovir recipients gained more weight and had a larger increase in head circumference during the first 6 months than did control patients. As significantly more episodes of neutropenia occurred in the treatment arm, and as ganciclovir is known to have both gonadal toxicity and carcinogenicity in animal models,[147] the decision to treat symptomatic infants requires balancing the potential benefits and risks. Ganciclovir is teratogenic[147] and thus should not be used during pregnancy. Current options for women who acquire primary or symptomatic secondary infection during pregnancy are limited.

PREVENTION

Several interventions can help prevent CMV infection in specific settings. CMV titers are high in semen and in cervical and vaginal secretions, suggesting that condoms are likely to prevent transmission between sexual partners. Indeed, condoms are effective barriers to CMV transmission in experimental systems.[155]

As described above, serological screening or leukoreduction of blood products can reduce the incidence of transfusion-related CMV transmission. In the setting of SOT or HSCT, the selection of grafts from a seronegative donor when the recipient is also seronegative is beneficial. However, the shortage of solid organs and the difficulties in finding appropriated donors for HSCT often preclude this option. Thus, several interventions have been adopted to prevent CMV infection and disease in these settings. After HSCT, prophylactic and preemptive antiviral therapy strategies have been shown to effectively reduce the incidence of CMV disease posttransplant.[41] In the realm of SOT, many centers use prophylaxis for high-risk transplants (D+/R-) and will use preemptive antiviral therapy in the D+/R+, D–/R–, and D–/R+ transplants.[156]

The Institute of Medicine of the National Academy of Sciences recently placed CMV in its "highest priority" category for vaccine development.[157] A primary target population for such a vaccine would be young adults, especially seronegative women prior to childbearing age, in whom a vaccine would have the potential to reduce the risk of congenital CMV disease. A safe and effective vaccine could be used in other groups including seronegative day-care workers and seronegative patients prior to transplantation. Several vaccine candidates have been tested in phase I studies or are under development including live, attenuated viruses based on the CMV (Towne strain), canarypox vectors expressing gB or pp65, soluble recombinant gB, and various DNA vaccines.[158] Earlier studies with the CMV (Towne) vaccine demonstrated partial protection of seronegative women exposed to seropositive infants and reduced severity of disease in seronegative recipients of kidneys from seropositive donors.[159,160] Given that CMV persists even in the presence of an immune response and prior infection does not prevent reinfection with a new strain, development of an effective CMV vaccine will be a challenging goal.

26 Epstein-Barr Virus Infection

John W. Sixbey

DEFINITION

Herpesviruses are classified according to biologic characteristics into three subfamilies: the *alpha-*, *beta-*, and *gammaherpesvirinae* (see Chapter 23). The gamma herpesvirus subfamily, distinguished on the basis of establishing latent infection in lymphocytes, contains both the *Lymphocryptovirus* and *Rhadinovirus* genera defined by similarities in genome structure, gene organization, and relatedness of major viral proteins. These gamma herpesvirus genera include two members that infect humans and are implicated in oncogenesis. One of these, the Epstein-Barr virus (EBV, also called *human herpesvirus* 4) is the prototype *Lymphocryptovirus*. Kaposi's sarcoma associated herpesvirus (KSHV, or *human herpesvirus* 8) is a member of genus *Rhadinovirus*. In this chapter we emphasize select aspects of EBV biology as they may relate to sexual transmission and to clinical manifestations in the context of the general immunosuppression that accompanies HIV infections (for more general reviews, see refs. 1 and 2).[1,2]

HISTORY

Denis Burkitt, a medical missionary to East Africa in the 1950s, first postulated an infectious agent as the cause for a common childhood tumor (Burkitt's lymphoma) based on the epidemiologic characteristics of this disease in equatorial Africa.[3] Using lymphoma samples provided by Burkitt, Tony Epstein and his student, Yvonne Barr, established the first permanent human lymphocytic cell lines[4] and by electron microscopy discovered a new herpesvirus with distinct antigenic and biologic characteristics.[5–7] Paramount among these was the ability of this virus to confer unlimited growth potential to B lymphocytes in vitro.[8,9] Seroepidemiologic studies by Werner and Gertrude Henle indicated that like other herpesviruses, EBV infection was widespread,[10,11] providing an apparent incongruity of ubiquitous asymptomatic carriage of this first candidate human tumor virus. Global distribution and high seroprevalence suggested that the virus might play a role in a very common disorder as well, and the fortuitous seroconversion of a technician in the Henle laboratory during the course of infectious mononucleosis led to the identification of EBV as the causal agent of this much studied lymphoproliferative syndrome.[12] Subsequent nucleic acid hybridization analyses have implicated EBV as an etiologic agent in nasopharyngeal carcinoma,[13,14] Hodgkin's disease,[15–17] unusual T cell lymphomas,[18,19] and polyclonal B-lymphoproliferative disorders.[20,21] Although historically much of EBV research has been focused on the oncogenicity of EBV latency proteins expressed in human tumors, strikingly little is understood regarding the natural history of EBV infection. A reexamination of events surrounding viral acquisition and shedding at mucosal sites draws attention to relatively new and unexplored areas of EBV biology: the pathologic contribution from EBV replication, reinfection consequent to second exposures or reactivation of endogenous virus, and genetic recombination of coinfecting EBV genomes.

EPIDEMIOLOGY

Antibody to EBV can be detected in 90–95% of the population by adulthood.[10] Primary exposure often occurs in the first years of life, with seroconversion evident before the age of 5 years in 50% of children studied in the United States and Great Britain.[22,23] In economically advantaged communities, primary infection may be delayed until adolescence or early adulthood,[24] at which time acquisition of virus produces the clinical syndrome acute infectious mononucleosis.

VIRAL SHEDDING AND TRANSMISSION

Oropharyngeal sites

After initial exposure, EBV establishes a latent infection that persists for the life of the host. The lifelong virus carrier state is accompanied by asymptomatic viral shedding that provides a readily available source of infectious virus for person-to-person

spread. Suspicion that infectious mononucleosis was related to an orally transmitted pathogen (hence the expression "kissing disease"[25]) was confirmed by the demonstration of cell-free virus in throat washings and saliva of infectious mononucleosis patients.[26,27] That intimate contact is required for transmission of virus was verified by epidemiologic studies wherein susceptible roommates of college students with acute infectious mononucleosis were shown to be at no greater risk for EBV seroconversion than the uninfected student population at large.[28,29] In young children, the route may be more indirect, associated with smaller virus inoculums and inapparent symptomatology. After recovery from acute infectious mononucleosis, EBV can be detected readily in the oropharynx for at least 18 months.[30] In healthy seropositive adults followed prospectively over 15 months, 90% shed EBV at some point, as detected by the standard lymphocyte transformation assay, with 25% shedding virus on every testing occasion.[31] Immunocompromised patients have still higher rates of viral shedding,[32] and increased levels of EBV excretion into oropharyngeal secretions are characteristic of individuals infected by HIV-1.[33,34]

Genital tract

Identification of EBV at oropharyngeal sites,[26,27,30] together with the experimental infection of mucosal epithelium derived from normal human cervix,[35] raised the possibility of broader mucosal involvement including the genital tract. In fact, infectious EBV can be recovered from genital mucosa of women with acute infectious mononucleosis,[36] suggesting that virus is either conveyed from the oropharynx to distant mucosal sites by trafficking EBV-infected lymphocytes or that infection has been initiated by introduction of exogenous virus at that anatomic site. Transmissibility of genital virus is suggested by the successful isolation in the lymphocyte transformation assay of EBV from filtrates of cervical washings[36] as well as from vulvar ulcerative lesions.[37] Analogous to the persistent shedding of virus from oropharyngeal sites, EBV can also be recovered from the cervix of women without serologic evidence for recent EBV infection.[36] Indeed, the prevalence of EBV DNA in cervical samples from women attending sexually transmitted disease (STD) clinics ranges from 28% to 40% by polymerase chain reaction (PCR) analyses.[38–40] A possible etiologic role for EBV in subclinical genital lesions was indicated by a study of koilocytotic lesions of the vulva in which EBV DNA was detected in almost half of vulvar biopsies at sites of acetowhite lesions after application of 3% acetic acid.[41] In contrast, 11% of cell samples from normal vulvar mucosa contained EBV DNA.

In healthy, sexually active uncircumcised men, EBV DNA was detected by PCR in cells scraped from the coronal sulcus of the glans penis in 13% of study participants.[40] Forty-eight percent of EBV-seropositive men with urethral discharges secondary to gonococcal infection had EBV DNA detected in their genital tract secretions,[42] representing either lymphocyte-associated virus within the cellular inflammatory infiltrate or cell-free infectious virus. Although the transmissibility of cell-associated virus by the genital route remains to be determined, infection via transfer of latently infected cells has been shown to occur in other contexts. For example, the introduction of EBV-infected cells by blood transfusion[43–45] or tissue transplantation[46,47] causes both asymptomatic seroconversion and clinical disease.

Few studies to date have directly addressed sexual transmission of EBV or the possibility of acquiring classic infectious mononucleosis after genital tract infection. Sexual behavior was found to contribute to asymptomatic acquisition of EBV in a longitudinal study of 45 seronegative women 15–19 years of age, 22 of whom seroconverted within 5 years of study enrollment.[48] Risk of seroconversion increased with number of sexual partners and was greatest after acquisition of a new sexual partner, although rarely contemporaneous with the first exposure. In one instance, EBV DNA was detected in a cervical cytologic sample at the visit immediately preceding detection of serum antibodies; in 5 others, viral DNA was detected simultaneously with seroconversion. Cervical samples from women who seroconverted were EBV DNA positive on as many as seven occasions over greater than a 3-year interval, with four women still positive at the end of follow-up.[48] The continued presence of virus over prolonged sampling periods, together with a high EBV DNA copy number in cervical samples,[48,49] makes sexual transmission of EBV highly probable. Similarly, a highly significant correlation between seropositivity for EBV, sexual intercourse, and an increasing number of sexual partners was found in a cross-sectional analysis of 1006 new University students.[50] In this study, two-thirds of infectious mononucleosis cases were statistically attributable to sexual intercourse, whereas only a tenth of asymptomatic primary infections were linked to sexual activity.

EBV GENOTYPES AND COINFECTION

Despite obvious epidemiologic implications of a genital distribution of EBV, direct sexual transmission has not been unequivocally shown. What may ultimately allow osculatory versus venereal routes of transmission to be distinguished are EBV genotypic markers used for tracking discordant strains of virus within individual subjects. Both primary infection and carrier states are now known to be more complex than previously thought, with both tissue compartmentalization and cyclic exchange of multiple EBV genotypes occurring at distinct anatomic sites within an infected host.[51–53]

EBV isolates can be categorized broadly into two types now called *EBV-1* and *EBV-2* (formerly types A and B). Each is distinguished on the basis of polymorphisms in the genes

that encode the EBV nuclear antigens (EBNAs), specifically EBNA2, 3A, 3B, and 3C.[54–56] EBNA2 differs more extensively between genotypes than the other EBNA proteins[55,56] and is primarily responsible for the biologic differences between type 1 and type 2. Specifically, type 1 strains transform primary B lymphocytes in vitro with greater efficiency than type 2 EBV, resulting in a cell growth phenotype readily maintained in culture.[57,58] Such polymorphisms in the EBNA genes generate immunologic responses that are both type-specific and cross-reactive. Although antibodies to EBNA2 and 3A are partially cross-reactive between types, the antibody responses to EBNA3B and 3C are largely type-specific.[59,60] Similarly, both type-specific and cross-reactive cytotoxic T cell responses can be detected.[61–63]

Once thought to be restricted in its geographic distribution,[64] EBV-2 (like EBV-1) circulates widely in all human populations.[38,65,66] Coinfection with both EBV-1 and EBV-2 has been reported in from 9% to 27% of immunocompetent adults,[38,65] suggesting either the simultaneous acquisition of both types during primary infection or reinfection on a second exposure. Although it has been long assumed that persistent carriage of EBV by a healthy host precludes second infections,[66] the independent acquisition of a second virus is suggested by a study of EBV genotypes in throat and genital washings of women at an STD clinic.[38] Not only were coinfections more common in the STD study population, perhaps reflecting multiple exposures, but disparate EBV types were found in the oropharynx versus genital tract of a single participant. Such anatomic segregation of types is consistent with two separate introductions of virus into the same host. Unlike the case with herpes simplex 1 and 2, neither EBV genotype showed a predisposition toward one specific anatomic location.

Coinfection with type 1 and type 2 EBV is especially apparent in immunocompromised patients[38,67–69] such as recipients of bone marrow or organ transplants and HIV-1-infected individuals. The increased load of endogenous virus that accompanies immune suppression facilitates detection of the spectrum of resident virus in this clinic population. Moreover, immune impairment itself may render this group more susceptible to repeated infection from new viral exposures, whether in the form of administered blood products or multiple sexual partners. A high prevalence of EBV-2 in homosexual men has been suggested to indicate sexual transmission of that genotype.[70]

In addition to the type 1 and type 2 classification of EBV, individual strains within the two major types can be distinguished by changes in EBNA1, BZLF1, and LMP1 gene sequences of EBV. EBNA-encoding genes contain repeat regions, the number of which varies between individual isolates. Such variability is visible on DNA blots as restriction fragment length polymorphisms or as size differences in EBNA proteins on immunoblots.[71,72] Unlike with type differences, however, presence of multiple strains does not necessarily reflect repeated infection, because intratypic diversity may also be generated within an individual by heterologous recombination between repeat sequences during replication of endogenous virus. Diversity in LMP1 coding sequences has provided consistent sequence variations that have been particularly useful for defining phylogenetically distinct strains of EBV.[73,74] Strain-specific markers have been used to document multiple infections within a host, to track exchange of virus strains between tissue compartments and to monitor spread of EBV infection between patient and contact.[51–53,71,75,76]

IMMUNOLOGY AND PATHOGENESIS

An elusive aspect of EBV biology is how a ubiquitous and persistent pathogen that normally achieves a natural rapport with its host may on occasion be highly pathogenic years after primary infection. Emerging possibilities that more fully acknowledge EBV opportunism in the context of the life-long carrier state include de novo infection of neoplastic tissue newly prone to infection by virus endogenous to the host as well as generation of viral recombinants that may have altered pathogenicity and tissue tropisms. New clinical settings characterized by enhanced viral exposure and immunosuppression,[77] when viewed against the traditional EBV diseases Burkitt's lymphoma and nasopharyngeal carcinoma, are informative with regard to EBV pathophysiology.

MUCOSAL DETERMINANTS OF EBV TROPISM

Consideration of EBV as a sexually transmitted agent highlights interactions between virus and cells at mucosal surfaces, where the major disease manifestations of the virus occur. In fact, it is only by viewing infection within the context of epithelial and lymphoid tissue interrelationships that a unified view of EBV pathogenesis emerges. The possibility of a regular exchange of virus between epithelium and circulating lymphocytes first became evident in studies of primary EBV infection, where the detection of EBV DNA and RNA in desquamated epithelial cells from throat and cervical washings indicated epithelial cell foci of EBV replication.[36,78,79] Viral recombinants generated in oropharyngeal epithelium can be subsequently recovered in peripheral lymphocytes.[80] Despite the proclivity of EBV to remain latent in lymphocytes in vitro, virus transfer between cell types is almost certainly bidirectional. Initiation of virus replication is thought to occur in latently infected, circulating memory B cells concurrent with their differentiation into plasma cells.[81,82] Mucosal seeding by trafficking lymphocytes has been demonstrated convincingly in an organ transplant recipient who developed oropharyngeal shedding of virus strains acquired from transfused blood.[45] The notion of the intercellular exchange of virus as a natural component of EBV's life

cycle is reinforced by findings of persistent replication in healthy oral epithelium of chronic carriers,[83–85] marking it as one site of EBV egress and host-to-host spread, if not a source for reinfection of lymphocytes within the persistently infected host.

Alternate replication in B lymphocytes and epithelial cells switches tropism of the virus in a manner that has implications for spread both within and between hosts, virus originating in epithelial cells more efficiently infecting B cells and vice versa.[86] Preferential infection of B lymphocytes occurs via an interaction of the major viral glycoprotein gp350 with the cellular attachment receptor, the complement receptor type 2 (CR2 or CD21),[87] and of a trimeric EBV glycoprotein complex of gH, gL, and gp42 with the entry coreceptor, HLA class II.[86] Epithelial cells lacking CR2 and HLA class II are infected by as yet poorly understood mechanisms requiring glycoprotein complexes without gp42. Although both two-part and three-part complexes are normally found on the virus envelope, their ratio is skewed toward a gH/gL predominance after EBV replication in B cells, where newly synthesized gp42 interacts intracellularly with coreceptor HLA class II to deplete its representation on the viral envelope.[86]

Cell-to-cell spread of virus in immune hosts may also be influenced by the presence of secretory antibody at mucosal surfaces. EBV-specific dimeric IgA facilitates uptake of EBV into epithelial cells via the basolateral polymeric immunoglobulin receptor while concurrently neutralizing infection of B lymphocytes by competing for the viral ligand of CR2.[88,89] Entry into polarized epithelium is likely to be achieved by multiple and as yet incompletely understood routes, including interactions between viral BMRF2 and cellular integrins.[90,91]

EPITHELIAL CELL-DERIVED RECOMBINANT EBV

Although lymphocyte culture has provided suitable models for study of EBV latency and virus-induced lymphoproliferation, systems permissive of EBV replication have not been available to address biologic issues raised by viral shedding at mucosal surfaces. EBV infection in AIDS patients has been particularly instructive by providing the opportunity to observe replicative EBV infection in the epithelial setting.[77] (Fig. 26-1A) shows a cross section through the epithelial lesion oral hairy leukoplakia, with abundant viral replication in the outer, more differentiated layers of epithelium. Unlike permissive epithelial cell infections with other herpesviruses, replication of EBV within this lesion is noncytolytic, possibly a consequence of the concurrent expression of both replicative and transforming EBV proteins within the cell.[92,93] Viral gene products that extend cell survival include lytic cycle BHRF1, a homologue of Bcl-2 that is expressed at high levels in oral hairy leukoplakia, and latency gene LMP1 that can induce expression of the antiapoptotic cellular gene A20.[94,95]

Expression of latency gene EBNA2 may contribute to yet a second distinguishing attribute of this lesion, coinfection with type 1 and type 2 EBV, and generation of intertypic and intratypic recombinants.[68,80,96–101] By upregulating expression of attachment receptor CR2 on infected epithelial cells, EBNA2 may facilitate superinfection by multiple EBV genotypes in this replicative environment.[102] Recent detection of type 1 and type 2 recombinants[100,101,103] confirms not only coinfection of the human host with separate genotypes but also superinfection of a single cell by two distinct and replicating viruses. Moreover, now there is unequivocal evidence that epithelium-derived EBV recombinants can disseminate via lymphocytes,[76,80,104] demonstrating not only their infectivity but also a role for epithelium in viral seeding of peripheral blood lymphocytes.

The larger issue is to what extent EBV biology in oral hairy leukoplakia reflects events in healthy virus carriers. EBV coinfection and recombination have also been described in the general population.[38,65,80,96,101,103,105] More importantly, both intertypic recombinants and nontransforming variants of EBV generated by intratypic recombination appear to be transmissible between healthy hosts independent of the parental virus genotypes.[96,103] Although the pathophysiologic significance of recombinant strains remains unclear, such genomic variability at mucosal sites may generate novel viral determinants capable of disturbing the usual virus-host balance in healthy carriers. For example, nontransforming virus has been implicated in a rare form of chronic active EBV infection in an 8-year-old child.[105] EBNA2-deleted variants, impaired in their ability to transform B lymphocytes in vitro, have been postulated to contribute to the genesis of a subset of Burkitt's lymphomas.[96,106] Defective, rearranged EBV genomes identified in hairy leukoplakia[97] have the potential of enhancing replication of standard latent EBV genomes,[107] thereby inducing the exuberant viral replication characteristic of oral hairy leukoplakia. Furthermore, such defective genomes have been detected, in the absence of prototypical virus, in sporadic Burkitt's lymphoma and Hodgkin's lymphoma.[108,109]

CELL-MEDIATED IMMUNE CONTROL IN CHRONIC EBV CARRIERS

The overall size of the EBV-infected B cell reservoir is largely controlled by $CD8^+$, HLA class I-restricted, EBV-specific cytotoxic T lymphocytes (CTLs). Up to 5% of the total circulating $CD8^+$ T cell pool may be committed to this single virus in the EBV-carrier state,[110] indicating the critical role for T-cell surveillance in maintaining the host: virus balance. Impaired CTL responses in immunosuppressed patients such as transplant recipients or HIV-1-infected individuals[32,111] leads to an expansion of the infected B cell population and potentially fatal lymphoproliferative disease. The contribution of virus-specific CTLs in immune regulation of EBV-induced

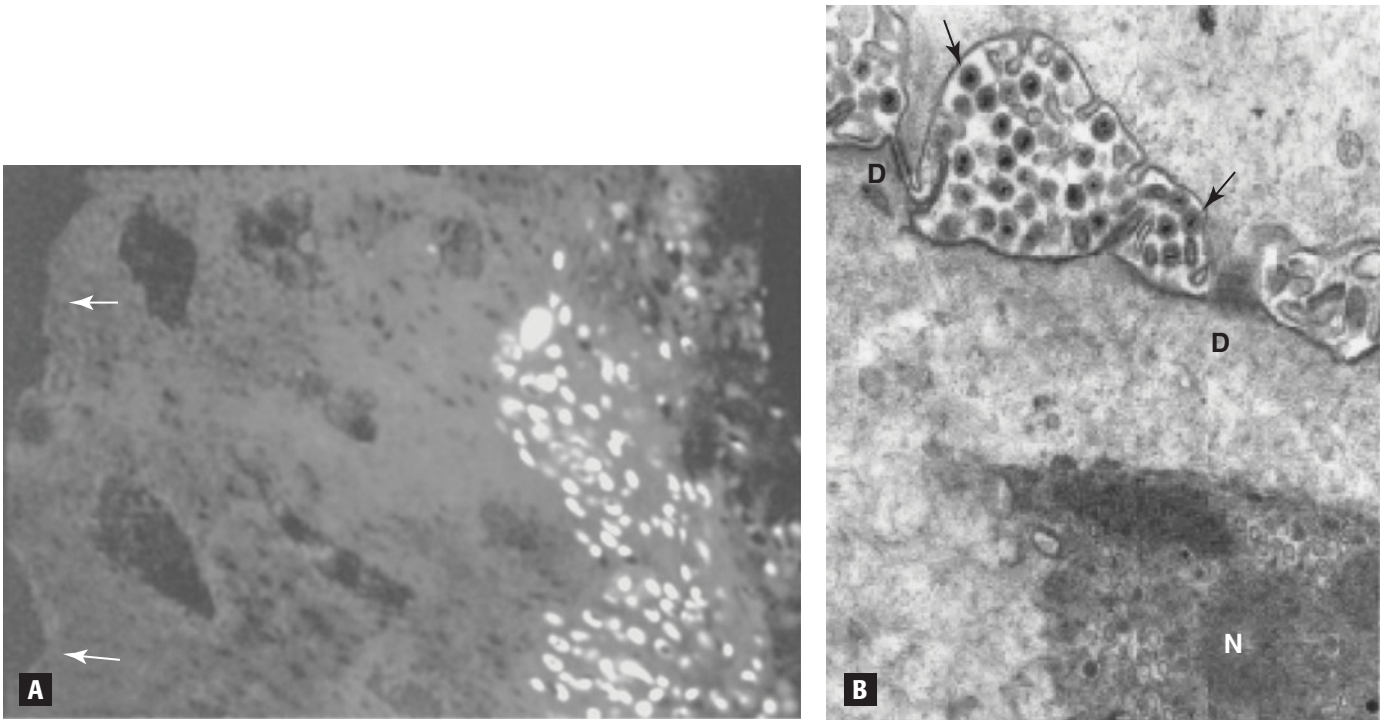

FIGURE 26-1. EBV replication in oral hairy leukoplakia of AIDS. **A.** A cross section of the mucosal lesion immunostained for EBV immediate-early antigen BZLF1 demonstrates replication in the upper layers of thickened epithelium. Nucleus (*N*) contains immature virus particles (*D*, desmosomes).

lymphoproliferation has been made clear by recent therapeutic interventions involving adoptive transfer of virus-specific T lymphocytes to restore immunity against EBV infection in bone marrow transplant recipients.[112–114]

Of the nine EBV proteins expressed during latent infection in cultured lymphoblastoid cell lines, only a subset (EBNA3A, 3B, and 3C) provides what appear to be dominant CTL targets (with some responses also seen to EBNA1, EBNA2, EBNA-LP, LMP1, and LMP2).[115,116] Apart from deficient CTL activity, downregulation of latent gene expression in vivo may also facilitate the escape of infected cells from immune destruction. Three patterns of latent gene expression (latency I, II, and III) first observed in cultured cells[117] have parallels in EBV-associated tumors. In Burkitt's lymphoma (latency I), for example, only a single viral antigen is expressed, reducing tumor susceptibility to EBV-specific CTL surveillance.[118] In contrast, immunoblastic B cell lymphomas (latency III) typical of immunocompromised patients express the full spectrum of EBV latent proteins and remain sensitive to CTL control if intact.

CLINICAL MANIFESTATIONS

INFECTIOUS MONONUCLEOSIS

Primary EBV infection in infancy or early childhood is usually subclinical, but when delayed until the second decade of life, it manifests as infectious mononucleosis in up to 50% of patients. A self-limiting lymphoproliferative disease, the syndrome consists of fever, headache, pharyngitis, lymphadenopathy, and general malaise. Resolution of symptoms may take weeks to months, but primary infection is always followed by the establishment of a permanent viral carrier state. Diagnostic features of acute infection include the appearance of heterophile antibodies and a prominent atypical lymphocytosis, reflecting the unusually strong T-cell response elicited by virally infected B cells. Predominantly CD8+, the reactive T cells comprise both nonspecific and HLA-restricted EBV-specific cytotoxic T cells reactive to both EBV lytic and latent cycle antigens.110 The exaggerated nature of the T cell response suggests that the syndrome is largely immunopathologic in nature. The greater frequency of symptomatic infection in adolescence may relate not to age but rather to a larger inoculum of transmitted virus and the ensuing T cell reaction.

AIDS-RELATED MANIFESTATIONS OF EBV INFECTION

HIV-related immunosuppression disrupts the usual homeostasis achieved between EBV and host, increasing the risk for both reactivation of latent EBV and acquisition of coinfecting strains. Reduced immune control results in elevated levels of EBV in the oropharynx as well as blood of HIV-infected patients,[33,34] similar to what has been described in transplant recipients.[32,113] There is some evidence to suggest that episodes of EBV reactivation may have clinical consequences. Most EBV malignancies in the population at large

are preceded by antibody responses indicative of an enhanced level of viral activity[119–121]; deregulation of the virus-host balance may favor emergence of a malignant cell clone. Medical consequences of the high EBV burden in AIDS are reflected in unique pathology as well as in the increased frequency of otherwise rare EBV diseases.

Oral hairy leukoplakia

Oral hairy leukoplakia is a hyperplastic EBV-induced mucocutaneous epithelial cell disease and the first pathologic manifestation attributable to replicative EBV infection,[77] making the lesion unique in EBV biology. It is seen in up to 25% of homosexual men with AIDS but has been reported as well in other immunocompromised patients and, rarely, healthy individuals.[77,80] Clinically, the lesion is an asymptomatic, poorly demarcated keratotic area with a corrugated or "hairy" surface varying in size from a few millimeters to extensive lingual and oral mucosal involvement. Typically on the lateral borders of the tongue, the whitish, slightly raised lesion is often mistaken for thrush. Histopathologic features include a thickening of epithelium, with characteristic balloon cells resembling koilocytes, and a hyperkeratosis resulting in microscopic hairlike projections. An abundance of viral particles can be seen in the outer layers of epithelium (Fig. 26-1 B), consistent with the notion that EBV replication is linked to terminal differentiation of cells.[35,78] Epithelial dysplasia is not a feature of these lesions, and malignant transformation of oral hairy leukoplakia has not been reported.

EBV-associated malignancies in AIDS

Non-Hodgkin's lymphoma, an AIDS-defining cancer some 60 times more common in AIDS patients than in the general population,[122] can be divided morphologically into Burkitt-like and immunoblastic lymphomas (see Chapter 76). Both have a higher association with EBV (30–40% and 75–80%, respectively) in AIDS than in non-AIDS groups.[123,124] Tumors may carry either type 1 or type 2 virus,[125–127] reflecting the relative prevalence of each genotype within the HIV-infected population. Burkitt's lymphomas appear early in the course of AIDS, prior to profound immunosuppression, whereas immunoblastic lymphomas typically occur in late-stage AIDS when cellular immunity is compromised. The timing of immunoblastic lymphomas may be explained by their expression of latent viral proteins (type III pattern of EBV latency)[128] that in an immunocompetent host provide ample targets for EBV-specific cytotoxic T cells. Appearance of the malignancy coincidental with diminished immune surveillance suggests an opportunistic proliferation similar to post-transplant lymphoproliferative disease. A relatively new entity associated with patients infected by HIV is plasmablastic lymphoma, which occurs preferentially in the oral cavity. A variant of diffuse large B cell lymphomas, it has immunoblastic morphology with a plasma cell phenotype and up to 80% of cases contain EBV.[129–131] B cell associated antigens CD20 and CD45 are typically absent, but tumors strongly immunostain for plasma cell reactive antigens.

Two malignancies that are not associated with EBV in the general population but which regularly contain the viral genome in patients with HIV-1 infection are leiomyosarcoma[132,133] and primary central nervous system lymphoma (PCNSL).[134,135] The incidence of PCNSL has dramatically declined since the era of highly active antiretroviral therapy (HAART), a trend evident to some extent with all non-Hodgkin's lymphomas.[136–138] Leiomyosarcoma, a mesenchymal malignancy with smooth muscle differentiation, has been shown by in situ cytohybridization to contain EBV in affected muscle cells of both children and adults with HIV infection.[132,133] Sites of occurrence can be unusual (e.g., epidural, laryngeal, adrenal) and multicentric.[139]

Hodgkin's lymphomas in the setting of AIDS contain EBV in 75–90% of the cases,[140,141] reflecting the unusually high frequency in the HIV-infected population of mixed-cellularity and lymphocyte-depletion subtypes[142] known to be most closely associated with EBV in the general population.[15,16] Although not considered an AIDS-defining illness, Hodgkin's lymphoma occurs with increased frequency in the setting of HIV infection.[143] The disproportionate distribution of subtypes and unfavorable clinicopathologic features make the entity distinct to AIDS.[140,141]

Our understanding of the precise role of EBV in the biology of each malignancy remains rudimentary. Because EBV terminal repeat sequences are variably reiterated in each infectious particle, they provide a viral measure of clonality in infected cell populations.[144] The uniform number of terminal repeats found in tumor cells implies infection preceded clonal expansion. Since EBV was present at the genesis of the tumor, the virus has been deemed causal. Recent findings suggest an alternate interpretation for EBV clonality in EBV-associated malignancies that is consistent with the notion of infection as a sequel to malignant transformation, at which time EBV might provide additional growth or survival advantages.[145,146] Chance infection of an emerging neoplasia by virus endogenous to the host is consistent with the characteristic sporadic association of EBV with any one cancer and a host environment made conducive to EBV replication by immunosuppression.

TREATMENT

The nucleoside analog acyclovir is ineffective in the treatment of latent EBV infection characteristic of viral-induced lymphoproliferation but, as a potent inhibitor of EBV DNA polymerase, can inhibit EBV replication. Although capable of blocking viral shedding from the oropharynx in infectious mononucleosis patients, the

drug does not reduce the load of latently infected B cells in the peripheral blood or affect the disease course. In contrast, acyclovir effectively resolves the permissive infection in oral hairy leukoplakia, although cessation of treatment often results in a recurrence of lesions within 1–4 months.[147,148]

The advent of HAART has led to an improvement in prognosis of patients with AIDS-related lymphomas[136–138] (see Chapter 76). Improved immune function has made patients better able to tolerate standard chemotherapeutic dosage regimens, with overall survival in most cases comparable to that of the general population of cancer patients.[138] EBV targeted therapies for EBV-positive tumors have shown promise in select patient groups, including some with HIV. Adoptive immunotherapy, successfully pioneered for the immunoprophylaxis and therapy of posttransplant lymphoproliferative disease,[113,114] takes advantage of virus-specific markers on tumor cells as targets for infused EBV-specific cytotoxic T cells. Other strategies under consideration include pharmacologic modulation of EBV expression by 5-azacytidine, an inhibitor of DNA methyltransferase, with the intent of converting a tumor with limited viral antigen expression to one with a lytic or latency III phenotype amenable to immune recognition and destruction.[149,150] In addition, the induction of the EBV lytic cycle in tumors by pharmacologic agents, when combined with ganciclovir, leads to conversion of the latter to its active cytotoxic form by EBV-encoded kinases, causing tumor cell death.[151] Two studies, using low-dose hydroxyurea shown to induce EBV episomal loss from tumor cells in vitro, demonstrated good responses in three patients with EBV-associated PCNSL.[152,153] Cidofovir, member of a promising newer class of antiviral molecules, the acyclic nucleoside phosphonate analogs, has shown an antitumor effect against EBV-transformed epithelial cells and lymphocytes in experimental animals.[154,155]

PREVENTION AND CONTROL

Largely because of the global significance of EBV-related malignancies, concerted efforts toward vaccine development are underway.[156] One prototype subunit vaccine is based on the abundant viral envelope glycoprotein gp350 that binds the B-lymphocyte receptor CR2 and elicits neutralizing antibody against infectious virus.[157] Other strategies focus on the use of peptides derived from latent antigens to stimulate cytotoxic T cells central to the control of EBV-infected B lymphocytes.[115,116] With respect to precautions in clinical settings, physical isolation of patients with acute EBV infections is not required. However, individuals with a recent history of acute EBV infection should not be selected as blood or tissue donors when possible because of the enhanced viral load accompanying primary infection.

27 The Biology of Genital Human Papillomaviruses

Erin M. Egelkrout and Denise A. Galloway

GENERAL PROPERTIES AND CLASSIFICATION

Papillomaviruses are a group of small DNA viruses that primarily induce epithelial cell proliferation, or papillomas, in higher vertebrates. Infections are strictly genus or species specific and there is considerable tropism among the viruses for particular anatomic sites. Viral particles are nonenveloped, have an icosahedral symmetry, and encapsulate a double-stranded circular genome of 7.9 kb that is associated with cellular histones (for more extensive reviews see Ref. 1). For some time papillomaviruses could not be efficiently propagated in tissue culture and so little was known about the virus life cycle. Early information about the function of viral genes came from studies using individual cloned genes in various cellular or in vitro assays. However, in recent years much progress has been made in propagation of the virus in organotypic raft cultures, allowing a clearer understanding of the viral life cycle and the role of individual viral proteins.[2–8] Unlike most other virus groups, types are not based on antigenic diversity, but rather on DNA homology (see below). The genomes of over 100 human papillomavirus (HPV) types have been molecularly cloned and completely sequenced and partial sequences for potentially up to another hundred types have been detected by PCR-based assays.[9,10] The sequences are available through Genbank.

More than 30 HPV types infect the genital tract. The consequences of infection with genital HPVs vary, and at least some of the variation is type-specific, as discussed in detail in Chapter 28. The genital HPVs have been grouped into high- and low-risk types, based on the potential of the infected cells to progress to cervical carcinoma.[11] For example, approximately 50% of invasive squamous cell cancers of the cervix (SCC) harbor the high-risk HPV 16, whereas only 1 of 932 SCCs collected worldwide contained the low-risk HPV 6.[12]

GENOME STRUCTURE AND FUNCTION

Sequence analysis of cloned viral genomes has shown that the genetic organization of all human and animal papillomaviruses is well conserved. The genomic map of HPV 16 is depicted in a linear form in Fig. 27-1. All eight open reading frames (ORFs) are located on one strand of DNA, and accordingly, transcription of viral genes has been shown to use only one strand as template.[13] The ORFs E6, E7, E1, E2, E4, E5 are designated as early, and L1 and L2 are late, based on the expression of only the early region in BPV-1 transformed cells, and expression of the late region in productively infected cells.[14,15] E3 and E8 are not present in all genomes. They do not always code for viral proteins, although an E2$^{\alpha}$E8 fusion protein has been reported for HPV-31.[16] An approximately 850 bp segment between L1 and E6 is devoid of ORFs and has been variously designated as the noncoding region (NCR), upstream regulatory region (URR), or long control region (LCR). This region contains a number of cis-acting sequences necessary for viral DNA replication and the regulation of transcription. A detailed review of papillomavirus genome structure and gene expression can be found in Zheng and Baker.[17]

Transcription of the viral genome is very complex and produces many alternatively, and multiply, spliced RNAs, mostly in low abundance (Fig. 27-1 and reviewed in Ref. 13). Transcription initiates at several different promoters, though early and late genes seemingly share at least some of the same promoters. All of the early RNAs terminate at a polyadenylation site at nucleotide (nt.) 4215 and the late RNAs use a poly-A site at nt. 7321. Characterization of the mRNAs indicates that some genes, e.g., E7 or E5 are translated only from bi- or poly-cistronic messages, though the low-risk viruses have an additional promoter for expression of E7.[18] An mRNA encoding L2 has not been unambiguously identified, though the L2 protein has been readily detected.[14,19] Additionally, some ORFs are spliced together to encode fusion proteins, e.g., E1$^{\alpha}$E4, while other ORFs encode multiple products, e.g., E2, E2C, E2M and E6, E6*, E6**. Thus, although all genital HPVs encode eight ORFs, the exact number of viral proteins that are expressed during infection is not known precisely.

Knowledge about the function of HPV gene products has increased in recent years but is still incomplete because of the

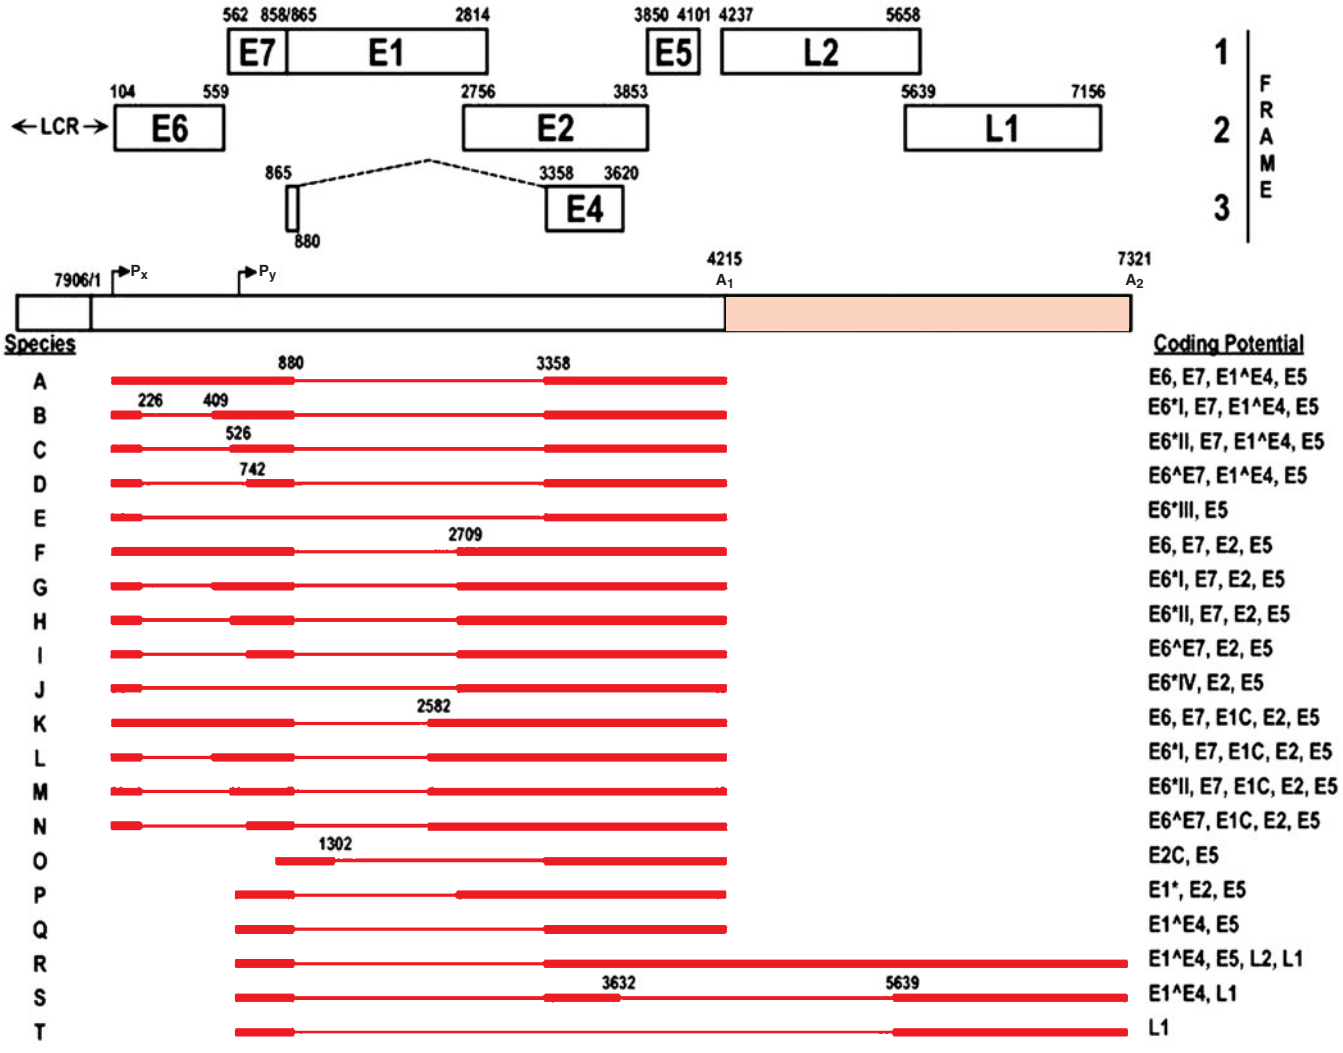

FIGURE 27-1. Genome organization and transcription. Genome structure and transcription map of HPV-16. The bracket line in the middle of the panel represents a linear form of the virus genome for better presentation of head-to-tail junction, promoters (arrows), and early (A_E), and late (A_L) polyadenylation sites. The open reading frames (ORFs) (open boxes) are diagramed above the bracket and the numbers above each ORF are the nucleotide positions of the first nucleotide of the start codon and last nucleotide of the stop codons in the HPV-16 genome. The E4 ORF spans two exons and formation of the intact E4 ORF requires RNA splicing (dashed lines). LCR indicates a long control region. Below the bracket line are the reported RNA species derived from alternative promoter usage and alternative splicing. Exons (heavy lines) and introns (thin lines) are illustrated on each species of the RNA, with splice site positions being numbered by nucleotide positions in the virus genome. Although all early transcripts driven by early promoter P97 are illustrated with a 5,-end from nt. 97, multiple transcription starting sites in W12 cells have been mapped by 5, RACE at nt. 83 (frequency[F] 3), 91(F2), 93 (F2), 94(F1), 95(F4), 96(F8) (Carl C. Baker, unpublished data). Similarly, all late transcripts driven by differentiation-inducible promoter P670 are shown for convenience with a 5,-end from nt. 670, but the real 5, ends in W12 cells have been mapped by 5, RACE to nt. 682(F4), 713(F5), and 774(F3) (Carl C. Baker, unpublished data). (Reprinted by permission from Zheng ZM, Baker CC. Papillomavirus genome structure, expression, and post-transcriptional regulation. *Front Biosci* 2006; 11: 2286–2302.)

limited ability to study HPV infections in cultured cells. Many of the HPV proteins interact with multiple cellular proteins and serve a variety of functions. Table 27-1 summarizes information about the products encoded by the ORFs and their presumed functions, which will be discussed in more detail below.

VIRION STRUCTURE

Two proteins, the major capsid protein L1 and the minor capsid protein L2, form the HPV virion coat.[20–22] In early studies, the three-dimensional structure of several papillomavirus virions was determined by cryoelectron microscopy and image analysis[23,24] as shown in Fig. 27-2A. Capsids are ~60 nm in diameter and are composed of 72 pentameric capsomers arranged on a skewed icosahedral lattice with a triangulation number of 7 dextro. The shell, made of L1 protein, is ~2 nm thick and appeared much smoother on the internal surface than the external surface with a fairly contiguous density. Capsomers extended radially 6 nm from the shell and appeared as five pointed stars. Intercapsomer interactions were restricted to the shell. Twelve capsomers are pentavalent (contacting 5 neighboring capsomers) and 60 capsomers are hexavalent. The

Table 27-1. Characterization of Proteins Encoded by HPV ORFs

ORF	Proteins	Approx. Size	Functions	Refs.
E1	E1	68 kDa	Binds origin of replication; ATP-dependent helicase	137–149
	E1C	8 kDa	Unknown; encoded by several HPV mRNAs	
	E1N	23 kDa	Unknown; detected in BPV-1 transformants	
E2	E2	48 kDa	Site-specific ($ACCN_6GGT$) transcription factor; heterodimerizes with E1 to facilitate replication initiation	82,87–89,99,150,151–154
	E2C	28 kDa	Lacks transactivation domain; may function to inhibit E2	
E3		unknown	Only present in BPVs	
E4	E1^E4	17 kDa and smaller processed forms	Very abundant protein; contains few codons of E1 Fused to E4; interacts with cytokeratins; can cause G2 arrest	190–198
E5	E5	10 kDa	Promotes proliferation through growth factor signaling pathways (low-risk); transforming activity in vitro	199–211
E5b		unknown	Only present in HPV 6, 11	
E6	E6	150 a.a.	Eliminates functional p53 (high-risk); alters transcription; activates hTERT	227–291
	E6*, E6**	40–60 a.a.	Unknown but may inhibit activity of E6; predicted in high-risk HPVs	
E7	E7	100 a.a. migrates 20 kDa (high risk)	Promotes proliferation by inactivating pRb and CKI function	292–352
E8	E8^E2	28 kDa	Only present in BPVs, HPV 6, HPV 31	
L1	L1	55 kDa	Major capsid protein; sufficient for self-assembly into capsid, neutralizing epitopes	20–44
L2	L2	50–60 kDa, migrates as 72 kDa	Minor capsid protein, may function in viral entry and capsid assembly	20–44

capsomers are composed of five subunits of L1 with an axial dimple of 3 nm. The location of the minor capsid protein, L2, was not apparent in the image reconstructions. At a resolution of 3.5 nm, capsids or virus-like particles (VLPs) generated by self-assembly of L1 are identical to authentic HPV virions.[25]

Several studies in recent years have refined the structure of the HPV virion. These studies have been facilitated by the development of methods to produce GST-tagged fusions of the viral capsid proteins in *E. coli*[26] and production of VLPs, which are empty shells of the viral capsid proteins. In particular, these studies have clarified interactions within and between capsomers. Two cysteines (175 and 428 in HPV16) that may participate in formation of disulfide bonds and thus stabilize the virion have been identified.[27,28] The crystal structure of the T = 1 HPV 16 L1 capsid has recently been described.[29] This was prepared using 12-pentamer "small VLPs" with deletions of the first few amino acids of the N-terminus and the last few amino acids of the C-terminus. Later an atomic model was developed by combining image reconstructions of cryoelectron microscopy of bovine papillomavirus with crystal structure coordinates from an HPV 16 L1 VLP.[30] Some nonconserved residues near the C-terminus are exposed on the capsid surface, and the L1 C-terminus of one capsomer "invades" a neighboring capsomer.

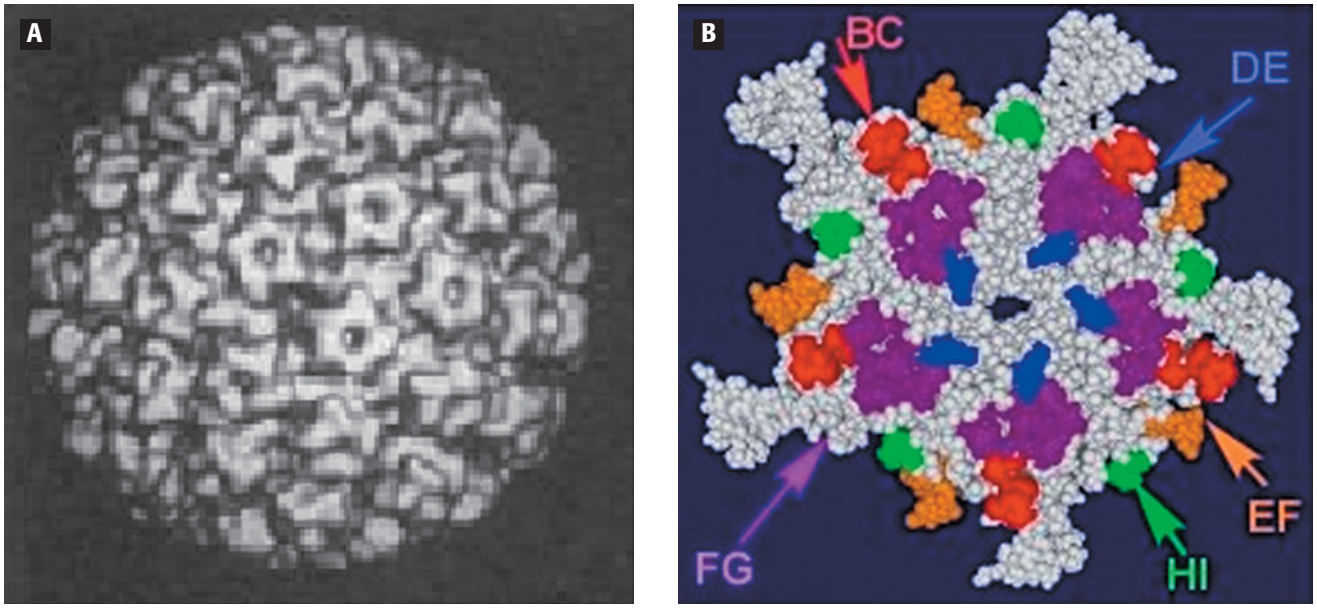

FIGURE 27-2. A. Structure of the HPV virion. A three-dimensional reconstruction of cryoelectromicrographs of a vaccinina virus-expressed HPV 1 capsid containing L1 and L2. (Reprinted by permission from Hagensee ME, Olson NH, Baker TS, Galloway DA. Three-dimensional structure of vaccinia virus-produced human papillomavirus type 1 capsids. *J Virol* 1994; 68(7): 4503–4505.) **B.** Molecular model of capsomer structure and hypervariable loops. Each loop is shown in a different color (Reprinted by permission from Orozco JJ, Carter JJ, Koutsky LA, Galloway DA. Humoral immune response recognizes a complex set of epitopes on human papillomavirus type 6 l1 capsomers. *J Virol* 2005; 79(15): 9503–9514.)

This structural information has been useful in elucidating the nature of HPV epitopes recognized in the immune response to HPV. Epitopes are generally characterized as being either linear, or dependent on sequence alone, or conformation-dependent. Five loops on the capsomer surface with hypervariable sequence between different HPV types have been identified and are designated by two letters as BC, DE, EF, FG, and HI in Fig. 27-2 B. A large proportion of the known antibodies to HPV recognize epitopes in one of these loops or incorporating multiple loops. The variability in these loops generally prevents antibodies to one HPV type from recognizing other HPV types. This has been studied by preparation of chimeric VLPs in which different parts of the L1 sequence for different HPV types have been exchanged. For example, the FG and HI loops are both important for binding of the H16.V5 monoclonal antibody, while the FG and DE loops have been linked to antibody H16.E70 binding.[29,31–37] The C-terminal arm, also exposed on the virion surface, contains the epitope for the antibody H16.U4.[34]

There is also some debate as to whether there is a single immunodominant epitope recognized in the immune response to HPV. In one early study, monoclonal antibodies against HPV 6, 16, 18, and 33 were used to block the reactivity of human sera with capsids of the corresponding HPV type. A single monoclonal antibody for each type blocked reactivity of most sera, suggesting the existence of a single dominant epitope.[32] In contrast, in a later study mapping the epitopes on the surface of HPV 6 capsomers recognized by human sera using chimeric HPV 6 and 11 VLPs, Orozco et al. found that sera recognized a variety of different epitopes.[38] Another recent study used neutralization assays to test a panel of chimeric HPV 16 and 31 VLPs for their ability to block neutralizing activity of sera obtained from a University of Washington natural history study.[39] Some chimeric VLPs retained wild-type HPV16 ability to block neutralization, some had an intermediate activity, and some, like HPV 31, could not block neutralization. Transfer of neutralizing activity required sequences from more than one loop. These studies argue against the presence of an immunodominant epitope.

Finally, while in early studies the presence of L2 did not affect virion assembly or structure,[25] recent work suggests L2 can facilitate virion formation.[40,41] Positively charged sequences on L2 are thought to interact with viral DNA and facilitate genome packaging.[42] Finnen et al. analyzed assembly into complexes of HPV 11 L1 and L2 produced by coexpression in bacteria.[40] They identified an L1-binding domain consisting of amino acids 396–439 in the carboxy terminus of L2. At either pH 5.2 or 6.8, L1 + L2 assembled into $T = 1$ VLPs, while L1 alone assembled into either $T = 7$ or $T = 1$ VLPs at pH 5.2 but could not assemble into VLPs at pH 6.8. A widely cross-reactive neutralizing epitope near residue 108 has also been identified on the N-terminus of L2, suggesting that part of the L2 protein is exposed on the virion surface, possibly as a loop.[43,44]

TAXONOMY AND PHYLOGENETIC RELATIONSHIP

Originally, the family *Papovaviridae* included the genus *Papillomavirus* and the genus *Polyomavirus*. However,

subsequent studies indicated that there is significant divergence between the papovaviruses and the papillomaviruses in virion diameter, genome size, transcriptional organization, and other aspects of their biology. They have therefore been reclassified as separate families by the International Committee for Taxonomy of Viruses. They are also now divided into different genera and further subdivided into species, consistent with the classification of other viruses.[45] The genetic relationships among HPV types have been examined by the construction of phylogenetic trees based on various segments of the genome (reviewed in[45] (Fig. 27-3). The genera are designated by the letters of the Greek alphabet, and the species are designated by a number. The genus alpha papillomavirus contains the mucosotropic HPVs that infect the genital tract, as well as some HPVs that infect cutaneous epithelium. Viruses that fall within a species have the same biologic behavior. For example, HPV 16 and other types in the same species are a cause of cervical cancer, while HPV 6 and related types tend to cause warts.

Originally, HPV types were based on <50% homology as determined in liquid hybridization assays,[46] but DNA sequence data revealed more extensive homology among types. Based on criteria adopted by the Papillomavirus Nomenclature Committee, types are defined as having less than 90% homology of the aggregate E6, E7, and L1 ORF DNA sequences. A new type can only be assigned once the

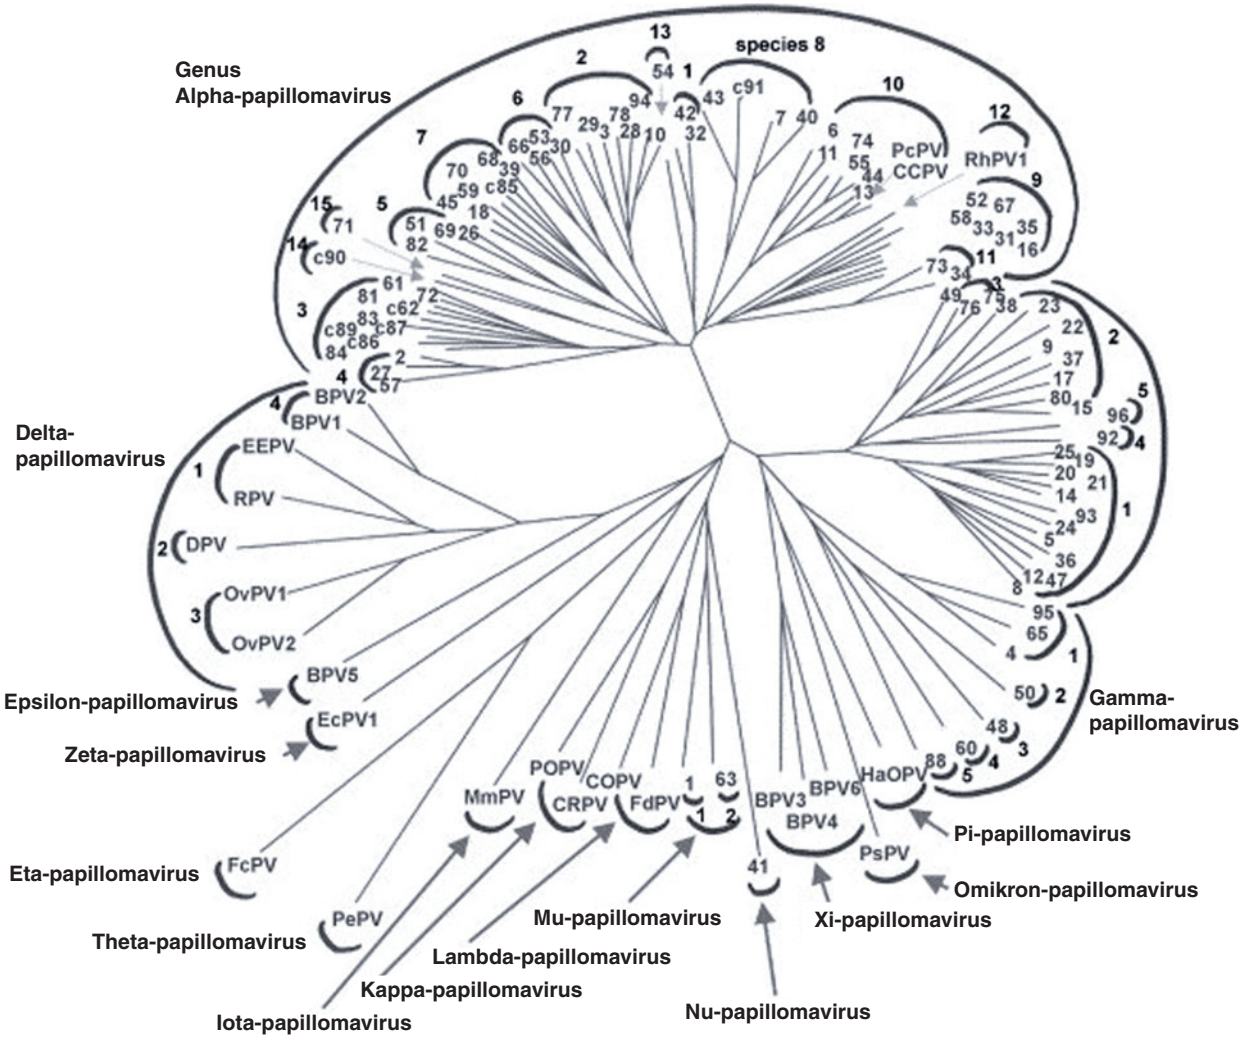

FIGURE 27-3. Phylogenetic tree containing the sequences of 118 papillomavirus types. The L1 ORF sequences were used in a modified version of the Phylip version 3.572 and based on a weighted version of the neighbor-joining analysis. The tree was constructed using the Treeview program of the University of Glasgow. The numbers at the ends of each of the branches identify an HPV type; c-numbers refer to candidate HPV types. All other abbreviations refer to animal papillomavirus types. For the meaning of each abbreviation, please refer to Table 3 in Ref. 51 (within Ref. 45 of this chapter). The outermost semicircular symbols identify papillomavirus genera, e.g., the genus alpha-papillomavirus. The number at the inner semicircular symbol refers to papillomavirus species. To give an example taken from the upper part of the figure, the HPV types 7, 40, 43, and cand91 together form the HPV species 8 in the genus alpha-papillomavirus. (Reprinted by permission from de Villiers EM, Fauquet C, Broker TR, Bernard HU, zur HH. Classification of papillomaviruses. *Virology* 2004; 324(1): 17–27.)

complete 7.9-kb genome has been cloned. HPV subtypes have between 2% and 10% sequence divergence and variants of a type have <2% divergence. The extent of intratypic variability may differ among types. For instance, there is no evidence of subtypes of HPV 16, with sequence variation running around 1%. On the other hand, a few subtypes of HPV 6 and HPV 45 have been found. Variants of a particular type are often grouped by geographical region of origin and ethnic groups, e.g., European, Asian American, North American, and African. While HPV types clearly vary in their biological properties, much remains to be learned as to whether subtypes or variants have distinct biological behavior. However, a number of studies have found some differences in the pathogenicity of different variants.[47–49]

VIRAL LIFE CYCLE

It was initially difficult to study the life cycle of papillomaviruses because the full infectious life cycle could not be recapitulated in vitro. Viral infection or transfection of viral DNA into keratinocytes grown in monolayer cultures results in limited transcription and replication, without formation of infectious progeny, and a gradual loss of viral DNA.[50] Infectious virus has been produced in a xenograft system in which HPV 11 virus was used to infect fragments of tissue that were then implanted under the renal capsule of nude mice.[51] Characterization of viral transcripts produced in the xenografts has provided a great deal of information about HPV 11 transcription.[52] Analyses of naturally occurring lesions have provided complementary results. Viral transcripts have been analyzed in cell lines harboring episomal HPV genomes grown in monolayers or organotypic cultures.[53,54] Upon induction of complete keratinocyte differentiation, viral DNA replication, late gene expression, and formation of viral particles were observed,[55,56] confirming the dependence of viral gene expression on the differentiated state of the host cell. These in vitro observations are consistent with the restriction of vegetative HPV replication and formation of progeny to the most terminally differentiated layers of the epithelium. However, amplification of viral DNA and expression of the late gene *L1* has been reported in parabasal spinous layers of benign warts infected with HPV-1.[57]

The introduction of HPV genomes into keratinocytes followed by differentiation in organotypic cultures provides a means to do genetic analyses.[53] This approach has been used for HPV 11,[2,3] 16,[4,5] 18,[6] 31b,[7] and 45.[8] It has allowed development of a large body of new information on the expression of viral proteins and viral replication as described in subsequent sections. A recently described method for production of infectious HPV particles in 293TT cells without viral replication or epithelial cell differentiation should also allow many new studies.[58]

ATTACHMENT, ENTRY, AND UNCOATING

Despite the exquisite species and cell-type specificity of HPV infections, studies with labeled viral particles have shown that HPVs bind promiscuously to a wide range of cell types.[59,60] The inclusion of reporter DNA with the particles showed that entry also occurred in many cell types, indicating that the restriction of viral tropism is not due to a cell-type-specific receptor or coreceptor. The α6 integrin has been proposed as a candidate receptor,[61] but this has not been substantiated by others.[62] Shafti-Keramat et al. found keratinocytes lacking α6 integrin to be permissive for HPV 11 infection and have proposed syndecan-1 as the primary receptor.[62] The L1 protein apparently mediates binding to the cell; VLPs containing L1 can only bind and can block binding of L1/L2 containing virions.[59]

Several recent studies have provided new information about the mechanism of entry into the cell, translocation to the nucleus, and uncoating of the viral genome. Heparan sulfate proteoglycans, probably carried on syndecans, are important for binding to some target cells.[62–65] Clathrin-mediated endocytosis is thought to allow entry of the virus, although one study has suggested that while HPV-16 and HPV-58 use this pathway for cell entry, HPV-31 uses caveolae-mediated endocytosis.[66–68] A 23 amino-acid peptide at the amino terminus of L2 facilitates exit from the endocytic compartment.[69] The L2 C-terminus also has been reported to interact with the motor protein dynein, which may facilitate movement of the viral genome to the nucleus,[70] and the tSNARE protein receptor syntaxin 18,[71] which helps mediate protein trafficking through the endoplasmic reticulum. The Hsp70 chaperone protein has been suggested as a mediator of uncoating.[72] Disruption of interpentameric disulfide bonds is also required for viral particle disassembly.[27] Several studies have identified a potential role for interaction of HPV coat proteins with the Kap alpha 2 and Kap beta 1 nuclear import receptors.[73–76] Day et al. have suggested that L2 is involved in chaperoning the viral genome to nuclear domain 10 (ND10) by a mechanism dependent on promyelocytic leukemia (PML) protein.[77] Finally, the kinetics of absorption and entry has been examined and found to be relatively slow.[78]

TRANSCRIPTION OF VIRAL GENES

Transcription of HPV genes is tightly coordinated with the differentiated state of the cell, as evidenced by different RNA transcripts in different layers of the epithelium[79,80] (Fig. 27-4). Expression of E1 and E2 is thought to occur in basal cells to maintain episomal replication of the HPV genome. Transcription of E6 and E7 is required to promote proliferation of parabasal cells, in order to provide the replication machinery for viral DNA replication. In the high-risk viruses, E6 and E7 transcription is directed from a single promoter,

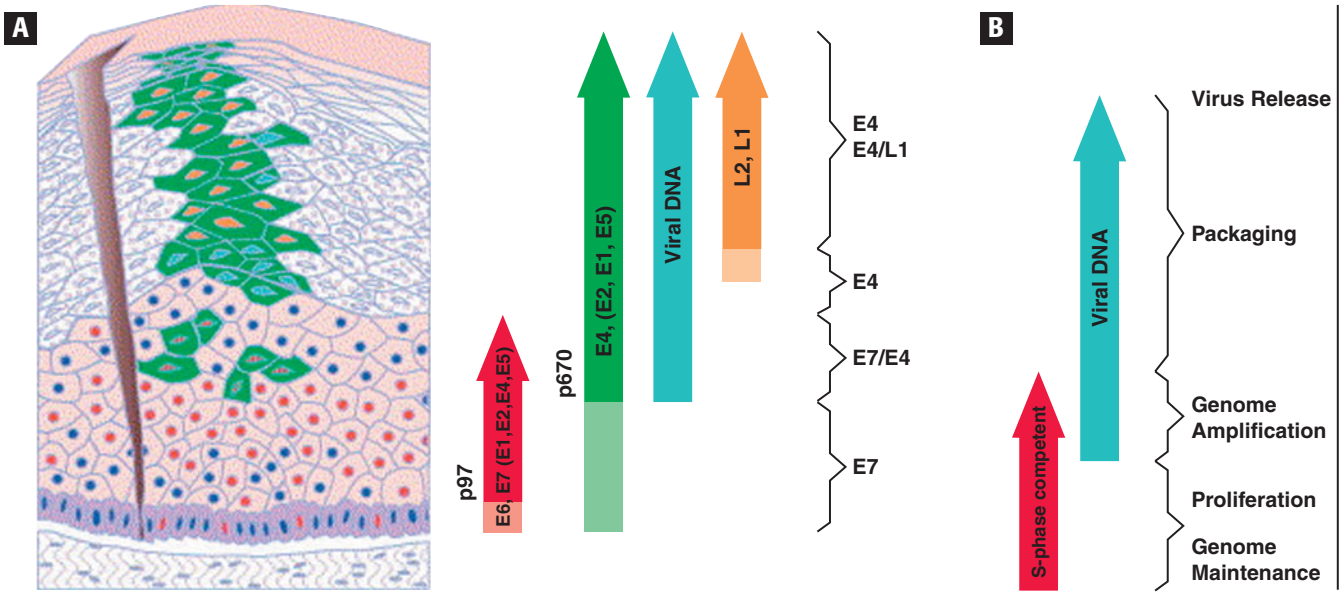

FIGURE 27-4. Life cycle organization during productive infection by HPV types from supergroup A. **A.** Diagrammatic representation of the skin to reveal the pattern of *HPV16* gene expression as the infected cell migrates toward the epithelial surface. Other supergroup A viruses, such as HPV2 and HPV11, follow a similar pattern. After infection (in this case through a cut), the viral genome is maintained as a low copy number episome. During epithelial differentiation, the p97 promoter directs expression of the *E6* and *E7* genes necessary for S-phase entry (red). The p670 promoter is upregulated in the higher epithelial layers, and viral replication proteins (E1, E2, E4, E5) increase in abundance (green), facilitating amplification of viral genomes (blue). Changes in mRNA splicing allow E4 to persist into the upper epithelial layers where the viral capsid proteins (yellow) are found. **B.** Cells in the lower epithelial layers are S-phase competent. Viral genome amplification begins in these cells but ceases once the cells lose their ability to express S-phase proteins. Although amplified viral genomes can be detected throughout the upper epithelial layers, cells that are actively supporting genome amplification appear confined to a region where E7 expression coincides with the high-level expression of E4, and probably also, an increase in the abundance of E1 and E2. The papillomavirus life cycle. *J Clin Virol* 2005; 32: S7–S15.)

p97 for HPV 16 and p105 for HPV 18,[81,82] whereas the low-risk viruses use separate promoters for E6 and E7.[81] However, transcription from other novel promoters has been reported for HPV-16,[83,84] HPV 18,[85] and HPV 31b.[86]

A basal level of transcription from the p97/p105 promoter is regulated by the keratinocyte-dependent enhancer in the NCR and can be repressed by binding of E2 to its cognate recognition sequences located adjacent to the p97/p105 TATA boxes.[82,87] E2 has a role in repressing transcription from the viral promoter and its loss on viral DNA integration allows increased expression of the oncogenic proteins E6 and E7. E2 also activates transcription under some circumstances.[88] Variations in binding to four different E2 binding sites may contribute to transcriptional regulation.[89] Interestingly, the E8E2C protein of HPV-31 had an ability to repress transcription from a single promoter-distal E2 binding site. This activity was lacking in the full-length E2, suggesting that E8E2C has a role in regulating transcription.[90] E2 binds the general transcription factor TFIIB[91] and is thought to directly inhibit HPV transcription at a step subsequent to binding of TBP or TFIID to the TATA box.[92] It interacts with numerous other transcription factors and chromatin modification factors including CBP,[93] p/CAF,[94] C/EBP,[95] nucleosome assembly protein 1,[96] and Top BP1.[97] An interaction between bromodomain protein 4 and E2 is required for transcriptional activation by E2.[98] Two crystal structure studies of the amino terminal transcription activation domain of E2 suggested that dimerization of E2 helps recruit distal transcription factors to the viral transcription complex[99] and that there is a high degree of overlap of regions important for transcription and replication.[100] Interestingly, E2 has been reported to repress transcription from the viral promoter in an integrated but not the episomal state.[101] Another recent study indicates that both integration of HPV and loss of episomes expressing E2 is necessary for progression to cervical carcinogenesis.[102] Transcription is also regulated through binding sites for numerous common cellular transcription factors such as YY1, SP1, AP-1, Oct1, NF1, and Brn-3a and other silencer and enhancer elements.[2,103–107].

Some progress has been made in identifying changes in transcription factor binding involved in the switch from early gene to late gene expression. Viral late gene transcription is controlled by another promoter, p670 in HPV 16. A viral transcript expressed from this promoter and encoding the first few codons of E1 fused to the E4 ORF appears to be the major viral transcript in HPV-infected cells and specifies the viral protein designated E1$^{\alpha}$E4.[108] Regulation of the E1^E4 promoter is not well understood; however, this promoter appears to be used for transcription of the late gene products, L1 and L2, and both the capsid proteins and E1$^{\alpha}$E4 are only

expressed in the most differentiated layers of the epithelium.[109] Binding activity of CCAAT displacement protein inhibits expression of HPV 6 E6, E7, and E1 but decreases on keratinocyte differentiation.[110] Sen et al. carried out extensive analysis of cis regulatory elements within the region from nt. 7511–7762, known as the keratinocyte enhancer region of HPV 31.[111] Numerous changes in the complex of transcription factors binding to a given cis-regulatory element at different stages of the viral life cycle were identified. For example, one region was found to bind C/EBPβ in undifferentiated cells but an NF-1-like factor bound C/EBPβ in differentiated cells. The transcription factor hSkn-1a has been reported to displace YY1 to activate the p670 late promoter of HPV 16.[112] Recent work using array analysis found changes in binding of at least 36 HPV DNA-interacting factors over the course of differentiation and identified novel associations of HPV-16 promoter regions with C-Myb, Pax5, NFATx, and WT1.[113] Interestingly, the C/EPBβ transcription factor has been reported to activate transcription from the late promoter but to inhibit transcription from the early p97 promoter.[114] The transition to late gene expression may require differentiation but not viral DNA amplification.[115,116] In one study mapping the elements controlling transcription from the HPV 31 late promoter p742, Bodily and Meyers identified a 150-bp region in the E7 ORF as the core promoter and found that while sequences in the NCR can enhance expression from p742, they do not confer responsiveness to differentiation. The region containing the start site was dispensable for basal expression but required for differentiation response.[116]

Late gene expression is also governed at the level of usage of the polyadenylation site, since late mRNAs do not terminate at the early poly A site at nt. 4215, but continue to the site at nt. 7321 (see Fig. 27-1). Inhibition of late gene expression by use of the early poly A site has been linked to a combination of the AAUAAA sequence, binding of cleavage-stimulation factor and other factors, an enhancer element in the early region 3' UTR, and a negative regulatory element in the L2 ORF.[117,118] A negative regulatory element in the 3' untranslated region of the *L1* gene is important for posttranscriptional control.[119] This region contains several splice sites and binds numerous splicing factors.[120,121] A splicing silencer in the L1 coding region[122] and a splicing enhancer in the E4 coding region have been described that may regulate gene expression.[123] A region in the 3' end of HPV 16 early mRNAs that destabilizes mRNA and results in decreased protein levels has also been identified.[124]

The effects of chromatin structure on viral gene expression have also been the subject of much recent work. The HMG-I(Y) architectural protein and the histone acetyltransferase p300/CBP have been identified as part of the HPV 18 enhanceosome.[125] The ability of E2 to activate transcription is inhibited by CpG methylation.[126] In the same study, the HPV 16 NCR was hypermethylated in undifferentiated cells but hypomethylated in differentiated cells, suggesting one mechanism by which viral gene expression changes over the course of infection. Inhibition of histone deacetylase (HDAC) activity with trichostatin A preferentially upreguated HPV 11 promoter activity in the basal and parabasal layers of organotypic rafts.[127] A shift in DNAase 1 accessibility from the NCR near the E6 ORF in undifferentiated cells to a region between nt. 659 and 811 in differentiated cells was found by del Mar Pena and Laimins.[128] Interestingly, inhibition of deacetylation was not sufficient for late gene activation. There is some evidence for an association between genomic hypomethylation and carcinogenic progression.[129]

Much recent work has been done in characterizing how different papillomavirus genes are expressed from polycistronic transcripts. Recent work suggests that for HPV-16 and 18, E7 is translated by translational reinititation from spliced E6*I transcripts,[130] although a leaky scanning mechanism has also been reported.[131] It should be noted, however, that expression of HPV 16 E7 from a monocistronic transcript has also been reported.[132] Remm et al. describe expression of HPV-18 E1 by discontinuous ribosome scanning on an mRNA containing E6, E7, and E1.[133] A recent study suggests that control of viral gene expression is also regulated at the level of translation. Oh et al. found that HPV E7 expression was correlated with phosphorylation and inactivation of the translation inhibitor dIF4E:4E-BP1.[134]

VIRAL REPLICATION

It is widely believed that papillomaviruses have two modes of replication—stable replication of the episomal genome in basal cells and runaway, or vegetative, replication in more differentiated cells to generate progeny virus. The initial stages of infection may involve limited amplification of the viral genome to maintain a stable but low copy number of viral genomes in basal cells. The origin of replication is located in the NCR and contains an AT rich region, a region with dyad symmetry repeats to which E1 binds, and an adjacent E2 binding sequence.[135,136]

E1 is the origin-binding protein and has ATP-dependent helicase activity. It recognizes overlapping arrays of hexanucleotide sequence[137] to which E1 is proposed to bind sequentially,[138] finally binding the DNA as a double hexamer.[139] E1 also interacts with the cellular polymerase–primase complex,[140,141] Rep A,[142] and topoisomerase I.[143] It may disrupt chromatin structure by interaction with histone H1[144] and hSNF5.[145] Its activity is regulated by phosphorylation and interaction with CDK/cyclin complexes.[146–149]

Although E2 is not absolutely required for replication in vitro, it strongly stimulates replication in vitro and is necessary for replication in vivo,[150,151] presumably by recruiting other components to the preinitiation complex. Interestingly, in HPV 31 four binding sites for E2 have been characterized

and may cooperate to regulate viral replication.[152] HPV E2 interacts directly with E1.[153,154] Numerous studies have examined the regions of interaction with E1. In general, the carboxy-terminal regions of E1, including the ATP-binding domain, have been identified as important for specificity of interaction with E2,[155–157] while the amino terminal domain of E2 is important for E1 interaction.[154] Interestingly, for bovine papillomavirus, there is an interaction between the DNA-binding domains of E1 and E2, as well as between the helicase domain of E1 and the transactivation domain of E2.[158,159] It has been proposed that interaction between the DNA-binding domains prompts a bend in the DNA that facilitates the second productive interaction between the helicase and transactivation domains.[160] The x-ray crystal structure of the HPV 18 E2 activation domain bound to the E1 helicase domain suggested that E2 prevents hexamerization of E1 in part by preventing ATP binding.[161] It has also been proposed that there is a sequential binding of E1 dimers to opposite faces of the double helix.[162] E2 helps to recruit the E1 protein to the origin of DNA replication in a two-step process in which E2 is displaced at later stages of replication,[163] possibly through the action of the chaperone proteins Hsp70 and Hsp40.[164] The E1–E2 interaction has also been proposed to suppress nonspecific DNA binding activity of E1 and to increase high-affinity binding at the replication origin.[165,166] Alternative mRNA splicing may also regulate the relative ratios of E1 and E2, which in turn helps control viral replication during different stages of the viral life cycle.[167] E2 is also thought to have a role in tethering of viral DNA to mitotic chromosomes, possibly through interaction with the cellular bromodomain protein Brd4.[168,169] It has been reported that TATA-binding protein disrupts the E1–E2 interaction and inhibits replication, possibly facilitating a switch in the major role of E2 from replication to transcription.[170]

Apart from the origin-dependent initiation of replication, all other factors required for viral replication are encoded by the cell. It is unclear what regulates the switch from episomal to vegetative replication, except that it may depend on factors only found in terminally differentiating cells. One study with BPV-1 found that episomal replication occurred in proliferating cells and extensive amplification of viral DNA only occurred in growth arrested cells.[171] Two modes of episomal or maintenance replication have been proposed. The genome may replicate once per S phase or by a random-choice mechanism.[172] The switch could be regulated in part by p53, which interacts with HPV-16 E2.[173] It has been reported that p53 inhibits amplificational replication, suggesting that HPV-mediated degradation of p53 could be important[174] and also that stable maintenance episomal replication of bovine papillomavirus is not sensitive to p53.[175]

Changes in transcription factor binding to the HPV URR are likely to be important in regulating viral replication. The CCAAT displacement protein negatively regulates replication.[176] In one study of the role of different regions of the HPV 31 NCR on replication during different phases of the viral life cycle, Hubert et al.[177] found that disruption of binding sites for several transcription factors, including AP1 and Sp1, in the keratinocyte enhancer region could reduce replication levels. An analysis of the replication efficiency of constructs with chimeric NCRs derived from different HPV 16 variants showed that small changes in the NCR sequence affect replication levels and are responsible for the increased replication level of some American variants relative to European and African variants.[178] Differences in replication correlated with differences in expression of E1 and E2 and may depend on binding sites for transcription factors AP-1, Sp1, and YY1. It has also been reported that the YY1 transcription factor can directly bind and inhibit E2.[179]

Disruption of a splice site at nt. 3295 of HPV 31 prevented episomal maintenance replication but allowed immortalization of a cell line with integrated copies of the viral DNA, suggesting a role for E1-E4 and E5 in replication. Using a simple differentiation system consisting of suspension of keratinocytes in methylcellulose, it was found that amplification of viral DNA correlated with expression of the viral protein E1-E4 and the cellular proteins involucrin and transglutaminase.[180] Amplification was not correlated with expression of keratin-10. The E8-E2C protein has also been reported to repress replication from extrachromosomal origins of replication.[181]

VIRUS ASSEMBLY AND RELEASE

It has been difficult to develop experimental models to study virus assembly or release. However, improvement of organotypic raft culture methods and methods for preparation of VLPs have provided some information. Viral particles have been observed in the nucleus of infected cells in the granular layer of the epithelium, where packaging of the genome likely occurs. There is no evidence that HPV infections are cytolytic; release of viral particles is a result of degeneration of desquamating cells. Changes in the morphology of the cornified cell envelope in HPV 11-infected cells, due to reduction in expression of loricrin, have been observed.[182,183]

Several studies have examined the role of disulfide bonds in capsid and virion assembly.[27,28] One study proposed that L2 facilitates virion formation at a step prior to disulfide bond formation and helps link viral DNA to the capsomers.[41] This is also supported by experiments with organotypic raft cultures, in which HPV-31 mutant genomes lacking L2 were found to produce virions with a 10-fold reduction in the amount of encapsidated DNA.[184] The PML/ND10 nuclear subdomain may be a site of virion assembly. Using bovine papillomavirus, Day et al. showed that L1 and E2 can be recruited to the PML protein oncogenic domains[185] by L2. It has been suggested by Florin et al. that L1 and L2 translocate to the nucleus separately and that L2 induces reorganization of ND10 nuclear subdomains before

interacting with L1[186] and that the chaperone protein Hsc70 helps to translocate L2.[187] However, others have found that nuclear localization, but not PML localization, was required for L2 incorporation into VLPs.[188] Finally, the observation that a fraction of E1 and E2 show colocalization with ND10 structures may indicate some coupling between viral DNA replication and virion assembly.[189]

FUNCTIONS OF E4

Numerous reports suggest that HPV E1^E4 plays a role in various aspects of the viral life cycle. Its expression causes collapse of the keratin intermediate filament network.[190,191] Expression of E1^E4 also induces cell cycle arrest at the G(2)/M boundary.[192] This arrest has been correlated with retention of Cdk1/cyclinB as well as Cdk2/cyclin A complexes in the cytoplasm and their sequestration to the cytokeratin network[193,194] and is in some cases dependent on expression of Wee1.[195] It has also been reported to cause relocalization of PML protein, suggesting a potential role in viral replication or assembly.[196] Mutational analysis suggested that E1^E4 has separable roles in how the virus affects differentiation, the level of amplification of viral DNA, and the proportion of cells in the suprabasal layer of a raft culture that synthesize DNA.[197,198]

FUNCTIONS OF E5

The E5 protein also may have some role in cell cycle control and in some papillomaviruses such as BPV-1 it is a major transforming protein. HPV E5 has been reported to localize to the Golgi apparatus and the endoplasmic reticulum, as well as the plasma membrane.[199] HPV 16 E5 prevents maturation of the MHC class I and II antigens and sequesters the MHC complex to the Golgi apparatus.[200,201] Interaction with the epidermal growth factor receptor (EGFR)[202] and enhancement of EGF signaling has also been described,[203] possibly by inhibition of c-Cbl-1-mediated degradation of EGFR.[204] Hyperplasia in transgenic mice expressing HPV 16 E5 was dependent on EGFR.[205] Activation of EGFR has also been reported to lead to increased expression of vascular endothelial growth factor.[206] However, in one recent study comparing E5 from BPV-1 and HPV-16, HPV-16 E5 could support anchorage-independent growth in soft agar, but unlike BPV-1 E5 did not induce focus formation or activate growth factor receptors, PI3 kinase or c-Src.[207] The overexpression of E5 can either protect cells from[208] or sensitize cells to[209] apoptotic stimuli. In organotypic raft cultures with a mutant HPV 31 genome lacking E5, reductions in genome amplification and late gene expression were observed, as well as decreased expression of cyclin A and cyclin B, but no change in EGF receptor phosphorylation was observed.[210] In similar experiments with HPV-16, viral DNA amplification was observed but there was a subtle reduction in the number of suprabasal cells undergoing DNA synthesis.[211]

ROLE OF HPVS IN CANCER

A role for HPVs in the etiology of anogenital cancers has been firmly established based on a large number of molecular and epidemiologic studies. HPV DNA can be detected in nearly 100% cervical tumors.[212] In one study, no significant variation in positivity was found among countries, though the rates of cervical cancer varied markedly.[12] The association of HPV with other genital tract tumors has been less well studied, and while the prevalence of HPV appears to be lower than in the cervix, consistently high levels of association have been reported.[213,214] The epidemiological and clinical relationship between preneoplastic lesions and HPV-containing anogenital cancers will be discussed in Chapter 28; this section will focus on the biological characteristics of high-risk HPVs that lead to the development of neoplasia.

E6 and *E7* are the two viral genes that are invariably retained and expressed in tumors,[215] and these two oncoproteins from the high-risk types, but not from low-risk types, are sufficient to immortalize cells in culture.[216,217] Studies have shown that E6 and E7 can independently extend the life span of cells in culture, and together they efficiently immortalize human epithelial cells (reviewed in Ref. 218). E6 and E7 alone can immortalize cultured cells at a lower efficiency and this involves additional cellular changes. Immortalized cell lines are not tumorigenic when assayed in nude mice, but tumorigenic derivatives have been established spontaneously with long-term culture[219] or induced by carcinogen treatment.[220] Tumorigenicity is accompanied with additional cytogenetic changes. Taken together the current evidence suggests that the high-risk HPV E6 and E7 oncoproteins provide several critical functions for the development of neoplasia (Fig. 27-5). Firstly, E7 disrupts the signal that normally prevents a cell from entering S phase once the cell has left the basal layer. The increased number of proliferating cells increases the number of cells that are available as targets for additional genetic alterations, or "hits," that lead to neoplasia. Secondly, both E6 and E7 bypass damage-induced DNA checkpoints and other growth arrest signals. Inactivation of cell cycle checkpoints allows genetic instability, and the failure to eliminate cells that have undergone potentially deleterious changes contributes to the development of neoplasia. Thirdly, E6 activates the expression of telomerase, allowing the continued proliferation of cells[221] and blocks the apoptotic response. The development of invasive cancer, or tumorigenicity in animals, requires the activation of genes that favor penetration of the basement membrane, altered interactions with the matrix to permit growth in the stroma or other tissues, and new growth factor requirements. Additional cytogenetic changes accompany tumorigenicity. Inactivation of checkpoints allows the continued genetic instability that gives rise to the new genetic changes required for tumorigenicity.

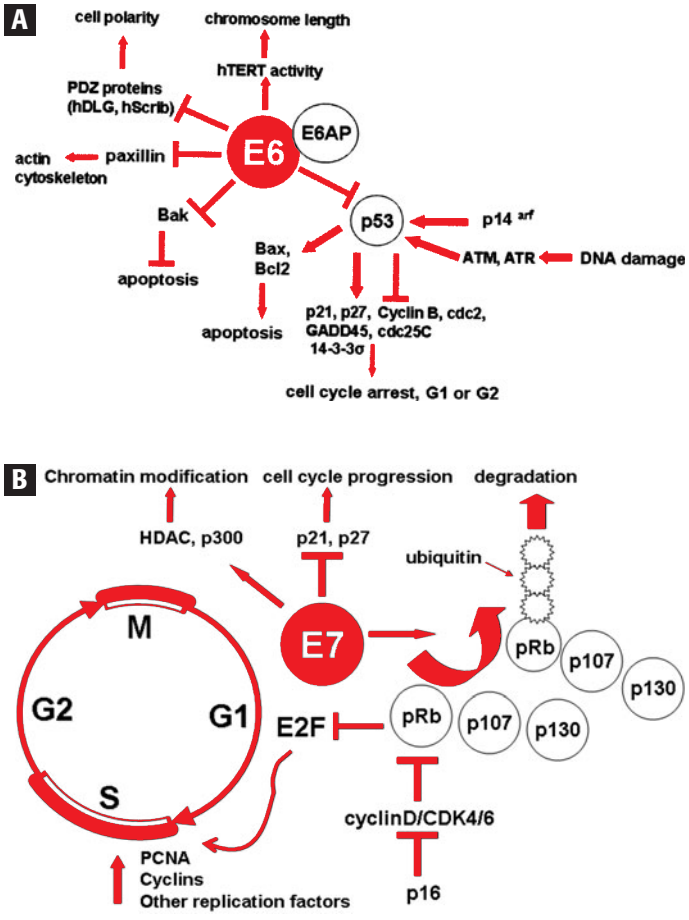

FIGURE 27-5. Role of HPV E6 and E7 in neoplasia. **A.** HPV E6 affects cell cycle progression by a number of different mechanisms. One of the most important is by causing proteasome-dependent degradation of the tumor suppressor protein p53 by the cellular ubiquitin ligase E6AP. In the absence of HPV E6, p53 activity is induced by various stresses including DNA damage, partly through the ATM and ATR kinases. This leads to activation (p21) or repression (cyclins, cdc2) of various genes leading to cell cycle arrest and to apoptosis. HPV E6 also causes activation of the catalytic *hTERT* component of telomerase and disrupts normal apoptotic response to DNA damage, in part by causing degradation of pro-apoptotic factors such as Bak. Finally, infection causes changes in the actin cytoskeleton and cell polarity by affecting the PDZ-domain-containing proteins and paxillin. **B.** HPV E7 affects cell cycle progression by causing proteasome-dependent degradation of the tumor suppressor protein pRb or the related pocket proteins p107 and p130 by an unknown mechanism. This allows expression of many genes required for entry into S phase and cell cycle progression including, but not limited to, proliferating cell nuclear antigen (PCNA) and cyclins. It also affects other factors important in cell cycle control such as the cyclin-dependent kinase inhibitor p21 and histone deacetylases.

Predictions about the role of HPV in neoplasia obtained from experimental studies are consistent with the natural history of cervical cancer. Among women who develop squamous intraepithelial lesions, the time from first detection of viral DNA to lesions is short, ~2 years, though factors like number of partners and infection with other STDs may influence the interval (reviewed in Ref. 222). Even mildly dysplastic lesions show an increase in proliferation and polyploidization. These changes result as a direct consequence of expression of E6/E7. The median age of carcinoma in situ (CIS) in the United States is 29,[223,224] indicating that approximately a decade has elapsed between the initial infection and severe dysplasia. CIS lesions are characterized by their aneuploid DNA content and thus reflect the genetic instability that accompanies prolonged expression of E6/E7. The preneoplastic lesions can regress spontaneously. One principle explanation for their regression is likely to be an effective immune response, and generalized T-cell deficiency has been associated with increased dysplasia (reviewed in Refs. 225 and 226). Other explanations may include the fact that some, perhaps most, alterations will be deleterious, resulting in cell death. The median age of invasive cervical cancer in the United States is 49, indicating that additional changes required for invasion and metastasis are acquired slowly over time.

FUNCTIONS OF E6

The genital HPV E6 proteins are approximately 150 amino acids in length and contain four cys-x-x-cys motifs involved in binding zinc.[227,228] High-risk E6 is primarily localized to the cell nucleus and E6 proteins have activities that activate or repress various heterologous promoters.[229–232] HPV 16 E6 binds to p53[233] in concert with a cellular ubiquitin conjugating enzyme, E6AP, and targets p53 for degradation.[234] Interestingly, the E6*I isoform has been reported to interfere with the ability of wild-type E6 to degrade p53.[235–237] HPV 6 E6 has greatly reduced ability to bind p53 in vitro,[233,238,239] it does not target p53 for degradation in vitro, and the intracellular level of p53 in cells expressing 6 E6 is unaffected.[239] Sedman et al.[240] found that mutant p53 could cooperate with 16E7 to immortalize human keratinocytes, suggesting that the inactivation of p53 might be the sole function of E6 in immortalization; however, inactivation of p53 was not required for E6 to immortalize mammary epithelial cells.[241] Using mutants of 16E6 that resulted in degradation of p53 but failed to immortalize human embryonic kidney cells in cooperation with 16E7, Nakagawa et al.[242] concluded that degradation of p53 was necessary but not sufficient for E6-mediated immortalization. However, in other reports immortalization without degradation of p53 has also been observed.[241,243]

Another important function of HPV E6 is the activation of hTERT, the catalytic subunit of telomerase.[221] This activation is at least partly dependent on binding sites for the c-Myc and SP1 transcription factors in the hTERT promoter.[244] Binding of c-Myc to the hTERT promoter has been detected by chromatin immunoprecipitation.[245,246] However, the exact role of c-Myc is not yet clear, as telomerase activity does not clearly correlate with levels of c-Myc.[244,247,248] E6 has also been reported to cause degradation of c-Myc.[249] Induction of hTERT expression by HPV 16 E6 has recently been shown to also depend on the NFX-1 transcription factor.[250] Two isoforms of NFX-1 have opposing effects on hTERT transcription.

A 91-kDa form represses telomerase transcription and is targeted by HPV 16 E6 for degradation via the E6AP ubiquitin ligase. A second 123-kDa isoform actually activates telomerase expression and is not targeted for degradation. In addition to hTERT, another important transcriptional target of E6 is transforming growth factor β-1.[251] The advent of microarray analysis has made possible identification of numerous genes involved in regulation of differentiation whose expression is effected by E6.[252]

HPV 16 E6 has been shown to bind many other cellular proteins that may have a role in induction of neoplasia. In addition to p53, E6 binds and inactivates the related protein p73.[253] Other binding partners include BRCA1,[254] the focal adhesion protein paxillin,[255] the calcium binding proteins ERC-55 (E6BP)[256] and fibulin-1,[257] the E6TP RapGAP,[258,259] the AP-1, TRIP-BR-1, and hADA3 transcription factors,[260–262] minichromosome maintenance protein-7,[263] several PML proteins,[264] the Jak-STAT pathway regulator Tyk2,[265] IRF-3,[266] protein kinase N,[267] and the GADD34/PP1 phosphatase complex that helps regulate the translation initiation factor eIF-2α.[268] E6 also binds and inactivates the histone acetyltransferase p300,[269,270] which has been reported to impact expression of both p53[271] and hTERT.[272] A number of other binding partners contain a PDZ motif that binds to a short region at the C-terminus of high-risk E6 proteins. These include hDLG,[273,274] hScrib,[275] MAGI-1,[276] and MUPP1.[277] E6 causes degradation of many of these proteins, but their significance to the viral life cycle or to the induction of neoplasia is still unclear. In one study mutation of the PDZ binding domain of E6 did not affect the ability of E6 to immortalize human mammary epithelial cells.[241] Other studies suggest that the PDZ-binding domain does contribute to the oncogenic potential of E6.[278–281] A number of these PDZ-domain proteins are involved in cell adhesion. Both the hDLG and hScrib proteins also bind the APC tumor suppressor.[282] The PDZ domain has also been reported to be responsible for activation of the NFκB transcription factor by E6.[283] In particular, this interaction is necessary for induction of the apoptosis-inhibiting protein cIAP. E6 also interacts with other proteins involved in regulation of both the intrinsic and extrinsic pathways of apoptosis, such as Bak[284] and Bax,[285] which it targets for degradation, as well as tumor necrosis factor[286] and FADD.[287,288] These studies showed that depending on the experimental conditions, E6 has been reported both to prevent apoptosis and to sensitize cultured cells to apoptotic stimuli.

Numerous studies have addressed the specific regions of interaction between E6 and its binding partners. The binding between E6 and p53 is dependent on residues in the zinc binding region in E6.[238,239,289,290] Binding between E6 and E6AP is disrupted by a mutation of amino acids 9–13 of E6,[247] although amino acids from 19 to 128 have also been suggested to be important.[235,243] Recently a solution structure of HPV 16 E6 has been reported,[291] which suggested that many of the sites deemed crucial for p53 and/or E6AP binding may disrupt the overall structure of E6. Their results mutating a large number of surface exposed residues only found F47 disrupting p53 binding and did not identify any residues that were critical for E6AP binding.

FUNCTIONS OF E7

The genital HPV E7 proteins are approximately 100 amino acids and contain two cys-x-x-cys repeats in the carboxy terminal half of the protein that binds zinc.[292] The amino terminal half of E7 shares two conserved regions of homology (CR1 and CR2) with the E1A oncoproteins of adenoviruses and with the polyomavirus T antigens. All of these oncoproteins bind to the retinoblastoma (Rb) tumor suppressor, p105Rb,[293] and other Rb-related pocket proteins, such as p107 and p130,[294] through a well-defined motif, LxCxE, present in CR2. This motif binds to a cleft between the A- and B-box portion of the Rb pocket in a manner also dependent on a conserved group of adjacent lysine residues.[295,296] Binding to HPV E7 disrupts the interaction between Rb and E2F.[297] This allows activation of numerous E2F-responsive genes necessary for transformation including, but not limited to, cyclin E,[298,299] cyclin A,[298] proliferating cell nuclear antigen (PCNA),[300] and cdc25.[301] Expression of E7 also results in elevated levels of the cyclin-dependent kinase (CDK) inhibitor $p16^{INK4A}$.[299]

HPV 16 E7 binds Rb much more strongly both in vitro[302] and in vivo[303] than does HPV 6 E7, and transformation activity parallels Rb binding activity. Interestingly, HPV 1 E7 has been shown to bind Rb with high affinity though it failed to transform cells.[304] In that study, 1 E7 was not able to transactivate an E2F responsive promoter, suggesting that although 1 E7 bound Rb, it was not able to inactivate the tumor suppressor activity of Rb.[305] It was subsequently found that HPV 16 E7 targets pRb and other pocket proteins for degradation by the ubiquitin-proteasome pathway.[306–310] In contrast, HPV 1 E7 binds but does not degrade Rb.[311] Several studies have shown that mutated 16 E7 proteins that were unable to bind to Rb were transformation deficient[312–317] though one study has shown that immortalization of keratinocytes might not involve Rb binding.[318] Although Rb binding was required for transformation, a number of mutated E7 constructs were fully competent to bind Rb yet were still transformation deficient.[316,317] HPV 16 E7 with a mutation of amino acid 2 from histidine to proline retains the ability to disrupt pRb/E2F complexes but is unable to degrade Rb or extend the life span of cultured cells.[308] HPV 16 E7 targets all three pocket proteins for degradation. Interestingly, HPV 6 E7 has been reported to target p130 for degradation.[319]

The mechanism by which E7 targets pRb for degradation is not yet known and requires binding of other cellular factors to E7. The stability of both pRb and E7 itself is dependent on ubiquitination and degradation by the proteasome, but the mechanisms may be different.[306,307,309,310] E7 has also been

reported to interact with one component of the proteasome,[320] although mutation of the binding site did not stabilize Rb. One possible candidate for involvement in E7 regulation of pocket protein stability is the SCF (Skp/cullin/F-box) E3 ubiquitin ligase. E7 is targeted for degradation by this multiprotein complex using the SKP2 F-box specificity factor.[321] SKP2 has been reported to interact with pRb but its role in pRb stability in the presence of E7 has not yet been conclusively shown.[322] SKP2 was also shown to target p130 for degradation.[323,324] Darnell et al. found that overexpression of the serine proteinase inhibitor plasminogen activator inhibitor (PAI-2) could stabilize pRb by interaction of Rb with a novel Rb-binding motif, PENF, in PAI-2.[325] They hypothesized that this interaction prevents pRb cleavage by some protease, possibly calpain, and that this cleavage may precede proteasomal degradation of pRb.

Although pRb binding and degradation through the CR1 and CR2 motifs is the most critical role of E7 in transformation, other cellular factors are also important and degradation of Rb alone cannot abrogate growth arrest in cultured cells.[308] Mutations affecting the zinc fingers found in the carboxy terminal end of E1A and E7 have both been shown to be transformation deficient, suggesting that important factors also bind in this region. A number of E7-binding cellular factors are involved in regulation of gene expression through modification of histone acetylation levels. The amino terminal region of E1A oncoprotein can bind to p300,[326] a CREB-related transcription factor.[327] Recently, p300 binding activity has also been identified for E7,[328,329] although the binding site was characterized as being in a more central region of E7 overlapping the pRb-binding domain. This interaction could contribute to transformation by affecting acetylation and expression of Rb/E2F target genes or by acetylation of Rb itself, as described for E1A.[330] The difference in reported binding sites may also explain earlier work in which E1A constructs mutated in the p300-binding domain can complement E1A proteins mutated in the Rb-binding domain, while HPV 16 E7 constructs mutated in the Rb-binding domain could not complement E1A proteins mutated in the p300-binding domain.[331] E7 has also been reported to bind the pCAF acetyltransferase.[332] In contrast to this effect on acetyltransferases, E7 interacts with the members of the HDAC protein family[333] and the Mi2 component of the NURD HDAC complex as well.[334] Disruption of E7-HDAC binding interferes with maintenance of the HPV genome and the ability of E7 to extend the life span of cultured cells.[335]

Another important E7-interacting cellular protein is the CDK inhibitor p21, the inactivation of which is important for E7 abrogation of cell cycle arrest.[336] Although E7 has been reported to increase p21 levels,[337–339] it may inactivate it in part by changing its subcellular localization.[340] Other important factors reported to interact with E7 that cannot be fully discussed here include, but are not limited to, BRCA1,[254] TATA box binding protein,[341] Oct-4,[342] the Rb associated factor p600,[343] the Smad proteins,[344] insulin-like growth factor binding protein 3,[345] interferon regulatory factor-1,[346] M2 pyruvate kinase,[347] the MPP2 fork head domain transcription factor,[348] AP-1,[349] and the promyelocytic leukemia protein.[350] Finally, phosphorylation of E7 by casein kinase II is important for its ability to facilitate S-phase entry[351] and may regulate binding of some of these interacting proteins.[352]

COMBINED FUNCTIONS OF E6 AND E7

Many studies have identified effects on cellular pathways linked to the combined expression of E6 and E7. Microarray studies are beginning to allow increasingly comprehensive examination of changes in gene expression in response to expression of HPV oncoproteins. One study using microarray analysis of organotypic raft cultures identified alterations in 1381 genes on expression of HPV E6 and E7.[353] Interestingly, genes that were downregulated tended to be involved in protein translation. A cooperative effect of E6 and E7 has also been reported in downregulation of expression of TGF β-2[354] and IL-8.[329]

Two other key pathways linked to both E6 and E7 are the Notch pathway and the pathway regulating EGF and angiogenic factors such as VEGF. Both upregulation[355–357] and downregulation[358] of the Notch1 pathway in association with progression to cervical cancer and expression of E6 and/or E7 has been reported. The discrepancies may be due to changes in subcellular localization[357] and on the exact levels of expression in various experimental systems.[356] Apoptosis is inhibited by this pathway through PI3K and Akt.[359] In general, expression of E6 and E7 correlates with increased expression of VEGF and EGF, and there is a complex feedback mechanism whereby they regulate each others' expression.[360–362]

The exact combination of the effects of HPV E6 and E7 necessary for immortalization and transformation, in particular whether p53 inactivation, telomerase activation, or both, is required, has also been the subject of a number of studies. Kiyono et al. found that disruption of the pRb/p16^{INK4A} pathway in combination with expression of hTERT was sufficient for immortalization of HMECs.[241] In some other studies it has been suggested that both degradation of p53 and E7 functions in addition to inactivation of p16^{INK4A} are required for immortalization.[363] Some discrepancies may be accounted for by the fact that hTERT levels on overexpression are typically approximately 10-fold higher than those induced by hTERT. Park and Androphy have suggested that the requirement for p53 degradation depends on the presence of functional E7.[364]

Finally, several studies have addressed the relative roles of E6 and E7 in transgenic mice. These studies have identified distinct roles in progression and promotion of tumorigenesis.[365–368] While E7 acted primarily at the promotion stage of carcinogenesis, E6 had a greater effect at the progression stage.

DISRUPTION OF CELL CYCLE CONTROL

In normal epithelium, proliferation is restricted to a few cells in the basal layer; suprabasal cells exit the cell cycle and undergo terminal differentiation. Experimental studies have shown that high-risk E7 prevents quiescence, resulting in proliferating cells throughout the epithelium. [369,370] Although the molecular mechanism that imposes a G1 arrest on epithelial cells as they leave the basal layer is not fully known, both Rb and the CDK inhibitor (CKI) p21 have been implicated. p21 associates with the G1 cyclin/cdk complexes, preventing the phosphorylation of Rb and other critical targets required for progression into S phase.[371] The E7 protein is capable of uncoupling proliferation and differentiation, allowing cellular and viral replication in cells expressing differentiation markers.[369,370,372] The mechanism likely involves both release of E2F and binding to $p21^{cip1}$.[373–375]

Large hyperchromatic nuclei characteristic of polyploid nuclei are observed in cells engineered experimentally to express E7 or E6/E7, as well as in HPV-associated lesions. This observation suggests that the viral oncoproteins can disrupt the S/M checkpoint that ensures that S phase does not reinitiate without an intervening round of mitosis. Inactivation of p53 has been shown to disrupt the mitotic spindle checkpoint,[376] and some studies have suggested that p21 is required for S/M coordination, though the mechanism is not known.[377] Thus, E7 bypasses control of epithelial cell proliferation and both E6 and E7 may contribute to the development of polyploidy by disrupting the S/M checkpoint.

In response to DNA damage, cells arrest in the G1 and G2 phases of the cell cycle, presumably to allow time to repair the damage before initiating DNA synthesis or mitosis.[378] Arrest in G1 is dependent upon the ability of a cell to induce p53, which results in the transactivation of a number of p53 responsive genes, the most critical of which appears to be $p21^{cip1}$.[379,380] By binding to cyclin/CDK complexes, p21 inhibits progression from G1 into S phase. Induction of p21 also inhibits PCNA-dependent DNA replication, though short-range DNA synthesis required for repair is not affected.[381,382] Other genes involved in DNA repair are also transactivated by p53. As an alternative to growth arrest, cells can undergo apoptosis in response to DNA damage. The decision as to which pathway to take is not completely understood but is influenced by cell type specific factors, the presence or levels of p53, and conflicting signals for growth proliferation and growth arrest (reviewed in Ref. 383; p53-inducible genes such as Bax can promote apoptosis). Additionally, as discussed above, E6 is also able to directly target components of the apoptotic pathway for degradation.

Both E6 and E7 are able to bypass DNA-damage-induced arrest by distinct pathways. Expression of HPV proteins interferes with a variety of mechanisms of DNA repair including nucleotide excision repair and repair of thymine dimers.[384] Elimination of p53 by HPV 16 E6 leads to low levels of p21 and efficient bypass of the DNA-damage-induced G1 checkpoint.[385,386] Using mutated E6 proteins it was demonstrated that the ability to abrogate G1 arrest was completely correlated with E6-mediated degradation of p53.[239] However, E6 has been reported to interfere with the fidelity of DNA end-joining by both p53-dependent and p53-independent pathways.[387] E6 also interacts with the repair protein XRCC1 to disrupt single-strand break repair.[388] The inability of HPV 6E6 to bypass a DNA-damage-induced growth arrest reinforces that 6E6 is not able to inactivate p53.

HPV 16 E7, but not 6E7, bypasses a damage-induced G1 checkpoint through mechanisms that are not completely understood.[385,389,390] These effects have been thought to be independent of p53, but Song et al., using a combination of mice overexpressing E6 or E7 in p53 wild-type or null background, suggested that some effects of E7 are dependent on p53.[391] Inactivation of Rb by 16E7 obviates the requirement for cyclin D/cdk4 activity[392] and the subsequent release of E2F transcription factors from Rb activates the transcription of genes required for S phase, including cyclin E,[393,394] which has been shown to be required for S phase entry.[395] Accordingly, cyclin E has been shown to be elevated in E7 expressing cells.[298] However, by analysis of mutations in the E7 C-terminus, inactivation and destabilization of pRb was shown to be insufficient for bypass of DNA-damage-induced growth arrest.[308] Inactivation of growth arrest signals likely involves additional activities of E7 that include direct binding to CKIs.[374,375,396] In particular, inactivation of p21 by E7 is important.[336] Interestingly, Therrien et al. have reported that both global and transcription-coupled nt. excision repair were impaired in the presence of E6, while only global repair was disrupted in the presence of E7.[397] An increase in levels of MDM2 has also been observed on expression of E7 in keratinocytes, which may contribute to the ability of E7 to abrogate to mitotic spindle checkpoint.[398]

Recent work also suggests further functions of HPV E2 in cell cycle disruption. E2 has been reported to directly interact with and regulate the stability and subcellular localization of E7.[399] As discussed in an earlier section, E2 also interacts with p53. E2 expression induces apoptosis or senescence in a number of experimental settings.[400–403] Interestingly, the ability of E2 proteins to interact with p53 and induce apoptosis varies between the high- and low-risk HPV types.[404] The gene expression profile of cells undergoing E2-induced senescence has been analyzed and showed a downregulation of chromatin regulatory factors.[405] E2 has also been reported to interact with E6 and to inhibit the ability of E6 to degrade PDZ-domain containing substrates.[406]

ADDITIONAL CELLULAR FACTORS

A great deal of interest has focused on the observation that integration of HPV sequences into the cellular genome

frequently accompanies progression to malignancy.[407–409] Unlike retroviruses there is no specific integration site on the HPV genome, but the frequent disruption of the early region has been postulated to provide a means to increase E6/E7 gene expression by either eliminating transcriptional repression by E2[410] or exchanging the viral 3′ end of the E6/E7 RNA which contains an RNA destabilizing element for a more stable 3′ end encoded by cellular sequences.[411] The chromosomal site into which HPV sequences integrate is nonspecific, or at least occurs on many different chromosomes. Integration of HPV genomes has been reported to occur preferentially at fragile sites,[412–414] perhaps because the chromatin structure provides easier access for recombination complexes. Integration near matrix attachment regions has also been observed.[415] Some studies have found integrated HPV sequences in proximity to cellular protooncogenes.[412,413,416] Interestingly, in one study of HPV-18 integration occurred near the c-myc protooncogene in 30% of cases.[417] Activation of c-myc on integration has also been reported.[418] A new potential tumor suppressor gene, APM-1, has been identified by cotranscription with HPV-68.[419] However, consistent activation of oncogenes as a consequence of HPV integration has not been demonstrated. A detailed review of known integration sites is found in Ref. 409. Although integration of HPV sequences into the cellular genome is a frequent feature of invasive carcinomas, it is not obligatory as some HPV 16-positive tumors retain only episomal genomes.[420–422] In one study of the physical status of HPV-16, Arias-Pulido et al. found HPV-16 to be 61.9% episomal, 29.4% mixed, and 8.7% integrated in cervical CIS and 39.1% episomal, 45.7% mixed, and 15.2% integrated in invasive cervical cancers.[423] It should be noted that the presence of high copy number episomes may prevent detection of integrated genomes. Extensive deletions of E1 and E2 were also found.

The identification of consistently observed chromosomal abnormalities in cervical carcinomas was initially hampered by the difficulty of obtaining a sufficient number of metaphases for karyotypic analyses. Early studies found that cervical carcinomas were frequently aneuploid or tetraploid and reported frequent alterations in chromosomes 1, 3, and 11.[424–426] Loss of heterozygosity has also been reported for 3p.[427] Comparative genome hybridization overcame the need for mitotic cells and identified overrepresentation of 3q as pivotal genetic change that marked the transition from severe dysplasia to invasive cancer.[428,429] A phosphatidylinositol 3-kinase gene located in this region has been postulated to be important.[430] A gain of 3q was observed in 1/13 severe dysplasias and in 9/10 invasive cervical cancers. In more recent work, alterations on many other chromosomes have been reported, including 2, 4, 5, and 10.[431–433] Gain of chromosome 20q has been reported in several studies.[434–436]

HPV immortalized human epithelial cells are generally not tumorigenic, but long-term passage in culture can spontaneously give rise to tumorigenic derivatives,[219] or they can be induced by treatment with carcinogens.[220] These experimentally derived tumor cell lines have been used to identify genes that may be responsible for the conversion to malignancy. Cytogenetic changes that accompany the progression to tumorigenicity were studied in a HPV 18 immortalized cell line, 18–11.[437] A striking but unstable aberration of chromosome 3 occurred very early after establishment of the cells in culture. Postcrisis, the length of the derivative 3 stabilized, but the long arm contained a complex rearrangement of other chromosomes. Concomitant with the development of tumorigenicity the ETS2 oncogene, which maps to 21q22, was translocated to the derivative #3.[438] A similar translocation of ETS2 to 3qter was observed in the carcinogen-induced tumorigenic line. Importantly, cytogenetic analyses of cervical cancers have frequently reported changes in chromosome 3,[426] suggesting that the model systems mimic authentic tumor development.

Some progress has been made in recent years toward understanding the mechanism by which HPV causes chromosomal instability. Overexpression of HPV-16 E6 causes premature mitotic chromosome segregation[439] and chromosomal abnormalities, in particular formation of anaphase bridges, have been correlated with telomerase levels in E6-expressing cells.[440,441] Expression of E6 and E7 has been linked to upregulation of a number of genes involved in regulating the G2-M phase transition, in particular Plk1, Aurora-A, cdk1, and Nek2[442] and the upregulation of Plk1 has been linked to E6-induced tetraploidy.[443] In early studies, it was found that HPV E6 and E7 cooperate to induce aberrant centrosome duplication and tetrasomy, although E7 alone, but not E6 alone, could cause the abnormalities.[444,445] These abnormalities were an early event after infection and could be observed in organotypic raft cultures in which E6 and E7 were expressed from an HPV episome.[446,447] Later work showed that both E6 and E7 could disrupt spindle checkpoint control and cause anaphase bridge formation.[448]

The same group has observed that while E7-induced abnormalities occur early in cells with a normal appearance, E6-induced abnormalities occur in multinucleated cells. Interestingly, the ability of E7 to induce centrosome abnormalities appears to be independent of its effects on pRb[449] but dependent on CDK2.[450] Finally, in one study numerical chromosomal abnormalities were observed with intermediate levels of E7 expression, while both numerical and structural abnormalities were observed on high levels of E7 expression.[451] Thus, while the mechanisms are not entirely understood, both E6 and E7 appear to contribute to the induction of chromosomal instability.

28 Genital Human Papillomavirus Infection

Rachel L. Winer and Laura A. Koutsky

INTRODUCTION

At least 40 of the over 100 different human papillomavirus (HPV) types primarily infect genital epithelium.[1] The great diversity of HPV types reflects the ability of this group of viruses to exploit the different microenvironments of the largest organ in humans—the skin. To some extent, the epithelial tropism of different HPV types corresponds to different clinical manifestations (Table 28-1).[1–3] For example, HPV 2 and HPV 4 are often detected in common warts of the hands,[4–6] HPV 6 and HPV 11 are most frequently detected in genital warts (condylomata acuminata),[7,8] and HPV 16 or HPV 18 is detected in a high percentage of invasive cancers of the genital tract and anus.[9–12] While a restricted number of genital HPV types have been linked with cancer,[13] most have been linked with development of squamous intraepithelial lesions (SILs) of the cervix, vagina, vulva, penis, or anus.[14] In the future, genital warts, precancerous genital lesions, and genital tract cancers are likely to become less common, as the newly developed prophylactic HPV vaccines become more widely available.[15]

This chapter provides an overview of the epidemiology and clinical aspects of genital HPV infection. Results from the prophylactic HPV vaccine trials are also discussed. Chapter 27 covers the biology of the virus, Chapter 57 provides an overview of the epidemiology and clinical aspects of HPV-related genital cancers, and Chapter 58 reviews current concepts in cervical cancer screening.

DEFINITIONS

The majority of newly acquired genital HPV infections appear to be subclinical and asymptomatic. Clinically visible manifestations of HPV include warts that may be condylomatous, papular, flat, or keratotic in appearance. Subclinical infections may appear as flat "aceto-white" lesions that are visible with colposcopic magnification of epithelium that has been treated with a mild acetic acid (vinegar) solution, or as SILs that are diagnosed microscopically on the basis of characteristic cytologic and histologic features.[16] Low-grade SIL (LSIL), the cytological equivalent of histologically confirmed cervical intraepithelial neoplasia grade 1 (CIN 1), is the morphologic manifestation of vegetative viral replication. High-grade SIL (HSIL), the cytological equivalent of histologically confirmed cervical intraepithelial neoplasia grade 2 or 3 (CIN 2-3), including carcinoma in situ, is considered to be a precancerous lesion with a high potential for malignant transformation. If left untreated, HSIL often will persist for years, developing additional genotypic and phenotypic changes that eventually result in an invasive carcinoma.[17]

For some individuals, detection of HPV DNA in genital specimens is the only evidence of current infection. Many adults without clinical, microscopic, or molecular evidence of HPV infection have serum antibodies to specific HPV types, indicating past infection. However, because a portion of individuals with genital HPV infection do not develop antibody responses that can be detected using current assays, false-negative HPV serology results limit the value of serologic testing for prior HPV infection (see reviews by Carter and Galloway and Konya and Dillner).[18,19]

HISTORY

Written descriptions of condylomatous warts of the genital tract and anus date as far back as the first century A.D. (see reviews by Oriel and Rosenbaum).[20,21] Within the first decade of this century, the viral etiology of both common skin warts and genital warts was demonstrated.[22] During the 1930s, work with the cottontail rabbit papillomavirus provided important clues as to the role of this family of viruses in the development of tumors.[23,24]

Although the cytologic manifestations now known to be characteristic of cervical HPV infection were first described in 1956,[25] it was not until the 1970s that these cellular changes were attributed to HPV infection.[26,27] Also during this decade, the genetic heterogeneity of HPVs was first demonstrated through use of molecular hybridization techniques.[28–31] Throughout the 1980s and 1990s, several

Table 28-1. Clinical Manifestations Associated with Different HPV Types

Clinical Manifestation	HPV Types
Skin lesions	
Plantar warts	1
Common warts	2, 4, 26, 27, 29, 57
Flat warts	3, 10, 28, 49
Butcher's warts	7
EV-associated lesions (benign or malignant)	5, 8, 9, 12, 14, 15, 17, 19–25, 36–38, 46, 47, 50
Genital	
Condylomata acuminate	6, 11
Noncondylomatous lesions and/or CIN	6, 11, 16, 18, 26, 27, 30, 31, 33, 34, 35, 39, 40, 42–45, 51–53, 56–59, 61, 62, 67–71, 73, 74, 81
Carcinoma	16, 18, 26, 31, 33, 35, 39, 45, 51–53, 56, 58, 59, 66–68, 73, 82
Nongenital mucosal	
Mouth (focal epithelial hyperplasia)	13, 32
Laryngeal papilloma	6, 11
Maxillary sinus papilloma	57
Carcinoma (head/neck/lung)	16, 18, 30

Papillomavirus and HPV typing. *Clin Dermatol* 1997; 15(2): 199–206; Munoz N, Castellsague X, de Gonzalez AB, Gissmann L. Chapter 1: HPV in the etiology of human cancer. *Vaccine* 2006; 24S3: S1–S10.

epidemiologic and molecular studies provided firm evidence linking specific HPV types with the development of most genital tract and anal cancers.[13,17,30,32–36]

PATHOGENESIS

HPVs are epitheliotropic, and replication that results in infectious progeny takes place in differentiating squamous epithelium.[37,38] Viral DNA, but not structural (capsid) protein, can be detected in the lower layers of the epithelium.[39] Capsid protein and infectious virus are found in the superficial differentiated cell layers. HPV-infected epithelium characteristically has a hyperplastic prickle cell layer (acanthosis), with a stratum corneum consisting of only one or two layers of parakeratotic cells. The dermal papillae are elongated, and there is a sharp border with the dermis (Fig. 28-1). Koilocytes, which are mature squamous cells with a large, clear perinuclear zone, may be scattered throughout the outer cell layers. The nuclei of koilocytes may be enlarged and hyperchromatic, and double nuclei are often seen.[40] Ultrastructural studies show virus in some of the cell nuclei. Although koilocytes are thought to represent a specific cytopathic effect of HPV, koilocytotic features are often subtle, and other cellular changes may mimic koilocytic changes. Thus, detection of koilocytes is not a sensitive or reliable predictor of cervical HPV infection.[41]

PREVALENCE AND INCIDENCE

PREVALENCE

The point prevalence of genital HPV infection detected by polymerase chain reaction (PCR)-based methods among populations of women with cytologically normal Pap smears

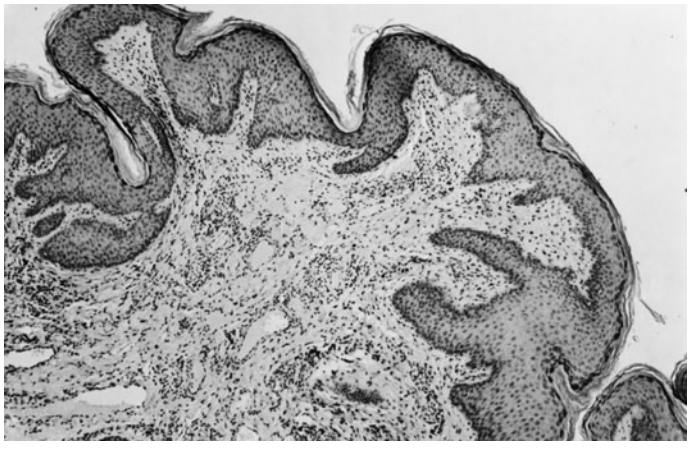

FIGURE 28-1. Biopsy of condyloma acuminatum, showing acanthosis, elongated dermal papillae, and sharp border with dermis. H&E stain (*Courtesy of E. Stolz*.)

has ranged from 1.5% to 44.3%,[42–63] depending on the population studied and the sensitivity of the PCR assay used. In general, sexually active younger women are more likely to have HPV DNA detected in genital tract specimens than older women. HPV 16 appears to be the most common type among cytologically normal women, as well as the most common cancer-associated type.[9,42,64–70] The worldwide distribution of HPV types detected in LSILs (from a worldwide meta-analysis[71]) and in cervical specimens taken from cytologically normal women (from an International Agency for Cancer Research (IARC) pooled analysis[42]) is shown in Table 28-2.

Genital HPV infection is also common in men, with prevalence estimates from studies using PCR-based methods ranging from 3.5% to 46.4% (see review by Partridge and Koutsky[72–75]). In a population of university students, the prevalence of HPV infection in 213 male students was similar to the prevalence in 418 female students (28%).[76] In case–control studies of the male role in the epidemiology of cervical cancer in Colombia and Spain, cell samples for detection of HPV DNA were collected from the distal urethra and the external surface of the glans and coronal sulcus of the penis. In Colombia, 26% of husbands of 210 women with cervical cancer and 19% of husbands of 262 women without cervical cancer were positive for HPV DNA by PCR,[77] whereas in Spain, 18% of husbands of 183 women with and 4% of husbands of 171 women without cervical cancer were positive for HPV DNA.[78]

Serologic assays for specific HPV types have been used to detect antibodies to virus-like particles (VLPs), which are conformationally correct viral capsids that have been synthesized from the L1 protein of the virus. Seroprevalence studies using VLPs as antigen suggest that, among women without clinically evident HPV-related disease, 2–43% have antibodies to HPV 16, and 9–25% have antibodies to HPV 6 or 11.[8,52,79–87] The seroprevalence of other types, including 18, 31, 33, 39, 58, and 59, has ranged from 9% to 23%.[84,86,88] The wide range of seroprevalence estimates may be due in part to differences in populations surveyed and to use of different assays, capsid antigen preparations, or cutpoints for distinguishing seropositives from seronegatives. Whereas HPV DNA tends to be most prevalent in women under 25 years of age, seroprevalence tends to peak in women over 25 years of age.[89–94] HPV antibodies are more commonly detected in women than in men.[8,89,90,93,95–98] Data collected from the National Health and Nutrition Examination Survey between 1991 and 1994 suggest that 18% of women and 8% of men in the general U.S. population harbor antibodies to HPV 16.[95]

Table 28-2. Worldwide HPV DNA Prevalence of Types Commonly Detected in HPV-Positive Low-Grade Cervical Lesions and in HPV-Positive Cervical Specimens from Women with Negative Cytology

	HPV-Positive Low-Grade Cervical Lesions[a]	HPV-Positive Cervical Smears from Women with Negative Cytology[b]
HPV type	Percentage positve	Percentage positive
16	26.6	19.7
31	11.7	7.5
51	10.9	4.0
53	10.1	1.2
56	9.7	7.1
52	8.8	5.3
18	8.6	7.2
58	8.5	7.6

33	7.6	5.8
59	6.0	2.9
35	5.9	5.9
45	4.9	5.6

[a]Meta-analysis including 5,910 cases of HPV-positive low-grade cervical lesions from Europe (46.5%), North America (32.9%), South/Central America (14.8%), Africa (3.0%), and Asia (2.9%) (Clifford et al.[71])

[b]Population-based IARC pooled-analysis including 1,429 HPV-positive cervical specimens from Asia (34.9%), South America (34.4%), Europe (14.4%), and Sub-Saharan Africa (14.3%) (Clifford et al.[42])

GEOGRAPHIC DISTRIBUTION

Studies on the evolution of papillomaviruses (Chapter 27) suggest that the known HPV types have existed in nearly identical molecular form since humans first migrated out of

Africa.[99] Worldwide variations in the prevalence of genital HPV infection exist and are linked to regional variations in cervical cancer rates.[51,100–111] Recent data also suggest that the distribution of HPV types detected in women varies by geographical region.[9,42] For example, while HPV 16 is the most common type detected in invasive cervical cancers from all world regions, it is detected more frequently in cases from North America, Europe, and Australia than in cases from Asia, Africa, and South and Central America. Types 35, 52, and 58, on the other hand, are more commonly detected in the latter world regions.[9] Similar patterns have been observed among cytologically normal women.[42] Studies of invasive cervical cancers obtained from different regions of the world also suggest that variants of HPV types may segregate according to geography. Based on DNA homology, HPV 16 isolates have been classified into five major lineages, including Asian variants, American-Asian variants, European variants, African-1 variants, and African-2 variants.[112,113] Compared to the HPV 16 prototype, non-European variants generally have greater nucleotide sequence divergence than European variants. Among European women with cervical cancer, European variants predominate, while African-1 and African-2 variants are more common in Africa.[114–116] Non-European HPV 16 variants are associated with an increased risk of high-grade cervical or anal dysplasia and cervical cancer.[114,115,117–122] Recent data also suggest that non-European variants of HPV 18 and HPV 52 are associated with an increased risk of cervical cancer.[120,123–126] Other work has shown that variants of HPV 16 and HPV 18 appear to persist longer in a host whose race indicates an ancestral geographic distribution that was once shared with that of the variant. For example, European variants of HPV16 and HPV18 persist longer in white women, and African variants persist longer in African American women.[127]

INCIDENCE

A population-based study in Rochester, MN, reported an incidence of genital warts of 1.06 per 1000 population in the late 1970s.[128] In Borås, Sweden, the incidence of genital warts was estimated to be 2.4 per 1000 population in 1990.[129] Among privately insured individuals in the United States, the age-adjusted incidence of genital warts ranged from 1.2 to 2.1 per 1000 population between 1998 and 2001.[130,131] In all of these studies, genital warts incidence peaked at lower ages in women than in men. A recent study of female university students showed that most genital warts developed within 12 months after infection with HPV 6 or 11; overall, women developed genital warts within 3 years[132] (Fig. 28-2).

Recent studies have estimated the incidence of subclinical HPV infections among women testing negative for HPV DNA at an enrollment visit. A comparison of 3-year cumulative incidence estimates from a population of 15–19-year-old

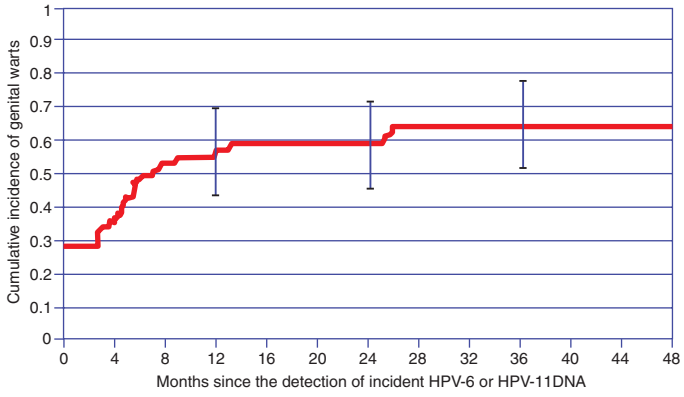

FIGURE 28-2. Kaplan–Meier survival analysis using detection of clinically visible genital warts as the outcome. Line represents proportion of women who developed clinically visible genital warts among women with incident HPV 6 or HPV 11 DNA infections (n = 54). (Adapted from Winer RL, Kiviat NB, Hughes JP, et al. Development and duration of human papillomavirus lesions, after initial infection. *J Infect Dis* 2005;191(5):731–738.)

females from the UK (44%)[70] and two populations of female university students from the United States (both 43%)[66,133] shows that acquisition of HPV infections is common among sexually active young women. Higher rates have been reported among women attending family planning clinics.[134,135] Studies enrolling women with a wider range of ages have reported age-related declines in HPV incidence,[65,136–138] although secondary, minor peaks in incidence have been observed in older women.[136,137] Incidence rates are generally higher for oncogenic HPV types than for nononcogenic types,[65,66,70,133–136] and infection with multiple types is common.[65,66,139,140]

Only a handful of studies have estimated the incidence of HPV infections in men. In studies of male soldiers, 13.8% of 250 Danish soldiers and 21.4% of 210 Mexican soldiers tested positive for HPV DNA after testing negative at an enrollment visit 6–8 months and 1 year earlier, respectively.[141,142] At a Swedish STD clinic, 19.7% of 76 men testing negative for HPV DNA at enrollment tested positive at a follow-up visit an average of 3.5 months later.[143] In a small cohort of 85 male and 162 female STD clinic attendees with multiple sex partners, the incidence of HPV infection was similar for men (50.5 per 100 person years) and women (47.1 per 100 person years).[144]

TIME TRENDS

In the United States, an eightfold increase in the age- and gender-adjusted incidence of genital warts was reported between the periods 1950–1954 and 1975–1978 (from 13 per 100,000 to 106 per 100,000).[128] During these years, rates of other STDs were increasing dramatically in Europe and North America and the population of sexually active young adults was also increasing.[145] Other data have shown 2.5–4.5-fold increases in the incidence of genital warts in the United States

and in Europe between the late 1960s and early 1980s.[146–148] More recently, the age-standardized rate of new genital warts claims among privately insured individuals in the United States increased from 118 per 100,000 in 1998 to 205 per 100,000 in 2001.[130]

TRANSMISSION

SEXUAL TRANSMISSION

Genital HPV infections are transmitted primarily through sexual contact. Sexual transmission of clinically evident HPV infection was noted in 1954, when Barrett et al.[149] reported on 24 women with genital warts who noticed the warts 4–6 weeks after their husbands had returned from the Far East. All husbands reported sexual contact with women while overseas, and all husbands had recently had penile warts. Oriel observed that 64% of 88 partners of individuals with genital warts developed warts, and newly developed warts were more infectious than older lesions.[21] Other data supporting the sexual transmission of HPV include the fact that HPV DNA is rarely found in genital tract specimens of women who have not had vaginal intercourse.[133,150–152] (HPV infections detected in women who have not had vaginal intercourse have been associated with reports of genital skin-to-skin contact,[133,153,154] indicating that HPV is transmissible through nonpenetrative sexual contact.) In addition, studies among young women show a positive trend between increasing numbers of sex partners and increasing prevalence of genital HPV infection (see review by Xi and Koutsky[58]). Positive associations between numbers of sex partners and HPV prevalence have also been observed among men, though less consistently (see review by Partridge and Koutsky[72]). Recent longitudinal studies have demonstrated that HPV acquisition in young women is strongly associated with reports of new and recent sex partners,[66,133,135,136,155–158] suggesting that the risk of genital HPV infection with each new sex partner is high. Unlike certain bacterial STDs,[159] genital HPV does not appear to require core groups (small segments of the sexually active portion of the population with very high rates of partner change) to sustain high rates of infection in communities throughout the world.[159]

Concordance of specific HPV types among sex partners has been demonstrated. In studies using PCR-based methods, type-specific concordance has ranged from 23% to 65%.[160–164] Concordance for the same HPV 16 variant has also been demonstrated.[165,166] The transient nature of HPV infections and differences in the sensitivities of sampling methods for men versus women may explain why concordance rates are lower than may be expected.

Abrasion of the epithelial surface is likely to facilitate HPV infection within areas of stratified squamous epithelium. It is less clear, however, whether abrasion facilitates HPV infection of metaplastic epithelium within the cervical transformation zone, where virtually all cervical cancers arise.

NONSEXUAL TRANSMISSION

The transfer of HPV by fomites is important in the transmission of skin warts;[167] whether this occurs with genital HPV types has not been well-evaluated. Digital transmission may occur. In a study of men and women with genital warts, 27% of subjects had the same HPV DNA types detected in genital samples and in finger brush samples.[168] Blood-borne transmission of HPV has not been reported.

Although rare, perinatal transmission does occur. As discussed in Chapter 81, a small minority of infants born to women with genital warts during pregnancy develop laryngeal papillomatosis,[169] and perinatal transmission appears to play a role in cases of condylomata developing within the first week of life.[170–172]

SUSCEPTIBILITY TO HPV INFECTION

Some papillomavirus-related lesions such as focal epithelial hyperplasia and the macular–papular warts seen in individuals with epidermodysplasia verruciformis appear to be influenced by genetic predisposition.[173] Human leukocyte antigen (HLA) haplotypes may influence susceptibility to HPV infection and carcinogenic progression. Results from a longitudinal study suggest that HLA class II polymorphisms are involved in the clearance and maintenance of infection.[174] Furthermore, studies from different geographic regions have demonstrated a protective effect of the DRB1*13 allele against the development of high-grade neoplasia and cervical cancer (see review by Hildesheim and Wang[175]). Results from studies exploring other polymorphisms in relation to carcinogenic progression have been less consistent.[176]

Generally, an increased genital HPV prevalence has been observed among patients with immune-related disorders. Numerous studies have consistently demonstrated a high prevalence of HPV among HIV-seropositive populations of women[177–192] and men.[193–200] Studies have also shown increased HPV incidence[178,201] and increased frequencies of infections with multiple HPV types[202] among HIV-infected individuals. One interpretation for the increased prevalence among HIV-seropositive individuals is that HIV-induced immunosuppression leads to reactivation of viruses that are otherwise undetectable. Renal allograft recipients are also at high risk of genital HPV infection, with recipients demonstrating a higher prevalence of HPV 16 or 18 DNA than control subjects.[203–205]

RISK FACTORS

As noted above, many recent studies have demonstrated a strong and consistent association between increasing numbers

of new and recent sex partners and increasing likelihood of detecting HPV DNA in genital tract specimens. Characteristics of women's male partners are also important with respect to female HPV acquisition. In case–control studies, male partners of women with cervical cancer have reported higher numbers of female sex partners than male partners of control women without cervical cancer.[77,78,161,206–209] In a cross-sectional study, Burk et al.[151] examined the relationship between HPV infection among women and the behavioral characteristics of their regular male partners. The lifetime number of partners of the woman's male partners and duration of her sexual relationship were positively associated with HPV detection among women. Similarly, in a recent IARC pooled analysis, women who reported that their husbands had had extramarital sexual relationships (either before or during marriage) were more likely to test positive for HPV infection.[210] Data from longitudinal studies support these trends. It has been shown that the risk of female HPV acquisition is positively associated with women's estimates of her male partners' lifetime number of partners[66,133] and that not knowing a male partner's prior sexual experience is also associated with an increased risk of acquisition.[133,211] Furthermore, two recent studies of adolescent females noted that associations between increasing male partner age and likelihood of female HPV detection were likely reflective of the positive correlation between male partner age and prior sexual experience.[211,212] An increased risk of HPV acquisition has also been associated with knowing a partner for less than 8 months before engaging in intercourse.[133] These data suggest that the better and longer a woman knows her male partner prior to intercourse, the lower her risk of becoming infected with HPV.

Male circumcision has also been investigated as a risk factor for HPV infection in both men and women, with conflicting results. A handful of studies have reported significantly lower HPV prevalence in circumcised men compared to uncircumcised men,[142,213–215] whereas other studies reported no significant associations.[76,216] One of these studies reported that circumcision was protective against prevalent HPV infections and repeat detection of prevalent infections at a 1-year follow-up visit, but not against new infections detected at follow-up.[142] While circumcision status of male partners has not been associated with the risk of female HPV acquisition,[133] some,[215] but not all,[206,208] case–control studies have reported that male partners of women with cervical cancer are less likely to be circumcised than those of control women.

Data on the association between smoking and HPV infection are inconclusive. Most studies have failed to link smoking to HPV detection in women and men.[142,217–232] Several other studies have reported positive associations between increased detection of genital HPV infection and past[216,233] or current smoking;[55,94,216,234–238] in some cases, these associations were diminished after adjustment for numbers of sex partners and other covariates.[94,236,237] One study reported that the positive association between smoking and female HPV infection was restricted to HIV-positive women.[239] In two other studies, significantly lower HPV prevalence was observed for former or ever smokers compared to women who had never smoked.[240,241] A handful of prospective studies reported no significant associations between smoking and female HPV acquisition,[66,155,156,236,237] whereas another prospective study of young women detected a significant positive association between current smoking and incident HPV infection, even after adjustment for measured sexual behavior variables.[133] It is unclear whether this finding reflects an actual smoking-related increase in HPV acquisition or if smoking is a marker of other unmeasured risky sexual behaviors.

Several lines of evidence suggest that HPV infection may be influenced by hormonal factors. Estrogen stimulation enhances expression of the HPV 16 E6 and E7 genes in SiHa cervical carcinoma cells.[242] Hormonal contraceptive (HC) use has been associated with condylomata acuminata.[243] Anecdotal reports suggest that during pregnancy, when levels of estrogen and progesterone are high, condylomata acuminata increase in size in some women.[244] The relationship of HC use to HPV infection is difficult to ascertain, given the strong correlation between HC use and sexual activity. Although some studies report an association between use of HCs and detection of HPV DNA independent of correlated variables such as sexual activities,[133,222,237,245–247] most studies do not.[48,95,105,156,219,220,224,226,230,233,234,236,240,248,249] Use of HC may represent a surrogate marker for sexual behavior that places a woman at high risk of genital HPV infection.

Some studies show a significantly higher HPV prevalence in pregnant women than in nonpregnant women[229,250–253] and a decreasing prevalence post partum.[250,252,254] The increased HPV detection rate among pregnant women may result from hormonal effects, since estrogens and progestagens show a steady increase during pregnancy and decrease post delivery. Alternatively, slight immune tolerance or local physiologic change during pregnancy may be responsible for the increased detection rates. It should be noted, however, that most studies failed to find a significant association between increased HPV prevalence and pregnancy.[47,255–266] One methodologic difficulty in studies of the effect of pregnancy on HPV detection is lack of comparable controls.

NATURAL HISTORY

It is generally accepted that HPV infections in women are detected transiently, with most new infections becoming undetectable within 1 to 2 years.[66,69,70,136] HPV 16 appears to persist longer than other HPV types.[67,69,141,267] Little is known about HPV persistence in men, but studies testing men at two points in time suggest that a majority of HPV infections in men are also detected transiently.[142,143,201] It is still not clear whether genital HPV infections are entirely eliminated by the host or

merely become suppressed at a level below detection, possibly through immunological mechanisms. Therefore, it should be noted that in epidemiological studies of HPV infection, the term "persistence" refers to persistent detection of infection rather than true viral persistence. A lack of consensus on what constitutes a persistent infection (for example, HPV positivity on two consecutive visits 6 months or 1 year apart) makes it difficult to compare results across studies.

After infection by HPV 16, serum antibodies develop in most women but they appear to develop slowly, and detection of HPV DNA and serum antibodies do not always coincide.[268–270] Persistent detection of HPV DNA is associated with higher rates of HPV 16 seroconversion.[269] A study of women attending a public university[268] showed that, overall, 67% of women with incident HPV 16 infection and 94% of those with prevalent HPV 16 infection developed HPV 16 antibodies. In comparison, only 5% of women with incident genital HPV infection with other HPV types and 4% of those who were repeatedly negative for HPV DNA showed HPV 16 seroconversion. Importantly, among women with incident HPV 16 infection, the median time to seroconversion was 8.3 months. In another population of female university students, Ho et al.[270] reported that the median time to seroconversion among women with incident HPV 16 infections was also 8.3 months. Seroconversion data among men with incident HPV 16 infections are not available.

Simultaneous coinfection with different HPV types has been commonly observed, but the effect of coinfection on type-specific persistence is unclear. Among populations of women, Rousseau et al.[139] reported that persistent detection of type-specific HPV DNA was unrelated to coinfection with other HPV types,[139] and Liaw et al.[67] reported that HPV 16 positivity did not affect the persistent detection of other HPV types. On the other hand, Ho et al.[66] reported that detection of multiple HPV types was a predictor of persistently detected infection. In a study of male soldiers in Mexico, Lajous et al.[142] also reported that repeat detection of type-specific HPV DNA at two visits 1 year apart was positively associated with the number of types detected at the first visit.

It is currently unknown whether an initial infection with a specific HPV type confers immunity against reinfection with the same type of virus. A study by Xi et al.[271] characterized persistence of HPV 16 infection at the variant level. Seventy women who were repeatedly HPV 16 DNA positive two to eight times over an 8–32-month interval showed the same predominant variant at every visit. Sequencing of clones from a subset of specimens indicated that many women were infected by more than one variant but that only one major variant seemed to predominate over time, whereas minor variants appeared to be more transient. These results suggest that HPV 16 establishes a persistent infection in which a single variant predominates, while coinfection may result in minor populations of HPV 16 variants.

All HPV types are linked to the development of low-grade cervical SILs,[16] whereas high-grade cervical SILs are usually positive for oncogenic HPV types.[272] In a cohort of young women in the United States, Moscicki et al.[155] reported that 15% developed LSIL within 3 years after initial HPV infection, and in the UK, Woodman et al.[70] reported that the 3-year cumulative incidence of any cytologic abnormality after initial infection was 33%. In another cohort of young women in the United States, Winer et al.[132] reported that approximately 50% developed a low-grade lesion within 3 years after initial HPV infection (Fig. 28-3A). The latter study also reported that rates of lesion detection tend to increase with increased screening frequency, due to spontaneous regression of most low-grade lesions. Therefore, the shorter interval between follow-up visits (4 vs. 6 months) may explain why that study detected LSIL in a higher proportion of women. Half of newly detected low-grade lesions appear to regress within 6–9 months.[70,132,273] It also appears that vaginal SIL is not uncommon among women with incident HPV infections. While less commonly detected than cervical SIL, one study reported that almost 30% of women with incident HPV infections developed vaginal SIL within 3 years (Fig. 28-3B), and the median duration of these lesions was less than 5 months.[132]

Results from natural history studies suggest that LSILs are transient manifestations of productive HPV infections, whereas HSILs are cervical cancer precursor lesions. This is in contrast to the previously held theory that cervical carcinogenesis always follows a progression from persistent HPV infection to development of low- and then high-grade lesions. Several recent studies have shown that cervical high-grade lesions are a relatively early manifestation of HPV infections in young women. Woodman et al.[70] reported that the risk of high-grade lesions was highest in the first 6 months after initial HPV infection. It has also been shown that histologically confirmed high-grade lesions are common after infection with HPV 16 and 18 infections,[132,274] with one study reporting that 27% of women with incident HPV 16 or 18 infections developed histologically confirmed CIN grade 2 or 3 within 3 years (Fig. 28-3C) and that the median time to development was 14 months.[132] Along with data suggesting that long-term persistence (defined as repeated detection of the same HPV type on two visits at least 5 years apart) is similar for oncogenic and nononcogenic types (with the exception of HPV 16),[267] these results suggest that persistence of oncogenic HPV DNA is more of a risk marker for underlying high-grade disease than a risk factor for developing high-grade lesions[275] (see Chapter 57).

CLINICAL MANIFESTATIONS

Genital warts and HSIL are the two most common HPV-related clinical manifestations that require treatment. Although colposcopic examination and HPV DNA testing of genital tract

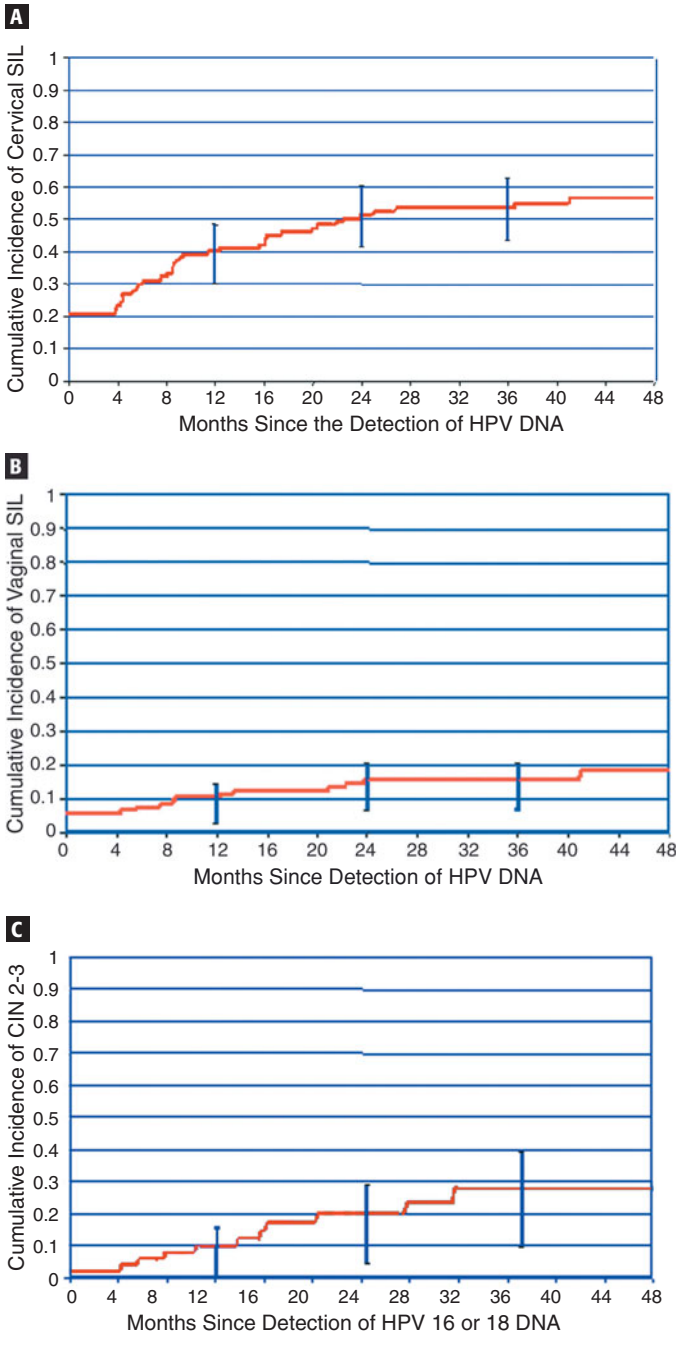

FIGURE 28-3. Kaplan–Meier survival analysis using detection of, **A.**, cervical SIL, **B.**, vaginal SIL, or, **C.**, biopsy-confirmed CIN 2–3 as the outcome. Lines represent proportion of women who developed the outcome among women with incident HPV DNA infections of any type (n = 195) or incident HPV 16 or 18 DNA infections (n = 60). (Adapted from Winer RL, Kiviat NB, Hughes JP, et al. Development and duration of human papillomavirus lesions, after initial infection. *J Infect Dis* 2005;191(5):731–738.)

epithelium would reveal SIL and HPV infection of the vagina, vulva, anus, or penis in a high proportion of sexually active adults, the clinical significance of SIL at sites other than the cervix (and perhaps the anus) is not clear. As discussed in Chapter 57, there is good support for the idea that high-grade cervical SIL represents an early stage in the development of invasive cervical cancer. In the anal canal, the dentate line corresponds to a squamocolumnar junction similar to that of the cervix. Individuals who engage in anoreceptive intercourse are at increased risk of HSIL of the anus,[193,195–199] and by analogy to the cervix they are at increased risk of invasive anal cancer. It has also been reported that the majority of anal cancers in women and homosexual men are positive for oncogenic HPV DNA.[276] The clinical diagnosis and management of SIL and cancers of the genital tract is discussed in Chapter 58.

GENITAL WARTS

Individuals presenting with genital warts rarely report symptoms other than the appearance of new bumps or growths on their genitalia. Occasionally, patients will report itching, burning, pain, or bleeding. Some, perhaps most, individuals with genital warts never become aware of their presence. Women with external genital warts may report an abnormal vaginal discharge, which probably is due to a coexisting vaginal infection such as bacterial vaginosis and not HPV.[277]

Most genital warts occur on the penis, scrotum, urethral meatus, and perianal area in men and on the introitis, vulva, perineum, and perianal area in women. Less often, they may be found on the cervix and vaginal walls in women and the pubic area, upper thighs, or crural folds in both men and women.[278–283] Because genital warts frequently occur with more than one lesion on one genital site and with lesions on different genital sites, it is important to examine the entire genitalia. Speculum exam for vaginal and cervical warts is recommended for women with external genital warts. Colposcopy is indicated for women with cervical warts, anoscopy for men and women with recurrent perianal warts and a history of anoreceptive intercourse, and urethroscopy for men with warts at the distal urinary meatus and terminal hematuria or abnormal urinary stream. Use of mild (3–5%) acetic acid solutions to detect "subclinical" HPV infections of the external genitalia is not recommended because the predictive value and therapeutic benefit of this procedure have not been established.

Condyloma acuminatum appearing on the lips, tongue, or palate is a rare manifestation of infection by genital HPV types.[284,285] Some patients with oral condylomata will have concomitant genital or anal warts, and most give a history of oral sex. Although transmission of HPV by orogenital contact occurs, it is not a significant route of transmission.[133,286,287]

The four morphologic types of genital warts are condylomata acuminata, which have a cauliflower-like appearance (Fig. 28-4); papular warts, which are flesh-colored, dome-shaped papules, usually 1–4 mm in diameter (Fig. 28-5); keratotic warts, which have a thick, crust-like layer and may resemble common skin warts or seborrheic keratosis (Fig. 28-6); and flat-topped papules, which appear macular to slightly raised (Fig. 28-7).[22,26,283,288–292] In general, condylomas are most frequently detected on moist, partially keratinized

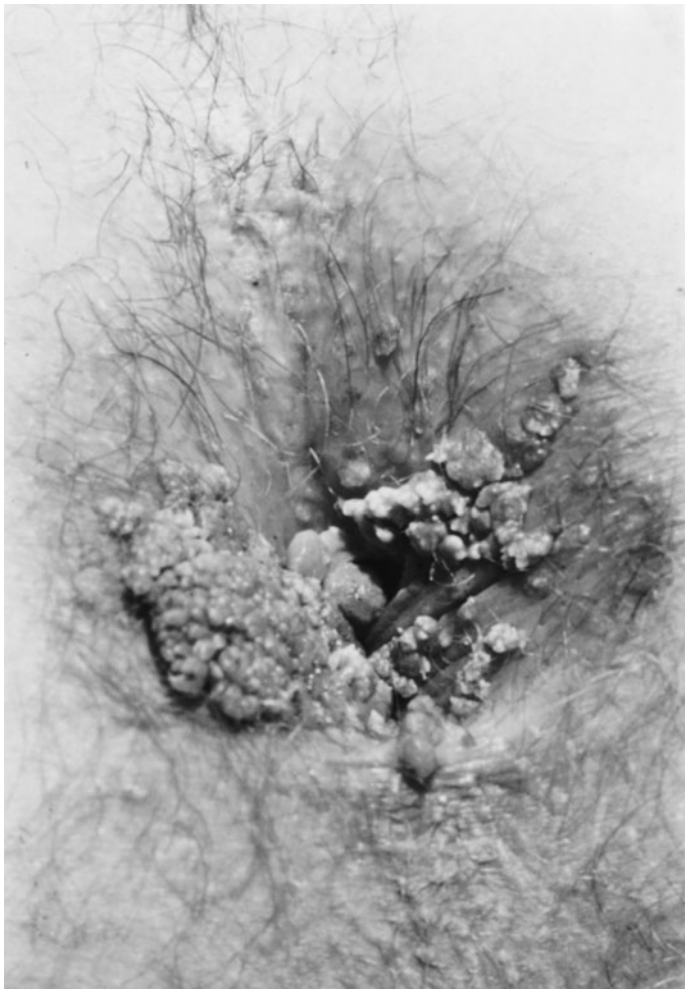

FIGURE 28-4. Anal condylomata acuminata. (*Courtesy of E Stolz.*)

FIGURE 28-5. Papular penile warts. (*Courtesy of KR Beutner.*)

epithelium, papular and keratotic warts on fully keratinized epithelium, and flat papular warts on either partially or fully keratinized epithelium. Regardless of morphology and anatomic location, most genital warts are caused by HPV 6 and to a lesser extent by HPV 11 and other HPV types.[7,8,293,294] A variant of dome-shaped and flat-topped papules, often referred to as

FIGURE 28-6. Keratotic penile warts. (*Courtesy of KR Beutner.*)

FIGURE 28-7. Flat-topped macular warts. (*Courtesy of KR Beutner.*)

"bowenoid papullosis," shows HSIL on histology and is usually hyperpigmented and positive for HPV 16 DNA.[295]

Some individuals, particularly those with reduced cell-mediated immunity due to HIV, immunosuppressive therapy, Hodgkin's disease, or pregnancy, develop very large genital warts. On rare occasions, these large warts become locally invasive, destructive but nonmetastasizing tumors that are called giant condylomas or Buschke–Lowenstein tumors.[296] These tumors are usually positive for HPV 6 DNA.

The differential diagnosis for genital warts includes papular anatomic structures such as skin tags (acrochordons), pearly penile papules, vestibular papillae, sebaceous (Tyson's) glands, melanocytic nevi, and acquired papular lesions including molluscum contagiosum, Crohn's disease, seborrheic keratosis, lichen planus, lichen nidus, and condyloma latum.[297–303]

Macular or flat lesions considered in the differential diagnosis of genital warts include psoriasis, seborrheic dermatitis, circinate balanitis of Reiter's syndrome, Bowen's disease, eryth-roplasia of Queyrat on the glans penis, and HPV-associated squamous cell cancers.[297,304,305] If the diagnosis of warts is questionable, a skin biopsy of the lesion may be performed.

MANAGEMENT

As noted above, the prevalence of genital HPV infection is high among sexually active adults, multiple epithelial sites may be infected, and multiple HPV types may be present. Diagnosis and treatment of subclinical genital HPV infections in young adults would be a monumental undertaking, and with the exception of HSIL, of unclear benefit but appreciable risk of scarring, hypo- or hyperpigmentation, and pain.[306–308] Although the clinical and morphologic manifestations of HPV infection are usually cleared with treatment, it is likely that virus persists in at least a few epithelial cells in some individuals. Treatment of genital warts is usually effective at inducing a wart-free state and may reduce the amount of infectious virus present. Treatment of cervical SIL, particularly HSIL, reduces a woman's risk of invasive cervical cancer (see Chapter 58).

In most settings, patients with genital warts are examined and treated for other STDs. Their current sex partners are also offered examination and treatment for macroscopically visible warts and other STDs. These visits provide an opportunity to counsel and educate. Counseling sessions involve educating patients about their diagnosis, treatment options, probability of recurrences, relationship of HPV infection to cancers, and infectivity. Most patients with genital warts are contagious to uninfected sex partners.[21,149] Treatment with clearance of warts probably reduces infectivity, but data addressing this issue are currently not available. Whether individuals with asymptomatic HPV infection are as contagious as patients with genital warts is unknown.

GENERAL PRINCIPLES OF TREATING GENITAL WARTS

Small warts of short duration (less than 1 year) respond better to therapy than large warts of long duration.[21] Although there are no data to show that treatment reduces the probability of transmission, it might. Without treatment, genital warts may disappear, stay the same, or grow larger in size or number.[309–314] Most genital warts are treated because they are aesthetically unpleasant. Clinical trials suggest that clearance rates are similar for the more widely accepted treatment modalities. Clearance rates have ranged from 23% to 94%.[315–317] While development of new lesions at previously treated sites is common, posttreatment recurrence rates are not well defined, because few subjects have been studied and follow-up protocols have not been standardized. For example, in some studies a recurrence is defined as a new wart at the same site detected within a 6-month follow-up period, whereas in another study a recurrence is defined as new warts in the same anatomic area arising 2–4 months after initiation of therapy.

Choice of treatment is guided by patient preference, with consideration given to the patient's age and ability to comply with moderately complicated directions, to the location and number of warts, and to the clinician's training. Several treatment sessions are usually required to achieve a wart-free state. Thus, time spent counseling patients as to the high probability of recurrence during the first 3 months of therapy and the need for multiple treatment sessions is important. There is no need to use expensive and toxic therapies as first-line therapy. Also, there are no data to support use of multiple rather than a single type of treatment on a single wart. Referral to a specialist is indicated for patients with extensive or refractory disease, cervical warts, or warts on the rectal mucosa.

Genital wart therapies are classified as patient applied or provider administered. Patient-applied treatments include podofilox (Condylox™) solution and gel, and imiquimod (Aldara™) cream. To self-treat, patients must be able to identify and reach the warts and to follow the treatment application instructions. The provider-administered treatments include topical treatments—cryotherapy, podophyllin resin, trichloroacetic acid, or bichloroactetic acid; excisional treatments—curettage, electrosurgery, scissors excision, shave excision, or laser vaporization; or injectable treatments—interferon or 5-fluorouracil/epinephrine gel implant.

Podofilox 0.5% solution or gel is an antimitotic agent purified from podophyllin resin. Unlike podophyllin, podofilox has a stable shelf life, does not need to be washed off after application, and is less likely to cause systemic toxicity.[315,318,319] Treatment consists of twice-daily application by a cotton-tipped swab for 3 days followed by no treatment for 4 days for up to 4 weeks. Imiquimod 5% cream, which stimulates the production of interferon and other cytokines,[320,321] is applied to warts with fingers three times per week (every other night) for up to 16 weeks. The treatment area is washed with mild soap and water 6–10 hours after application of imiquimod cream. For both of these patient-applied therapies, the prescribing clinician provides the first application, instructing the patient in proper use. Imiquimod and podofilox have not been approved for treatment of perianal, rectal, urethral, vaginal, or cervical warts. Safety for use in pregnant patients has not been established for either agent.

Cryotherapy, which destroys the wart and a small area of surrounding tissue through freezing, is recommended for small warts that are not extensive. One to six freeze–thaw cycles per wart per treatment session may be required. Most patients will require one to two treatment sessions per week for an average of 4–6 weeks. A cryoprobe, modified Q-tip, or fine spray is used to apply liquid nitrogen to each wart. Cryotherapy may be painful, and a local anesthetic is recommended unless only one or two small warts are being treated. Safety and efficacy are highly dependent on clinician's skills and training. Podophyllin resin, an antimitotic plant compound, is applied to warts as a 10–25% solution in ethanol or tincture of benzoin and allowed to dry. One to four hours after treatment, the compound is completely washed off. It is applied to the warts by a clinician using a cotton-tipped swab once to twice a week for up to

6 weeks. Applications are limited to 0.5 mL or 10 cm^2 per treatment session to decrease the potential for systemic effects such as bone marrow depression. Podophyllin is not used in pregnancy. Trichloroacetic or bichloroacetic acid in 80–90% solution may be used to treat small moist warts. The solution is applied by the clinician to each wart. Treatment may be repeated weekly for up to 6 weeks. Due to the low viscosity of these solutions and risk of local irritation, care must be taken to reduce contact of the solution with surrounding normal epithelium. Some clinicians recommend the application of sodium bicarbonate (baking soda) to the uninvolved surrounding epithelium to remove unreacted acid.

Warts may be removed by curettage, electrosurgery, excision by scissors or scalpel, or laser vaporization. Local anesthetic is applied before the excisional procedure is performed. Simple office surgery is often used for extensive or large warts and for treatment of warts during pregnancy. Electrosurgery is contraindicated for patients with cardiac pacemakers or for lesions proximal to the anal verge.

Other treatments, including intralesion injection of interferon and 5-fluorouracil/epinephrine gel implants, have been shown to be as effective as the modalities discussed above in clearing warts that are small in number and size. Side-effect profiles and expense have limited the use of these alternative treatment modalities.[322–324]

All wart treatments may cause mild local irritation and infrequently cause serious pain or systemic effects. If complete wart clearance is not achieved within 6 weeks for provider-applied therapies or at the end of the manufacturer's specified treatment schedule for patient-applied therapies, use of a different treatment, performance of a skin biopsy, or referral to a specialist is recommended.

FOLLOW-UP

After warts have cleared and possible complications of therapy have resolved, further follow-up of immunocompetent patients is not necessary. A follow-up visit scheduled 3 months after clearance, however, may be helpful for identifying recurrent warts and offering an additional opportunity for patient education and counseling. Furthermore, because genital wart recurrences are much more common in immunosuppressed patients, it may be helpful to provide these patients with repeated evaluations over an extended period of time. Annual cervical cytologic screening is recommended for women with or without genital warts, and the presence of genital warts per se is not an indication for cervical colposcopy.

PREVENTION

BEHAVIORAL INTERVENTIONS

Genital HPV infections are so prevalent and so often asymptomatic that risk of infection with one or more HPV types appears to be high, even among individuals with relatively few sex partners. Nonetheless, there is epidemiological evidence to suggest that certain behavioral interventions could be effective in reducing HPV transmission and HPV-related morbidity. For example, the "ABC" (an acronym that stands for abstain, be faithful, use condoms) approach, an HIV prevention campaign that was successful in Uganda,[325] could be useful in HPV prevention. Abstinence or lifelong mutual monogamy undoubtedly reduces risk of infection, since virgins are rarely positive for genital types of HPV DNA. Condoms are clearly effective in reducing the risk of genital transmission of HIV,[326] but data on protection against other STDs, including HPV, are more limited.[327,328] There is evidence that condoms protect some women from developing high-grade cervical neoplasia[329,330] and invasive cervical cancer.[208,331] Furthermore, in a recent clinical trial randomizing couples to either use or not use condoms, those randomized to use condoms exhibited significantly higher rates of regression of cervical neoplasia and penile lesions and were more likely to have cleared their HPV infections after 2 years.[332,333] In another recent study of HPV-positive female adolescents, condom use was associated with shorter infection duration.[334] Results from a recent prospective cohort study[335] further suggest that condoms offer some protection against acquisition of new HPV infections. Eighty-two female university students were enrolled prior to or within 2 weeks before their date of first intercourse and followed at 4-month intervals. In addition, they recorded daily sexual behavior information into web-based diaries every 2 weeks. It was reported that women who used condoms for all sex acts in the 8 months prior to HPV testing were 71% less likely to acquire a new HPV infection than women who used condoms less than 5% of the time, even after adjustment for numbers of new sex partners and perceived numbers of male partners' previous sex partners. Specific features of the study design, including frequent longitudinal HPV testing, precise measurement of condom use frequency, and restriction to newly sexually active women, may explain why this study is the first to demonstrate a significant protective effect of condoms on HPV acquisition by females.[335] It is not surprising, however, that some HPV infections were detected among women reporting consistent condom use, as HPV can be transmitted through nonpenetrative sexual contact with both male[133] and female[153] partners and imperfect condom use does occur.

PROPHYLACTIC HPV VACCINES

Two newly developed prophylactic HPV vaccines are showing considerable promise. Results from four published randomized controlled trials demonstrate with remarkable consistency that when administered to susceptible young women (15–26 years of age) prophylactic HPV vaccines provide

high-level protection (90% or better) from infection, persistent infection, and high-grade lesions caused by the targeted HPV type(s).[274,336–342]

Both vaccines are composed of HPV type-specific L1 proteins that self-assemble into noninfectious, recombinant VLPs. One of the vaccines, Gardasil ® (Merck & Co., Inc.), protects against HPV types 6, 11, 16 and 18 (quadrivalent) and the other, Cervarix ® (GlaxoSmithKline), protects against types 16 and 18 (bivalent). HPV 16 and 18 cause of about 70% of cervical cancers worldwide, and HPV 6 and HPV 11 cause about 90% of genital warts.[8,68] Both vaccines, which are administered at 0, 1 or 2, and 6 months in a series of three 0.5-mL intramuscular injections, were developed to protect against HPV 16- and HPV 18-related genital disease, including cervical, penile, vulvar, vaginal and anal cancer, and precancerous lesions. In addition, the quadrivalent vaccine was developed to protect against HPV 6- and HPV 11-related diseases including genital warts and laryngeal papillomatosis.

Phase IIb trial data indicate that these prophylactic VLP-based vaccines are generally safe and well tolerated. Pain, redness, or swelling at the injection site was reported more often among vaccine recipients than among placebo recipients in the quadrivalent vaccine trial (86% vs. 77%) and in the bivalent vaccine trial (94% vs. 88%). Systemic adverse events including headaches, fatigue, and gastrointestinal symptoms were reported by a similar proportion of vaccine and placebo recipients in both trials: 69% in the quadrivalent vaccine trial and 86% in the bivalent vaccine trial. Findings from these trials also indicate that both vaccine formulations are highly immunogenic, with seroconversion rates to all targeted HPV types of over 98%.[337,341]

Four to five years of follow-up showed high-level vaccine efficacy for preventing infection and cervical lesions among susceptible young women (i.e., women without PCR or serological evidence of prior infection by the targeted HPV types). The quadrivalent HPV 6/11/16/18 vaccine was 94% (95% CI 83%, 98%) effective in preventing persistent HPV 6/11/16/18 infection and 100% (95% CI 31%, 100%) effective in preventing HPV 6/11/16/18-related CIN.[342] The bivalent HPV 16/18 vaccine was 95% (95% CI 64%, 99%) effective in preventing persistent HPV 16 or 18 infection of the cervix, and 100% (95% CI 42, 100) effective in preventing HPV 16/18-related CIN.[338] Results from a large phase IIb trial of monovalent HPV 16 vaccine (n = 2391) with 4 years of follow-up also showed high-level efficacy (100%, 95% CI 74%, 100%) for prevention of HPV 16-related CIN 2–3 among susceptible young women.[274]

These phase IIb trials also showed that vaccine-induced protection was robust. Women with relatively low levels of antibodies after vaccination appeared to be protected, and rare instances of possible break through infections did not appear to be correlated with low antibody titers. A portion of women enrolled in the trials did not receive all three doses of vaccine within 6 months of the first dose, suggesting that there might be flexibility around the timing of vaccine administration. However, efficacy for less than three doses cannot be inferred, as the number of women who received only one or two doses was insufficient to determine efficacy for less than three doses.

In addition to trials of young women, other ongoing trials will assess vaccine safety, immunogenicity, and efficacy in different populations. Safety and immunogenicity have been evaluated in boys and girls 9–15 years of age (quadrivalent vaccine) or girls 10–14 years of age (bivalent vaccine). Both vaccines are generally safe and highly immunogenic in children. Trials of women over 25 years of age (both bivalent and quadrivalent vaccines) and of young men (quadrivalent vaccine) are ongoing. Other populations to be studied include infants, and immunocompromised children and young adults (e.g., those with HIV/AIDS, transplants, chronic immunosuppression, or autoimmune diseases).

Recent results from the phase III quadrivalent HPV 6/11/16/18 vaccine trials showed high-level efficacy (94% or better) for prevention of HPV 16- and HPV 18-related CIN 2–3 or worse, and prevention of HPV 6-, 11-, 16-, and 18-related CIN, vaginal intraepithelial neoplasia, vulvar intraepithelial neoplasia, and condyloma acuminatum in susceptible populations.[343] Results from an interim analysis of the phase III bivalent 16/18 vaccine trials also showed high-level efficacy (90%) for prevention of HPV 16/18-related CIN 2-3 among susceptible women.[344] Regulatory agencies in several countries including Australia, Canada, the European Union, Mexico, and the United States have approved the use of the quadrivalent HPV 6/11/16/18 vaccine. In the United States, the Centers for Disease Control and Prevention (CDC) Advisory Committee for Immunization Practices (ACIP) recommended that the approved vaccine be routinely administered to girls when they are 11–12 years old. The ACIP recommendation also allows for vaccination of girls as young as 9 years of age as well as vaccination of girls and young women 13–26 years of age.[345] Australia approved the same HPV vaccine for girls and young women 9–26 years of age and for boys 9–15 years of age. The vaccine is not approved for use in pregnant women. Additional safety data, including data on pregnancy, fetal, and infant outcomes, are being collected in the on-going phase III trials and will continue to be collected in post-marketing surveillance studies after the vaccines are licensed and used in countries throughout the world.

Now that the prophylactic quadrivalent HPV 6/11/16/18 vaccine is commercially available, effective implementation strategies need to be developed. Key issues include how to provide public, provider, and policy maker education about the efficacy and safety of the vaccine; which age groups to recommend for routine and catch-up vaccinations; whether to vaccinate males as well as females; and how to make sure that women continue participating in cervical cancer screening programs. Even when

HPV vaccine coverage becomes widespread, cervical cancer screening will be needed, because cancer-causing HPV types that are not targeted by the vaccine will continue to circulate in the population and because the vaccine will not prevent cervical cancer among women with established HPV 16 or HPV 18 infections. Additional issues that are more acute in less developed countries are the cost of the vaccine, need for refrigeration and clean injection equipment, administration of three vaccine doses to adolescents who have limited access to clinical services, and cultural beliefs that involve sex and gender. As HPV immunization programs are implemented throughout the world, it will also be important to evaluate the duration of protection, need for a booster dose, and the impact of vaccination on the transmission dynamics and natural history of HPV types not included in vaccines.

29 Viral Hepatitis

Stanley M. Lemon, Anna Lok, and Miriam J. Alter

HISTORY AND DEFINITIONS

Although viral hepatitis is unquestionably an ancient disease, it is only in the past 40 years that an appreciation has emerged of the diversity of infectious agents capable of causing the clinical syndrome of acute hepatitis. The era of modern hepatitis virology began with the discovery of Australia antigen by Blumberg and associates in 1965 and the subsequent association of this antigen with hepatitis B.[1,2] Knowledge in this area has since continued to expand rapidly, and at least five distinctly different human viruses (classified as hepatitis A through E) are now generally recognized to be causative agents of acute and/or chronic viral hepatitis (see Table 29-1).

Hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis delta virus (HDV), and hepatitis E virus (HEV) all share a remarkable tropism for the liver despite profound differences in their physical structure, pathobiology, and epidemiology. Each of these viruses is a cause of clinically overt acute hepatitis associated with frank jaundice. The severity of the liver disease, which frequently accompanies acute infection with these viruses, generally distinguishes them from cytomegalovirus and Epstein-Barr virus, which typically cause much milder liver dysfunction during primary infections. Within the United States, almost all cases of acute hepatitis are caused by infection with HAV (51%), HBV (40%), or HCV (9%).[3] These acute hepatitis virus infections cannot be distinguished from each other without serologic testing. Acute hepatitis represents a considerable disease burden within the United States, with an estimated 40,000–60,000 clinical cases occurring annually during the past 5 years. Only a fraction of these cases are reported to public health authorities, and a substantial number of additional infections do not come to medical attention because they are asymptomatic. Fulminant hepatic failure and death occur in a very small proportion of patients with acute hepatitis A or B, but these clinical endpoints are rarely associated with acute HCV infection in the United States.[4,5]

The major burden of disease due to hepatitis virus infections stems from the chronic liver damage that occurs in individuals who develop persistent infections. The proportion of persons who become persistently infected is highly dependent on the infecting virus. Persistent infections with HAV are not well documented and may never occur. On the other hand, more than 50% of persons infected with HCV fail to clear the virus and most eventually develop biochemical and histologic evidence of chronic liver disease.[6] HBV has an intermediate tendency to establish persistence, with the risk of persistent infection being highly dependent on the age at the time of infection and immunologic competence of the individual.

It is appropriate to focus attention on the hepatitis viruses in a textbook concerned with sexually transmitted diseases (STDs). Although these are systemic infections that are also commonly transmitted by other means, HBV is a sexually transmitted infection, and sexual activity may profoundly influence the risks for acquisition of HAV. To a lesser extent, sexual behavior may also influence the risk of infection with HCV and HDV. Vaccines are now available for the prevention of hepatitis B (and with it hepatitis D) and hepatitis A.[7] These vaccines provide a unique means of prevention among STDs, and they should be used in populations at risk of these infections. This chapter will discuss the epidemiology and pathobiology of the hepatitis viruses and the use of hepatitis vaccines in populations at risk of STDs. Aspects of the management of patients with viral hepatitis are considered in Chapter 66.

HEPATITIS A

HEPATITIS A VIRUS

Physical characteristics and replication cycle

HAV is classified as the type species of the genus *Hepatovirus* of the family *Picornaviridae*. The virus is a small 27-nm, spherical, nonenveloped particle.[8,9] Its RNA genome is single stranded, positive sense, and approximately 7.5 kb in length.

Table 29-1. Human Hepatitis Viruses

	Taxonomic Classification Virus Family (Genus)[a]	Genome[b]	"Viral" Envelope	Modes of Transmission[c]	Persistent Infection	Disease Associations[d]
Hepatitis A Virus ("infectious hepatitis")	*Picornaviridae* (*Hepatovirus*)	L/ss RNA 7.5 kb	No	ET ST PT (rare)	Extraordianrily rare if ever	AH, FH
Hepatitis B virus ("homologous serum hepatitis")	*Hepadnaviridae* (*Orthohepadnavirus*)	C/ds DNA 3.2 kb	Yes	HT ST NT	Common in infants and immunocompromised persons	AH, FH CH HCC
Hepatitis C virus ("post-transfusion NANB hepatitis")	*Flaviviridae* (*Hepacivirus*)	L/ss RNA 9.6 kb	Yes	PT ST (occasional) NT (occasional)	85% of all infected Persons	AH CH HCC
Hepatitis D virus ("delta hepatitis")	Unassigned genus (*Deltavirus*)	C/ss RNA 1.7 kb	Yes	PT ST (occasional)	Common if patient is an HBV carrier	AH, FH CH
Hepatitis E Virus ("enterically transmitted NANB hepatitis")	Unassigned genus (Hepevirus)	L/ss RNA 7.2 kb	No	ET	Never	AH, FH

[a]Virus family (genus).

[b]L, linear; C, circular; ss, single-stranded; ds, partially double-standed; kb, kilobases.

[c]Documented modes of transmission: ET, enteric transmission; HT, horzontal transmission (see text); NT, perinatal transmission; PT, percutaneous transmission; ST, sexual transmission.

[d]AH, acute hepatitis; FH, fulminant hepatitis; CH, chronic hepatitis and cirrhosis; HCC, hepatocellular carcinoma.

The genome organization includes a 5′ nontranslated segment, ~734 bases in length,[10] followed by a single long open-reading frame encoding a polyprotein of ~2227 amino acids, and a short 3′ noncoding region that terminates in a 3′ poly(adenylic acid) tract (Fig. 29-1). A small, genome-linked protein (VPg) is covalently attached to the 5′ end of virion RNA. Genome-length cloned cDNA and RNA derived from it are infectious in cell cultures.[11]

Within the infected cell, virion RNA acts as a messenger for synthesis of a large polyprotein, which is cotranslationally processed by the virus-specified $3C^{pro}$ proteinase into both structural and nonstructural proteins[12,13] (Fig. 29-1). Three capsid proteins (VP1, VP2, and VP3, ranging from 222 to ~280 amino acid residues in length) have been demonstrated in purified virus preparations. Virion RNA also serves as template for (−)-strand RNA synthesis, which acts, in turn, as template for synthesis of more (+)-strand genomic RNA. This newly synthesized (+)-strand RNA is either used for further rounds of replication or packaged within the capsid proteins for export from the hepatocyte across the apical canalicular membrane into the bile. As with other picornaviruses, replication occurs in the cytoplasm of the infected cell and RNA transcription proceeds asymmetrically, with an excess of (+)-strand molecules synthesized under direction of the virus-specified $3D^{pol}$ RNA-dependent RNA polymerase.[8]

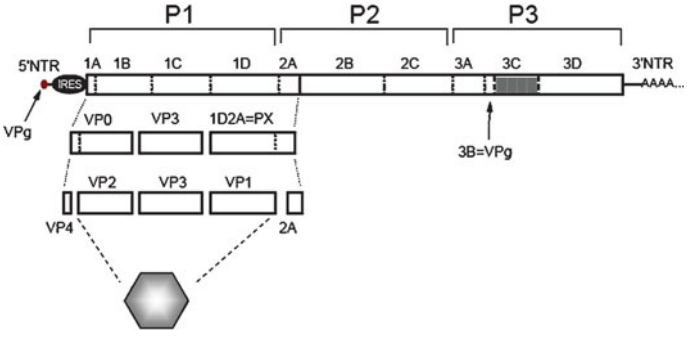

FIGURE 29-1. Genomic organization of HAV. The ~7.5-kb single-stranded (+)-sense RNA genome has a 5′ untranslated region (5′NTR) approximately 740 bases in length, followed by a long open-reading frame (boxed region). The 5′ terminus of the RNA is covalently linked to a small viral protein (VPg). There is a short 3′ untranslated region, followed by a poly(adenylic acid) tail. Translation is under direction of an internal ribosome entry site (IRES), which is located within the 5′NTR. This leads to synthesis of a large polyprotein, which is cotranslationally processed by a viral proteinase ($3C^{pro}$) into capsid precusor proteins, VP0, VP2, PX (representing the P1 segment of the polyprotein), and a series of proteins, which are active in replication and which include the RNA polymerase, $3D^{pol}$ (P2-3 segments). "PX" in VP0 undergoes further cleavage to VP4 and VP1 following packaging of the viral RNA.

HAV may be propagated in cell cultures with reasonable efficiency. However, in most in vitro systems, HAV does not produce a cytopathic effect; there is no shutdown in host cell protein synthesis such as occurs with poliovirus infection. A variety of primate cell lines are permissive for HAV replication, but primary isolation of wild-type virus is difficult and frequently entails a period of several weeks (or longer) between inoculation of cell cultures and the first detection of viral antigen.[14,15] Thus, virus isolation is not useful for diagnosis. Furthermore, virus yields from cell culture are relatively low. Nonetheless, the ability of this virus to be propagated in cell culture has made it possible to develop conventional formalin-inactivated vaccines (see below).

No significant antigenic differences have been found among strains collected from widely separated geographic regions.[16,17] Substantial evidence suggests that the critical antigen(s) of HAV are conformationally determined and are thus "assembled" rather than "linear" structures determined solely by the primary amino acid sequences of the capsid protein. Analysis of HAV using neutralizing murine monoclonal antibodies indicates the presence of an immunodominant antigenic site on the virus capsid that is involved in antibody-mediated neutralization. Genomic sequencing of viral escape mutants selected during growth of the virus in the presence of neutralizing monoclonal antibodies has shown that such resistance can be conferred by substitutions at amino acid residues within VP3 and VP1, which contribute to this site.[18] The conformational nature of the critical HAV antigens has prevented development of a vaccine, based on expression of antigen from recombinant cDNA.

Pathobiology

Chimpanzees, several species of marmosets, and New World owl monkeys are susceptible to HAV and may be infected by either oral or percutaneous inoculation of virus.[19,20] Although disease in these primates is usually mild compared with symptomatic infections in adult humans, the course of the infection is otherwise very similar. Infection of the hepatocyte is central to the pathogenesis of hepatitis A. Studies with animal models have provided conflicting evidence for the replication of virus within the gastrointestinal epithelium, even though relatively large amounts of virus are present in feces from 1 to 4 weeks after exposure (Fig. 29-2). However, strong data support replication of the virus within crypt cells of the small intestine.[21]

Fecal shedding of the virus reaches its maximum just prior to the onset of hepatocellular disease, at which point the individual is probably most infectious. HAV, replicated predominantly within hepatocytes, is present in the bile and feces.[22] Viral antigen also has been detected within the cytoplasm of hepatocytes, as well as within germinal centers of the spleen and lymph nodes and along the glomerular basement membrane in some primates.[23] There is an extended viremia that

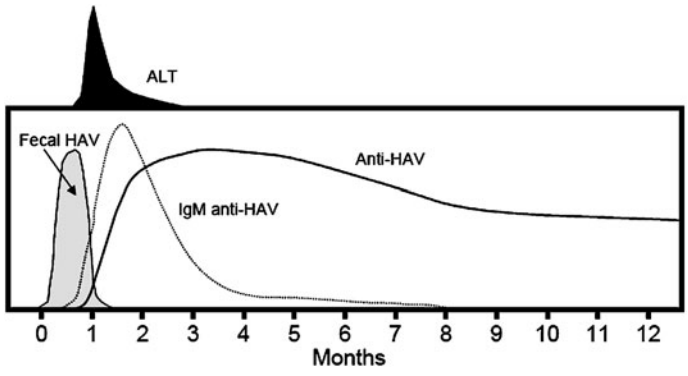

FIGURE 29-2. Typical clinical and virologic course of HAV infection. Temporal patterns are shown for the fecal excretion of HAV, the short-lived IgM-specific anti-HAV response, and the long-lasting total anti-HAV response. At the top is shown the serum ALT pattern, which reflects the acute liver injury associated with this infection.

persists for several weeks during the prodrome and early clinical phase of the illness; it roughly parallels the shedding of virus in the feces but is of much lower magnitude.[24] At the onset of hepatic inflammation in experimentally infected primates, the titer of infectious virus is greatest in liver, followed by feces, and then serum. The situation is likely to be similar in infected humans. Viral RNA may be detected in the feces for weeks after the onset of symptoms, but it is likely associated with only very low infectivity after the first 2 weeks of illness. Chronic fecal shedding of virus has not been observed. Epidemiologic studies noting the disappearance of HAV from closed populations with the passage of time argue against its existence.[25] Relatively prolonged shedding of the virus has been reported in infected premature infants[26] but has not been documented in other immunocompromised persons.

The mechanisms responsible for hepatocellular damage are poorly characterized. However, type A hepatitis appears to be due to an immunopathologic response to infection of the hepatocyte, rather than to a direct cytopathic effect of the virus. HLA-restricted, virus-specific, cytotoxic, CD8+ T cells have been recovered from the liver of persons with acute hepatitis A.[27–29] Virus-specific cytotoxic T cells have been shown to secrete gamma interferon, which likely stimulates the recruitment of additional, nonspecific inflammatory cells to the site of virus replication within the liver.[30] A recent study found that patients with fulminant hepatitis A were more likely to have low or undetectable serum HAV RNA at presentation compared to those with a nonfulminant course, lending further support to the role of host immune response in hepatocellular damage.[31]

Immunity

Little is known about the innate immune response to HAV. However, like many other viruses, HAV has evolved mechanisms to block interferon-mediated innate responses.[32] Protective immunity to HAV is conferred by antibody to the

virus (anti-HAV), which generally appears in the serum concurrent with the earliest evidence of hepatocellular disease (Fig. 29-2). This early antibody largely comprises IgM, although IgG may also be present shortly after the onset of symptoms.[33] IgG anti-HAV persists for life and confers protection against reinfection.[34] Reexposure of seropositive individuals may lead to increases in anti-HAV titer but is not associated with liver disease.[35] Both fecal and serum IgA anti-HAV have been described,[36] but the role of secretory immunity in protection against HAV infection appears to be very limited.[37] Both NK cell and virus-specific, HLA-restricted cytotoxic T-cell activities have been described.[27,29,38] Along with the induction of interferon synthesis, such cellular effector mechanisms are likely to play an important role in clearing virus from the infected liver.

Transmission

With a few notable exceptions, the transmission of HAV between individuals is by the fecal–oral route, which includes sexual practices, such as oral–anal contact (see below). The potential for household transmission and even common-source outbreaks is enhanced by the large amounts of virus present in feces and the extraordinary physical stability of the virus.[39] Virus is concentrated from contaminated coastal waters by filter-feeding shellfish; hepatitis A may result if such shellfish are ingested inadequately or uncooked. In experimentally infected nonhuman primates, HAV has been detected in saliva during the incubation period.[40] However, transmission by saliva has not been demonstrated.

Percutaneous transmission of HAV has been documented with transfusion of blood and blood products, but such instances are relatively rare because the frequency of viremia (which only occurs during acute infection) is exceptionally low in blood donor populations. Nonetheless, outbreaks of hepatitis A have been reported among users of injection and noninjection drugs in Australia, Europe, and North America. In the United States, users of injected and noninjected methamphetamine have accounted for up to 48% of reported cases during certain outbreaks.[41,42] In addition, injection-drug users (IDUs) have a higher prevalence of anti-HAV than the general U.S. population. Transmission among IDUs probably occurs through both fecal–oral and percutaneous routes. Although not widely appreciated, it seems likely that HAV is often transmitted percutaneously among IDUs who share paraphernalia for the preparation and injection of drugs.[43–44] Viremia persists for several weeks during acute infection,[24,40] and the exceptional physical stability of the virus (which exceeds that of HBV or HCV) would favor such transmission. Within the United States, the reported frequency of hepatitis A among such individuals has remarkably paralleled that of hepatitis B and hepatitis C, peaking in the late 1980s and since declining substantially.

EPIDEMIOLOGY

Population studies

The incidence of HAV infection is highly related to the current level of hygiene and sanitation, and the infection is most endemic in the less developed parts of the world, where poor socioeconomic conditions facilitate transmission of the virus. In the developed world and in some developing countries, the seroprevalence of HAV infection has declined, presumably because of improvements in hygiene associated with rising socioeconomic conditions.[45,46] Because of this trend, the percentage of the adult population susceptible to the virus has undoubtedly increased and will probably continue to do so. In testing carried out as part of the third U.S. National Health and Nutrition Examination Survey between 1988 and 1994, anti-HAV was detected in 31% of Americans over 6 years of age.[47] The prevalence of antibodies increased with age and was higher among foreign-born immigrants (especially those of Mexican-American ethnicity). These results confirm and update earlier results showing that the prevalence of anti-HAV is related to age as well as socioeconomic factors within the United States.[48] The age-related nature of antibody prevalence in some Western countries appears to be due largely to a cohort effect created by the decreasing incidence of HAV infection. This general trend toward decreased incidence in developed countries pre-dated the introduction of hepatitis A vaccine but has likely been accelerated by it in countries that have embraced immunization.[46] By 2004, reported cases of hepatitis A had dropped to an all-time low in the United States, approximately 1.9/100,000 persons per year.[46]

In contrast to the United States and other developed countries, most infections occur during early childhood in many developing nations,[49] often at an age at which specific symptoms of hepatitis A are minimal or absent (see below). In these countries with highly endemic infection, virtually the entire population has been infected and is immune by age 10.[50] In other developing countries, sanitary conditions have improved. Although transmission among young children is still common, a higher proportion of adolescents and adults remain susceptible and, when infected with HAV, are likely to develop symptomatic illness. The potential impact of this transitional pattern is typified by an epidemic of hepatitis A in Shanghai, which reportedly involved over 300,000 persons in early 1988.[51]

Endemic hepatitis A

The vast majority of HAV infections occur sporadically, presumably as a result of person-to-person spread of virus. Transmission occurs most frequently among close contacts, especially in households and extended family settings.[52] Because the majority of children have asymptomatic or

unrecognized infections, they play a key role in HAV transmission and serve as a source of infection for others. In one study of adults without an identified source, 52% of their households included a child aged <6 years, and the presence of a young child was associated with HAV transmission in the household.[53] In studies in which serologic testing of the household contacts of adults without an identified source of infection was performed, 25–40% of contacts aged <6 years had serologic evidence of acute HAV infection (IgM anti-HAV).[54,55] Recommendations to immunize children against hepatitis A in states having consistently increased incidence rates of the disease were made in the late 1990s and have been associated with dramatic reductions in disease incidence.[46]

Sexual transmission

Hepatitis A, like other predominantly enteric infections, may be transmitted during sexual activity. However, the importance of sexual behavior in determining the risk of HAV infection varies widely among different populations. Sexual activity undoubtedly plays a greater role in the spread of HAV in industrialized nations, where most adolescents and adults are susceptible, than in developing nations, where HAV is highly endemic and most of the population is immune. Sexual activity also plays a greater role in the spread of HAV when sexual practices facilitate fecal–oral exposures. Thus, the risk for infection is particularly high among men who have sex with men (MSM).

Hepatitis A outbreaks among MSM have been reported frequently. Cyclic outbreaks have occurred in urban areas in the United States, Canada, Europe, and Australia and can occur in the context of an outbreak in the larger community.[56–65] While some studies of these outbreaks identified specific sexual practices, such as higher numbers of partners and oral–anal contact, as risk factors for infection, other studies did not identify such associations.

Early seroprevalence studies also demonstrated an increased risk of HAV infection among MSM. In a study from Seattle, 30% of 102 MSM recruited from an STD clinic had anti-HAV antibodies, compared with only 12% of age- and socioeconomically matched heterosexual males.[56] The risk of previous infection was related to age, number of sex partners, and duration of homosexuality. In another study from San Francisco, 28% of MSM, aged 17–22 years, had serologic evidence of past infection.[44] Anti-HAV seropositivity was independently associated with Hispanic ethnicity, less than a high school education, and a history of more than 50 lifetime male sexual partners. Recent infection was documented in 3.3% of susceptible men. It was independently associated with insertive anal intercourse and the sharing of contaminated needles.[44] In the Seattle study,[56] an annual infection rate of 22% was observed when seronegative MSM were followed prospectively. Men reporting frequent oral–anal exposure were found to be at significantly increased risk of becoming infected with HAV.[56] In retrospect, it is apparent that an epidemic of hepatitis A had occurred among MSM in Seattle at the time of this study. Most of the men who were studied had been homosexual for many years (mean = 12.4 years for those without anti-HAV). If the annual risk of acquiring hepatitis A were constant at 22%, the expected antibody prevalence would have been far greater than the observed 30%. This periodicity is further demonstrated by the results of seroprevalence studies of MSM conducted during the past 10 years, which have not consistently demonstrated an elevated prevalence of anti-HAV compared with a similarly aged general population.[66] An increase in the pool of susceptibles increases the probability of disease, when HAV is reintroduced into the community. Recent incidence data from the United States have shown highest hepatitis A rates among men aged 25–39 years.[67]

An association between hepatitis A and sexual activity is more difficult to demonstrate in countries with moderate-to-high endemicity of infection. In a study carried out in Madrid, Spain, a region where hepatitis A is moderately endemic, there were no differences in the prevalence of anti-HAV in homosexual and heterosexual men.[68] At an average age of 28–29 years, 43–47% of these men were positive for anti-HAV antibodies.[68] However, a history of oral–anal contact was associated with anti-HAV seropositivity independent of sexual orientation.

Despite this evidence for sexual transmission of HAV, hepatitis A differs from most other STDs in at least two important ways. First, infection with the virus produces solid immunity so that symptomatic reinfection never occurs. Second, the infected individual is infectious for a relatively brief period of time. There is no prolonged carrier state. Although there has been little effort to formally model the sexual transmission of HAV, these facts suggest that several conditions may be required to sustain sexual transmission of HAV within a population. These include (1) a high degree of susceptibility among the population at risk, as defined by negative tests for anti-HAV, (2) sexual promiscuity, so that multiple partners may be exposed during the relatively brief period when virus is shed, and (3) sexual practices facilitating fecal–oral spread of virus. Epidemics of hepatitis A among urban MSM have generally included all of these elements. The sporadic nature of these outbreaks further suggest that introduction of virus into the sexually active population may be an additional requirement.[56,60,62–64]

Although vaccination of children can result in fewer adult cases associated with contact with children, transmission among selected groups of adults can be sustained in the absence of transmission among children. Thus, within the United States, cases increasingly are concentrated among adults in identified high-risk groups, such as international travelers, users of illegal drugs, and MSM. The relatively high

disease rates among adult men younger than 40 years are a manifestation of this phenomenon.

CLINICAL MANIFESTATIONS OF HEPATITIS A

In the individual patient, acute illness due to HAV is indistinguishable from that due to hepatitis B or hepatitis C.[69] The incubation period of hepatitis A is relatively short, averaging about 4 weeks (Fig. 29-2). Under the age of 3 years, less than one in 10 infected children develop symptoms of hepatitis, whereas most infected adults are symptomatic.[70] Symptoms are often abrupt in appearance, although there may be a prodromal period of low-grade fever, malaise, headaches, and myalgias. Anorexia, nausea, and vomiting occur early in the illness, and diarrhea is not uncommon, especially among children.[69] The specific diagnosis of viral hepatitis, however, is often not suggested until the occurrence of dark urine or jaundice. Serum aminotransferase elevations are similar in magnitude to those seen in acute hepatitis B, although they generally do not persist as long. Most infected individuals will have normal aminotransferase levels by 6 weeks after the onset of symptoms, although 10–20% of cases may have minor enzyme abnormalities persisting for up to 3 months and occasionally longer.

Chronic viral hepatitis has not been documented to follow HAV infection, and there is no evidence of long-term persistence of the infection. However, it has been suggested that in rare instances HAV infection may trigger the onset of chronic autoimmune liver disease.[71] Although jaundice may occasionally be prolonged for several weeks or more ("cholestatic hepatitis"), it is not indicative of severe hepatocellular disease and uniformly resolves with time.[72] Occasional cases of "relapsing hepatitis A" have been noted. These patients have symptomatic and biochemical evidence of recurrent hepatitis, usually occurring within several months of acute type A hepatitis.[72,73] The pathobiology of this condition is uncertain, but it always resolves without progression to chronic hepatitis. Hepatitis A accounts for less than 10% of all cases of fulminant hepatitis,[74] and the mortality in acute symptomatic hepatitis A is probably less than 0.1–0.2%. In an initial report from the U.S. Acute Liver Failure Study Group that included 354 patients enrolled between 1998 and 2001, 16 (4.5%) had hepatitis A.[75] A recent update that included 973 patients enrolled up to 2006 found that only 30 (3%) had hepatitis A (Lee WM, personal communications, September 2006). Several reports suggest that patients with underlying liver disease are more likely to develop fulminant hepatitis when infected with hepatitis A. Patients with acute liver failure due to HAV are more likely to recover spontaneously than those with acute liver failure due to HBV infection.

DIAGNOSIS OF HEPATITIS A

The diagnosis of hepatitis A rests entirely on serologic methods (Table 29-2). Anti-HAV is usually measured by solid-phase enzyme-linked immunosorbent assay (ELISA). Absence of anti-HAV is strong evidence against current infection with HAV. However, the detection of anti-HAV in a patient with hepatitis does not prove infection is recent or responsible for current symptoms. A specific serodiagnosis requires the demonstration of IgM anti-HAV, which is present in virtually all patients with acute hepatitis A (Fig. 29-2). IgM anti-HAV may be detected by sensitive antibody-capture immunoassays for as long as 6 months after the onset of symptoms.[33,76]

Table 29-2. Common Diagnostic Markers of Hepatitis Virus Infections

	Diagnostic Marker	Significance of Marker
HAV	Anti-HAV	Past or present infection, immunity to HAV
	IgM anti-HAV	Recent acute infection with HAV
HBV	HBsAg	Current acute or chronic infection with HBV
	HBeAg	High-titer HBV carrier, high infectivity
	HBV DNA	Current infection (quantitative measure of viremia)
	Anti-HBs	Immunity to HBV (vaccine or natural infection)
	Anti-HBc	Past or present infection with HBV
	IgM Anti-HBc	Recent acute infection with HBV
	Anti-HBe	Reduced viral replication (except with precore mutants)
HCV	Anti-HCV (ELISA)	Probable infection with HCV (~15% may have cleared infection)
	Anti-HCV (RIBA)	Recombinant immunoblot confirms screening ELISA
	HCV RNA	Definitive evidence of current infection (bDNA or RT-PCR assay)
HDV	Anti-HD	Active or recent infection with HDV

PREVENTION OF HEPATITIS A

Passive immunization

Immune globulin (IG), if administered within 2 weeks of exposure, is 80–90% effective in protecting against illness associated with HAV infection.[77] Infection is also probably prevented if IG is given soon enough after exposure. IG confers immediate protection against hepatitis A, while hepatitis A vaccine does not produce protective levels of antibodies to HAV until 2–4 weeks after active immunization (see next section). Thus, IG continues to have an important role in the management of exposed persons.[78–80] Postexposure prophylaxis with IG (0.02 mL/kg intramuscularly) is recommended for household and sexual contacts of patients with hepatitis A.[80] Postexposure prophylaxis is generally not recommended in the setting of a common source outbreak, because such outbreaks are usually recognized only well into their course. IG has not been demonstrated to be effective in prevention of disease more than 2 weeks after exposure.

Active immunization

Whole cell inactivated vaccines have largely replaced IG for preexposure prophylaxis of hepatitis A.[7,9] Hepatitis A vaccines contain formalin-inactivated viral particles that are produced in cell culture, purified, and adsorbed to aluminum hydroxide.[81,82] Immunization elicits serum neutralizing antibodies (anti-HAV), which protect against both infection and disease.[83] At present, two similar vaccines are licensed in the United States for persons 12 months old or older: *Havrix* (GlaxoSmithKline Biologicals) and *Vaqta* (Merck). Both are produced from virus grown in infected human diploid fibroblasts. Each vaccine is available in adult and pediatric/adolescent formulations (for persons at least 18 years old, there is a combination hepatitis A and hepatitis B vaccine, *Twinrix* [GlaxoSmithKline Biologicals]). Comparative clinical trials of these vaccines have not been reported, but they appear to be comparable with respect to their clinical performance. Reactogenicity is relatively low and similar to that reported with hepatitis B vaccines. The most common adverse events include soreness at the site of intramuscular injection, which occurs in 21–56% of recipients. Fever has been reported in up to 4%.[84] Anaphylaxis, Guillain–Barré–Landry syndrome, and more obscure neurologic syndromes have been reported rarely. For adults over 17–18 years of age, both vaccines are given on a two-dose schedule, usually with 6–12 months intervening between doses. The package insert should be reviewed for specific details concerning administration.

Efficacy trials of hepatitis A vaccines have been limited to children, but it is reasonable to assume that similarly impressive results would be achieved in adults who develop comparable anti-HAV responses. In a randomized, placebo-controlled trial, carried out among children aged 2–16 years, in Monroe County, New York, a single 25-U dose of *Vaqta* provided complete protection against symptomatic hepatitis A during a seasonal outbreak of disease (95% confidence interval was 87–100%).[85] The last case of hepatitis in an immunized child occurred 18 days after vaccine administration. Similar protection was observed in Thai children who had completed a primary immunization series with two 360 El. unit doses of *Havrix* (95% confidence interval = 74–98%).[86] Immunization also has been shown to prevent asymptomatic infection.[87]

Hepatitis A vaccine is recommended for persons at increased risk of hepatitis A.[80] This includes MSM, injection and non-injection illicit drug users, international travelers to hepatitis A endemic regions, and others. The decision to use vaccine in any risk group should reflect the perceived risk, the potential severity of infection, and the cost of the vaccine. The Advisory Committee on Immunization Practices of the U.S. Public Health Service recently endorsed universal childhood immunization against hepatitis A within the United States.[80] This followed recommendations a decade earlier to immunize children aged 2 years and older in 17 states within the United States, where hepatitis A incidence was especially high, a recommendation that was followed by sharp overall reductions in the incidence of the disease, not only in children but also in adults.[46,88] The presence of anti-HAV obviates the need for immunization in an individual, but serologic testing is not necessary prior to immunization. Preimmunization screening is not likely to be cost effective, unless the prevalence of antibody exceeds 30%, and, thus, is not warranted in most U.S. populations.

HEPATITIS B

HEPATITIS B VIRUS

Physical and chemical characteristics

HBV, a hepadnavirus, is one of a family of related DNA viruses infecting the livers of a variety of avian and mammalian species. The HBV virion (also known as the Dane particle) is a complex, double-shelled, 42-nm spherical particle, with an outer surface envelope surrounding a core structure containing a small DNA genome (Fig. 29-3). This genome is unique among human viruses in that it is a circular DNA molecule that is double stranded for 50–85% of its length, with a total genome length equivalent to double-stranded DNA of approximately 3200 base pairs[89–91] (Fig. 29-4). The genomes of a number of HBV strains have been molecularly cloned and fully sequenced. The partially double-stranded DNA consists of a long strand, which is (−)-sense (i.e., antimessenger sense), and a shorter (+)-sense strand, which overlap at their 5′ ends (see Fig. 29-4).[92] Within the (+)-strand, there are four overlapping, open-reading frames utilizing all three

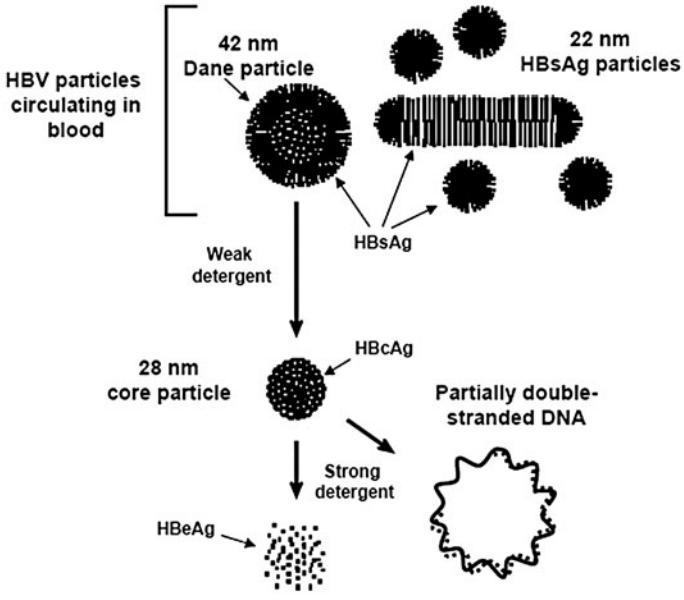

FIGURE 29-3. Structure of HBV. A variety of HBV particles are present in the blood of an infected person. These include the 42-nm-diameter infectious virion (Dane particle) and usually a much greater number of smaller, noninfectious, spherical or elongated HBsAg particles. Treatment of the Dane particle with weak detergent removes the surface envelope (HBsAg), leaving a smaller core particle (HBcAg). Stronger detergent treatment disrupts the core, releasing soluble HBeAg and the partially double-stranded DNA genome. (Modified from a figure courtesy of Dr. A.J. Cann, Leicester University.)

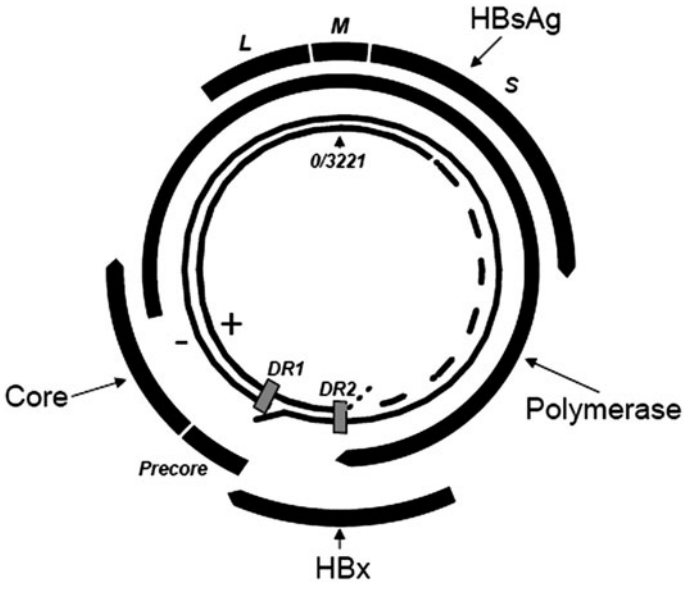

FIGURE 29-4. Organization of the circular 3.2-kb HBV genome. At the center of the figure is a schematic depicting the complementary linear full-length (−)-strand and partial (+)-strand DNAs, which are held in a relaxed circular conformation by the cohesive overlap formed by their 5′ ends. The solid lines represent DNA present within Dane particles, while the large dashed line represents the (+)-strand DNA segment that is synthesized following entry of the virus into the cell. Small boxes represent the two direct repeat elements (DR1 and DR2). The four overlapping open-reading frames are shown at the periphery: HBsAg (which encodes the L, M, and S envelope proteins), DNA polymerase/reverse transcriptase (pol), X, and core (which encodes both HBcAg and HBeAg).

translation frames (i.e., encoding different amino acids from the same nucleotide sequences) (Fig. 29-4). Given the small size of the genome, this parsimonious use of the genomic DNA provides for a relatively large amount of genetic information. There are no segments of the DNA that are not translated into protein. The four open-reading frames encode a DNA polymerase/reverse transcriptase, the core protein (and the closely related precore protein, which is converted to the "e" protein by post-translational processing), a family of three surface envelope proteins with common carboxy termini (see below), and the "X" protein. This latter protein has been described to have numerous interactions with host cell proteins and is a nonspecific transactivator of host cell transcription.[93,94] However, its precise role in viral replication and the pathogenesis of hepatitis B disease remains obscure.

The DNA genome of HBV replicates via reverse transcription of an intermediate RNA molecule (the "pregenome"), directed by the viral DNA polymerase/reverse transcriptase.[92] The replication cycle of HBV thus resembles in gross detail that of the RNA-containing retroviruses, including the human immunodeficiency virus (HIV) (see Chapter 20). Indeed, the genomic organizations of these viruses bear some superficial similarities (Fig. 29-5). The principal difference in the replication cycles of these virus families lies in the fact that the DNA form of the HBV genome is packaged for export from the cell in virus particles, while it is the RNA form of the viral genome of HIV and other retroviruses that is present in extracellular viral particles. The clinical significance of these similarities in the replication cycles of HBV and HIV is reflected in their shared sensitivity to antiviral suppression by certain nucleoside analog inhibitors of reverse transcriptase, such as lamivudine[95] (see Chapter 66).

In addition to the genomic DNA, the core of the HBV particle contains the DNA polymerase/reverse transcriptase, which also has an associated RNase H activity. Within the core particle, the DNA polymerase is active and in the presence of appropriate deoxynucleoside triphosphates will use the single-stranded, (−)-sense HBV DNA as a template to extend the (+)-sense molecule[96] (see Fig. 29-4). The major core protein is a 21-kDa molecule with specific antigenic activity (hepatitis B core antigen, or HBcAg). HBcAg is released from the intact virion by detergent treatment, which removes the surface envelope and leaves an intact 27-nm core particle. More vigorous disruption of the virus core releases an antigenically distinct, soluble viral antigen (HBeAg)[97] (Fig. 29-3). HBeAg is closely related to the core protein, as it is the product of proteolytic processing of the precore molecule and thus translated from the same reading frame.[98] The DNA sequence unique to the precore region encodes a signal sequence that directs the precore protein into a secretory pathway (see Fig. 29-4). During this process, both the amino terminal signal peptide and a carboxy terminal peptide are

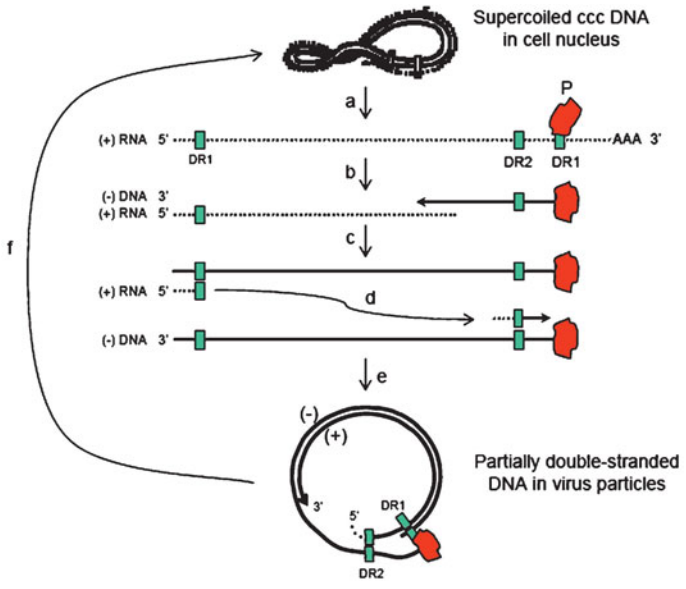

FIGURE 29-5. Schematic depicting the HBV replication cycle. The transcriptionally active form of the viral DNA is the completely double-stranded, supercoiled cccDNA that is present within the nucleus of the cell (shown at top of the figure) [1]. RNA transcription from cccDNA results in a greater-than-genome length (+)-strand "pregenome" pgRNA containing two copies of the DR1 direct repeat [2]. Protein-primed (P) reverse-transcription with associated degradation of the pregenomic RNA template is carried out by the viral DNA polymerase/reverse transcriptase and leads to production of genome-length (−)-strand DNA [3]. This occurs within immature core particles and is the step in replication that is blocked by lamivudine. Subsequent RNA-primed synthesis of the (−)-strand DNA [4] results in the partially double-stranded form of the genome found in mature virions [5]. Completion of DNA synthesis, removal of the primer moieties, and repair of the DNA strands lead to new cccDNA following infection of a subsequent cell by mature virions [6]. (Modified from a figure courtesy of Dr. A.J. Cann, Leicester University.)

cleaved from the precore protein to generate HBeAg. Thus, although the soluble HBeAg and particulate HBcAg have completely distinct antigenic specificities, these molecules have identical amino acid sequences throughout much of their length. The immune responses to these closely related molecules comprise very different Th-cell subsets.[99] Several lines of evidence suggest that the function of HBeAg may be to induce immune tolerance to HBV, thereby promoting viral persistence.[100]

HBV variants with mutations within the precore region have been described.[101–104] These precore mutants are unable to express HBeAg due to the presence of a stop codon within the precore region (see Fig. 29-4) but retain the ability to replicate and express the core protein (HBcAg). Precore variants usually emerge during the course of chronic HBV infection, around the time of HBeAg to anti-HBe seroconversion. De novo infection with precore variants is uncommon. Mutations in the basal core promoter region have also been described.[105] These mutations downregulate HBeAg production and are selected during the course of chronic HBV infection.

The surface envelope surrounding the virus core is a complex structure, containing as its major antigen a 24-kDa glycoprotein (hepatitis B surface antigen, or HBsAg, also called the S protein, and previously known as "hepatitis associated antigen" or "Australia antigen"). An antigenic determinant common to all HBV strains ("a") is associated with HBsAg. In addition, two pairs of mutually exclusive allelic antigens ("y" vs. "d," "w" vs. "r") have been defined.[106] Of the four possible major serotype combinations, only three ("ayw," "adw," and "adr") have been found with any degree of frequency, and these occur in distinct, but possibly changing, geographic and demographic distributions. More recently, HBV has been classified, based on nucleotide sequences, into eight genotypes, A–H, the prevalence of which vary in different geographical regions.[107] Recent data suggest that HBV genotypes may play a role in determining the activity and risk of progression of liver disease, as well as response to interferon therapy.

In addition to HBsAg, the Dane particle contains two related proteins, large envelope (p39 and gp42) and middle envelope (gp33 and gp36), each of which exists as a doublet due to partial glycosylation. L, M, and S thus denote the large, middle, and small envelope proteins. These share in common the 226 amino acids of the S protein (HBsAg) at their carboxy terminus. They are coterminal translation products of the same open-reading frame but are produced from distinct mRNAs, in which translation is initiated from different in-frame AUG initiation codons[89,90] (Fig. 29-4). The roles of the L and M proteins in the biology of HBV remain controversial, although both have been proposed to contain the virion receptor binding site. The inclusion of these antigens in future vaccines may result in improved immunogenicity (see below). HBsAg is usually produced in excess by infected hepatocytes, and, in most carriers of HBV, genome-free, subviral, 22-nm spherical or filamentous HBsAg particles greatly outnumber the genome-containing, infectious Dane particles in the blood (Fig. 29-3). These subviral particles, as well as the surface envelope of the Dane particle, also contain host cell-derived materials, including human albumin. While all three envelope proteins, L, M, and S, are expressed on the surface of Dane particles, only the small surface protein, S, is present in subviral particles.

Replication cycle of HBV

Attempts to propagate the virus in conventional cell cultures generally have not been successful. However, cells transfected with cloned HBV genomic DNA produce Dane particles, which are detectable by electron microscopy and infectious for chimpanzees.[108,109] Such cells have been useful in dissecting the molecular steps in HBV replication and in assessing the response of HBV to candidate antiviral agents. However, no type of cultured cell is highly permissive for viral replication.

Early studies with the duck hepadnavirus (duck hepatitis B virus, or DHBV) and subsequent work with HBV led to the conclusion that replication of this DNA virus proceeds via an

RNA genomic intermediate.[92] This conclusion was based on the identification of immature intracellular core particles containing full-length RNA genomic intermediates and reverse transcriptase activity and the observation that synthesis of (−)-strand viral DNA is not inhibited by actinomycin-D (which typically blocks DNA-directed but not RNA-directed DNA synthesis). Current concepts concerning the replication of HBV may be summarized briefly as follows (Fig. 29-5).[89–91] After attachment and penetration of the hepatocyte, synthesis of the incomplete (+)-strand of the gapped virion DNA is accomplished, possibly under direction of a cellular enzyme(s). Subsequent ligation of the gapped DNA (relaxed circle form) results in a fully double-stranded, covalently closed circular DNA (cccDNA), which exists as a supercoiled episomal form in the nucleus. This supercoiled episomal DNA does not replicate a DNA-dependent DNA synthesis mechanism and serves only a transcriptional role.[110] Nonetheless, its amplification and persistence in the cell is central to the replication cycle of the virus. The cccDNA is the template for the subgenomic (+)-strand RNA transcripts encoding the envelope proteins, as well as a somewhat greater than full-length (+)-sense RNA pregenome (pgRNA). There is only a single poly(adenylic acid) addition site located within the core gene, and all the messenger RNAs are therefore 3′ coterminal. The core protein and the DNA polymerase are translated from pgRNA, while the X protein appears to be expressed from a unique transcript. The pgRNA serves a dual role, however, as it is also encapsidated within immature cytoplasmic core particles along with the DNA polymerase (reverse transcriptase). Within these immature core particles, the long (−)-sense DNA strand is synthesized by reverse transcription of the pgRNA, probably with concomitant degradation of the RNA directed by an associated RNase H activity. Subsequently, (+)-sense DNA is replicated from the full-length (−)-strand, but this process is often incomplete, resulting in a partially double-stranded DNA molecule encapsidated within the Dane particle as it exits the cell (Fig. 29-5).

The mechanism by which the cellular pool of supercoiled cccDNA is expanded is uncertain. It has been suggested that amplification might be the result of intracellular nuclear import of nucleocapsids[110]; alternatively, it might result from superinfection of the hepatocyte by additional virions. Either way, it is important to note that the maintenance of the cellular pool of supercoiled HBV cccDNA is not as dependent on the viral reverse transcriptase activity as are relaxed circular DNA forms of the genome. Thus, nucleoside analogs that are approved at present for the treatment of hepatitis B have no significant direct effect on cccDNA. Recent studies have shown that treatment with adefovir or pegylated interferon can decrease the pool of supercoiled cccDNA, but the effect on cccDNA is substantially less than the reductions in total HBV DNA.[111–113] The resistance of cccDNA to nucleoside analogues that act primarily through inhibition of reverse transcription of pgRNA and the long half-life of infected hepatocytes (and hence cccDNA) account for the high rate of viral relapse when treatment is stopped. Mathematical modeling estimates that it would take more than 10 years to eliminate cccDNA, even with nucleoside analogs that have a low propensity to generate drug-resistant mutants.[111] Thus, antiviral therapies for hepatitis B are suppressive rather than curative, much as acyclovir is not curative for genital herpes infections. During viral replication, double-stranded HBV DNA may become integrated at a low frequency into host chromosomal DNA. Unlike conventional retroviruses, however, this process is not obligatory for viral replication and appears to be a random event.

Pathobiology

The pathobiology of HBV infection is complex and incompletely understood.[91] Following exposure, virus presumably gains access to the liver via the blood stream. HBsAg is found within the cytoplasm of hepatocytes, whereas HBcAg is usually restricted to the hepatocyte nucleus. There is evidence that HBV may also replicate within certain mononuclear cells of the bone marrow or blood,[114] but the liver is the primary site of HBV replication. This tropism may result in part from the involvement of tissue-specific virus enhancer regions and promoters regulating HBV gene expression, the presence of virus-specific receptors on only certain cell types, or both. There is no evidence for replication of the virus at mucosal surfaces.

Acute hepatitis B

The majority of infections are self-limited (Fig. 29-6, top panel). HBsAg may appear in the blood as early as 6 days after percutaneous exposure, although this interval is usually from 1 to 2 months after mucosal exposure.[115] Shortly afterward, circulating Dane particles, HBeAg, and DNA polymerase may be detected. This stage of detectable viremia is often brief. HBsAg synthesis is more abundant and typically more persistent, however, and it may be detected for up to 5 months or in some cases even longer.[115] The first humoral immune response to the virus, consisting of IgM antibody to HBcAg (IgM anti-HBc), develops shortly after the appearance of HBsAg.[116,117] Following the disappearance of circulating DNA polymerase and HBeAg, antibody to HBeAg (anti-HBe) may also be detected. Almost all (95–99%) healthy adults who are infected with HBV will eventually clear HBsAg from the circulation, and most, but not all, will develop antibody to HBsAg (anti-HBs). There may, however, be a delay of weeks to months prior to the first appearance of anti-HBs, even after the disappearance of HBsAg. During this so-called "window period," anti-HBc and anti-HBe are the only serum markers of HBV infection. Symptoms of hepatitis usually develop after HBsAg has been circulating in the blood for 3–6 weeks and usually occur while HBsAg is still

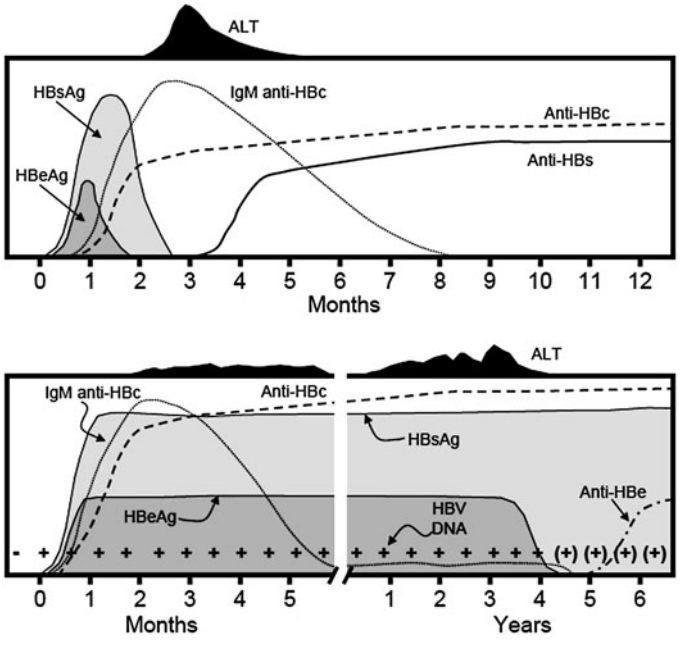

FIGURE 29-6. **(Top panel)** Typical virologic and serologic course of acute, self-limited HBV infection. **(Bottom panel)** Typical virologic and serologic course in a patient with chronic HBV infection, in which the infection is not cleared and persistent HBV infection becomes established. Clinical evidence of hepatitis (e.g., ALT elevation) is often very limited during the acute stages of such infections. Late clinical complications include cirrhosis, and hepatocellular carcinoma. Persistently infected patients with chronic hepatitis B can be distinguished from those with acute hepatitis B by the presence of high-titer IgM antibody to HBcAg in the latter. The degree of virus replication during the chronic phase of the infection is reflected in the presence of serum HBeAg and serum HBV DNA (not shown). Patients with chronic HBV may undergo a late HBeAg "seroconversion" event, in which HBeAg is lost and anti-HBe appears; most of these individuals will continue to have HBV DNA detectable at low levels, shown as "(+)." Nonetheless, this is associated with an improved prognosis and is an important endpoint for antiviral therapy.

present (approximately 90% of patients). Symptoms may develop during the "window period," however, or even after the appearance of anti-HBs. The appearance of anti-HBs signals the resolution of the infection. This antibody is protective against reinfection[118] and represents responses against the S, M, and L envelope proteins. Anti-HBc and anti-HBs usually persist for years following infection, with anti-HBs conferring protection against reinfection on reexposure.

Chronic hepatitis B

A small proportion (1–5%) of infected adults fail to resolve the infection and become chronic HBsAg carriers (Fig. 29-6, bottom panel). Such individuals frequently have little or no evidence of acute liver disease when initially infected. Development of the chronic carrier state is more frequently seen in individuals who are immunocompromised (those with underlying HIV infection).[119] Almost all infants who are infected neonatally become carriers. HBsAg may persist in the blood of these individuals for years in large and relatively constant amounts and may be associated with the presence of either HBeAg or anti-HBe.

Carriers who are positive for HBeAg usually have high serum HBV DNA levels[120]; such carriers should be considered to be especially infectious.[121,122] Chronic HBsAg carriers typically have very high titers of anti-HBc and usually do not have anti-HBs. Atypical individuals, however, may have both HBsAg and anti-HBs directed against a different HBsAg serotype.[123] These individuals should be regarded as infected, since the anti-HBs is not effective in neutralizing the infecting HBV serotype. Some individuals have isolated anti-HBc, with no detectable HBsAg or anti-HBs. These persons may be low-level HBV carriers with subdetectable levels of HBsAg or rarely HBV variants that are not detected by commercially available HBsAg assays. Most persons who are coinfected with HCV or HIV and have isolated anti-HBc have low-level HBV infection.[124] Other persons with isolated anti-HBc have recovered from HBV infection but no longer possess detectable anti-HBs; such persons will develop anamnestic response when given HBV vaccine.[125] Rarely, persons with isolated anti-HBc are in the window phase of acute HBV infection and will test positive for IgM anti-HBc. Isolated anti-HBc may also be due to a false-positive test result.

While most persistent HBsAg carriers are asymptomatic and do not have evidence of significant liver disease, a minority has elevated serum aminotransferases and varying degrees of inflammation and fibrosis on liver biopsy. This histologic lesion may progress in some cases to cirrhosis. Coinfection with HCV or HDV and heavy alcohol consumption may accelerate progression of liver disease. The presence of HBeAg often correlates with high serum HBV DNA levels (up to 11 $\log_{10}$ genome copies/mL) and active liver disease, and conversely seroconversion from HBeAg to anti-HBe in carriers with chronic hepatitis is frequently followed by normalization of aminotransferases[126] (Fig. 29-6, bottom panel). Along with clearance of HBV DNA, this is the desired endpoint in antiviral treatment of HBeAg-positive chronic hepatitis B (see Chapter 66) and has been shown to correlate with decreased risk of liver failure and improved survival.[127] Nonetheless, the use of sensitive assays for detection of HBV DNA has led to the recognition that HBV replication persists in most carriers after HBeAg seroconversion.[91] The majority of carriers enter into an inactive carrier state after HBeAg seroconversion with typically low serum HBV DNA levels (<3 $\log_{10}$ copies/mL) and normal aminotransferases. Approximately 4–20% of inactive carriers have one or more reversions back to HBeAg positivity. Among those who remain anti-HBe positive, 10–30% continue to have elevated aminotransferases and high HBV DNA levels (up to 9 $\log_{10}$ copies/mL) after HBeAg seroconversion. Roughly 10–20% of inactive carriers may have reactivation of HBV replication and exacerbations of hepatitis after years of quiescence.[128–131] Therefore, serial testing is necessary to determine if an HBsAg, HBeAg-negative carrier is truly in the "inactive carrier state" and life-long follow-up is required to confirm that the inactive carrier state is maintained.

Persistent high-level HBV replication and continued hepatic necroinflammation after HBeAg seroconversion is usually associated with the selection of precore and/or basal core promoter mutations. These HBV variants were initially reported in the Mediterranean countries and the Far East but are present worldwide, and their prevalence along with "HBeAg-negative chronic hepatitis" appears to be increasing. A recent study found that precore and/or basal core promoter variants were detected in roughly 30% of patients, with chronic HBV infection presenting to tertiary liver centers in the United States.[132]

Because immunosuppressed patients are less likely to develop overt signs of hepatitis and because replication of large quantities of virus occurs in many completely asymptomatic carriers, it seems likely that the host immune response is intimately involved in the expression of liver disease. Much has been learned about this process from studies of transgenic mice expressing HBV proteins, as well as infected humans. HBV-specific cytotoxic T cells have been shown to be directed against epitopes within both the core and the surface proteins.[133,134] The local expression of IFN-γ and other cytokines by these virus-specific CD8+ cytotoxic effector cells may serve to recruit monocytes and other inflammatory cell types to the site of infection. These appear to contribute significantly to the inflammatory process, but in a fashion that is less specifically directed than the $CD8^+$ cells. Thus, hepatitis associated with HBV infection appears to be immune mediated, rather than a direct result of virus-induced cytopathology. These cellular immune responses play a central role in resolution of the acute infection. $CD8^+$ cells have been shown to be capable of inhibiting a post-transcriptional step in virus replication.[135] Individuals who fail to develop an acute immune response leading to hepatitis following acute infection with HBV are probably more likely to go on to become chronic carriers than those who do develop hepatitis. However, it is interesting to note that long-term persistence of the viral DNA has been documented by sensitive assays even in individuals who have appeared to resolve the infection and who have robust cytotoxic T-cell responses.[136,137] Thus, the virus may persist in individuals who have serologic recovery from acute HBV infection but be held in check by the immune system.[137]

Liver cancer

There is a strong association between persistent HBV infection and primary carcinoma of the liver.[138,141] Infection with HBV usually precedes the development of hepatocellular carcinoma by years, although the tumor occasionally develops during childhood. Integrated HBV DNA is present within tumor tissue in most individuals, but this is not always the case and there is no specific site at which the viral DNA is integrated into the host genome. Apparently random integration of viral DNA may disrupt normal control of cellular growth and differentiation in some cases.[142–144] However, it seems more likely that hepatocellular cancer usually develops as part of a multistep process, in which chronic inflammation, associated with hepatocellular regeneration and increased cellular proliferation, plays a prominent role. Free radicals produced as a product of the ongoing inflammatory response may cause damage to cellular DNA, ultimately contributing to the evolution of hepatocellular carcinoma. This is in line with recent data, suggesting that high serum HBV DNA levels and recurrent exacerbations of hepatitis are associated with an increased risk of hepatocellular carcinoma.[130,145] A similar mechanism of carcinogenesis may account for liver cancer in patients who are infected with HCV, which does not replicate through a DNA intermediate and which thus never integrates its genetic information into the host cell genome (see below). Mutations within tumor-suppressor genes have been noted in many HBV-related hepatocellular carcinomas.[146–148] An additional factor that may contribute to the oncogenic potential of HBV is the promiscuous transcriptional transactivating activity and multiple other suspected functions of the HBx protein.[149]

The association of HBV with hepatocellular carcinoma is found worldwide. Although HBV-related hepatocellular carcinoma is a more significant problem in those countries where the HBsAg carrier rate is high in the general population, chronically infected people who emigrate from these countries contribute disproportionately to hepatocellular carcinoma rates in their adopted countries. Hepatocellular carcinoma is also being recognized as a major problem in MSM with HIV infection, although it appears that this is primarily due to coinfection with HCV rather than HBV.[150,151] Nonetheless, it is increasingly clear that persons coinfected with HBV and HIV have increased mortality from liver disease compared to those who are infected only with HBV or HIV.[152,153] Not surprisingly, immunization with hepatitis B vaccine has been shown to reduce the risk of HBV-related chronic liver disease and hepatocellular carcinoma.[154–156]

Immunity

Infection with HBV induces antibodies directed against each of the individual viral antigens: anti-HBs, anti-HBc, and anti-HBe (Table 29-2, Fig. 29-6). Of these, the antibody most clearly associated with protection is anti-HBs.[118] Protection afforded by anti-HBs extends to all HBV serotypes, although HBV variants have been identified with potential "escape" mutations in the S protein.[157,158] Some evidence suggests that the evolution of such escape mutations may contribute to vaccine breakthroughs in immunized infants who are born to HBV-carrier mothers. However, there is no evidence that the protective efficacy of HBV vaccines is decreasing as a result of these escape variants. The presence of anti-HBe in the blood of an HBsAg carrier generally correlates with reduced

infectivity,[121,159] but there is no evidence that anti-HBe by itself has any protective effect. Although anti-HBs accounts for the protection afforded by immunization, it is very likely that memory T cells also contribute to durable immunity in those who have recovered from hepatitis B. A detailed discussion of the complex roles played by T-cell immunity to hepatitis B are beyond the scope of this chapter, but virus-specific T-cell responses probably contribute to both the liver injury associated with the infection and the control and eventual elimination of the virus.[160,161]

Transmission

HBV is transmitted by percutaneous or permucosal exposure to blood or body fluids that contain blood. Blood is the major source of virus for transmission, and it may contain a very high titer of virus. HBsAg has been found in other serum-derived body fluids of infected individuals, including saliva, vaginal secretions, and semen, and the presence of Dane particles has been confirmed in saliva by electron microscopy.[162] HBV DNA can be detected by nucleic acid hybridization in both saliva and semen of many HBeAg-positive carriers.[163,164] Southern blot analyses have shown that the quantity of virus in saliva and semen is usually 1000-fold less than that present simultaneously in the blood but still may be as high as 10^6 genome copies per mL.[163] HBV carriers with high serum titers of virus are more likely to have virus detectable in these secretions by these relatively insensitive methods. Most of this virus appears to be extracellular. Its presence in saliva and semen presumably reflects leakage from the circulation, and not the replication of virus at oropharyngeal or genital sites. Although studies directly examining the infectivity of various body fluids are limited, virtually any body fluid or secretion from an HBeAg-positive HBV carrier should be considered to be infectious.

Percutaneous exposures associated with HBV transmission have included receipt of blood transfusion or organ or tissue transplant from an infectious donor; IDU, including sharing of injection-preparation equipment; and frequent exposure to blood or needles among health-care workers. Transmission of HBV via transfusion of whole blood and blood components is rare because of donor selection procedures and routine testing of donors for HBsAg and anti-HBc[165] and has been eliminated via plasma-derived products through viral inactivation procedures. Among persons with bleeding disorders cared for at hemophilia treatment centers during 1998–2002 in the United States, no viral hepatitis infections, including HBV, were attributable to blood products received during that time.[166] HBV infection has also become a rare event in health-care workers since implementation of routine hepatitis B vaccination and use of standard precautions to prevent exposure to bloodborne pathogens.[167] Although the number of new cases of IDU-related hepatitis B declined dramatically during the 1990s, the incidence of HBV infection among new injectors remains high, ranging from 10 to 31 per 100 person years.[168–170]

Outbreaks of HBV infections among patients due to contaminated equipment used for therapeutic injections and other health care-related procedures continue to be identified in Western countries and contribute to a substantial burden of infection worldwide.[171] In most cases, transmission resulted from noncompliance with aseptic techniques for administering injections and with recommended infection control practices designed to prevent cross contamination of medical equipment and devices. HBV transmission episodes related to tattooing and acupuncture have also been reported.[172,173]

HBV is commonly transmitted from HBsAg-positive mothers to their infants at or near birth.[121,159] As infected infants usually become chronic carriers, often for life, perinatal transmission of virus contributes disproportionately to maintenance of the carrier pool in areas of high HBV endemicity. The presence of maternal HBeAg or high serum HBV DNA level is associated with an increased risk of transmission of virus to the newborn.[121,159] While intrauterine infection may occur, most infections are probably acquired at the time of birth. Transmission may be due to direct contamination of the infant's circulation with maternal blood at the time of delivery. Testing of cord blood for markers of HBV infection is not helpful in identifying infection in newborns. If the infant has no evidence of infection by the fourth month of life, he or she has a high probability of remaining free of infection subsequently. Infants who receive postexposure prophylaxis (HBIG and vaccine series) should be tested for anti-HBs and HBsAg at 9–15 months of age to confirm protection or detect "breakthrough" infections, which occur in a small proportion of immunized infants.[174] There is no epidemiologic evidence to incriminate breast feeding as a risk factor in transmission of the virus. Immunization is very effective in preventing maternal–infant transmission of HBV (see below).

Transmission of HBV from HBsAg carriers to their household contacts is well documented.[175] Follow-up studies of the susceptible household contacts of children with chronic HBV infection found that new HBV infections developed in 14–60% of their household contacts.[176,177] Data from cross-sectional studies have demonstrated that household contacts of HBV-infected persons are more likely to have serologic markers of HBV infection (25–30%) than the household contacts of persons not infected with HBV (2–8%).[178,179] When the chronically infected person was a child, serologic evidence of HBV infection was more common in other children in the household than in adults. These types of epidemiologic surveys suggested that "horizontal" transmission to young children was probably the most common means of transmission of this virus worldwide.[180] The exact mechanism by which this occurs is not known, however. Early

experiments demonstrated that HBV-containing serum was infectious when given orally to susceptible individuals,[181] but the virus inoculum used in these studies included large amounts of exogenous protein, which may have protected the virus from inactivation by mucosal enzymes, gastric acid, or bile. Attempts to transmit HBV to susceptible nonhuman primates by oral administration of infectious saliva were unsuccessful, even though saliva transmitted infection when inoculated percutaneously.[182,183] Such evidence suggests that the oropharynx is a relatively hostile portal of entry for HBV but is compatible with anecdotal reports that bites by infected individuals may transmit infection. It is probable that most "horizontal" transmission within families and among young children is due to inapparent percutaneous exposures to saliva or blood.[180] Such exposures may be relatively infrequent but apt to occur repeatedly over an extended period of close contact with a persistently infected carrier.

Among adults, sexual activity is one of the most frequent routes of transmission for HBV. Follow-up studies of the susceptible sexual partners of persons with acute hepatitis B demonstrated that HBV infection developed in 18–30%. Among susceptible spouses of persons with chronic HBV infection, the seroprevalence of HBV infection ranged from 25% to 59%. Homosexual and heterosexual activities with >1 partner in the previous 6 months were independent risk factors for acquiring acute hepatitis B.[184,185] Historically, MSM were one of the groups at highest risk of HBV infection. Infection in this risk group was associated with receptive anal intercourse, increased numbers of sexual partners, and increased years of sexual activity[186,187] (see below). Similar factors were associated with an increased risk of HBV infection among heterosexual men and women, including number of sexual partners, number of years of sexual activity, and history of other STDs.[188,189] In addition, human semen has been shown to transmit infection when instilled into the vagina of susceptible gibbons.[183]

EPIDEMIOLOGY

Population studies

The endemicity of HBV infection varies greatly worldwide and is influenced primarily by the predominant age at which infection occurs.[121,190] Endemicity of infection is considered high in those parts of the world where at least 8% of the population is HBsAg positive, and 70–90% of the population has serological evidence of previous HBV infection. Almost all infections occur during either the perinatal period or early in childhood, which accounts for the high rates of chronic HBV infection in these populations. Risk of HBV infection continues after the first 5 years of life, but its eventual contribution to the high rate of chronic infection is less significant. Chronic infection with HBV is strongly associated with HCC, and areas with a high endemicity of chronic HBV infection have the highest death rates from this neoplasm.

In areas of the world with an intermediate pattern of HBV infection, the prevalence of HBsAg positivity ranges from 1% to 7% and serological evidence of past infection is found in 10–60% of the population. In these areas, there are mixed patterns of infant, early childhood, and adult transmission.

In most developed parts of the world, including the United States and Western Europe, the prevalence of chronic HBV infection is <1%, and the overall infection rate is 5–7%. The highest incidence of acute hepatitis B is among young adults, and high-risk sexual activity and injectable drug use account for most cases of newly acquired hepatitis B.[191–194] In the United States, heterosexual activity accounts for 40% of new hepatitis B cases, while MSM represent 15% of new cases. Among sexually active populations, current HBV infection data are limited, however. In a multicity survey of young (<30 years old) MSM, HBV prevalence ranged from 10% to 25%.[195] Among HIV-positive persons, the incidence of HBV infection was 13.3% among heterosexuals and 7.1% among MSM[196]; prevalence of chronic infection was 3.9% among heterosexuals and 9.2% among MSM. Among HIV-positive heterosexual women with >10 lifetime partners, 48% had serologic evidence of HBV infection.[197]

Sexually transmitted hepatitis B among MSM

Sexual transmission of HBV was first suggested by the occurrence of acute hepatitis B among sexual contacts of HBsAg carriers.[198] An increased prevalence of HBsAg and anti-HBs was noted subsequently among prostitutes and individuals attending venereal disease clinics.[186,199–201] Overall, however, the most striking serologic evidence relating HBV transmission to sexual practices was found among MSM prior to the AIDS epidemic and subsequent educational campaigns promoting safe sex practices. Of over 600 New York City homosexual men who were solicited for study through recognized gay-oriented organizations and health clinics in the mid-1970s, 4.6% were found to be HBsAg carriers and 51.1% were found to have had past infection to the virus, as evidenced by HBsAg or anti-HBs positivity.[186] These men were predominantly Caucasians, under 40 years of age, and highly educated. Female homosexuals were not at increased risk for infection, as only 6.3% had anti-HBs and none were carriers. Of the gay men evaluated in this study, 23% gave a past history of viral hepatitis, and in these individuals the total seroprevalence rate was 65%. There was a high degree of correlation between numbers of previous sex partners and serologic evidence of past HBV infection. Of those with less than 10 sex partners during the previous 6 months, only 30.9% had been infected with HBV, compared with 60.5% of those with more than 10 sex partners.[186] The highest rates for HBsAg (7.5%) were found among men reporting predominant or exclusive

involvement in rectal intercourse, while those reporting oral–genital sex had significantly lower rates for both HBsAg (2.3%) and anti-HBs (39% vs. 51%). The duration of homosexual activity was also related to past HBV infection and was more important than age at the time of screening. Injection drug use did not appear to be an important variable. A high prevalence of HBV infection was documented among gay men in many other studies.[187,200,202–205]

Several factors account for the high risk of HBV infection among MSM, which was noted in these early studies. One of the most important factors was the number of sexual partners. The typical homosexually active male frequenting Denver's steam baths in the late 1970s had eight different male sexual contacts per month.[206] These contacts were largely anonymous and could total as many as 1000 over the lifetime of a gay man. In addition, the relatively high HBsAg carrier rate found among MSM in these studies meant that such anonymous sexual contacts often involved repeated exposure to HBsAg-positive partners. Schreeder et al.[187] estimated that the average openly homosexual male had 4.2 sexual contacts with HBsAg-positive men annually. However, these studies were conducted in the years immediately preceding licensure of the hepatitis B vaccine and the recognition of AIDS. During the mid-1980s, the adoption of safer sex practices by many MSM appears to have altered the epidemiology of HBV in this high-risk group. Although the overall incidence of hepatitis B increased within the United States from 1982 to 1988, the proportion of hepatitis B cases among men who were associated with homosexual activity fell from 30% to 12% in four sentinel counties studied by the Centers for Disease Control and Prevention.[189] In contrast, the proportion attributed to heterosexual contact increased from 10% to 20% among men and from 22% to 34% among women during this same period. Nonetheless, in a study published in 1995,[207] serologic evidence of previous HBV infection among MSM living in high risk, inner-city neighborhoods of San Francisco, was positively associated with numbers of lifetime sexual partners, as well as non-white ethnicity, and a history of injection drug use in a sexual partner. In sharp contrast to homosexually active men, there are no data showing an increased risk of hepatitis B among gay women.

Receptive or insertive anal intercourse is a second important factor influencing the risk of acquisition of HBV among MSM.[186,187] Nonspecific proctitis may result from receptive anal intercourse, and breakdown of normal mucosal barriers may facilitate transmission of virus. In one study, over a quarter of MSM had experienced rectal bleeding during a 4-month period. This was related both to the number of sex partners and to the participation in receptive anal intercourse.[187] In this same study, insertive oral–anal contact was also associated with HBV infection. In contrast, oral–genital or oral–oral contact between MSM had little apparent influence on the risk of becoming infected with HBV. These findings were confirmed in a prospective study of homosexual men enrolled in the Multicenter AIDS Cohort Study.[205] In this study, 19.8% of initially seronegative men seroconverted to HBV during a 30-month period. Insertive anal intercourse was the major risk factor identified for HBV seroconversion, raising the possibility that transurethral exposure may be important in acquisition of the infection.[205] Based on a similar analysis of new HIV infections and a comparison of the prevalence of each virus, the investigators concluded that HBV is transmitted 8.6-fold more efficiently than HIV among homosexually active men.[205]

These data suggest that traumatic sexual practices that lead to small breaks in the skin and mucosa play a prominent role in the transmission of HBV, by facilitating exposure to virus in blood. In one survey, one out of five gay men reported rectal bleeding after intercourse and 9–16% had fissures, cracks, or tears in the rectum or anal skin over a 12-month period.[208] In yet another study, 13 of 22 HBsAg-positive gay men were found to have rectal mucosal lesions, usually consisting of multiple, punctate bleeding points within 6 cm of the anal verge.[209] HBsAg was identified in swab specimens from such lesions, as well as in swabs taken from apparently normal rectal mucosa and anal sphincters. HBsAg was identified in feces from these men, a finding that may, in part, explain the risk of infection associated with insertive oral–anal contact and anal intercourse.

Another important factor in the transmission of HBV among MSM is that HBsAg-positive homosexual men are often HBeAg positive. Approximately 65% of HBsAg-positive MSM are positive for HBeAg, while anti-HBe may be detected in 25%.[210–212] In contrast, only about 10% of asymptomatic, HBsAg-positive blood donors are HBeAg positive. This difference most likely reflected relatively recent acquisition of the infection by many homosexually active men. The presence of HBeAg correlates with high replicative activity of the virus and is associated with an increased risk of heterosexual,[175] needlestick,[122] and maternal–infant transmission of HBV.[121,159] Thus, its frequent presence in homosexual men implies a high risk of infectivity. The titer of HBeAg correlates directly with the amount of virus present in semen and saliva.[163] Cellular immunodeficiency due to HIV in dually infected persons may result in higher levels of HBV viremia and enhanced potential for transmission.[213–215]

Heterosexual transmission of HBV

Extensive evidence also supports the transmission of HBV by heterosexual contact. Sexual partners of HBsAg-positive carriers frequently have serologic evidence of HBV infection.[175,198] In one study, either HBsAg or anti-HBs was found in 27% of spouses of HBsAg carriers but only in 11% of spouses of noncarrier controls.[186] Although nonsexual, household contacts of HBsAg carriers may also have serologic evidence of past HBV infection[175]; the risk appears to be

greater for sexual partners of index cases. The sexual partners of individuals with acute hepatitis B are clearly at increased risk of acquiring infection, when compared with other members of the household. Mosley[216] reported that 18% of susceptible cohabiting spouses eventually became infected with HBV, whereas other family members generally did not. Similarly, Koff et al.[217] found that three of 13 sexual partners, compared with zero of 68 nonsexual domestic contacts, became infected with HBV in this setting. The risk of heterosexual transmission appears to be higher when the HBsAg-positive partner has detectable serum HBV DNA.[218] This is not surprising, since the amount of virus in saliva and semen is related to the magnitude of the viremia.[163] While it is likely that virus is transmitted by vaginal intercourse, it is difficult to assess the role of inapparent percutaneous or mucosal exposures resulting from the sharing of razors, toothbrushes, or other personal articles between partners. Available data do not support a major role for salivary exchange in the transmission of virus among sex partners.[219,220]

In one study, the prevalence of HBV infection among white heterosexuals attending a clinic for STDs in Arizona, who were without other risk factors such as injection drug use, was related to numbers of previous sex partners.[188] Serum markers of HBV infection were present in 21% of those with five or more sex partners during the preceding 4 months, but in only 6% of those with fewer than five partners. A similar correlation existed for total numbers of lifetime sex partners, among both male and female clinic patients. In addition, a similar survey of heterosexual college students without other risk factors for HBV acquisition also demonstrated a positive correlation between numbers of previous sex partners and risk of HBV infection.[221] As many as 40–50% of cases of acute hepatitis B reported in the United States during the late 1990s were thought to be contracted through heterosexual exposure (Centers for Disease Control and Prevention, unpublished data).

Studies in a number of diverse populations, carried out at sites as diverse as San Francisco, California, and Mwanza, Tanzania, have confirmed a strong association between higher numbers of recent or lifetime sexual partners and the risk of HBV infection among heterosexual persons.[207,221–224] Indeed, this association exists even among individuals with acute hepatitis B in Taiwan, a country with a very high overall prevalence of HBV infection.[221] In addition, an increased risk of HBV infection has been observed in heterosexual persons with a past history of STDs, particularly syphilis, but also gonorrhea or herpes simplex virus type 2 seropositivity.[222–227] It is not clear whether this association is simply indicative of common risk factors for HBV and these other STDs, or whether it reflects an increased risk of transmission of HBV to persons who have active ulcerative genital lesions.

CLINICAL MANIFESTATIONS OF HBV INFECTION

Many adults infected with HBV probably have silent infections, which result in permanent and solid immunity. Only one-third of seropositive homosexual men relate a past history of viral hepatitis.[186] However, in a placebo-controlled trial of an HBV vaccine conducted among homosexual men in New York City, 64% of infections in placebo recipients were associated with clinical evidence of disease.[118] The onset of illness is generally more insidious than in hepatitis A, and evidence of hepatocellular disease resolves more slowly. The incubation period is usually from 40 to 110 days but may be shorter with large inoculum or percutaneous exposure and prolonged by administration of partially protective IG preparations.[115] A small proportion (1% or less) of icteric adults develop acute hepatic failure, and about three out of four of these unfortunate patients will die as a result of their infection in the absence of liver transplantation.[228] An initial report from the U.S. Acute Liver Failure Study Group, which included 354 patients enrolled between 1998 and 2001, found that 7.3% of cases were due to HBV.[75] A recent update that included 973 patients enrolled up to 2006 reported that the proportion of cases due to HBV remained steady at 7% (W.M. Lee, personal communication, September 2006). Fulminant disease may be more common following infection with pre-core mutants.[229] Recent studies suggest that the risk of fulminant disease may depend in part on the HBV genotype.[230,231] Infection with HDV may be the immediate cause of severe disease in many patients presenting with what looks like fulminant hepatitis B in countries where HDV infection is endemic (see below). As a rule, elderly patients tolerate acute hepatitis more poorly than younger individuals.

Approximately 15–20% of patients develop a transient serum sickness-like illness during the prodromal or early acute stage of hepatitis B.[232,233] This syndrome is characterized by an erythematous macular or maculopapular, occasionally urticarial skin rash, polyarthralgia, and frequently frank arthritis. The arthritis may be migratory, is frequently symmetrical, and may involve both large joints of the extremities and proximal interphalangeal joints of the hands. Synovial fluid findings are variable, but leukocyte counts as high as 90,000 per cubic millimeter (often with a predominance of neutrophils) have been reported. Serum aminotransferases are usually elevated and may be the best clue to the proper diagnosis.

A striking feature of hepatitis B is the development of persistent infection. Out of 429 hospitalized patients with acute icteric hepatitis B, 43 became persistent carriers of HBsAg in one study.[234] Overall, however, the frequency with which acute infection leads to the chronic carrier state is undoubtedly much lower, as these hospitalized patients represented a selected population. Among immunocompetent adults, progression to the chronic carrier state (HBsAg positive for >6 months) probably occurs in 1% or less. A follow-up study of American soldiers who were infected by administration of contaminated yellow fever vaccine in 1941–1942 suggested that long-term persistence after acute infection is a very rare

event in adults.[235] The HBsAg carrier rate was only 0.26% in recipients of the contaminated vaccine who were studied 40 years after exposure to the contaminated vaccine. Up to a third of chronic HBsAg carriers develop histologic evidence of chronic hepatitis with fibrosis, while the remainder have a more benign disease characterized by minimal inflammatory changes on liver biopsy or no histologic changes at all.[235] While chronic hepatitis B may progress to cirrhosis and death, spontaneous remissions can occur.[236] On the other hand, reactivation of HBV replication and recurrence of active liver disease can occur either spontaneously or after immunosuppressive therapy. In addition, a wide variety of immunopathological conditions are associated with persistent circulating HBsAg, including generalized necrotizing vasculitis (polyarteritis nodosa),[237–239] chronic membranous and membranoproliferative glomerulonephritis,[240] and essential mixed cryoglobulinemia.[241] The latter condition, however, is much more frequently associated with hepatitis C. [242,243]

DIAGNOSIS OF HEPATITIS B INFECTION

The diagnosis of HBV infection is based on serology (Table 29-2). Approximately 90% of patients with acute hepatitis B have detectable HBsAg, when they first present for medical care.[117] This antigen may be detected by any of a variety of sensitive assay methods. Approximately 10% of patients with acute HBV infection are HBsAg negative, however, and these cases are more difficult to document. In such patients, anti-HBc is uniformly present, while anti-HBs may be found in some. Anti-HBs and anti-HBc generally persist for many years after acute infection; their presence is not diagnostic of acute hepatitis B. In contrast, specific tests for IgM anti-HBc have proven very useful in the diagnosis of acute infection. IgM anti-HBc is detected in almost all cases of acute hepatitis B and typically persists after acute infection for 6–24 months. While many chronic HBsAg carriers have persistent IgM anti-HBc, the titer is usually substantially lower than that found in acute infection, and it is usually not detected in commercial assays (thus preserving IgM anti-HBc as a specific marker for acute infection) except during severe exacerbations of chronic hepatitis. The IgM antibody is often 7S rather than 19S IgM in chronic carriers.[244] The presence of HBeAg in an HBsAg-positive individual suggests a high degree of infectivity.[121,122] Conversion of HBeAg to anti-HBe in a patient with chronic hepatitis B generally signals a resolution of hepatocellular disease (Fig. 29-6, bottom panel) and, in some cases, even heralds an end to the HBsAg carrier state.[126] However, it has become increasingly clear in recent years that HBV replication persists after HBeAg seroconversion.[91] Serum HBV DNA levels even may be as high as 8–9 $\log_{10}$ copies/mL in some patients. Recognition that HBV replication persists throughout the course of HBV infection, and that the balance between host immune response and virus replication varies during the course of chronic HBV infection, is critical in the management of patients with chronic HBV infection.[245]

Quantification of serum HBV DNA is crucial in the evaluation and management of patients with chronic HBV infection and in the assessment of the efficacy of antiviral treatment. A major dilemma in the interpretation of serum HBV DNA levels is the determination of cutoff values used to define treatment indications and response. Given that sensitive tests show that HBV DNA may persist even in persons who have serological recovery from acute HBV infection and that low levels of HBV DNA may not be associated with progressive liver disease, complete viral clearance is an unrealistic treatment endpoint. An arbitrary value of 5 $\log_{10}$ copies/mL had been chosen as a criterion for treating chronic hepatitis B.[246] However, chronic hepatitis, cirrhosis, and hepatocellular carcinoma have been found in patients with lower HBV DNA levels. Also, some patients with chronic hepatitis B have fluctuating HBV DNA levels that may vary from undetectable to >10 $\log_{10}$ copies/mL.[247] Thus, serial monitoring of HBV DNA levels is more important than any single arbitrary cutoff value in determining the prognosis and need for treatment.

PREVENTION

Hepatitis B vaccines are highly effective and provide protection against hepatitis B (and hepatitis D), by stimulating the production of neutralizing antibodies against HBV (anti-HBs).[7] Since homosexual men have historically had very high hepatitis B attack rates, early placebo-controlled clinical trials of these vaccines focused on this important risk group. Immunization was shown to reduce the incidence of hepatitis B among homosexual men by 90–95%,[118,208,248] and to similarly protect health-care workers with frequent exposure to blood.[249] Protection became evident within weeks of the first two doses of vaccine in homosexual males, even though the incubation period of hepatitis B is often 6 weeks or longer. These results suggest some degree of postexposure protection. In general, protection correlates with anti-HBs titers >10 mIU/mL.[118,248] Immunization also prevents perinatal infection in infants born to HBsAg-positive mothers. For maximal benefit in this setting, it should be administered within 12 hours of birth, in combination with hepatitis B IG.[250] Immunized infants appear to be protected against hepatitis B for at least 15 years.[251,252]

Symptomatic hepatitis B has almost never been observed in immunized persons who develop anti-HBs responses >10 mIU/mL, even though anti-HBs may fall to nondetectable levels in up to 50% of such persons within 5–10 years.[253] It is likely that continued protection against hepatitis B reflects the establishment of good immunologic memory by the vaccine. Some vaccine recipients may develop

anti-HBc, which is indicative of HBV infection, but they almost always do so in the absence of disease.[208,253]

Subunit hepatitis B vaccines contain recombinant HBsAg produced in the yeast, *Saccharomyces cerevisiae*. These have replaced earlier, chemically inactivated, subviral particle vaccines that were produced from plasma collected from chronic HBsAg carriers (plasma-derived vaccine). Two single-antigen recombinant vaccines, *Recombivax HB®* (Merck) and *Engerix-B®* (GlaxoSmithKline Biologicals) are licensed for use within the United States. A combination vaccine including both hepatitis A and hepatitis B antigens (*Twinrix®*, GlaxoSmithKline Biologicals) is also available for persons ≥18 years old, as are pediatric combination vaccines that include other pediatric vaccine antigens.[254,255] Both single-antigen vaccines contain purified HBsAg particles adsorbed to aluminum hydroxide. Since 2000, neither vaccine has used thimerosal as a preservative.[254] In general, the single-antigen vaccines are comparable to each other in terms of safety and efficacy and can be used interchangeably. However, the vaccines are provided in several different formulations and dosage strengths, making it essential that the package insert be carefully examined for details concerning administration. Hepatitis B vaccines are very safe.[253,254,256] Adverse events are usually confined to mild injection site reactions (up to 22% of immunized persons), while fever and other systemic symptoms are only infrequently reported. Anaphylaxis is a rare but well-documented complication of hepatitis B vaccine, and it is important that epinephrine always be available for immediate use. There are anecdotal reports of Guillain–Barré–Landry syndrome in some recipients of early plasma-derived hepatitis B vaccines, although it is not clear whether the vaccine played a causal role in such cases.[257] It does not appear to occur with increased frequency in recipients of the newer recombinant vaccines.[254]

A usual immunization course includes three doses of the vaccine. The final booster doses should be given at least 4–6 months after the initial, two-dose, primary immunization series, as this enhances peak antibody levels and ensures more durable protection. All three doses can be administered on an accelerated, monthly schedule in the hope of quickly stimulating immunity,[258,259] but this may reduce final anti-HBs titers and thus the duration of protection and should be followed by a final booster dose at least 4–6 months later. Almost all healthy infants, children, or young adults who receive a series of three intramuscular doses of a recombinant hepatitis B vaccine develop protective levels of anti-HBs. Immunogenicity may be reduced in persons over 40 years of age or who are otherwise immunocompromised (including persons with asymptomatic HIV infection).[7] Immunocompromised patients should receive larger doses of vaccine in anticipation of a poor response.

Current recommendations for use of hepatitis B vaccines center on a fourfold hepatitis B reduction strategy[254] (Table 29-3). This strategy includes (1) universal vaccination of infants beginning at birth, (2) prevention of perinatal HBV infection through routine screening of all pregnant women for HBsAg and immunoprophylaxis of infants born to HBsAg-positive women, (3) routine vaccination of previously unvaccinated children and adolescents, and (4) vaccination of previously unvaccinated adults at risk of HBV infection.[260] Anti-HBs testing is not routinely recommended following immunization (for exceptions refer to Refs.) and there are no recommendations for late booster doses of vaccine.

During 1990–2004, incidence of acute hepatitis B in the United States declined 75%.[261,262] The greatest decline (94%) occurred among children and adolescents, coincident with an increase in hepatitis B vaccination coverage. This success can be attributed, in part, to the established infrastructure for vaccine delivery to children and to federal support for perinatal hepatitis B prevention programs. There are long-standing recommendations to vaccinate persons who report a history of multiple sex partners, treatment for an STD, and MSM. However, vaccine is rarely offered in settings that provide health care to adults. Results of several studies indicate that health-care practitioners do not routinely ascertain high-risk sex or drug histories from their patients and miss opportunities to inform and vaccinate persons at risk of hepatitis B.[263] Even in settings that provide services specifically targeted to high-risk adults (e.g., STD treatment clinics, HIV counseling and testing sites, and drug treatment programs), hepatitis B vaccination is not offered routinely.[264] Thus, new implementation strategies are needed to protect adults currently at risk of HBV infection. In settings where a high proportion of persons are likely to be at risk of HBV infection (e.g., STD/HIV testing and treatment facilities, drug-abuse treatment and prevention settings, health-care settings primarily serving MSM, and correctional facilities), universal hepatitis B vaccination is recommended for all adults who have not completed the vaccine series. In primary care and specialty medical settings, standing orders should be implemented to administer hepatitis B vaccination as part of routine services.

TREATMENT

Treatment is discussed in detail in Chapter 66. The major dilemmas in treatment of hepatitis B are when to start and when to stop. Every hepatitis B carrier is a potential candidate for treatment; the decision is whether treatment should be initiated at the time of presentation or whether the patient should be monitored and treatment deferred. Although six different therapies have been approved, standard and pegylated interferon-alpha, lamivudine, adefovir, entecavir, and telbivudine, none eradicate HBV. Thus, careful consideration of the

Table 29-3. Persons for Whom Hepatitis B Vaccination Is Recommended

I. All infants

II. All children and adolescents <19 y of age

III. Persons at risk of infection by sexual exposure
- A. Sex partners of hepatitis B surface antigen (HBsAg)-positive persons
- B. All sexually active persons who are not in a long-term, mutually monogamous relationship (e.g., persons with >1 sex partner during the previous 6 months)
- C. Persons seeking treatment for a sexually transmitted disease
- D. Men who have sex with men

IV. Persons at risk of infection by percutaneous or mucosal exposure to blood
- A. Household and needle-sharing contacts of HBsAg-positive persons
- B. Current or recent injection-drug users
- C. Health-care and public safety workers with reasonably anticipated risk of exposure to blood or blood-contaminated body fluids
- D. Persons with end-stage renal disease, including predialysis, hemodialysis, peritoneal dialysis, and home dialysis patients

V. Others
- A. International travelers to areas with high levels of endemic HBV infection
- B. Persons with chronic liver disease
- C. Persons with HIV infection

VI. Settings where hepatitis B vaccination is recommended for all adults
- A. Sexually transmitted disease treatment facilities
- B. Human immunodeficiency virus testing and treatment facilities
- C. Facilities providing drug-abuse treatment and prevention services
- D. Correctional facilities
- E. Health-care settings primarily serving men who have sex with men
- F. Chronic-hemodialysis facilities and end-stage renal disease programs

patient's age, severity of liver disease, likelihood of response, and potential adverse events is needed before treatment is initiated.[265] Treatment is indicated if the risk of liver-related morbidity and mortality within the next 10–20 years is high, and there is high likelihood of achieving viral suppression during continued treatment or sustained viral suppression after a defined course of treatment. Treatment should be deferred if the risk of liver-related morbidity and mortality within the next 20 years and the likelihood of achieving sustained viral suppression after a defined course of treatment are low. Because of the fluctuating nature of chronic HBV infection, continued monitoring is essential for risk assessment. In general, treatment should be initiated if there are elevated aminotransferases and/or moderate–severe hepatic inflammation. Recent studies from Taiwan suggest that treatment should also be considered in older patients (>40 years) who have persistently high serum HBV DNA levels (>4 $\log_{10}$ copies/mL). However, most persons participating in these studies were infected at birth, and it is uncertain whether this recommendation is appropriate for persons with adult-acquired HBV infection.

In choosing which antiviral agent to use as the first-line therapy, consideration should be given to the safety and efficacy of the treatment, risks of drug resistance, the costs of the treatment, as well as patient and provider preferences, and, for women, whether they are likely to become pregnant in the foreseeable future. The advantage of interferon therapy is the finite duration and lack of emergence of specific drug-resistant mutations. The disadvantages include need for parenteral administration, frequent side effects, and costs. The oral nucleoside analogs have the advantage of ease of administration and safety. However, long durations of therapy are required and carry accompanying risks of drug resistance. For patients with HBeAg-positive hepatitis, treatment should be continued for at least 6 months after HBeAg seroconversion. For patients with HBeAg-negative hepatitis, the endpoint is unclear, as relapse is frequent even after serum HBV DNA has been undetectable for more than a year. Combination therapy seems to be a more logical approach, but none of the combination regimens tested to date is clearly superior.

For patients coinfected with HIV, the decision on HBV treatment should take into consideration the need for HIV treatment. For patients who are not in need of highly active antiretroviral therapy (HAART), or who are already well controlled on a HAART regimen that does not include a drug with activity against HBV, pegylated interferon-alpha may be considered as a first-line treatment, given its limited duration. However, adefovir or entecavir may also be used in this setting. For HBeAg-negative patients, earlier initiation of HAART may be considered in view of the need for very long-duration HBV treatment. For patients in whom HAART initiation is planned, it is best to use a regimen that includes drugs with activity against HBV; the combination of emtricitabine and tenofovir as a single pill is well suited for this purpose.

DELTA HEPATITIS/HEPATITIS D

CLINICAL VIROLOGY

HDV is a defective virus that is absolutely dependent on simultaneous HBV infection for provision of its envelope proteins.[266] Thus, HDV infects only patients with active HBV infection. The infectious HDV virion is a 35-nm particle found in the blood.[267] It has an outer envelope consisting of HBsAg (produced by the helper HBV infection) and an amorphous core containing a viral protein, delta antigen (HDAg), complexed with a small, circular, single-stranded RNA molecule ~1.7 kb in length.[268] This genomic RNA has a very high G+C content and extensive intramolecular complementarity, resulting in its assuming a rod-like, predominantly double-stranded secondary structure. Both genomic and antigenomic sense RNAs are present in the liver of infected individuals. Replication of the viral RNA is thought to occur by a "rolling circle" mechanism under the direction of a cellular polymerase, with nascent RNA molecules being capable of autocatalytic cleavage and self-ligation. The delta antigen is a highly basic phosphoprotein, which forms oligomers and has RNA-binding activity.[269,270] It is encoded by the antigenomic sense RNA, making HDV a negative-strand RNA virus. The provision of HBsAg, encoded by the HBV genome, is the only helper function required for HDV replication.

HDV infection may occur as a "coinfection" with acute hepatitis B in an individual who was previously susceptible to HBV, or as a "superinfection" in an HBV carrier.[271] Either type of infection may result in severe hepatitis with fulminant disease and death.[272] Coinfections are often marked by a biphasic serum aminotransferase response, while superinfections may be associated with transient (at times permanent) suppression of HBV replication markers. Those who survive acute coinfections usually go on to complete recovery and are not at increased risk of becoming chronic HBV carriers. On the other hand, HBV carriers surviving HDV superinfections frequently become carriers of HDV with clinically aggressive chronic liver disease.[271] The diagnosis of HDV infection is generally dependent on demonstration of antibody to HDAg (anti-HD), as this is the only widely available test (Table 29-2). Acute HDV/HBV coinfections are distinguished from HDV superinfection of a chronic HBsAg carrier by measurement of IgM anti-HBc, which is present in the former and absent in the latter. Indeed, persons presenting with what appears to be acute type B hepatitis, who lack this serum marker, should be suspected of having HDV superinfection.

EPIDEMIOLOGY OF HDV

HDV is found in the blood of anti-HD-positive HBsAg carriers, and the prevalence of anti-HD among American carriers is strongly associated with illicit injection drug use, hemophilia, or a history of multiple transfusions.[273,274] Geographic differences in the distribution of HDV are striking, however, and anti-HD is significantly more prevalent among HBsAg carriers from middle-eastern and Mediterranean countries. Outbreaks of fulminant delta hepatitis with high mortality rates have been reported among the indigenous populations of Venezuela and other South American countries, possibly representing widespread superinfection of HBsAg carriers.[275] The implementation of hepatitis B immunization programs, improvement in socioeconomic status, and education of IDUs have contributed to marked decreases in new cases of HDV infection in Mediterranean countries. However, HDV infection continues to be common in Eastern Europe and among indigenous populations in central and South America.

SEXUAL TRANSMISSION OF HDV

The extent to which HDV may be sexually transmitted remains unclear. HBsAg-positive homosexual men have a low

prevalence of anti-HD compared with other carrier groups, particularly IDU.[273,276–278] Accordingly, compared with IDU, a smaller percentage of homosexual men presenting with acute HBsAg-positive hepatitis in Los Angeles were found to have anti-HD.[271] These men also had a lower overall mortality than IDU with acute hepatitis B, reflecting their lower frequency of HDV infection. Nonetheless, HDV coinfection was found in 14% of homosexual men from Los Angeles with acute HBsAg-positive hepatitis,[271] many of whom denied a history of transfusions or injection drug use. Another survey found anti-HD antibodies in 9–15% of HBsAg-positive homosexual men living in Los Angeles and San Francisco, but only 0–1% of HBsAg-positive homosexual men in Chicago and Pittsburgh.[276] In the West Coast groups, the presence of anti-HD was correlated with numbers of previous sex partners, as well as injection drug use. In contrast, of 60 homosexual men with acute hepatitis B who were identified through the sentinel counties study of the Centers for Disease Control and Prevention, none had concomitant HDV infection.[277] Thus, except for reports from the West Coast of the United States,[271,276] HDV infection appears to be a relatively rare cause of hepatitis among homosexual men. A similar absence of HDV infection among homosexual men with HBV infection was observed in Sydney, Australia.[278] Fewer studies have focused on the potential for heterosexual transmission of HDV. However, a multivariate analysis of patients with acute delta hepatitis in Italy, a country with a generally high prevalence of HDV infection among HBsAg carriers, identified a history of having had >2 sex partners in the preceding 6 months as a significant risk factor for acquisition of the disease.[278]

PREVENTION AND TREATMENT

Although it is generally uncommon, the severity of liver disease accompanying acute and chronic HDV infections makes the potential for sexual transmission of HDV a concern worthy of continuing attention. However, there are no specific means for prevention of HDV infection other than immunization with hepatitis B vaccine, which provides protection by preventing the helper virus infection required for HDV replication.

Interferon is the only treatment that has demonstrated efficacy in chronic hepatitis D. Two recent studies confirmed that pegylated interferon can suppress HDV replication; ribavirin did not provide any additional benefit.[279,280]

HEPATITIS C

INTRODUCTION

HCV was identified and shown to be the cause of almost all cases of non-B post-transfusion hepatitis in the late 1980s.[281,282] The virus establishes a persistent infection in the majority of infected persons, many of whom develop evidence of chronic inflammatory liver disease.[6] These chronically infected persons are at risk of cirrhosis, liver failure, and hepatocellular carcinoma.[283,284] HCV infection accounts for 15% of acute viral hepatitis cases within the United States. However, it is by far the leading cause of chronic viral hepatitis and is present in over 40% of persons with chronic liver disease. The morbidity and mortality associated with HCV infection are due to its unique propensity to cause persistent infection in most persons, a feature that distinguishes this virus from other hepatitis viruses. The specific mechanisms underlying viral persistence are not known.

Although it has been controversial, the balance of evidence now favors the occasional sexual transmission of HCV. The risk of infection with HCV, like HBV, has been independently related to numbers of sexual partners in some STD clinic studies.[226,285] Although the risk of HCV infection has been shown to correlate with numbers of partners and/or specific sexual practices in some studies of homosexual men,[286,287] the risk of infection is overwhelmingly more closely tied to injection drug use.[286,289] The transmission of HCV is much more frequently associated with risks for percutaneous exposure such as sharing of paraphernalia for preparing and injecting drugs among illicit IDUs than with specific sexual behaviors. Sexual transmission of HCV appears to occur with a much lower efficiency than sexual transmission of HBV,[290,291] although the reasons underlying this difference are not understood.

HEPATITIS C VIRUS

HCV is classified within the genus *Hepacivirus* of the family *Flaviviridae*, in part because of a distant phylogenetic relationship with yellow fever virus and other classical flaviviruses. However, HCV has a number of unusual biological features that distinguish it from other flaviviruses. These include most notably the ability to establish persistent infections in the majority of infected persons. Much has been learned about the molecular virology of HCV and its interactions with host cells since the last edition of this textbook was published, and a complete description of these advances is well beyond the scope of this chapter. More detailed reviews can be found elsewhere.[392,293]

Virus structure and replication

The RNA genome of HCV is a single-stranded RNA molecule that is messenger sense.[281] Negative-strand replicative intermediates of the viral RNA have been demonstrated in the liver and serum.[294] However, until recently, little has been known of the replication cycle of HCV, because wild-type virus undergoes only very limited replication in any cell culture system studied to date. HCV replicates to low levels in primary chimpanzee hepatocyte cultures, and several B- and

T-cell derived lymphoid cell lines may be permissive for low-level HCV replication as well.[295–297] Generally speaking, however, the level of replication is insufficient for biochemical characterization of the virus and its replication. Complete cDNA clones of the HCV genome were constructed following identification of the virus, and the infectivity of RNA transcribed from several of these was established by demonstrating hepatitis associated with viremia in chimpanzees who were transfected in vivo by direct intrahepatic injection.[298,299] These clones have benefited many aspects of HCV research, including the search for more fully permissive cell culture systems. In 1999, the first subgenomic HCV RNA replicons that were competent for replication in human cells were described.[300] These RNAs express the nonstructural proteins of the virus and contain authentic 5′ and 3′ termini; they undergo efficient autonomous amplification following their transfection into permissive cell culture. Replicons propelled the field forward and led to many studies that have usefully characterized various aspects of viral RNA replication. However, it was not until 2005–2006 that the first cell culture-infectious viruses were described; these remain limited to only two virus strains at present but show promise of revealing previously unrecognized features of the viral life cycle, including aspects of viral entry into cells, assembly, and release.[301,302]

The positive-strand RNA genome of HCV has a relatively lengthy 5′ nontranslated region of approximately 342 bases, which contains an IRES that directs the 5′ cap-independent initiation of viral translation.[303] This is followed by a long, open-reading frame encoding a single polyprotein (Fig. 29-7). The polyprotein undergoes cotranslational processing events, directed by both host cell and virus-encoded proteinases. Several cleavages directed by host cell signal peptidases produce a series of structural proteins, which include the nucleocapsid protein (core), two envelope glycoproteins (E1 and E2), and a small membrane-associated protein (p7). Signal sequences within the amino terminal third of the polyprotein direct the secretion of the envelope proteins into the lumen of the ER, while the nucleocapsid protein remains within the cytoplasm. E1 and E2 become heavily glycosylated within the ER and the Golgi; these proteins have strong ER retention signals, and details of the viral assembly and secretion process remain obscure.[304,305] E2 contains a highly variable domain near its amino terminus (HVR-1 domain), which is likely to form an immunogenic loop on the surface of the virion and which may interact with neutralizing antibodies.[306,307] As such, it may be analogous to the V3 loop of HIV-1. It may also play a role in determining the interaction of the E2 protein with CD81, a putative coreceptor important for viral entry into cells.[308,309]

At least six nonstructural proteins are derived from the remainder of the polyprotein (Fig. 29-7). Each seems to have multiple functions, many of which are only partly understood. They include NS2, which includes in its C-terminal half a unique cysteine protease activity that spans the NS2B/NS3 junction and cleaves in cis at this site[310] and which also plays a role in viral assembly[311]; NS3, a serine protease/NTPase/RNA helicase responsible for the remaining processing events in the polyprotein[312,313]; NS4A, an NS3 protease accessory factor that is intercalated into the structure of the mature NS3 protease and also anchors the NS3/4A complex to cellular membranes as well as to other viral proteins contributing to the replicase[314]; NS4B, a hydrophobic protein that is responsible for reorganizing intracellular membranes into a "membranous web" that supports the replication of the viral RNA[315]; NS5A, a multifunctional protein that appears to play roles both in interferon-resistance and replication of the viral RNA[316,317]; and NS5B, the RNA-dependent RNA polymerase that forms the catalytic core of the replicase.[318] Many of these proteins have been shown to have important interactions with cellular proteins that promote the replication of the virus or contribute to the pathogenesis of the infection.[293] Prominent among these interactions is the ability of the NS3/4A protease to proteolytically target key cellular signaling molecules required for interferon-mediated antiviral cellular defenses.[319]

While interferon-based therapies are capable of curing many individuals with HCV infection, such treatment often fails and is associated with significant side effects (see Chapter 66). Thus, there has been strong interest in developing effective antiviral inhibitors of HCV replication. These have driven extensive studies of many of the nonstructural proteins, including high-resolution X-ray crystallographic analyses. The NS3/4A complex has been a

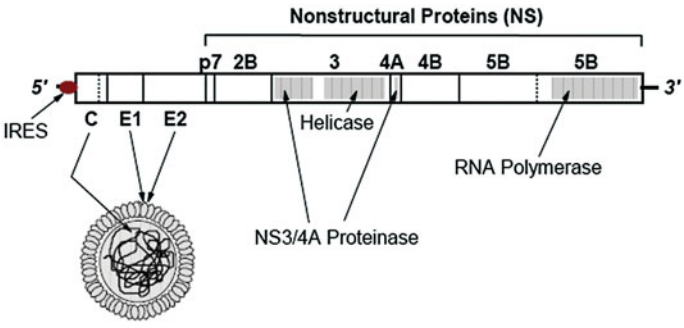

FIGURE 29-7. Organization of the 9.6-kb (+)-strand RNA genome of HCV. As in HAV (Fig. 29-1), the translation of a large polyprotein is directed by an IRES located within the 5′nontranslated RNA. This polyprotein is subsequently processed into the structural proteins, core (C), and the two envelope glycoproteins (E1 and E2), by cellular signal peptidase following translocation of part of the polyprotein into the endoplasmic reticulum. Following a *cis*-active cleavage directed by a cysteine proteinase activity spanning the NS2/NS3 junction, the NS3/4A protease directs further processing of the polyprotein, resulting in additional nonstructural proteins that are involved in viral replication. The major serine protease (NS3/4A) is a complex of NS3 and NS4A. NS3 also contains an RNA helicase, while NS5B possesses RNA-dependent RNA polymerase activity. These HCV proteins are targets of candidate antiviral drugs now in phase I/II trials.

prime target for development of new small-molecule inhibitors of viral replication, and multiple candidate drugs are now in early phase I/II clinical trials. Some of these have shown remarkable clinical efficacy in short-term dosing studies.[320] The same is true for inhibitors of the NS5B polymerase. Both allosteric (non-nucleoside) and active-site (nucleoside analog) inhibitors of NS5B have demonstrated promise as effective antiviral agents in early clinical studies. Although clinical experience remains very limited with either protease or polymerase inhibitors, antiviral drug resistance appears likely to be a significant risk with most, if not all, of these candidate therapies, which is not surprising, given the genetic diversity displayed by HCV strains, and will likely mandate the use of combinations of drugs in the future.

Genetic and antigenic heterogeneity

Different stains of HCV are classified as distinct "genotypes," based on the extent of nucleotide sequence divergence.[321,322] Genotype 1 is considerably more refractory to interferon therapy than non-1 strains, while spontaneous resolution of infection appears more common in genotype 3 infections.[323] Otherwise, there is little evidence for differences in the pathogenicity of various genotypes. The genetic distance between some genotypes is large enough to suggest that there may be biologically significant serotypic differences as well. Preliminary analyses with recently developed virus neutralization tests, based on the use of cell culture infectious virus, suggest that there may be significant serologic differences between HCV genotypes, while earlier studies using pseudotyped viruses suggest extensive cross immunity.[302,307] While early studies suggested that there is only low-level homologous protection when chimpanzees are challenged twice with the same strain of HCV,[324] more recent studies have shown extensive protection against reinfection in chimpanzees, even with viruses from diverse genotypes.[325]

■ NATURAL HISTORY AND PATHOGENESIS OF HCV INFECTIONS

About 60–85% of all infections lead to virus persistence, and this is often associated with evidence of chronic liver disease (Fig. 29-8). After many years, this process may culminate in cirrhosis and liver failure, or the development of hepatocellular carcinoma. These end-stage events in chronic hepatitis C may claim as many as 10,000 lives annually in the United States.[326]

Acute hepatitis C

The primary cell type infected by the virus is the hepatocyte. However, there is some evidence for infection of lymphoid cells,[327] and it is possible that this plays an important role in pathogenesis. Early studies in transfused individuals

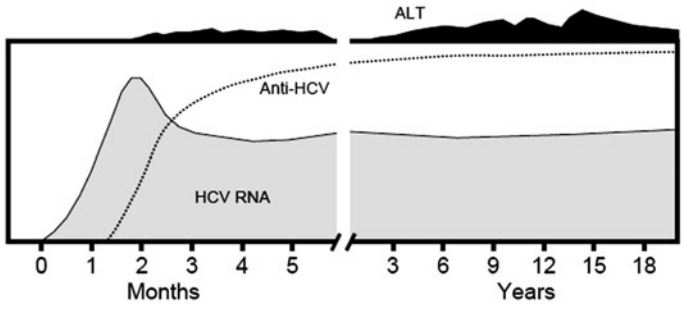

FIGURE 29-8. Typical virologic and serologic course of persistent HCV infection. Acute infection is often marked by little clinical evidence of hepatitis, despite the presence of relatively high levels of viral RNA in the blood that are detected by RT-PCR or sensitive bDNA hybridization assays. Anti-HCV detected by ELISA assays reflects specific antibody responses to a number of the viral proteins. Viremia is generally constant, while serum ALT levels can fluctuate significantly. The latter correlates poorly with the extent of histologic abnormalities in the liver. Late clinical complications include cirrhosis and hepatocellular carcinoma.

indicated that most HCV infections are associated with minimal symptoms and only rarely with identifiable jaundice.[328] In contrast, patients presenting to physicians with acute hepatitis C are much more likely to be icteric.[6] They represent only a small fraction of all acute infections. Quantitatively, virus replication appears to be greatest shortly after infection, with the magnitude of the viremia being highest during this period (Fig. 29-8). Clinical studies and analysis of experimentally infected chimpanzees have shown that the level of viremia declines with the appearance of antibody to viral proteins and T-cell-mediated immunity to HCV and, in most persons, remains constant at a relatively fixed level for many years thereafter.[6,329] However, in a substantial minority of infected persons, these immune responses clear the infection, and viral persistence is not established. The clinical outcome of acute HCV infection is dependent on the vigor of both $CD8^+$ and $CD4^+$ T-cell responses to the infection.[330–332]

Chronic hepatitis C

Approximately two-thirds of persons with chronic HCV infection go on to develop persistent or intermittent elevations in serum ALT levels.[6] At liver biopsy, these individuals may have intrahepatic inflammation and fibrosis, the extent of which does not correlate with the magnitude of serum enzyme elevations. As many as a third of patients found to have chronic hepatitis C will ultimately develop cirrhosis[6,284,333,334]; although it is not well defined, the fraction of all patients who are infected with the virus and progress to cirrhosis is undoubtedly far lower. Cirrhosis may be present within as little as 60 months of the initial infection but is identified typically in persons who have been infected for decades. Factors associated with disease progression include age at infection, regular alcohol consumption, coinfection with HIV

or HBV, and more recently obesity and insulin resistance.[335-336] Some patients, usually with well-established cirrhosis, develop primary hepatocellular carcinoma.[283] Chronic HCV infection is the most important etiology of hepatocellular carcinoma in western countries.

The major challenge to clinical investigators has been the discovery of specific markers that are predictive of progression of chronic hepatitis C to a clinically significant disease state. This remains an exceptionally difficult problem. There is no good correlation between biochemical markers and the extent of fibrosis or the presence or absence of cirrhosis. Indeed, many patients with cirrhosis have no obvious laboratory abnormalities.[333] In addition, quantitative measurements of the viremia ("virus load") are not useful in determining the extent of disease resistance.[335-336] However, hepatitis C antibody-positive individuals who have normal ALT levels and who test persistently negative for viral RNA are at low risk of significant liver disease. A minority of all anti-HCV-positive individuals will fall into this category; some of these individuals may have false-positive tests, while others may have successfully cleared prior infection.

Destruction of the liver cell is probably not caused by direct cytotoxic effects of HCV infection, but rather by immunopathological mechanisms. Liver injury most likely results from the direct action of virus-specific cytotoxic T cells, as well as from secondary mediators of inflammation (such as gamma interferon) that are released as a result of the vigorous virus-specific T-cell response.[161,329] Thus, T-cell-mediated responses have two effects on the disease process. They may suppress virus replication and lower the magnitude of viremia. However, in the absence of eliminating the virus altogether, cytotoxic T-cell responses also stimulate significant inflammation within the liver and are likely to be the proximate cause of inflammation, ALT elevation, and likely fibrosis.

Although both HCV- and HBV-related liver injury are immune mediated, the course of chronic HCV and HBV infections are different. Whereas chronic HBV infection is characterized by fluctuations in serum HBV DNA levels and exacerbations of hepatitis, chronic HCV infection usually progresses in a stepwise manner. Thus, assessment of the stage of hepatic fibrosis provides important prognostic information and is often used to determine the need for antiviral therapy. Because of the potential for complications and sampling error, many investigators have developed non-invasive models to predict hepatic fibrosis and/or cirrhosis, using routinely available laboratory test results, panels of special blood tests that include markers of liver inflammation and/or fibrosis, and most recently transient elastography.[337,339] Some of these models have a fairly high degree of accuracy, but they are mostly designed to categorize patients as having mild versus advanced liver disease and do not differentiate among the different stages of fibrosis.

The frequency with which HCV infection leads to clinically overt liver disease has yet to be well established. In a retrospective cohort study of transfused individuals carried out in the United States, overall mortality was not increased in persons who had been infected with HCV 18 years earlier.[333] Moreover, the risk of liver-specific mortality was only marginally increased in comparison with uninfected control subjects receiving equivalent numbers of transfusions. Although this study provides some level of comfort concerning this infection, this may be misleading. Most of the subjects were middle aged or older at the time of transfusion and subsequent infection with HCV and had other serious health problems such that 50% were no longer living after 18 years of follow-up. The impact of HCV infection may be quite different in individuals who are infected in the second and third decades of life and have many more years of life expectancy. Furthermore, when studied 18–20 years after their infection, as many as a third of the patients with transfusion-transmitted hepatitis C had elevated serum ALT activities indicative of chronic hepatitis. Moreover, among the patients from this group who underwent liver biopsy, approximately one-third had established cirrhosis.[340]

Consistent with this latter view, HCV is at present the leading cause of liver transplantation in the United States and an important overall cause of liver-related mortality. Concerns have been raised that HCV-associated mortality may increase significantly over the next two decades, as disease advances in large numbers of asymptomatically infected persons who are at present in the third and fourth decades of life.[326] Most of these persons probably acquired their infection due to limited injection drug use many years ago. Age-related seroprevalence data collected within the United States suggest that there has been a significant expansion of this pool of infected persons in recent decades.

Extrahepatic disease manifestations

Extrahepatic manifestations of HCV infection are relatively common and include most prominently glomerulonephritis and type II mixed cryoglobulinemia associated with vasculitis.[243,341,343] Such individuals have circulating immune complexes containing viral RNA. Other potentially associated clinical conditions include porphyria cutanea tarda, sicca syndrome, and a variety of autoimmune diseases, as well as B-cell lymphoma. The pathogenesis of these conditions is poorly understood.[293]

■ DIAGNOSIS OF HCV INFECTION

Serologically, infection is marked by the presence of antibodies to several viral proteins: core, NS3, NS4, and NS5[344,345] (Table 29-2). The presence of such antibodies may be detected by ELISA assays originally developed for

screening of blood donations. When such tests are found to be positive, confirmatory assays should be run to confirm the presence of infection. This usually involves detection of viral RNA in serum or plasma by a nucleic-acid-based diagnostic method such as RT-PCR,[346] although a confirmatory recombinant immunoblot assay (RIBA) for antibodies is also available.[347] The presence of antibodies to HCV signifies infection and not immunity. Positive reactions in assays for antibodies to E2 also correlate with serum RNA positivity[348] and thus are not likely to reflect immunity. Quantitative RT-PCR assays and more sensitive qualitative RT-PCR and transcription-mediated amplification (TMA) tests for viral RNA are useful for assessing the replicative activity of the virus and for monitoring response to therapy (see Chapter 66).[349] An international standard is used for determining quantity of circulating viral RNA and limits of detection of these assays.[350] HCV genotype should be determined in all patients who are being considered for therapy.

EPIDEMIOLOGY OF HEPATITIS C

Transmission of HCV occurs by both percutaneous and mucosal exposures. Since transmission by blood and plasma-derived products has been eliminated by donor testing and inactivation procedures, the overwhelming risk factor in almost all studies in industrialized countries is a history of illicit injection drug use.[351] Because active HCV infections are highly prevalent among IDUs, exposure to HCV occurs early in the career of an IDU and is facilitated by sharing paraphernalia for the preparation of drugs with others, independent of sharing syringes and needles. Thus, HCV is one of the first infections contracted by most IDU. Percutaneous exposures such as accidental needlesticks are a source for infection among health-care workers, although the prevalence of infection in this group is usually similar to that of the background population. Like HBV, patient-to-patient transmission of HCV from unsafe therapeutic injections and other health-care procedures occurs in developed countries and contributes substantially to the disease burden in the developing world.[352,353] HCV can remain viable on surfaces under ambient environmental conditions for at least 16 hours.[354] Cosmetic procedures such as tattooing and body piercing have not been associated with an increased risk for HCV infection.[355]

In contrast to large or repeated direct percutaneous exposures to blood, sexual activity appears to be an inefficient means for transmission of this virus. Unlike HBV or HIV, MSM have not been shown to be at higher risk of HCV than heterosexuals, and sexual behavior is usually of secondary importance in determining the risk of HCV infection. However, there are a number of studies that relate sexual practices or numbers of sex partners to infection with HCV. In addition, recent outbreaks of hepatitis C have been identified among MSM coinfected with HCV and HIV.[356–359] Maternal–infant transmission of HCV also occurs at much lower rates than with HBV but is increased when the mother is coinfected with HIV.[360–363]

Sexual transmission of HCV

Three general types of studies have attempted to document the sexual transmission of HCV. These include cross-sectional studies of populations at different levels of risk of acquiring STDs (such as MSM, prostitutes, STD clients, and blood donors), studies of sexual partnerships in which one partner is known to be infected with HCV, and case–control studies of individuals with acute hepatitis C. Each of these types of studies provides some support for the sexual transmission of HCV, but each also indicates that sexual transmission plays a limited role in determining the epidemiology of hepatitis C.

Osmond et al.[286] studied 735 homosexual or bisexual men in San Francisco. They found HCV antibodies in only 4.6% of these men, while 81% had one or more markers of HBV infection. When percutaneous exposures were controlled for, the risk of HCV infection was marginally greater in those with >50 sex partners/year, or >25 oral- or anal-receptive partners. In contrast, HBV infection was much more strongly correlated with these risk factors.[286] In a similar study, 2.9% of 1058 homosexual men included in the Pittsburgh arm of the Multicenter AIDS Cohort Study were found to be anti-HCV positive.[287] Multivariate analysis found that injection drug use was the most important risk factor. However, seropositivity to HCV was significantly associated with a history of previous STD (syphilis and rectal gonorrhea) and anal receptive or insertive intercourse, but not numbers of sexual partners.[287] These studies support a minor role for sexual transmission in determining the risk of HCV infection in homosexual men.

However, other studies have generated somewhat contradictory results. For example, Buchbinder et al.[288] studied 435 gay men attending a municipal STD clinic in San Francisco. Five percent of non-IDUs were seropositive for HCV, whereas 25% of homosexually active IDUs were anti-HCV positive. There was no independent association between HCV infection and any sexual-risk factor on multivariate analysis.[288] Another study of homosexual men carried out in Sydney, Australia, found 7.6% of homosexual men to be seropositive.[289] Using a case–control approach, the risk of HCV infection was found to be independent of sexual practices or numbers of sexual partners. In fact, men without HCV infection were significantly more likely to have engaged in unprotected insertive or receptive oroanal intercourse. The only recognized risk factors for HCV infection in this study were injection drug use and infection with HIV-1.[289]

Taken in aggregate, these studies suggest that sexual behavior plays only a minor role in determining the risk of HCV infection among homosexual men and that sexual

transmission of the virus is relatively inefficient. Studies in prostitutes and other high-risk heterosexual populations generally confirm this impression.

In separate studies carried out in Taipei, Taiwan, and Fukuoka, Japan, HCV seroprevalence rates among female prostitutes ranged from 6% to 12%.[364,365] The presence of HCV infection correlated with the length of time in prostitution and a history of syphilis. However, similar correlations were lacking among female prostitutes who were studied in Somalia.[366] When non-IDU women attending an inner-city STD clinic in Miami were studied, 4.4% were seropositive for HCV, compared with 22% for HBV and 7% for HIV.[285] Multivariate analysis indicated that HCV infection was more likely in women with >10 heterosexual partners in the preceding 5 years, those engaging in sexual practices more than once per week, and those with previous HBV or HIV infection.[285] A similar study carried out in Baltimore confirmed the association between numbers of sex partners (i.e., having had >1 sex partner in the previous month) and HCV infection among non-IDU patients attending an STD clinic.[226] In addition, this study found that the risk of infection was increased in men who reported a lack of condom use with sex during the month preceding their visit to the clinic.[226] In general, the risk of HCV infection is generally greater in STD clinic patients who are over 29–30 years of age.[226,291]

A number of studies have demonstrated that the rate of transmission of HCV within sexual partnerships is relatively low.[367,372] For example, Osmond et al.[371] documented HCV infection in only two of 31 exposed female partners of infected hemophilic men, compared with zero of 81 partners of noninfected hemophilics. Similarly, Hallam et al.[370] found only three of 104 long-standing sexual partners of infected hemophilic patients to be seropositive for anti-HCV. Each of the infected partners had other risk factors for infection. In another study, Eyster et al.[368] found that female sexual partners of multitransfused men were approximately 8.5 times more likely to be infected with HIV than HCV if their partner was infected with either virus. In a STD clinic population, Thomas et al.[373] demonstrated that the non-IDU female sexual partners of HCV-positive men were four times more likely to be infected with HCV than the female partners of HCV-negative men. No association was found for the male sexual partners of HCV-positive women. Thus, these studies document a low risk of male-to-female transmission within stable sexual partnerships. Fewer data address the issue of female-to-male transmission, but there is no evidence that transmission is increased in this direction.

It is possible, but not well documented, that HIV infection might increase the low risk of transmission of HCV within a sexual partnership. In a study of non-IDUs at risk of STDs, Lissen et al.[374] reported HCV infection to be about twice as prevalent in stable, heterosexual partners of HIV-infected persons (9.2%) as in the partners of those without HIV infection (4.1%). However, Eyster et al.[368] found that only five of 164 female sexual partners of multitransfused men who were infected with both HIV and HCV were seropositive for HCV.[368]

Although these results indicate a relatively low rate of transmission of HCV within stable heterosexual partnerships, some studies have found that cohabiting sexual partners are at a significantly increased risk of infection compared to other household contacts of HCV-infected persons.[375–377] This risk may be increased with older age and longer duration of marriage or sexual exposure.[375,376] Furthermore, in at least one study, the results of nucleotide sequence analysis of virus present in blood support the interspousal transmission of HCV.[375] Whether such infection occurs as a result of sexual intercourse or through other close, nonsexual contact remains uncertain.

Additional evidence for the occasional sexual transmission of HCV comes from a multivariate analysis of potential risk factors for HCV infection identified in a case–control study of blood donors in Sweden. HCV infection was independently correlated with injection drug use, blood transfusion, previous hospitalization, tattoos, and a history of previous STDs.[378] Among those non-IDU who did not have a history of blood transfusion, the prevalence of antibodies to herpes simplex virus type 2 was significantly increased in those infected with HCV compared to those without HCV infection. A case–control study of blood donors in the United States identified a history of blood transfusion, injection drug use, intranasal cocaine use, and "sexual promiscuity" (defined as a history of STD, sex with a prostitute, and/or five or more partners per year) as significantly associated with HCV infection.[379]

All of the above studies are consistent with the notion that HCV may be sexually transmitted occasionally and that sexual behavior may influence the risk of HCV infection. However, because most of these studies were cross sectional in nature, the temporal sequence of the exposure relative to onset of infection was unknown. In case–control studies of acute hepatitis C conducted during 1978–1985, sex with a partner who had hepatitis or sex with >2 partners in the 6 months before onset of disease was independent risk factor for acquiring HCV.[380] Among acute cases of hepatitis C reported in the United States during the 1990s, 15% had no risk factor other than sexual activity, of which two-thirds involved an anti-HCV positive sexual partner.[381] Most of these partner pairs were infected with HCV strains that were highly related, based on nucleic acid sequencing. The apparent inconsistencies in the risk of sexual transmission found between studies of persons with acute versus chronic hepatitis C might indicate differences in infectivity during the different phases of infection. The recent transmission episodes of acute HCV infection among HCV/HIV-coinfected MSM suggest that further investigation of this possibility might be worthwhile. However, it is clear from these studies that the sexual transmission of HCV is significantly less efficient than sexual transmission of HBV or

HIV, although there are insufficient data to quantify this risk for individual couples.

PREVENTION AND PATIENT COUNSELING

Prevention

Current understanding of protective immunity in hepatitis C is incomplete, but good evidence indicates that CD8+ memory T cells are essential for protection against persistent viral infection.[293,382] Efforts to develop a recombinant HCV vaccine based on envelope proteins expressed in eucaryotic cells have met with limited success. Infection was prevented in immunized chimpanzees following challenge with a low-dose, homologous inoculum, and more recent studies suggest that immunization with envelope protein-based vaccines may reduce the risk of viral persistence, if not entirely prevent acute infection following challenge in the chimpanzee model.[383–385] However, numerous technical difficulties hinder the commercial development of vaccines, including questions of efficacy and the presence of substantial genetic and probably antigenic heterogeneity among different HCV isolates. Although candidate vaccine have progressed to phase I clinical trials, it is unlikely that a vaccine will become available in the near future. Similarly, passive immunotherapy with pooled IG offers little promise of protection against HCV. Some early studies suggested that pooled IG might protect against disease if not infection.[386] However, IG preparations that are currently in the market are made from plasma pools, from which donor units containing HCV antibodies have been excluded. Such preparations are less likely to be protective than the IG lots used in early studies of passive prophylaxis of non-A, non-B hepatitis. Nonetheless, a study in which chimpanzees received a special HCV IG (HCIG) preparation prior to challenge with virus demonstrated no protection against infection, despite a significant prolongation of the incubation period.[387] Similarly, IG prepared from high-titered anti-HCV-positive plasma failed to prevent HCV reinfection after liver transplantation.[388]

Patient counseling

As indicated above, there is substantial evidence that HCV is only occasionally transmitted during sexual intercourse. Numerous partner studies demonstrate that the risk of transmission between individuals who are in a stable, monogamous relationship is quite low, although not completely absent. Thus, most experts do not routinely recommend the use of barrier prophylaxis by monogamous couples when one is found to be infected with HCV. Such a view is based in part on the absence of any data that condom usage would lower the already very low rates of transmission between sexual partners. On the other hand, many exposed individuals are relatively young, and there is clear evidence that HCV is a significant pathogen, albeit with a long clinical latent period. Furthermore, as detailed above, virus transmission has been documented between cohabiting sexual partners. Thus, recommendations for or against the use of condoms in this setting cannot be undertaken lightly or with any great degree of certainty. It is most important that providers make available to patients appropriate information concerning the risk and potential consequences of HCV transmission during sex. The decision regarding the use of barrier prophylaxis must ultimately be made by the affected individuals. Persons with hepatitis C should be counseled to avoid exposing others to their blood and to limit their alcohol intake.[389]

TREATMENT

Treatment of chronic hepatitis C is discussed in Chapter 66. Currently approved treatment consists of a combination of pegylated interferon-alpha and ribavirin.[390–392] Unless there are contraindications to the use of these treatments, patients with genotype 2 or 3 infection should be considered for treatment, given the high rate of sustained virologic response (70–80%) with a relatively short duration of treatment (24 weeks). Recent studies suggest that the duration of treatment may be further shortened to 12 or 16 weeks in patients with low pretreatment HCV RNA level or rapid virologic response (undetectable HCV RNA by week 4).[393-394] Patients with genotype 1 infection are often recommended to undergo liver biopsy, in order to stage the extent of fibrosis prior to making a decision on treatment, because of the need for longer duration of treatment (48 weeks) and the lower rate of sustained virologic response (40–50%). However, patients who decline liver biopsies should not be denied treatment if they are otherwise appropriate candidates. Patients with HIV coinfection have lower rate of response but should be considered potential candidates for therapy due to the accelerated nature of the disease in coinfected persons.[395-396] Patients who have a long history of alcohol or drug abuse are more difficult to treat, but successful results have been reported with multidisciplinary approaches.

In recent years, rapid progress has been made in the development of small-molecule antivirals with activity against HCV.[397] Both protease and polymerase inhibitors now in the clinic in phase I/II trials have shown substantial antiviral activity in chronically infected patients. Differences in sensitivity among HCV genotypes and the emergence of resistance appear likely to be significant issues in the future use of such antiviral drugs, suggesting that future treatment regimens will be based on combinations of agents, including interferon.

30 Molluscum Contagiosum

John M. Douglas, Jr.

DEFINITION AND HISTORY

Molluscum contagiosum is a benign papular condition of the skin, which is often sexually transmitted in adults. It is caused by the molluscum contagiosum virus (MCV), a member of the poxvirus family. Its characteristic appearance was first described in 1817 by Bateman, who labeled the disorder "molluscum," a common term then for pedunculated lesions, and described it as "contagiosum" to signify its apparent transmissibility, which he felt was due to the "milky fluid" which could be expressed from the lesions.[1,2] In 1841, Henderson and Paterson each described in this fluid cellular elements with large intracytoplasmic inclusion bodies (subsequently termed Henderson-Paterson, or molluscum, bodies), which they felt were responsible for causation and transmission of the disease.[1,2] Subsequent reports of transmission of infection to humans by direct inoculation of lesion material supported an infectious etiology. The findings of tiny "elementary bodies" within the molluscum bodies by Lipschutz in 1911, and of disease transmission by a "filterable agent" by Juliusberg in 1905 and Wile and Kingery in 1919, suggested a viral agent.[1,2] In 1933, Goodpasture demonstrated a marked similarity between the cellular inclusions and elementary bodies of molluscum contagiosum, fowl pox, and vaccinia and concluded that these infectious agents belonged to the same family of viruses.[1,3] With the eradication of smallpox, MCV is the only human-specific poxvirus.[4] Historically considered a minor clinical problem, molluscum contagiosum has become a common and often severe condition in patients with HIV infection.[5–8]

BIOLOGY

MCV is a member of the family Poxviridae, subfamily Chordopoxvirinae, and the only member of the genus Molluscipoxvirus.[9] Although never convincingly replicated in cultured cells, MCV has been purified from skin lesions.[4] MCV is considered to be a poxvirus based on size, structure, chemical composition, and physical and genomic characteristics.[1,7,10–12] Ultrastructural studies of MCV reveal a particle similar to vaccinia virus, with which it has been most extensively compared: brick-shaped, approximately $300 \times 220 \times 100$ nm in volume, with a biconcave viral core enclosed by an inner membrane and an outer envelope.[1,10,13]

The viral genome consists of a single molecule of linear double-stranded DNA 190 kilobases long.[10,11] Comparison of its sequence to that of other poxviruses indicates that it is among the most divergent of the poxvirus family.[9,14] Although the majority of MCV genes are homologous to genes of variola and vaccinia, particularly those needed for transcription and replication, approximately one-third are unique to MCV and appear to mediate virus-host interactions.[14,15] Many poxviruses encode proteins that help evade host immune defenses, often with homology to cellular genes from which they are likely derived, and those of MCV may be uniquely suited to infection restricted to the epidermis.[16,17] Immune evasion genes of MCV that are homologues to cellular genes include an antagonist to the CCR8 chemokine (MC148),[18,19] an IL-18 binding protein (MC54),[20] an MHC class I-like molecule that may interfere with viral antigen processing (MC80),[21] CD150-like molecules that may alter antiviral signaling functions (MC2, MC161, MC162),[22] a glutathione peroxidase that inhibits UV light- and peroxide-mediated apoptosis (MC66),[23] and inhibitors of tumor necrosis factor-α mediated apoptosis (MC159, MC160).[24,25] Another viral gene that modifies virus-host interactions (MC13) inhibits vitamin D and glucocorticoid nuclear receptor transactivation, which may enhance viral growth by increasing keratinocyte proliferation (inhibited by both vitamin D and glucocorticoids) and blocking terminal differentiation (promoted by vitamin D).[26]

Attempts at experimental cultivation of MCV have been frustrating and have limited the study of its life cycle.[10,17] There is no well-established animal model of infection, and even human transmission studies have been only variably successful.[1,2,11] MCV has been propagated in human foreskin

xenografts in athymic mice, offering hope of a model to test potential therapeutic agents; however, virions produced do not appear to be infectious and serial passage has not been successful.[27,28] The virus cannot be grown in cell culture,[10,17] a situation parallel to that of human papillomavirus (HPV). Virus derived from lesions will, however, cause functional changes in human primary fibroblast cells, inducing interferon production and induction of a characteristic cytopathic effect (CPE) with rounding of cells.[1,2,10,29,30] Because these changes are associated with transcription of late as well as early viral genes, a low level of viral replication is likely; however, production of virions does not occur.[30] The inability to propagate virus in cultured cells has also limited characterization of MCV subtypes; however, based on DNA restriction endonuclease techniques four genomic subtypes have been identified, MCV 1–4, with evidence also of minor subtype variants (e.g., types 1v, 1vb, 1vc).[10,31–36] The most common types, MCV-1 and MCV-2, are closely related in nucleotide sequence and genome organization, although their restriction maps differ substantially, in contrast to the restriction-site conservation seen with other poxviruses.[10]

EPIDEMIOLOGY

Characterization of the epidemiology of molluscum contagiosum has been limited by several factors. In most patients the lesions cause few problems and are self-limited.[2,37–40] Thus, it is likely that many infected patients do not seek medical attention, and there are few population-based data concerning those who do, since molluscum contagiosum is not a reportable disease. Furthermore, the inability to cultivate MCV in cell culture has restricted studies of virus transmission, asymptomatic infection, and seroprevalence; thus, most epidemiologic studies rely largely on detection of characteristic lesions by physical examination.[2,41]

Transmission of MCV occurs primarily by skin-to-skin contact by both sexual and nonsexual routes and is enhanced by warmth and humidity, with infection more common in underdeveloped and tropical climates.[1,2,38–40,42,43] The suspicion that genital molluscum contagiosum is sexually transmitted is supported by indirect evidence, including lesion location (e.g., genital and pubic skin), a frequent history of contact with multiple sexual partners and prostitutes, the history and presence of other STDs, the presence of genital lesions in sexual partners, and peak ages of occurrence (20–29 years) that are similar to those of other STDs.[2,38,39,44–46] There is no information about the efficiency of sexual transmission of MCV. The nonsexual form of the disease occurs primarily in children.[47,48] It involves the face, trunk, and upper extremities and appears to be transmitted by direct contact with the skin of infected individuals and/or fomites.[1,2,40,42,43] Infection has been associated with procedures causing skin trauma (e.g., shaving, tattooing, and electrolysis)[49] and with contact with fomites, such as baths, gymnastic equipment and towels, and especially swimming pools, which have contributed to community outbreaks.[1,2,40,42,43,50]

Data on rates of genital molluscum contagiosum are limited but suggest that incidence may be increasing. In the United States, a survey among private physicians demonstrated an 11-fold increase in visits by adults for molluscum contagiosum from 1966 to 1983,[44] although trend data since then are not available. In the UK, more recent data compiling trends in diagnoses made at genitourinary medicine (GUM) clinics indicate continued increases. Over the 10-year period from 1996 to 2005, the number of cases of molluscum contagiosum increased 134% in contrast to increases for first episodes of genital herpes and genital warts of only 13% and 12%, respectively. There was no increase in cases among men who have sex with men, suggesting that the rise is unlikely to be due to HIV-associated increases.[51] Similarly, an STD clinic in India reviewed diagnoses among persons seen in the clinic in 1993–2000 compared to 1977–85 and found that while bacterial STDs decreased and genital warts were unchanged, genital herpes increased 80% and molluscum contagiosum increased 880%.[52] Rates of nongenital molluscum contagiosum have been estimated from patients identified in dermatology clinics and in population-based surveys.[2,40,42,43,47,48,53] While uncommon in North America and Europe, accounting for only 0.1–1.2% of patients attending dermatology clinics,[40] infection was noted during community surveys among villagers in Fiji and New Guinea in 4.5% and 7% of the population, respectively.[40,43] Most cases were in children, and in surveys restricted to children in Fiji, New Guinea, and Japan, prevalence rates have ranged from 6% to 22%.[40,42,43] Of interest, studies from dermatology clinics in developed countries indicate that a substantial proportion of cases in children (24–49%) have coexisting atopic dermatitis.[54,55] Patients with HIV infection have prevalence rates ranging from 1.7% to 4.0%,[56–58] while rates are even higher in those with clinical AIDS, ranging from 5% to 18%.[59–62]

There are few data from population-based samples, although two recent studies have assessed incidence of cases of molluscum contagiosum seen by general practitioners in the Netherlands and in England and Wales, with similar findings. Both reported an annual incidence for all ages of 2.4/1000 and a cumulative childhood incidence (from 0 to 14 years of age) of 17%; incidence among adults was very low.[47,48] Of interest, given the rise in cases in the UK GUM clinics, the study from England and Wales documented a 49% increase in incidence between 1994 and 2000. It has been speculated that the gradual rise in molluscum contagiosum could be due in part to the cessation of routine smallpox immunization following eradication, although the lack of serologic cross-reactivity between vaccinia and MCV makes such an explanation

unlikely.[63] A more plausible explanation, given the high proportion of patients with molluscum contagiosum who have atopic dermatitis, is the growing prevalence of the latter condition in developed countries.[64]

Molecular epidemiologic studies indicate that MCV-1 occurs more commonly than MCV-2, although there is substantial geographic variability.[7,10,33,34,55,65,66] There is no association between subtype and anatomic site, as there is for HPV and herpes simplex virus (HSV), or between subtype and lesion morphology. However, MCV-2 appears to occur more frequently in adults than in children, especially in those who are HIV-infected.[10,33,65] Although mixed infections with both MCV-1 and MCV-2 and with subtype variants have been described, they are uncommon, and studies of family members with molluscum contagiosum and of multiple lesions from the same patient usually reveal identical subtypes.[34] Seroepidemiologic studies of MCV are limited and difficult to compare because of varying techniques and lack of adequate controls.[1,2,43,55,67–70] Two recent studies have compared seroprevalence in those with active infection to control populations. Using a purified whole virus ELISA, Konya found a seroprevalence of 77% in those with lesions compared to 23% in population controls; among cases, seroprevalence did not vary by HIV status, but among controls it increased with age.[69] In contrast, using an ELISA based on the immunodominant 70-kd protein, Watanabe found a seroprevalence of 58% in cases but only 6% in healthy controls.[70] Current assays do not distinguish between antibodies to MCV-1 and MCV-2.[68]

PATHOGENESIS, PATHOLOGY, AND IMMUNOLOGY

MCV has the most limited range of tissue tropism of any poxvirus. Infection occurs only in the epidermis, and dissemination does not occur even in profoundly immunocompromised hosts, as it can with vaccinia.[10,11] MCV has a predilection for follicular epithelium and thus is uncommon on nonhair-bearing sites such as the palms, soles, and mucosa.[71] Transmission is a result of skin inoculation, presumably following microscopic abrasions, and spread to "disseminated skin" sites probably occurs by external autoinoculation, with hematogenous or lymphatic spread unlikely.[5] Although some poxviruses can establish persistent infection in cell culture, there is no convincing evidence of persistence in vivo, and the issue of persistence has not been clarified for MCV.[11] The high rate of infection in adults with AIDS raises the question of possible reactivation from subclinical infection in the setting of immunosuppression,[6,7] supported by the finding of viral particles in skin adjacent to molluscum contagiosum lesions in persons with AIDS but not controls.[72] However, the predominantly nongenital distribution of lesions in these previously sexually active persons suggests that reinfection is more likely. The mechanism by which MCV stimulates basal cell proliferation and induces its benign tumors is not resolved. A protein homologous to epidermal and α-transforming growth factors identified in vaccinia and other poxviruses[10,11] has not been found in MCV, although the possibility of an uncharacterized growth factor remains a consideration.[11]

The pathologic changes induced by MCV infection are very characteristic[1,2,17,73,74] (Fig. 30-1). Lesions consist of focal areas of hyperplastic epidermis surrounding cyst-shaped lobules that are filled with keratinized debris and degenerating molluscum bodies. In the basal layer, the nuclei and cytoplasm of the keratinocytes are enlarged and there is an increase in the mitotic rate. In the spindle layer, as a result of viral replication in the cytoplasm, cells begin to display cytoplasmic vacuolization, enlargement, and then replacement by eosinophilic compartmentalized globules, the molluscum bodies, which are contained in well-defined sacs and which compress the nuclei to the cell periphery.[75] In the granular layer, the molluscum bodies become more homogeneous with loss of their internal structural markings and are finally desquamated into the cystic lobules.[1,2,73] Dermal changes are usually limited to stromal proliferation, although inflammation occurs in up to 20% of clinical lesions, with infiltration of the necrotic epithelium by lymphocytes, histiocytes, neutrophils, and occasionally multinucleated giant cells.[1,2,73,76] In HIV infection, lesion histology may be atypical, with hyperkeratosis and verrucous changes.[17]

FIGURE 30-1. Biopsy of a molluscum contagiosum lesion showing an area of epidermal hyperplasia surrounding a cystic lobule. Keratinocytes in the upper epidermis as well as those desquamated into the lobule, demonstrate large, round intracytoplasmic molluscum bodies. Hematoxylin and eosin stain. The importance of host immunity in the control of MCV remains poorly characterized. In the epidermis, the inflammatory infiltrate is usually minimal. While this has been ascribed to relative isolation from the immune system due to the superficial location of infection beyond the intact basement membrane and the sequestration of virions within the cytoplasmic sac,[5,10,11,77] it is increasingly likely that the immune evasion mechanisms described above play an important role in this minimal inflammatory response.[15] Epidermal inflammation occurs commonly after trauma, possibly as a result of disruption of these anatomic barriers, with a subsequent immune response which often precedes resolution of lesions.[5,10] Additionally, the greater prevalence of lesions in children than adults suggests the acquisition of host resistance with age.[40,43,47,48,53] Finally, the increase in rates and severity of infection in patients with AIDS indicates that intact cell-mediated immunity (CMI) is important in the control of MCV, as it is for vaccinia.[11] However, it is not clear whether a decrease in CD4 cells, Langerhans' cells, or another component of CMI is responsible for greater disease severity in AIDS.[6,78] Despite the relatively high frequency of detectable antibody in those with clinical lesions,[69,70] the role of humoral immunity in control of infection has not been defined.

CLINICAL MANIFESTATIONS

The incubation period of molluscum contagiosum averages 2–3 months, with a range of 1 week to 6 months.[2,41] Most patients are asymptomatic, the diagnosis being made incidental to another problem. A minority of patients complain of itching or tenderness.[2,38–40,79,80] Lesions begin as tiny papules which grow over several weeks to a diameter of 3–5 mm, occasionally enlarging to 10–15 mm, producing the "giant molluscum."[2] The flesh-colored papules are smooth, firm, and dome-shaped, with a highly characteristic central umbilication from which caseous material can be expressed (Fig. 30–2). In adults, lesions most often occur on the thighs, inguinal region, buttocks, and lower abdominal wall and less commonly on the external genitalia and perianal region,[2,7,81] a pattern contrasting with the distribution of genital warts. Children more typically develop lesions on the face, trunk, and upper extremities, often with a linear distribution suggesting autoinoculation by scratching; lesions on the palms, soles, and mucous membranes are rare.[2,38,40,43,79] Lesions are usually more widespread in children than in adults, and while adults with genital disease rarely develop extragenital lesions, 10–50% of infected children have lesions in the genital region.[40,80] The average duration of untreated disease is reported to be approximately 2 years, ranging from 2 weeks to 4 years; individual lesions usually resolve within 2 months.[37,40,43,79] Recurrences after clearance occur in 15–35% of patients;[37,40] whether these represent new infections or exacerbation of subclinical infections is unclear.[72]

FIGURE 30-2. Penile molluscum contagiosum lesions in an immunocompetent host, with typical dome shape and central umbilication. (*Courtesy of CAM Rietmeijer.*)

The most frequent complication of infection, "molluscum dermatitis," appears 1–15 months after the onset of lesions in up to 10% of patients.[2,5,7,82] It consists of a sharply bordered eczematoid reaction 3–10 cm in diameter around an individual lesion, may involve only a portion of lesions, and usually disappears as the lesion resolves. Lesions of the eyelid may induce a unilateral conjunctivitis. The pattern is usually that of a chronic follicular or papillary conjunctivitis, but corneal changes with a punctuate epithelial keratitis similar to that of trachoma can also occur.[2,7] Other inflammatory conditions seen in association with molluscum contagiosum include folliculitis, sycosis barbae, erythema annular centrifugum, and pseudoleukemia cutis.[2,7] Although it has been suggested that molluscum contagiosum lesions, like genital warts, worsen during pregnancy, there is little information on this issue.[39] Infection does not appear to affect the outcome of pregnancy, and while lesions have been reported in a child as young as 1 week old, no documented case of maternal-fetal transmission has been reported.[39]

While normal hosts usually have 10–20 lesions, immunocompromised patients may develop hundreds of lesions.[5–7,38–40] Widespread involvement of eczematous areas has been described in patients with atopic dermatitis and attributed to skin disruption, use of topical steroids, and/or an underlying immunologic disorder.[79,83,84] Patients with frankly abnormal CMI are also at risk of developing extensive disease. Cases have been described in patients with sarcoidosis, epidermodysplasia verruciformis, lymphoma, and leukemia and in those receiving immunosuppressive therapy,[2,5,7] although one review of molluscum contagiosum in children with

cancer indicated that the prevalence was no higher than in normal hosts.[85]

In contrast, patients with HIV infection clearly experience an increased rate of infection. First noted in the early years of the AIDS epidemic,[86,87] molluscum contagiosum in HIV-infected persons was recognized as a common opportunistic infection by the late 1980s.[5–7,59–61] Both the prevalence and the severity of disease increase with advancing immunodeficiency,[6,57,59–62] with lesions occurring in up to one-third of patients with CD4 counts of 100 cells/mm or lower.[88] The majority of lesions occur on the face and neck, especially in the beard area, where they are apparently spread by shaving; anogenital infection is relatively uncommon[6,88] (Fig. 30–3). Outbreaks with extensive lesions are common, and giant molluscum lesions are noted in up to 10% of patients.[6] Increased use of highly active antiretroviral therapy (HAART) would be expected to result in a reduction in molluscum contagiosum among persons with HIV infection. However, results to date comparing cohorts in the pre-and post-HAART eras have varied, with one demonstrating a reduction in prevalence[89] and several indicating no change.[90,91] There is one recent report of an increase in molluscum following introduction of HAART,[58] although this may reflect a transient phenomenon related to increased lesion inflammation following HAART-induced improvement in immune function and enhanced lesion recognition. This phenomenon is considered to be part of the "immune reconstitution inflammatory syndrome" and molluscum is reported to be a common dermatologic marker of this syndrome.[92,93]

DIAGNOSIS

The clinical diagnosis of molluscum contagiosum is usually made easily on the basis of the characteristic, pearly, umbilicated papules with caseous centers found on the face, trunk, extremities, or genital region.[2,7,38,81] The use of a hand held magnification lens may be helpful in seeing the umbilication.[79] Lesions are most frequently misdiagnosed as common or genital warts or keratoacanthomas.[2,7,38] Other considerations in the differential diagnosis include syringomas, plane warts, lichen planus, epithelial and intradermal nevi, sebaceous adenomas, histiocytomas, seborrheic and atopic dermatitis, basal cell epitheliomas, infection with HSV and varicella zoster virus, and lepromatous leprosy.[7,38,79,94] In patients with HIV infection, basal cell carcinoma and disseminated fungal infections (e.g., cryptococcosis, penicilliosis, histoplasmosis) are also considerations.[7,8] In atypical cases the diagnosis can be confirmed by demonstrating the pathognomonic enlarged epithelial cells with intracytoplasmic molluscum bodies on cytologic or histologic studies (see Fig. 30–1).[2,7,8,38,74,79] Other diagnostic approaches include detection of MCV antigen by fluorescent antibody, viral particles by electron microscopy, and MCV DNA by PCR.[36,41,95] Although not a diagnostic test, the CPE induced by MCV may be confused with that of HSV. Up to one-half of MCV lesions will induce CPE in cell culture,[96] and one laboratory reported that up to 10% of genital lesion specimens producing CPE were caused by MCV.[97]

Additional diagnostic concerns include screening for other STDs in those with genital lesions[38,46] and the possibility of an immunodeficiency, such as HIV infection, in those with widespread lesions. The issue of whether genital lesions in children should prompt a sexual abuse investigation is unresolved, although the presence of extragenital lesions suggests autoinoculation of the genital region, supporting a nonsexual route of transmission.[98]

TREATMENT AND PREVENTION

Treatment of molluscum contagiosum is generally simple and accomplished by eradicating lesions with mechanical destruction or techniques to induce local epidermal inflammation.[79,99,100] While therapy hastens resolution of individual lesions and may thereby reduce cosmetic concerns, autoinoculation, and transmission to others, the high frequency of recurrences and the benign and self-limited nature of the infection must be weighed against the pain and potential for scarring induced by destructive therapies, especially in children. Therapy is a higher priority in patients with many lesions, those whose lesions have persisted over time or are increasing, or those with large lesions.[79,99,100]

Although few controlled studies have been performed,[101] the simplest and most commonly recommended treatments are office-based techniques involving physical destruction of

lesions (e.g., excisional curettage, mechanical expression of the lesion core, cryotherapy, electrosurgery) or topical application of cytotoxic agents (e.g., cantharidin, trichloroacetic acid, retinoic acid, podophyllin).[79,99,100,102] Because avoidance of treatment-associated pain is important in small children, topical agents or the use of local anaesthetics prior to destructive techniques is recommended. One large uncontrolled study of provider-applied cantharidin therapy in children reported a 90% clearance rate and 95% patient satisfaction.[80] Patient-administered therapies are also of growing interest. A randomized controlled trial of 0.5% podophyllotoxin cream reported a cure rate of 95% compared to only 16% with placebo.[103] There is also interest in topical imiquimod, an immune response modifier licensed for treatment of genital warts. A randomized controlled trial of 1% imiquimod cream (applied 3 times daily 5 days a week for 4 weeks) in primarily adolescent/adult males reported a cure rate of 82% compared to 16% in placebo recipients;[104] however, smaller studies of the currently licensed 5% preparation used less frequently in children have reported lower clearance rates.[105–108] There are also reports of benefit with other patient-administered therapies including topical salicylic acid (alone or in combination with other agents such as povidone-iodine or acidified nitrite),[109–111] silver nitrate paste,[112] and potassium hydroxide.[113] Oral cimetidine may be useful as adjunctive therapy in patients with atopic dermatitis, but it is ineffective as monotherapy.[99]

No therapy is very effective in immunocompromised patients because of the increased occurrence of new lesions.[6–8] In HIV-infected patients, improvement of immune function following implementation of HAART has been associated with reports of dramatic improvement of molluscum lesions refractory to other therapy, usually with transient associated lesional inflammation suggestive of a local immune response.[11–116] There are also case reports of responses in patients refractory to other treatments to therapy with topical imiquimod,[105,117] pulsed dye laser,[118] photodynamic therapy,[119] or topical or parenteral cidofovir, a broad spectrum antiviral drug.[89,120–122]

Recommendations regarding prevention of transmission include avoiding the sharing of bathtubs, bath towels, and sponges.[79,99,123] While examination of sexual partners has been recommended in the past,[2,7,38] there is no evidence to support this practice, and it is not currently recommended in the absence of another STI.[102] Because of the widespread distribution of lesions, condoms do not appear to reduce the risk of sexual transmission.[124]

PART 6

Sexually Transmitted Bacterial Pathogens

This page intentionally left blank

31 Biology of *Chlamydia trachomatis*

Julius Schachter and Richard S. Stephens

The chlamydiae are distinguished from all other microorganisms on the basis of a unique growth cycle (Fig. 31-1).[1] This cycle involves an alternation between two highly specialized morphologic forms, one adapted to an intracellular and the other to an extracellular environment. Because of this cycle, chlamydiae have been placed in their own order and family *(Chlamydiales, Chlamydiaceae)*.[2] They are obligate intracellular parasites, and cannot be cultured on artificial media. Chlamydiae are restricted to an intracellular life style because they lack the ability to synthesize high-energy compounds, amino acids, vitamins, and cofactors. Thus, they depend on the host cell to supply them with ATP and necessary nutrients.

TAXONOMY

Chlamydia trachomatis, an important pathogen of humans, is one of several species within the genus *Chlamydia*.[2] A proposed division of the *Chlamydia* genus[3] has not been generally accepted.[4] An unfortunate consequence of the proposal has been the use of more than one genus name in the field. The properties of the four original species are shown in Table 31-1. *Chlamydia psittaci* is a common pathogen of avian species and domestic mammals, but only involves humans as a zoonosis.[5] *Chlamydia pneumoniae* is a common respiratory pathogen of humans that has been implicated as a possible cause of coronary artery disease.[6] *Chlamydia pecorum* is a pathogen of domestic animals.[7] Some *C. psittaci* strains are sexually transmitted in their natural hosts, and one—the guinea pig inclusion conjunctivitis (GPIC) agent—may offer a potentially useful animal model for the study of sexually transmitted chlamydial infections.[8,9]

C. psittaci, C. pneumoniae, and *C. pecorum* cannot be easily differentiated in the laboratory based solely on biochemical and phenotypic characteristics. Molecular techniques such as PCR or DNA hybridization or the use of monoclonal antibodies are required to differentiate the species. *C. trachomatis* is readily differentiated on the basis of two relatively simple laboratory tests (see Table 31-1). The simpler involves staining infected cells with iodine to determine whether the inclusions contain glycogen: *C. trachomatis* inclusions do, while inclusions of the other species do not. The second and less reliable test involves testing for susceptibility to sulfonamides: *C. trachomatis* strains are susceptible and other chlamydiae are usually resistant. Each of these species contains many different strains possessing a variety of serologic and biologic properties. Unfortunately, their intracellular growth cycle has limited studies on the physiology of these organisms, and other markers for speciation have not been identified. The growing application of PCR in defining DNA sequences of genes, such as the 23S and 16S ribosomal RNA genes, coupled with phylogenetic analyses using a large database of chlamydial sequences, has enabled unequivocal markers of evolutionary relatedness.[10] The use of DNA amplification based tests has become routine and found application for the identification

of strains, quantitation of chlamydial organisms and diagnostic detection.

The need for new tools for speciation is particularly acute within *C. trachomatis*. This species contains three biovars.[2,11] The lymphogranuloma venereum (LGV) biovar causes LGV, a systemic STD (see Chapter 33). The trachoma biovar includes those strains causing the more common genital tract diseases (urethritis, cervicitis, salpingitis, infant diseases, etc.) and trachoma. Differentiation of those *C. trachomatis* trachoma biovar strains that cause genital infection from those that cause trachoma has been impossible until recently. It seems that these strains are identical except that the trachoma causing *C. trachomatis* do not produce a functional tryptophan synthase.[12,13] This can be determined biochemically in tissue culture or by detecting the DNA sequence of the *trpA* gene. Thus, there is now an apparently stable biological marker to differentiate trachoma causing *C. trachomatis* strains from those isolated from the genital tract. The mouse pneumonitis (MoPn) biovar has now been placed in a separate species, *C. muridarum*. It does not infect humans and will not be discussed further in this chapter.

The trachoma and LGV biovars of *C. trachomatis* are related serologically but differ in the diseases they produce, in the type of cells they parasitize (in vivo and in vitro), in their experimental host range, and in a variety of other biological properties related to the infectious process (Table 31-2). The trachoma biovar has a very limited host spectrum in terms of susceptible cell types. In the natural host, it appears to infect only squamocolumnar cells; its strains are not efficient in infecting macrophages. LGV strains are more invasive and appear to be more efficient at replication in macrophages. Neither biovar will grow in polymorphonuclear leukocytes (PMNs). The basis for the biological differences between LGV and trachoma biovars is not yet understood despite analysis of the complete genome sequence for representatives of each.

HISTORY

Human diseases caused by *C. trachomatis* have been recognized since antiquity.[14] Trachoma is described in Egyptian papyri. LGV was probably described by John Hunter in the eighteenth century. The genital tract infections, such as nongonococcal urethritis and neonatal ophthalmia, caused by *C. trachomatis* were not recognized until it was possible to categorize these conditions following the identification of the gonococcus. With the introduction of ocular (Credé) prophylaxis with silver nitrate drops to prevent ophthalmia neonatorum and of culture and smear methods of diagnosing gonococcal infections, it became apparent that conjunctivitis in infants and urethritis in adult males both had nongonococcal forms.

C. trachomatis was first visualized in 1907 by Halberstaedter and von Prowazek in stained conjunctival scrapings taken from orangutans that had been inoculated with human trachomatous material. They quickly identified the typical intracytoplasmic inclusions, but initially they assumed that the organism was a protozoan. Shortly thereafter, similar inclusions were identified in human material from trachoma cases and then in conjunctival scrapings taken from infants with inclusion blennorrhea. Inclusions were then found in the genital tracts of mothers of the affected infants and in the urethras of the fathers. In the first decade of the twentieth century, the presence of these inclusions was associated with nongonococcal urethritis.[15]

C. trachomatis was first isolated from patients with LGV.[16] In the 1930s, the growth cycle of the LGV organism (as seen following intracerebral inoculation in mice and then in eggs) was noted to be similar to that found for the psittacosis organism, which had been isolated during the psittacosis pandemic of 1929–1930. The trachoma agent proved more difficult to recover, not being infective for mice. It was isolated by inoculation of embryonated hens' egg-yolk sacs by T'ang and associates in the 1950s.[17] These results were soon confirmed by a number of research teams in different parts of the world. In retrospect, it is likely that a previous isolation claim by Macchiavello was probably valid, but it was not confirmed and the isolate was lost. The first isolate of *Chlamydia* (other than LGV agents) from the genital tract was made in 1959 by Jones, Collier, and Smith, who recovered *C. trachomatis* from the cervix of the mother of an infant with ophthalmia neonatorum.[18] In 1964, chlamydiae were first recovered from the urethras of men epidemiologically associated with conjunctivitis cases.[19,20]

Table 31-2. Properties of the LGV and Trachoma Biovars of *C. trachomatis*

D. Infectivity reduced by treating cells with neuraminidase	–	+
E. Infectivity blocked by saturating cell surface with heat-killed homologous organism	–	+

For a number of years, there were very few groups actively pursuing the study of chlamydial genital tract infections. One of the reasons for this paucity of interest was the lack of a technology that lent itself to screening large numbers of specimens. All the early isolation studies (from 1960 to 1965) were performed using yolk-sac isolation procedures and thus were not clinically relevant because they could take up to 6 weeks to provide definitive answers. Dunlop and his colleagues at the Institute of Ophthalmology in London were the pioneering group that provided much of the impetus for continued research on chlamydial genital tract infections. In a series of studies, they found that a number of anatomic sites of the genitourinary tract could be infected with *C. trachomatis* and showed that approximately one-third of men with nongonococcal urethritis had the organism in their urethras.[21–23]

A major technical breakthrough by Gordon and his colleagues in developing a tissue culture isolation procedure for *C. trachomatis* made it possible to (1) screen large numbers of specimens and (2) obtain the result of an isolation attempt in 48–72 hours, which made the laboratory diagnosis clinically useful.[24] Again, English workers were in the forefront of applying this test, and a number of research groups in England independently published studies finding that one-third to one-half of men with nongonococcal urethritis had chlamydial infections.[25–28] The clinical syndromes associated with these infections rapidly expanded.[29] These syndromes are listed in Table 31-3 and discussed in Chapters 32, 33, and 83.

Today, culture-independent tests have revolutionized chlamydia diagnostics. Commercially available antigen detection methods and nucleic acid hybridization tests, when introduced in the 1980s, largely replaced the technically more demanding isolation procedures. However the most important advance came from the introduction of nucleic acid amplification tests (NAATs) in the 1990s.[30] NAATs are far more sensitive than previously available diagnostic tests, and are highly specific, as well. Because they can be used with noninvasively collected specimens (such as first catch urines from either sex, or vaginal swabs), NAATs are well suited for screening as well as diagnosis. These specimens can be self-collected, making possible population-based screening, determination of incidence, as well as prevalence, and expansion of control programs to venues away from the traditional medical or STD clinics.

EPIDEMIOLOGY

SEXUALLY TRANSMITTED CHLAMYDIAL INFECTIONS

There appear to be two major modes of transmission of *C. trachomatis*. LGV, wherever it is found, appears to be always sexually transmitted. In industrialized western society, virtually all *C. trachomatis* infections are sexually transmitted. Men who acquire genital infection with non-LGV *C. trachomatis* strains usually develop nongonococcal urethritis 1–3 weeks postinfection. Because chlamydiae are obligate intracellular parasites and can only survive by a replicative cycle that results in death of the infected host cells, they must be considered to be pathogens at all times and are not part of the normal flora of the male or female genital tract. They do not always produce clinically apparent infections, however. For specific discussions of the epidemiology of these sexually transmitted infections, see Chapters 32 and 33.

If infective genital tract discharges are inoculated into the eye either during sexual activity or by hand to eye contact, conjunctivitis may develop.[14,29,31] The disease caused by the trachoma biovar is called inclusion conjunctivitis, reflecting the diagnostic cytologic findings. In adults, it is an acute follicular conjunctivitis, which tends to follow a self-limited course. Keratitis and micropannus are common. Occasionally the disease persists beyond a few months and clinical features consistent with the diagnosis of trachoma may develop. Visual debility is rare. However, the regular appearance of corneal involvement (with the exception of Herbert's peripheral pits), similar to that found in classical trachoma, has led some workers to suggest that chlamydial infection of the eye represents a spectrum—from mild, self-limited, acute follicular conjunctivitis to chronic trachoma. The clinical picture is determined by the immunologic status of the host: previous exposure and hypersensitivity result in more severe disease, and reinfections or complicating bacterial infections interfere with spontaneous healing.[14,29,31]

Infants exposed to *C. trachomatis* during passage through the infected birth canal may also acquire the infection and can develop a number of diseases, including conjunctivitis and pneumonia (see Chapter 83). At least 60–70% of exposed infants acquire chlamydial infection.[32] Thus, both horizontal and vertical transmissions of *C. trachomatis* occur in industrialized society. Neither *C. pneumoniae* nor *C. psittaci* is sexually transmitted in humans.

ENDEMIC TRACHOMA

Child-to-child transmission is the most common method of chlamydial transmission in trachoma endemic areas.[14,29,31,33]

In many developing countries, trachoma is endemic, and in some it is hyper- or holoendemic. Several hundred million people are known to be afflicted with trachoma, and millions have been blinded. In holoendemic areas, children acquire the infection very early, either from persistently infected adults in their families or from exposure to other infected children. In some communities, all are infected by 2 years of age. Poor hygiene and unsanitary conditions contribute to the spread of the organism. Flies act as mechanical vectors in spreading infective ocular discharges. The disease begins as an acute mucopurulent conjunctivitis (often complicated by secondary bacterial infections) that becomes a chronic follicular keratoconjunctivitis, sometimes accompanied by a significant pannus (corneal neovascularization) formation and Herbert's pits.

In hyperendemic areas, active disease usually wanes when the children are 6–10 years old. Most of the children will be left with minor sequelae when the disease becomes inactive, and there will be no effect on vision. Some children with moderate to severe trachoma will develop badly scarred conjunctivae as a result of the necrosis of follicles. This scarring in the upper tarsal plate of the conjunctiva may with time result in distortion of the upper eyelid. The inturned upper lid margin causes the eyelashes to abrade and ultimately break down the corneal epithelium. It may take 25–30 years for this process to fully evolve, as the scars contract with age. Chronic, or recurrent infection, high-infectious load, and clinical severity are predictors of more severe sequelae.[34] The blindness seen in adults over 40 years of age usually reflect early childhood trachoma. In a hyperendemic area, age-specific blindness rates at age 60 may be 20% or more.[35]

A major breakthrough in trachoma control has evolved from the introduction of azithromycin. Single-dose therapy with this drug has become the treatment of choice for genital tract infection.[36] It is effective in treating trachoma,[37] and community-wide treatment with azithromycin dramatically reduces chlamydial infection in the hyperendemic area.[38] This approach has been integrated into a single strategy for elimination of blinding trachoma as a public-health problem. This SAFE strategy has four basic components: surgery for the redirection of inturned eyelashes (entropion) and correction of trichiasis (where the eyelashes actually abrade the cornea); *a*ntibiotic treatment or using azithromycin for antichlamydial therapy; *f*acial cleanliness; and environmental improvement.[39] Ultimately, these approaches have several long-term goals. The use of surgery is to prevent the development of blindness in those who already have lid damage from earlier chlamydial infection. The antibiotic treatment reduces chlamydial infection and facial washing, and provision of clean water and latrines are aimed at reducing further transmission of chlamydiae.

SEROVAR DISTRIBUTION

There are few studies aimed at determining the distribution of serovars in a community. Specific monoclonal antibodies

are available which can distinguish among the different serovars, but until this identification becomes more meaningful it will remain a research procedure. In trachoma endemic areas, there are usually only one or two serovars recovered in a community.[31,40] Most infections within a household appear to be of the same serovar. The genital serovars (see Table 31-3) are not evenly distributed. L2 appears be the most common of the LGV serovars, and the D and E serovars are the most commonly recovered trachoma biovars.[41] The A and C serovars have never been recovered from the genital tract, but the B serovar, which is commonly associated with endemic trachoma, has also been shown to cause genital tract infection.

There appear to be no biological markers associated with the different serovars that would tend to make such typing relevant from either a clinical or a public-health viewpoint. It appears that the serotype of a strain has evolved independently from its biological background.[42] However, a biological difference for strains isolated from trachoma patients has been identified. Isolates from trachoma patients lack a functional tryptophan synthetase gene, whereas isolates form the genital tract have a functional gene.[12,13] This is independent of serovar as serovars A, B, and C each have a deficient gene, but serovar B strains isolated from the genital tract have functional gene.[12] The tryptophan synthase enzyme converts indole into tryptophan. Gamma interferon is an important host response to chlamydial infection and is known to interfere with the completion of the chlamydial developmental cycle. Its action is thought to be due to tryptophan depletion. In vitro, the interferon's inhibitory effect in cell culture can be reversed by adding indole, if the chlamydiae possess a functional tryptophan synthase. This "indole rescue" was only observed with isolates of genital tract origin. This likely represents selection for a survival characteristic for the organism. The authors posit that presence of the enzyme will allow for productive infection in the genital tract where normal flora may produce indole, thus allowing the chlamydiae to escape the interferon effect.

Finer typing of *C. trachomatis* strains has been possible by genotyping the major outer membrane protein (MOMP) gene.[43,44] This is the most variable of the genes among the serovars of *C. trachomatis.* It has four variable sequence regions that may reflect specific antigenic sites that are under selective immunologic pressures.[45] Use of a combination of monoclonal antibodies together with genotyping has verified that there are 18 major serovars of *C. trachomatis*, but because of nucleotide (usually coding amino acid) changes within serovars, multiple genovars can be detected. To date, the study of these genovars has had limited application. Efforts to associate specific genovars and serovars with more invasive disease or with more inflammatory changes have been equivocal. Genotyping has been replacing serotyping as an epidemiologic tool because it provides finer discrimination, and does not depend on isolation.

Table 31-3. Human Diseases Caused by Chlamydiae

Species	Serovar[a]	Disease
C. psittaci	Many unidentified serotypes	Psittacosis
C. pneumoniae	TWAR	Respiratory disease
C. trachomatis	L1, L2, L3	Lymphogranuloma venereum
C. trachomatis	A, B, Ba, C	Hyperendemic blinding trachoma
C. trachomatis	B, D, E, F, G, H, I, J, K	Inclusion conjunctivitis (adult and newborn), nongonococcal urethritis, cervicitis, salpingitis, proctitis, epididymitis, pneumonia of newborns

[a]Predominant, but not exclusive association of serovar with disease. (Adapted from Schachter J. Chlamydial infections (in three parts). *N Engl J Med* 1978; 298: 428–435, 490–495, 540–549.)

BIOLOGY

DEVELOPMENTAL CYCLE

It is the developmental cycle of chlamydiae that sets them apart from all other bacteria. There are some differences in inclusion morphology within the chlamydiae, but all species appear to have essentially identical developmental cycles. The cycle may be divided into several steps: (1) initial attachment of the infectious particle, or elementary body (EB), to the host cell; (2) entry into the cell; (3) morphologic change to the reticulate particle, with intracellular growth and replication; (4) morphologic change of reticulate particles to EBs; and finally (5) release of the infectious particles.

The developmental cycle initially involves attachment to and penetration of EB to susceptible host cells.[46,47] The infectious EB is relatively resistant to the extracellular environment but is not metabolically active. This particle changes to a metabolically active and dividing form called the reticulate body (RB, or initial body) at some time within the first 6–8 hours after entering the host cell. This reorganization process is poorly understood. EBs are approximately 350 nm in diameter and have an electron-dense center; RBs are approximately 1 μm in diameter and are not electron dense.

After reaching the RB stage, chlamydiae synthesize their own macromolecules—RNA, DNA, and protein—using the host-cell pool of precursors.[48] Glycogen is produced by all *Chlamydia,* but it accumulates within the inclusions of *C. trachomatis,* reaching levels detectable by iodine stain at approximately 30–48 hours postinfection.[49] The RB divides by binary fission from approximately 8 hours to 18–24 hours postentry. This is the stage of greatest metabolic activity, when the organisms are most sensitive to inhibitors of cell-wall synthesis and inhibitors of bacterial metabolic activity. Beyond 18–24 hours, the numbers of EB increase and this form appears to predominate, although both EB and RB are found in the mature inclusion.

The entire cycle takes place within a chlamydia-modified intracellular vacuole, which undergoes a large increase in size. As the RB multiplies, there is traffic of lipids from the *trans*-Golgi into the inclusion, although the biological significance of this finding is unknown.[49] At some time between 48 and 72 hours, the cell and vacuole rupture, releasing the infectious EBs. The RBs are not stable outside the host cell. Thus, as part of their unique growth cycle, the chlamydiae appear to have evolved two morphologic entities—the compact, stable EB, which successfully persists in the extracellular environment and is responsible for cell-to-cell and host-to-host transmission; and the highly labile RB, which is the metabolically active and vegetative form that is noninfective and does not survive outside the host cell.

EB Attachment

The initial contact of the chlamydial EB with the susceptible host cell may involve a specific receptor–ligand interaction, but no such structures have been unequivocally identified on either the EB or the host cell. The attachment process may involve specific receptor sites as trypsin treatment of host cells renders them resistant to infection[46] and mutant host cells have been selected that are resistant to attachment by chlamydiae.[50] Although the binding target is not known, the presence of these sites could determine which cells are naturally susceptible. For some strains, attachment may be charge dependent. DEAE-dextran pretreatment of cells leads to marked enhancement of attachment and entry of the trachoma biovar, but not of the LGV biovar.[51] Treatment with negatively charged molecules such as heparin can inhibit chlamydial infectivity and elute EB from the surface of host cells. The attachment of *Chlamydia* to host cells and inhibition of phagolysosomal fusion are inhibited by specific antibody or by mild heat treatment of EB (56°C for 30 minutes).[52,53] Monoclonal and polyclonal antibodies to several different chlamydial antigens (usually specific for variable sequence regions of MOMP, but also including some to other proteins) have been found to neutralize infectivity in vitro by inhibiting attachment for cells lacking antibody Fc receptors. The function of antibodies to these antigens in naturally occurring infections is uncertain, but could contribute to protection from infection or reduce microbiological spread to other tissues.

Cell entry

Once attached, the EB is rapidly internalized by the host cell. If a mixture of EB and *Escherichia coli* or yeast are presented to susceptible host cells, the chlamydiae will be preferentially ingested.[52] Many of the cells that the chlamydiae infect are not considered phagocytes. Moulder has stressed the differentiation of host cells into professional and nonprofessional phagocytes and that chlamydiae induce phagocytosis by the nonprofessional phagocytes.[54] The mechanism of chlamydial uptake is not understood.

Ultrastructural studies on the entry of chlamydiae into susceptible cells suggest that they enter through clathrin-coated pits. This suggests that chlamydial entry is via a pathway similar to receptor-mediated endocytosis.[55] However, inhibitors of receptor-mediated endocytosis such as monodansylcadaverine or amantadine did not inhibit LGV biovar uptake in HeLa cells.[56] Entry may involve elements of receptor-mediated endocytosis process and may be chlamydia-directed by the secretion of chlamydial proteins into the host cell initiating an actin-based uptake mechanism.[57] Small GTPase cellular signaling events appear to serve the uptake process as activation of several members have been detected within minutes of chlamydial interaction with the host cell,[58] further implicating an important role for altering actin structure during the early infection stage. Once the chlamydiae penetrate the cell, they remain within an endosome throughout the growth cycle, and they specifically inhibit phagolysosomal fusion. Heat-killed or antibody-treated chlamydiae are not ingested at an enhanced rate and fail to inhibit phagolysosomal fusion. These two properties, induced phagocytosis and prevention of phagolysosomal fusion, are major virulence factors of this organism.

The EB is toxic. If the host cell ingests many particles (on the order of 100 EB), it may die with no resultant progeny.[59] Also, large concentrations of *Chlamydia* inoculated intravenously into mice will kill the animals; this "toxic death" appears to be a result of damage to the vascular endothelium. Chlamydiae do not produce an extracellular toxin.

Intracellular growth

The chlamydial particle enters the cell within an endosome and stays within that endosome through its entire developmental cycle. But phagolysosomal fusion does not take place.[47] The inhibitory signal is not associated with the RB, as after RBs are ingested there is fusion.[60] Inhibition is specific to the chlamydial phagosome, as fusion can take place in other phagosomes in the same cell.[61] Following entry, chlamydiae modify the inclusion vacuole by secretion of a family of proteins that become associated with the vacuolar

membrane[62] (see Fig. 31-2). Most of these proteins, called Incs, have no characterized function; however, IncA has been implicated with mediating fusion of vacuoles that harbor *C. trachomatis* organisms.[63] Interestingly, clinical isolates of *C. trachomatis* have been characterized that lack IncA expression and these strains form numerous inclusions within single cells following high-multiplicity infection (see Fig. 31-3).

Approximately 8 hours after entry into the cell, the EB has changed into an RB. The rigid structure of the EB is lost, and the RB is more permeable than the EB, allowing it to take up

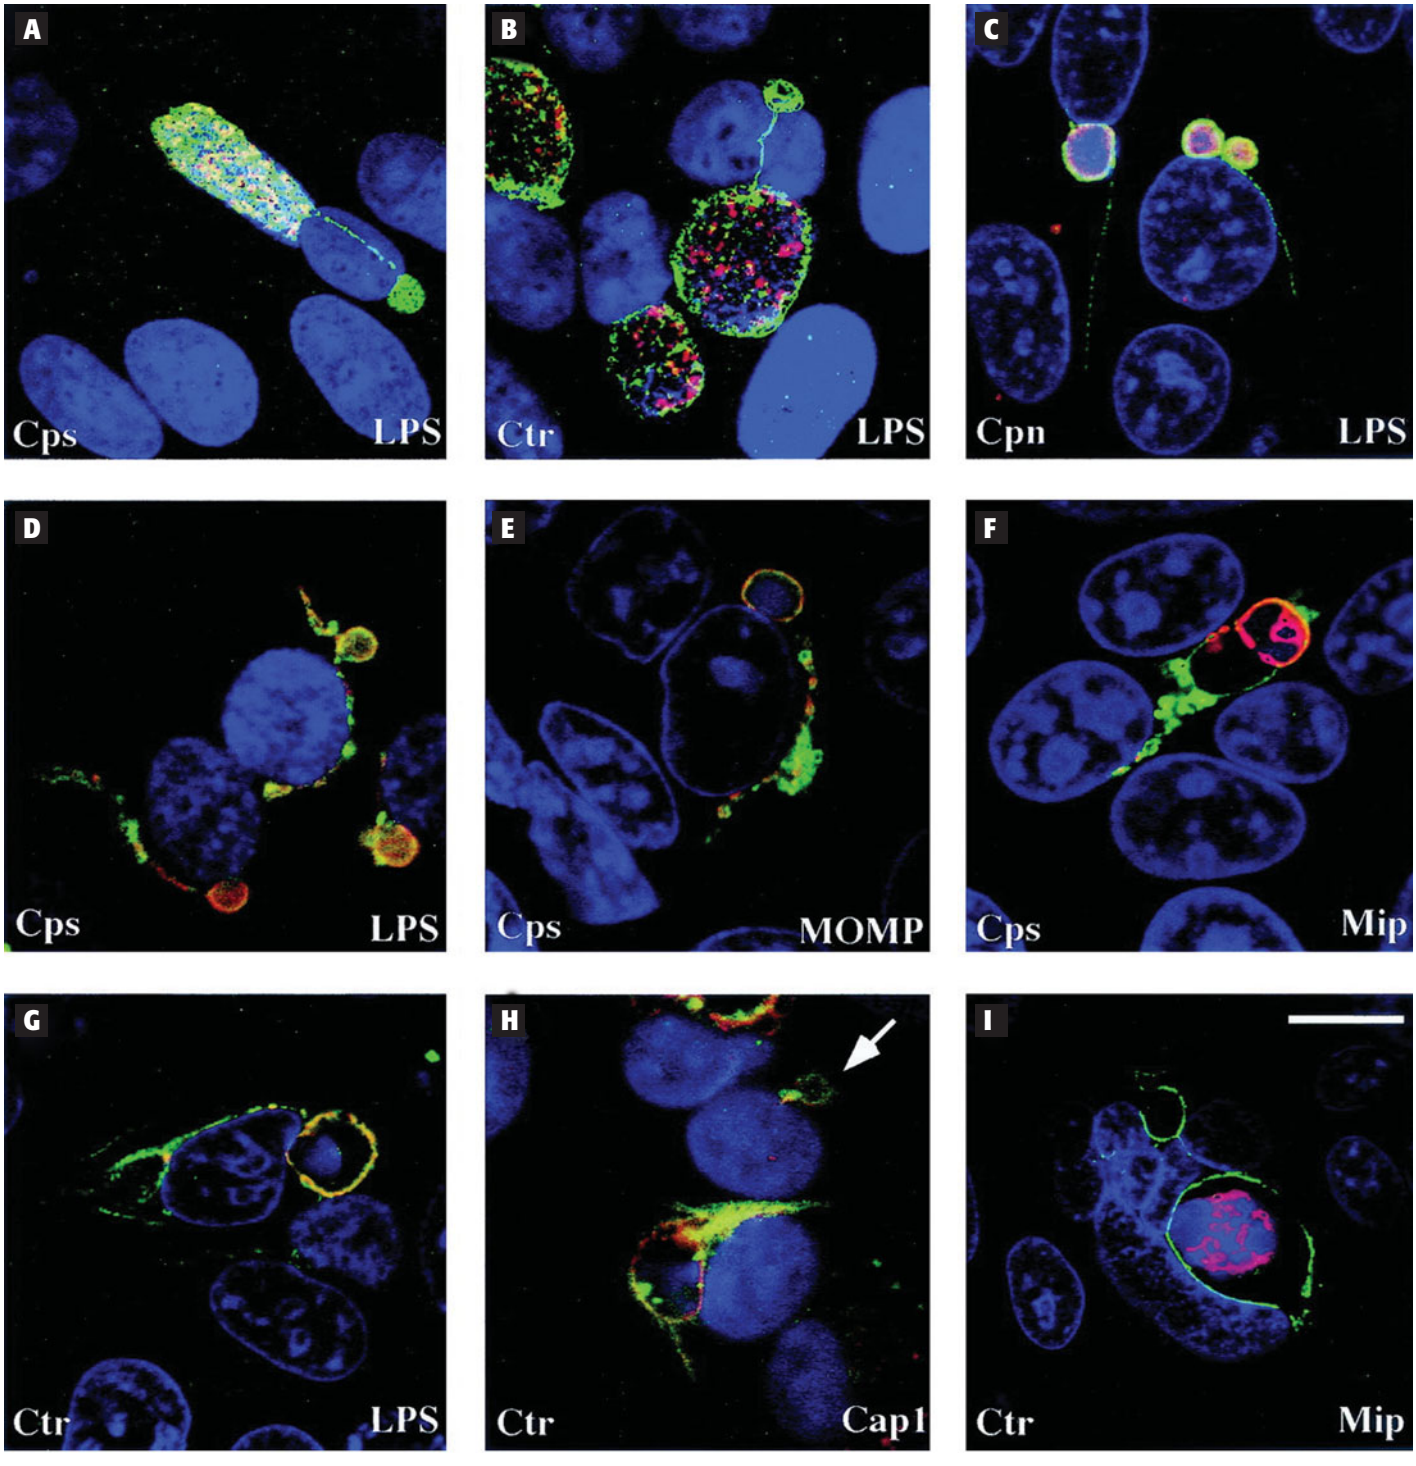

FIGURE 31-2. Antigen distribution within IncA-laden fibers of *Chlamydia*-infected cells cultured during standard growth conditions and in the presence of ampicillin. *C. psittaci* (Cps)-, *C. trachomatis* (Ctr)-, and *C. pneumoniae* (Cpn)-infected cells were cultured in MEM-10 (**A** to **C**) or MEM-10-containing ampicillin (**D** to **I**), prior to methanol fixation. All cells were labeled with anti-IncA antibodies (i.e., with fluorescein isothiocyanate). The antigens labeled with TRITC are depicted in the bottom right corner of each panel. Antigen colocalization was examined by using a confocal microscope. DAPI was used to label nucleic acids. The arrow in panel H shows the location of a vacuole embedded with chlamydial antigens that lack developmental forms. Bar, 8 μm (for all images). (From Brown WJ, Skeiky YA, Probst P, Rockey DD. Chlamydial antigens colocalize within IncA-laden fibers extending from the inclusion membrane into the host cytosol. *Infect Immun* 2002; 70: 5860–5864.)

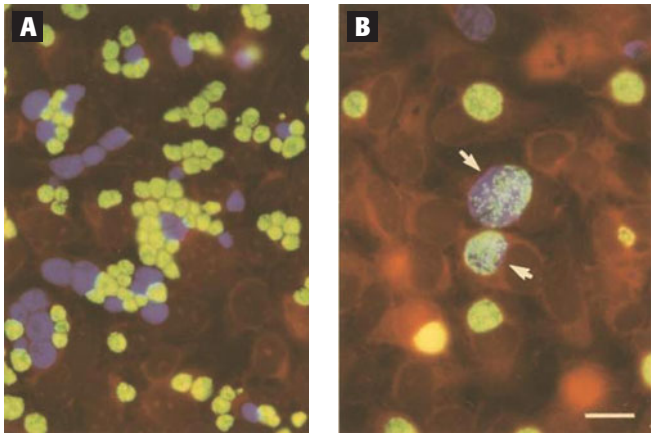

FIGURE 31-3. Dual infection of nonfusing, **A.,** and fusion-competent, **B.,** *C. trachomatis* strains cultured in HeLa cells and fixed for microscopy 30 h p.i. Within the nonfusing inclusions, serovar $J_{(s)}$ (green developmental forms) and serovar $K_{(s)}$ (blue developmental forms) remain segregated in individual vacuoles. Consistent with results of Ridderhof and Barnes [64], developmental forms of wild-type J (green) and K (blue) cells can be found within a single inclusion (arrows). The bar in panel B indicates 10 μm for both panels. (From Suchland RJ, Rockey DD, Bannantine JP, Stamm WE. Isolates of *Chlamydia trachomatis* that occupy nonfusogenic inclusions lack IncA, a protein localized to the inclusion membrane. *Infect Immun* 2000; 68: 360–367.)

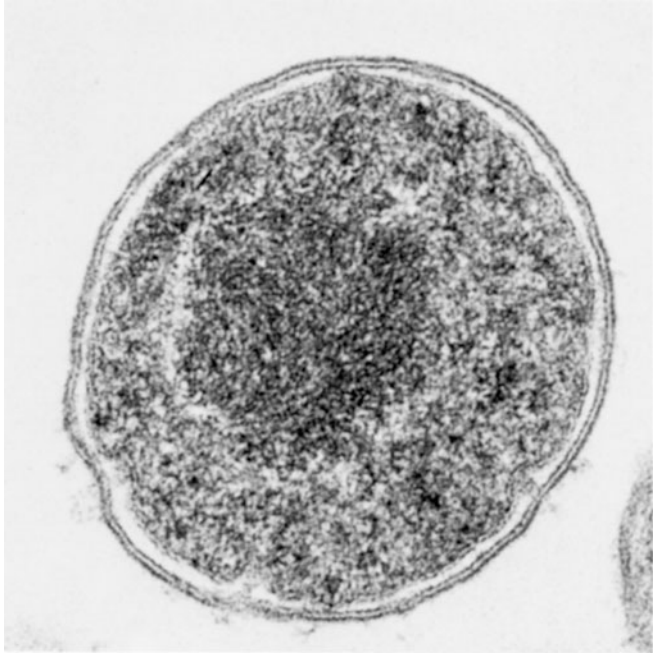

FIGURE 31-4. Electron photomicrograph of a thin section of a *C. trachomatis* **EB** (serovar L2/434). The trilaminar outer membrane (OM) and inner cytoplasmic membrane (IM) of the **EB** are shown at 118,000× magnification. (From Caldwell HD, Kromhout J, Schachter J. Purification and partial characterization of the major outer membrane protein of *Chlamydia trachomatis*. *Infect Immun* 1981; 31: 1161–1176.)

ATP and required nutrients. The inclusion and the RB act essentially as a reverse mitochondrion, with ATP and other nutrients entering the inclusion from the host cell.[65]

The RBs divide by binary fission for approximately 20–24 hours. After that time, some of the RBs become EBs by a condensation process, which is not clearly understood. Condensation involves reorganization of the outer membrane envelope by incorporation of cysteine-rich proteins and by expression of DNA-binding proteins that compact the chromosome into the electron-dense nucleoid.[66,67] Other RBs continue to divide. After replication of the RB, there is budding and blebbing of the outer membrane. Intermediate forms are also seen (see Fig. 31-1). The sequential synthesis of selected outer membrane proteins appears to reflect their putative function within the EB. Structural rigidity of the organism is maintained by disulfide bonds within the MOMP, which represents 60% of the outer membrane's weight.[68] The other cysteine-rich proteins of approximately 60 and 15 kDa are synthesized relatively late in the cycle.[69] The mature inclusion contains hundreds, even thousands, of EBs. The entire cytoplasm of the cell may be displaced by the inclusion. Throughout the infectious cycle, there is an inhibition of phagolysosomal fusion, and only at the very end is lysosomal enzyme activity noted.[70]

MORPHOLOGY AND COMPOSITION

The chlamydiae are structurally complex microorganisms which possess cell walls and membranes quite analogous in structure to the cell walls of gram-negative bacteria[71] (Fig. 31-4). Traces of muramic acid have been found in EB, but in quantities inadequate to maintain structural integrity by a peptidoglycan layer.[72] It is likely that the chlamydial cell wall is unique among bacterial species and probably represents a specialized structure compatible with the requirements of the chlamydial growth cycle.

The chlamydial cell wall consists of subunits approximately 20 nm in diameter arranged in a regular geometric pattern (Fig. 31-5).[71] The outer membrane of *Chlamydia* contains the MOMP which is approximately 30% of the weight of the organism and approximately 60% of the weight of the outer membrane.[73] The size of this protein varies by serovar, with a molecular weight range of 38–43 kDa.[74] It is a porin[75] and also appears to be the major structural protein that functions in maintaining the structural integrity of the cell wall.[73] It is a cysteine-rich protein which is linked by disulfide bonds to itself and likely to two other proteins, of approximately 15 and 60 kDa, to maintain structural rigidity.[76,77] MOMP is a transmembrane protein, with surface antigenic components responsible at least in part for serovar, serogroup, and species-specific serologic reactivity.[78,79]

Although this statement is probably too simplistic, it is likely that the major structural changes that occur when the EB changes to an RB represent a reduction of intermolecular disulfide links within the EB outer membrane. RB outer membrane structure is in some respects similar to that of the EB, although with less disulfide bridging between MOMP and RB lacks the other cysteine-rich proteins.[68,76] In the beginning

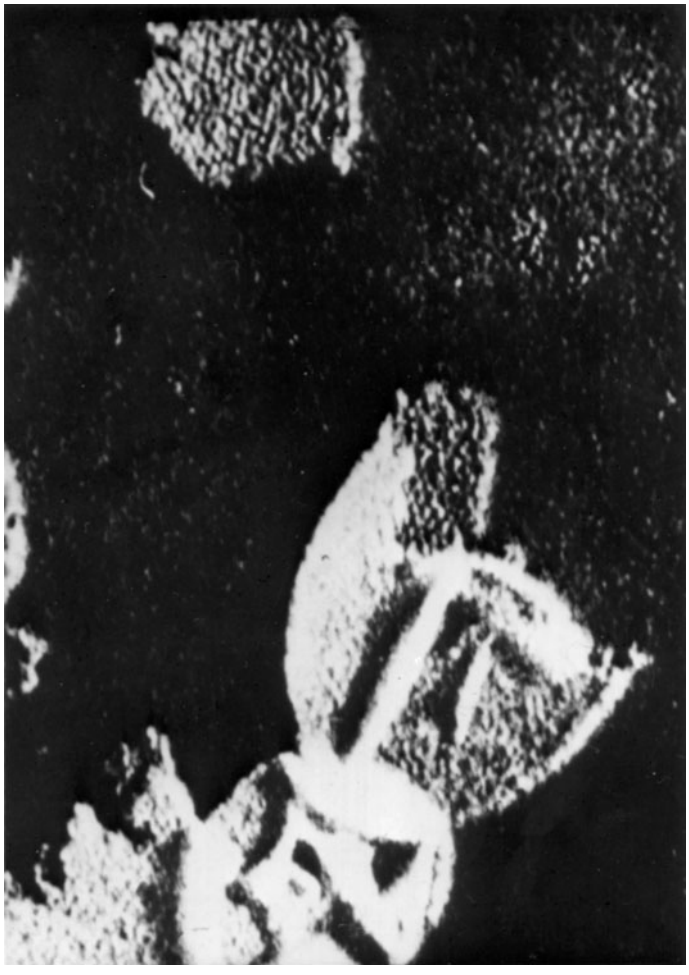

FIGURE 31-5. Fine structure of cell wall of meningopneumonitis organism. Shadowed preparation showing regular geometric arrangement of subunits approximately 20 nm in diameter. Approximately 75,000× magnification. (From Matsumoto A, Manire GP. Electron microscopic observations on the fine structure of cell walls of *Chlamydia psittaci*. *J Bacteriol* 1970; 104: 1332–1337.)

of the growth cycle, MOMP is reduced to the monomeric form, and it is found in the outer membrane throughout the chlamydial developmental cycle, whereas the other chlamydial proteins are synthesized later in the cycle.[68,69,76] The synthesis of these other proteins is regulated at the transcriptional level so that they are expressed at the time the EB will form and are oxidized into the complex that is important for structural rigidity of the EB. Enzyme-mediated oxidation–reduction reactions are probably important in the differentiation of particle types.

Supporting the concept that the EB–RB transformation is partly dependent on reduction of disulfide bonds is the observation that reduced and alkylated MOMP functions as a porin.[75] EB in the presence of dithiothreitol showed increased glutamine oxidation, reduced infectivity, decreased osmotic stability, and staining characteristics of the RB.[80] This would be consistent with a structural change that is also important in the developmental cycle, as the outer membrane would be permeable to the nutrients required for RB metabolism.

The chemical composition of the organism appears to be approximately 35% protein and 40–50% lipid. Both RNA and DNA are found, although RBs, being metabolically active, have more RNA. The common group antigen, lipopoly saccharide (LPS), may be released from the particles by treatment with detergents such as deoxycholate.[81]

Electron micrographs have shown the regular arrangement of spikelike protuberances, which occur in only a limited area of the EB (Fig. 31-6).[82] These projections are thought to be the type-III secretion apparatus. Type-III secretion systems are essential virulence determinants and function to deliver bacterial proteins into host-cell membranes or the host-cell cytoplasm. Only a few proteins (i.e., IncA and TARP) thus far have been shown to be secreted by this mechanism. However, given the probability of directing essential interactions with the host cell, identification and characterization of proteins delivered to the host cell by the type III secretion system promises to be a fertile research area.

Chlamydia appear to contain a number of penicillin-binding proteins.[83] The lack of muramic acid and peptidoglycan does not seem to jibe with the effects of penicillins. If one assumes that the ultimate effect of penicillin is the inhibition of cross-linking between tetrapeptide side chains of peptidoglycan, it would be reasonable to assume that chlamydiae have similar cross-linked tetrapeptides. These must link up with something other than peptidoglycan. Cycloserine, an inhibitor of tetrapeptide synthesis, is active against *Chlamydia* and its effect can be reversed by d-alanine, suggesting that such linkage occurs.[84]

GROWTH AND CULTURE

Because chlamydiae are obligatory intracellular parasites, it is necessary to supply a living host cell to support their growth, although host protein synthesis is not required. Tissue culture isolation procedures have made chlamydial isolation clinically relevant. The organism can be recovered from patients in 48–72 hours, a time period consistent with other bacteriologic procedures. A number of cell lines have been used as host cells, and a variety of treatments—physical or chemical—have been employed to increase the susceptibility of these cells to chlamydial infection.[14,85]

Modification of the host cells' charge by pretreatment of the monolayers with DEAE-dextran will enhance attachment by non-LGV *C. trachomatis* strains.[86] The single most important step in enhancing infection is centrifugation of the inoculum onto the tissue culture monolayer.[24,87] With the exception of LGV strains, the *C. trachomatis* strains are not efficient at attaching to and infecting cells in vitro. Indeed, a convenient method of differentiating LGV from the trachoma biovar strains is to measure the enhancement of infectivity achieved with centrifugation, for it is minimal with the LGV strains (e.g., <eightfold) and increased by $>10^2$ for the non-LGV strains.

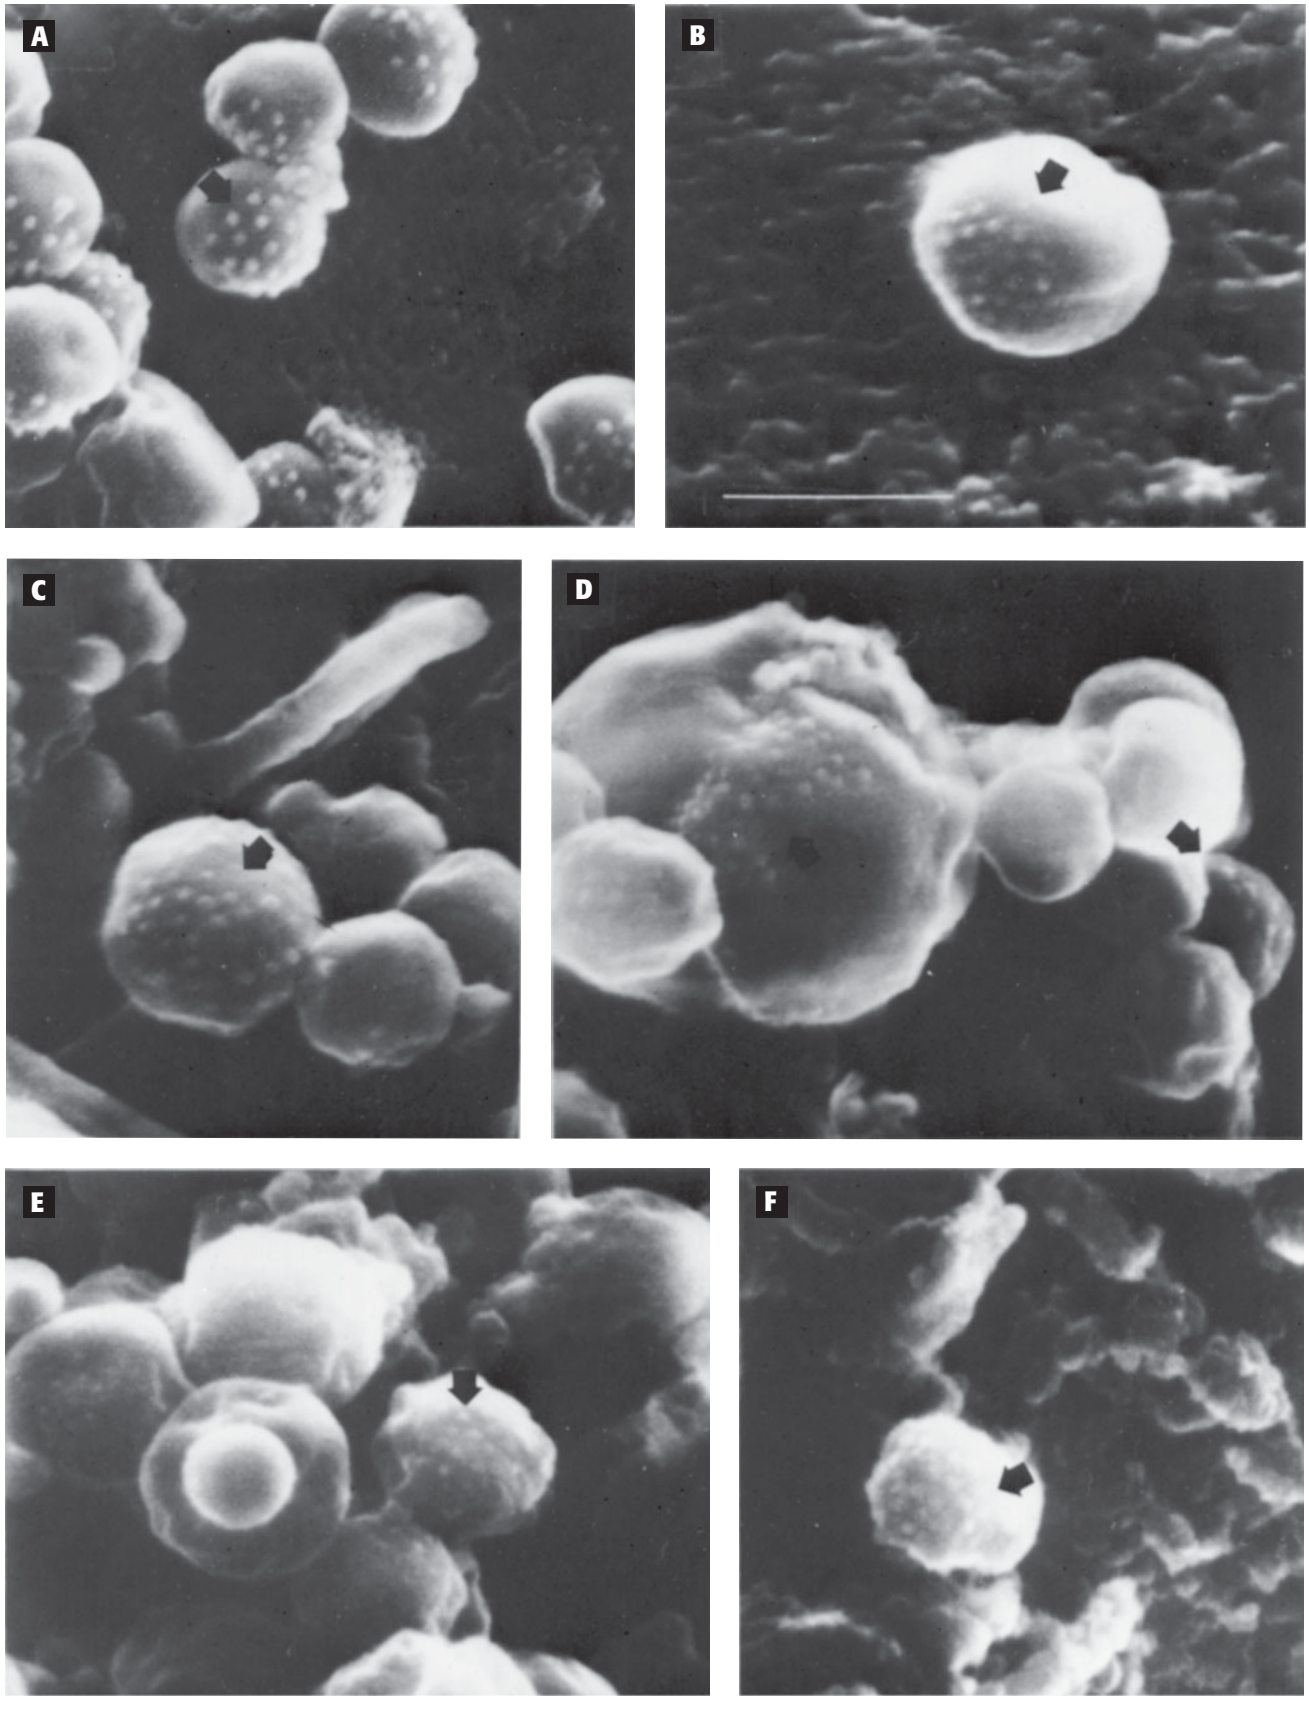

FIGURE 31-6. Scanning electron micrographs of two strains of *C. psittaci* and four strains of *C. trachomatis* settled onto L cells. **A.** *C. psittaci* (6BC). **B.** *C. psittaci* (feline pneumonitis). **C.** *C. trachomatis* (mouse pneumonitis). **D.** *C. trachomatis* (440L). **E.** *C. trachomatis* (G-17). **F.** *C. trachomatis* (UW-57). Arrows point to prominent arrays of projections. The bar in panel B represents 0.5 μm at 50,000× magnification. (From Gregory WW, Gardner M, Byrne GI, Moulder JW. Arrays of hemispheric surface projections on *Chlamydia psittaci* and *Chlamydia trachomatis* observed by scanning electron microscopy. *J Bacteriol* 1979; 138: 241–244.)

The growth of chlamydiae within the cell requires that the cell receives its essential nutrients. If the cell is starved, or if depletion experiments are performed with essential amino acids, some nutrients can be found to be growth limiting for chlamydiae, although often this reflects the requirements of the host cell more than those of the chlamydiae. The growth of *Chlamydia* in cell culture can be regulated by the amino acid concentration in the medium. Deprivation of the essential amino acids can render productive chlamydial infections to a nonproductive, persistent state. Addition of the required amino acids will then trigger growth of the chlamydiae.[88]

The most commonly used procedure involves treatment of host cells with cycloheximide before or after centrifugation of the inoculum (see Chapter 52).[89] Synthetic abilities of the host cell are largely stopped by the action of cycloheximide, and under these conditions, *C. psittaci* required isoleusine, valine, and phenylalanine.[90] *C. trachomatis* appears to require histidine, while *C. psittaci* does not.[91] Different *C. trachomatis* serovars can show different nutritional requirements.[91] Cysteine is needed for the production of the cysteine-rich proteins that are important in EB rigidity. Cysteine deprivation will, in fact, prevent the final differentiation of EB from RB.[92] The sensitivity of *Chlamydia* to amino acid concentrations may have important biological implications. The action of gamma interferon in reducing chlamydial replication and infectivity may be a direct result of reduced tryptophan levels in *Chlamydia*-infected cells.[93]

RB harvested at 20 hours, but not EB purified from *C. psittaci* and *C. trachomatis* infected cells, can support ATP-dependent and antibiotic-susceptible synthesis of proteins. MOMP and 12.5 and 60 kDa cysteine-rich protein are produced at a lesser rate than is found in infected cells.[94] Chlamydiae are capable of incorporating carbon from glucose-6-phosphate, pyruvate, and isoleucine into a trichloroacetic acid insoluble fraction. This activity was shown using a mixture of EB and RB and is ATP-dependent.[95] Cyclic AMP inhibits chlamydial growth, and the action has been shown to be on the RB-to-EB transformation.[96] RBs appear to have a receptor protein for cyclic AMP.[97] Hormone levels may affect chlamydial growth and metabolism. Estradiol enhances the growth of *C. psittaci* and *C. trachomatis* in HeLa cells.[98,99]

GENETICS

Technical considerations have prevented extensive genetic analysis of *Chlamydia*. Difficulties in developing a DNA transfer system and lack of suitable markers have restricted studies. Chlamydiae have one of the smallest bacterial genomes consisting of approximately 1.0–1.2 million base pairs, one-quarter of the size of most free-living bacteria such as *E.coli*.[100] All *C. trachomatis* serovars contain a 4.4-MDa plasmid.[101] Functions of the plasmid genes are not known, although some of the gene products are expressed during *C. trachomatis* infection in cell culture. Polypeptides encoded by these plasmids have been synthesized in an in vitro transcription translation system, and the polypeptides were not immunoreactive with antiserum prepared against chlamydiae,[102] but antiserum from infected individuals will recognize some of the plasmid gene products.[103]

Although basic chlamydial research has been hampered by the lack of genetic tools, the genomes of five chlamydial species have been sequenced and analyzed. These include strains of *C. trachomatis* and *C. pneumoniae*.[104–108] Remarkably, pairwise comparison of all genes between these genomes reveals that 88–98% of the encoded genes are shared (see Fig. 31-7). The *C. trachomatis* serovar D and the *C. trachomatis* mouse pneumonitis (CtMoPn, Fig. 31-7) have almost complete identity in gene content; even more remarkable is that the order of their genes is identical. The genes shared by the chlamydiae define the basic phenotypic and biological attributes that are common to the chlamydiae. Of interest too are the minor differences that are simply sufficient to define tissue and host specificity. The fundamental knowledge being deciphered from these genome sequences has had a dramatic effect on the progress of chlamydial research by refocusing old hypotheses, raising new hypotheses, and enabling hypothesis testing.

PATHOGENESIS

The pathogenesis of any of the infections with *C. trachomatis* has not been elucidated. It is clear that LGV is a systemic infection involving lymphoid tissues. In vitro studies have shown that the organisms are capable of replicating within macrophages.[109] To date, all information suggests that non-LGV *C. trachomatis* strains have a very limited host-cell range in vivo. They appear to be almost exclusively parasites of squamocolumnar-columnar epithelial cells. Because they are obligate intracellular parasites and kill host cells at the end stages of their growth cycle, these chlamydial strains must

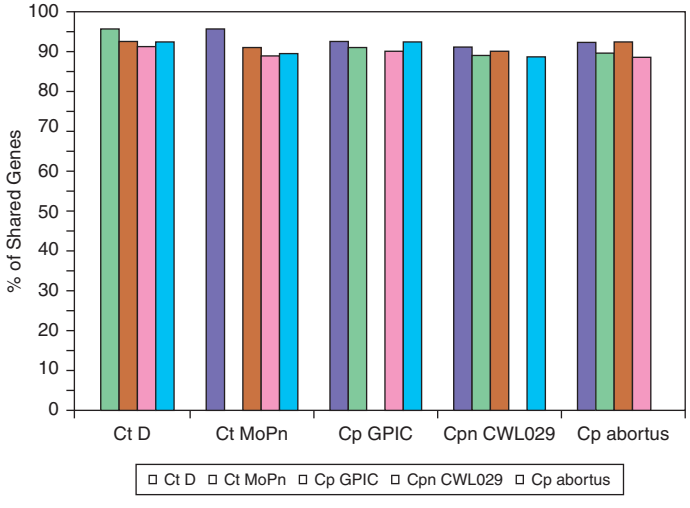

FIGURE 31-7. Level of shared genome content among chlamydial species.

cause some cell damage where they persist. There is little in vivo evidence for latency in the sense of persistence of nonreplicating chlamydiae.[110]

The disease process and clinical manifestations of chlamydial infections probably represent the combined effects of tissue damage from chlamydial replication and inflammatory responses to chlamydiae and the necrotic material from destroyed host cells. There is an abundant immune response to chlamydial infection (in terms of circulating antibodies or cell-mediated responses), and there is evidence that chlamydial diseases are diseases of immunopathology.[14,31,111,112]

There must be some sort of protective immune response to the organisms, because chlamydial infections tend to follow a fairly self-limited acute course, resolving into a low-grade persistent infection which may last for years. These infections may be activated by a variety of stimuli, of which steroids represent one class. Other reactivating agents are not yet known but must exist, as spontaneous exacerbations occur.[113]

LGV is a truly lymphoproliferative disease, and the other chlamydiae appear to be capable of causing a more localized lymphoproliferative response, in the sense that they can induce follicle formation in the mucous membranes. Although such a response is most well known for the conjunctiva (trachoma and inclusion conjunctivitis), follicular cervicitis and probably follicular urethritis (cobblestone appearance of Waelsch urethritis) are recognized entities. Follicles induced by *C. trachomatis* are authentic lymphoid follicles with germinal centers.

Trachoma has long been considered a disease in which reinfection is important.[31] It has been speculated that hypersensitivity to chlamydial antigens explains the deleterious outcome observed after inadequate vaccination and the more severe disease seen after heterotypic infection.[14,31] Resistance to reinfection appears to be predominantly serovar specific. In nonhuman primates, repeated (weekly) conjunctival instillation of *C. trachomatis* results in a disease with many of the manifestations of trachoma, including conjunctival scarring.[114] Similarly, in an experimental salpingitis model, it was found that severe salpingitis in nonhuman primates was also in part dependent on previous exposure to chlamydiae.[112] A common pathologic end point of chlamydial infection is scarring of the affected mucous membranes. This is what ultimately leads to blindness in trachoma and to infertility and ectopic pregnancy after acute salpingitis. There is epidemiologic evidence that repeated infection results in higher rates of sequelae. Thus women identified with repeat infection have more acute salpingitis than those with single infections.[115] From these epidemiologic studies, and the observational studies in trachoma, it is impossible to separate repeated discrete episodes of infection, from chronic, persistent infection as the precursor of severe late consequences.

The current prevalent theory is that much of the chlamydial disease is due to delayed hypersensitivity reactions to specific *Chlamydia* heat-shock proteins (HSPs).[116] These HSPs are similar to the HSPs of other organisms. HSP60 contains antigenic sites that are specific to chlamydiae, but it also has sites that are shared with mycobacteria and *E. coli*, and even with humans. It is clear that low-level infections can produce relatively high quantities of HSP60 and that women who suffer from tubal-factor infertility and ectopic pregnancy often have high levels of antibody to *Chlamydia* HSP60.[117,118] It should be stressed that this is still a theory and direct proof from either human or animal studies has not been generated. It is conceivable that the observed reactions are just a proxy for another reaction, but these were identified because the HSPs are plentiful and highly immunogenic.

There are no satisfactory animal models for genital *C. trachomatis* infection. Nonhuman primates are susceptible to ocular and genital infections with the trachoma biovar. Much has been learned about the pathogenesis and immunity in ocular infections. Data suggesting that prior exposure is important in the poor outcome after oviduct infection have also been obtained in this model.[112] However, because of expense and difficulty of obtaining a large number of nonhuman primates, attempts have been made to develop models in smaller animals. The genital tract of female mice that have been treated with progesterone can be infected, and ascending infections can result in salpingitis and infertility.[119] Some workers have attempted to exploit naturally occurring chlamydial infection in smaller animals. The *C. psittaci* GPIC agent and the mouse pneumonitis biovar of *C. trachomatis* are both capable of infecting genital tracts of their natural host.[8,9,120] They are sexually transmitted and can cause tubal-factor infertility as a result of ascending infection in the female genital tract.[121–123]

DIAGNOSIS

The diagnosis of chlamydial diseases is discussed in detail in Chapter 52.

ANTIMICROBIAL SUSCEPTIBILITY

There is no universally accepted protocol for testing the antibiotic susceptibility of *C. trachomatis*. A number of different procedures have been used, and the data in Table 31-4 present the range of results obtained for inhibitory levels in tissue culture systems. The simplest procedures involve infection of cell culture with a standard inoculum followed by addition of an antibiotic-containing medium. After an appropriate incubation period, inclusion counts are performed, and the concentration of antibiotic resulting in 50% or 100% reduction in inclusion count is accepted as the minimum inhibitory concentration (MIC). This procedure tends to overestimate the activity of the drugs tested. A more rigorous test involves blind passage of inclusion-negative monolayers, in an effort to assure that the drugs in question actually

killed the *Chlamydia.* In this test, the minimum concentration where no inclusions are detected on passage is considered to be the minimal cidal level.[124]

The most rigorous test of antimicrobial activity involves attempts to sterilize established infections in cell-culture systems. In this test, the tissue culture monolayers are infected with *C. trachomatis* for approximately 48 hours, and then different drug levels are added to the infected cell culture systems. After a subsequent 24-hour incubation period, the cell cultures are washed and passed to determine whether the chlamydiae have been eradicated. This procedure is likely to underestimate the effective levels of drugs, since the antibiotics are added after the time they would be most active. (That time is during active replication or metabolism, which peaks at less than 48 hours.) In addition, the technique suffers from technical objections concerning potential carryover of drugs into the second passage. This possibility is particularly present with those antimicrobials that are lipid soluble or that would have high intracellular penetration, as simple washing would not remove the drug from the monolayers and subsequent inoculum for the second passage.

C. trachomatis is susceptible to sulfonamides.[2] The organisms produce their own folic acid, and the enzymes in this synthetic pathway are susceptible to the action of the sulfonamides and to trimethoprim. Sulfonamides have been clinically effective in trachoma and LGV, but they are not used in treating most genital tract infections with *Chlamydia* because these drugs are not active against other organisms producing similar diseases.[29]

Azithromycin is currently considered the drug of choice for treating chlamydial infection.[125] Aside from excellent in vitro activity, this drug demonstrates prolonged bioavailability, which permits single-dose administration, and it accumulates within cells. Single-dose therapy with azithromycin has been shown to be as effective as a week-long course of doxycycline in treating chlamydial infection, but likely results in much better compliance, especially in nonstudy situations. The drug is similar to erythromycin in in vitro assays with MIC <1.0 mg/mL.[126]

Tetracyclines and erythromycin were formerly considered the drugs of choice in managing chlamydial genital tract infections. The organisms are highly susceptible in vitro and in vivo to the action of these antibiotics,[29,124] and resistance to these drugs has never been shown to occur naturally. Although there are documented treatment failures where chlamydiae have been isolated from patients following treatment, the recovered agents have been found to be wholly susceptible to the antibiotics.

A phenomenon termed heterotypic resistance was first reported by Jones and colleagues[127] and has been more fully described by Somani and colleagues.[128] In this description, a small proportion of the chlamydia inoculum exhibits multiple drug resistance and this is manifested by persistent aberrant inclusions that are seen on subsequent passage. These isolates have poor survival characteristics in vitro and ultimately are lost, or cannot be successfully cultivated further. Attempts have been made to correlate heterotypic resistance with clinical treatment failures; however, studies by Suchland et al.[129] have shown that heterotypic resistance is actually a phenomenon that can be observed with any *C. trachomatis* isolate and is dependent upon inoculum size. Thus, it really does not represent clinically relevant antibiotic resistance, but is rather an artifact of the assay procedures and inoculum sizes used.

Table 31-4. Minimum Inhibitory Concentration of Antimicrobial Agents for *C. trachomatis*

Drug	MIC (μg/mL or U/mL)
Rifampin	0.005–0.25
Tetracyclines	0.03–1
Azithromycin	0.03–1
Erythromycin	0.1–1
Ofloxacin	0.5–1
Ampicillin	0.5–10
Penicillin	1–10
Sulfamethoxazole	0.5–4
Clindamycin	2–16
Spectinomycin	32–100
Gentamicin	500
Vancomycin	1000

There is a suggestion that there may be some relative resistance to erythromycin and tetracycline, but there are no data to suggest that this has reached clinically relevant levels.[127,130] Rifampin, which is highly active in vitro, has not been widely used to treat human chlamydial infections. Resistance to this drug can be readily developed by passage in the laboratory in the presence of low concentrations of the antibiotic.[131] Rifampin-resistant mutants selected by serial passage at sub-MIC concentrations are still susceptible to rifalazil, a related drug.[132] In vitro a combination of azithromycin and rifampin has been shown to be more effective against *C. trachomatis* than either drug alone. The emergence of resistance to rifampin in vitro is prevented by the presence of azithromycin, and the persistent inclusions and the presence of rRNA transcripts that may be seen when azithromycin is used alone were reduced by the presence of rifamipin. This suggests that combination therapy may be more useful than monotherapy if new treatment approaches are needed.[133]

Aminoglycosides are not active against *Chlamydia,* and this has led to their widespread use in controlling bacterial contamination in clinical specimens being tested for the presence of *Chlamydia.* Common antifungal drugs such as amphotericin B and nystatin are also inactive against *Chlamydia,* as are the nitroimidazoles used to treat *Trichomonas* infections.

Penicillins are active against *Chlamydia* in vitro, but they are generally not clinically useful. By analogy from animal studies, it has been calculated that levels on the order of 20–30 million units of penicillin per day would be required for antichlamydial activity in vivo. Cephalosporins are not active. Chlamydiae do have a cell wall similar to that of other bacteria, and its synthesis can be inhibited by penicillins, but only in the early phases of the growth cycle. Addition of penicillins to infected cells in vitro cannot be expected to show marked activity after 16–20 hours of infection, as at that stage active cell-wall synthesis is minimal. It is likely that one of the cell-wall inhibitors will ultimately be found to be clinically active against chlamydiae. There are now several studies showing that a week of amoxicillin at 500 mg three times daily is effective in treating chlamydial infection in pregnant women.

Many quinolones are active against chlamydia in vitro, but only ofloxacin has been clinically useful to date. In vitro, resistance can be selected for by passage at subcidal levels. Quinolone-resistant *C. trachomatis* had a serine to isoleucine substitution in the amino acid position 83 in GyrA.[134]

IMMUNOLOGY

The biological role of antibodies or cell-mediated immunity (CMI) resulting from exposure to chlamydial antigens in either enhancing or protecting against disease or infection is not clear. Much of the difficulty in studying chlamydial antigens is due to technical problems in obtaining adequate quantities of organisms for the physicochemical fractionation procedures that are commonly used to study antigenic structure. Thus, these organisms are ideal candidates for study by modern techniques of molecular biology and genetics. What is clear is that the chlamydiae are highly complex organisms, which contain antigens of genus, species, subspecies, and serovar specificity.[135]

The most easily detected antigen is the chlamydial group antigen, shared by all members of the genus. This antigen is responsible for the complement-fixing reactions that have been commonly used to diagnose psittacosis or LGV. Other, apparently protein, group antigens have been identified but not been characterized. The major genus-specific antigen has been identified as the LPS.[136]

Chlamydial EB and RB contain an LPS antigenically similar to that of some gram-negative bacteria (*Acinetobacter calcoaceticus* and Re mutants of *Salmonella typhimurium*). Chlamydial LPS demonstrates a positive limulus lysate test. It is structurally similar to the lipid A and KDO core of LPS from rough (Re) mutants of *S. typhimurium.*[137] Its chemical composition is also similar to that of *S. typhimurium* LPS, but it appears to contain a unique constituent, 3-hydroxydocosanoic acid.[138] Chlamydial LPS has two antigen sites. One is identical to that of *A. calcoaceticus* and *S. typhimurium,* and the other is *Chlamydia* specific.[139] *Acinetobacter* LPS can be used as the CF antigen for antichlamydial antibodies, but not all sera that are positive against the chlamydial antigen will react to the *Acinetobacter* LPS.[137]

The antigens responsible for delayed hypersensitivity tests, such as the Frei test, which has been used in diagnosing LGV, have not been studied using modern techniques. The major antigen here is probably the LPS common group antigen because it is heat stable and sensitive to periodate. *C. psittaci* strains have been used successfully to prepare Frei antigens. There also appear to be specific antigens involved in delayed hypersensitivity responses, as more specific antigenic preparations can be developed by acid extraction from the crude group antigen.

Species-specific antigens appear to be shared by all members of a chlamydial species. They have been demonstrated by indirect hemagglutination, immunodiffusion with sonicated organisms, and crossed immunoelectrophoresis with solubilized organisms. MOMP has an important species-specific antigen.[78] Another species-specific antigen, common to *C. trachomatis*, has been purified to homogeneity by immunoabsorption with monospecific antibody.[140] It is pronase, heat sensitive, and of large molecular weight (1.55×10^5 Da). Antibody to this antigen is found in convalescent human sera from patients with LGV and those with high levels of antibody following other *C. trachomatis* infections.

The subspecies- or serovar-specific antigens are common only to selected strains within chlamydial species. These antigens have been the basis for a variety of serologic tests used for the classification of *C. trachomatis* isolates. They appear to be associated with the mortality observed following intravenous inoculation of mice with large quantities of viable chlamydiae. This death is termed a "toxic death" because it cannot be accounted for by multiplication of the organism; deaths occur within 24 hours, before a single cycle of replication can occur. The "toxic" effect of chlamydiae can be prevented by preincubation of the inoculum with hyperimmune serum. This "toxin" neutralization is strain specific and was first used to classify a variety of *C. psittaci* isolates.[141] A similar approach was used with *C. trachomatis* isolates, and it was found that immunization of mice could prevent lethality from homotypic toxic challenge. A mouse toxicity prevention test (MTPT) was developed which yielded a number of specific *C. trachomatis* serovars.[142,143] These serovars are identical to those shown by the microimmunofluorescence test (micro-IF).[144] The responsible antigens appear to be on the MOMP molecule.

Eighteen serovars prototypic strains of *C. trachomatis* have been characterized. A, B, and C serovars are usually associated with hyperendemic blinding trachoma in developing countries; D through K have been associated with oculogenital disease in industrialized societies; and L1, L2, and L3 are LGV serotypes. These serovars fall into two broad complexes (B and C) by micro-IF. Each complex shows extensive cross-reaction within the complex but little reaction with the other complex. Serovar-specific monoclonal antibodies are now available for typing purposes.

The MOMP is a porin and contains antigens of serovar, serogroup, and species specificity.[78,145] Because of MOMP's important structural and antigenic role, studies of the gene responsible for its synthesis have been of particular interest. The gene encoding MOMP and its amino acid sequence is known for all serovars.[146] The sizes of MOMP fall between 39 and 42 kDa depending on the serovar. There are five conserved and four variable sequence regions within the genes, and each variable region is antigenic and surface exposed. The most variable segments are approximately 11 amino acids long and occur one each in the amino-terminal half and the carboxyl-terminal half of the MOMP. It is likely that these sites are responsible for subgroup- or serovar-specific antigenic reactivity. The species-specific site is located adjacent to one of the variable regions near the carboxyl-terminus. Minor genus-specific reactivity has also been shown.

MOMP and the 60–62-kDa and 12–15-kDa proteins may be copurified by sarkosyl extraction of EB. The 60–62-kDa proteins are important immunogens and often found as a doublet.[147] It is now clear that one of these is a cysteine-rich structural protein, while the other is a loosely bound HSP60. While MOMP appears to be the immunodominant antigen, there may be a more selective response to 60–62-kDa proteins. The latter proteins are surface exposed and have species-specific antigens. In contrast, the 15-kDa proteins are not on the EB surface. They contain antigens of species and biovar specificity.[148] A second porin with surface-exposed, species-specific antigens is PorB. This protein is significantly less abundant than MOMP and is also highly conserved and lacks the variable sequence regions observed for *C. trachomatis* MOMP.[149]

Monoclonal antibodies directed against MOMP have been shown to be capable of neutralizing infectivity in cell culture and are protective against toxic effects seen in mice after intravenous inoculation of live EB. They can also neutralize infectivity for ocular infection in nonhuman primates.[150] Monoclonal antibodies against nonsurface subspecies, species-specific epitopes, or the LPS neither protected mice nor neutralized infectivity for the eye. The neutralization reactions usually appear to be serovar or serogroup specific.[151] Antibodies to PorB also neutralize infectivity in tissue culture, but have not been tested in animal models.[152]

The outer membrane of *Chlamydia* is a particularly interesting structure because in the EB it represents a target for immune attack. There have been a number of functions identified with putative protective antigens in the outer membrane. These functions, including host-cell attachment, enhanced phagocytosis, and phagolysosomal fusion inhibition, are all neutralized by specific antibody. Although a number of protein antigens have been identified, and MOMP and other proteins induce neutralizing antibody, no virulence antigen has been specifically identified.

CONTROL OF CHLAMYDIAL INFECTION BY THE HOST

In the majority of chlamydial infections, only a relatively small proportion of cells at affected sites are found to be infected. Because each inclusion releases hundreds of viable EB and relatively few nearby cells are infected, there must be control mechanisms that limit infectivity. The mechanisms are not clear, although T-cell functions are essential. Lymphokines have been shown to have an inhibitory effect on chlamydiae.[153] *C. trachomatis* is sensitive to alpha, beta, and gamma interferons.[154] The last of these appears to be most active. The lymphokine, which inhibits *Chlamydia* in human macrophages and in mice, has been identified as gamma interferon.[155,156] The interferon appears to delay the developmental cycle so that the RBs persist for a longer period of time.[157,158] This may result in persistent inapparent infection and may also play a role in immunopathogenesis. The mode of action appears to be the same as in other systems and involves depletion of tryptophan, making tryptophan unavailable to the chlamydiae.[93] The effect is reversible by addition of exogenous tryptophan.

It is likely that mechanisms such as the apparent effect of gamma interferon represent control of infection rather than protection against new infection. Antibodies may be involved in clearance and limiting infection.

IMMUNITY

Immunity induced by chlamydial infection is not well understood. It is clear that single infections will not result in solid immunity to reinfection. Multiple infections, homo- or heterotypic, are common. Unfortunately, the natural infection is not readily quantifiable in terms of inoculum size, and thus relative degrees of immunity may exist which are overcome with a sufficiently large challenge. Some immunity probably develops following initial or serial infection. In screening studies, younger women are found to have higher cervical infection rates than older women, who often have higher antibody levels. This speculation is also consistent with the observation that many isolate-negative individuals attending

STD clinics have IgM antibody to the organism.[159] This antibody could result from recent exposure and rapid resolution of the infection or its ablation by an immune response.

The only human chlamydial infection which has been subjected to extensive vaccine studies is trachoma. Unfortunately, these studies were performed without a sophisticated knowledge of the chlamydial immune response. These results have been summarized elsewhere.[14,31] The results from field studies on vaccine trials and infection of human volunteers and nonhuman primates indicate that there is a short-lived relative immunity to reinfection with homotypic challenge.

Data from ocular infection with *C. psittaci* in guinea pigs and *C. trachomatis* in nonhuman primates suggest an important role for antibody in host defense.[160–162] Antibody is capable of neutralizing chlamydial infectivity in cell culture. There are many possible modes of action. Antibody can inhibit attachment of the organism to the surface of a nonprofessional phagocyte, or result in failure to inhibit phagolysosomal fusion, or prevent a morphologic shift of the EB and RB by cross-linking surface proteins. Antibody may opsonize. Antibody that blocks attachment of *C. psittaci* to L cells enhances attachment to macrophages.[163]

There are now many in vitro studies showing that immunization with purified, synthesized, or recombinant peptides can induce neutralizing antibodies. Synthetic vaccines have been developed, sometimes by artificially juxtaposing synthesized conjugates of T-helper sites with selected B-cell sites predicted to result in neutralizing antibody and finding that such antibodies are indeed generated. In some instances, these immunizing peptides have been linked by genetic manipulation and expressed in *E. coli*. While it has been relatively easy to induce neutralizing antibodies as assayed in vitro, vaccines that elicit neutralizing antibodies have so far failed to protect animals from subsequent challenge.

C. trachomatis do not appear to survive well in PMNs.[164] It is possible that antibody-enhanced phagocytosis plays an important role in clearance of infection and in resistance to reinfection. *Chlamydia* are rapidly internalized by human PMNs, and the majority are rendered noninfectious within 1 hour. Most of the EB are found in PMN phagosomes where lysosomal fusion has occurred.[165] The mechanism of killing by PMNs is not known, but it is likely that oxygen-dependent and oxygen-independent mechanisms are involved. Killing is still seen in the presence of inhibitors such as azide or cyanide.[164] Chlamydiae act as polyclonal stimulators of B-lymphocytes.[166] Stimulation can be effected in mice that are LPS nonresponders, suggesting that something other than the genus-specific antigen is responsible.

Leukocytes clearly play an important role in resistance to infection and in clearance of primary infection. T-cell deficient mice do not produce significant levels of antichlamydial antibody.[167] Lymphocyte transformation in vitro and delayed hypersensitivity reactions are also T-cell dependent. They can be found in heterozygous mice and in mice who received thymus transplants, but are not observed in the nude athymic mouse.[168,169]

Williams and colleagues have exploited the athymic mouse model of respiratory infection with the mouse pneumonitis biovar of *C. trachomatis* to dissect the immune response.[167,169–171] Results of these studies have suggested a defense role for both antibody and CMI responses. Both $CD4^+$ and $CD8^+$ T cells have protective roles in animal models.[172] The predominant evidence suggests that Th1-type cell responses involving $CD4^+$ T-helper cells play an important role in protective immunity.[173,174] However, the actual mechanism of immunity is unclear, and the demonstration that cytotoxic $CD8^+$ T lymphocytes are capable of lysing chlamydia-infected cells suggests that these cells too could play a role.[175]

VACCINE AND VIRULENCE FACTORS

Because surface antigens would be likely vaccine candidates, efforts to identify the factors responsible for attachment, enhanced uptake, and inhibition of phagolysosomal fusion and modification of host-cell functions will continue to be stressed. For *C. trachomatis,* neutralization of infectivity appears to be serovar specific. The only antigenic sites of that specificity that have been clearly identified are on MOMP; however, peptides or subcomponents of MOMP fail to protect by vaccination and effective neutralization based upon MOMP will likely require conformationally authentic MOMP or its mimic.[176] MOMP antigenic variation is not observed with most other species of chlamydiae and those such as *C. pneumoniae* may entirely depend on conformational determinants of MOMP for antibody reactivity.[177]

The importance of T cells in immunity is a recurring theme. Both humoral and CMI responses are T-cell dependent. Identification of specific CD4 T-cell recognition sites may be crucial to understand the regulation of chlamydial immunity, especially at mucosal surfaces. Cytotoxic CD8 T cells can recognize and kill chlamydia infected cells,[175] and chlamydia-specific CD8 T cells promote resolution of infection in a murine model.[178]

A real challenge with vaccine development will be generating immune responses that appear to be better than those that occur after natural infection. While much progress is being made on the microbiologic front, it is clear that considerable input from immunologists will be required to generate optimal methods for antigen presentation to enhance mucous-membrane immunity. Even if protective immune responses can be induced by a vaccine, the ultimate success of such a vaccine will depend, in part, on the antigenic stability of the organism. There is evidence of a high degree of immunologic variation within the variable regions of MOMP. Identification of high rates of DNA polymorphism

in the MOMP gene among prostitutes in Nairobi suggests the possibility of immune selection and evasion, which may present further problems for developers of a vaccine unless they discover alternative antigens that mediate protection.[179] Genomics have led to the discovery of several new virulence proteins that represent promising new opportunities for vaccine development.[180]

32 *Chlamydia trachomatis* Infections of the Adult

Walter E. Stamm

Since the early 1970s, *Chlamydia trachomatis* has been recognized as a genital pathogen responsible for an increasing variety of clinical syndromes, many closely resembling infections caused by *Neisseria gonorrhoeae* (Table 32-1). Because many practitioners have lacked access to facilities for laboratory testing for chlamydia, these infections often have been diagnosed and treated without benefit of microbiological confirmation. Newer, molecular diagnostic tests have in part now addressed this problem, making specific diagnosis much more widely available. However, diagnostic tests are still not available to providers in developing countries. Unfortunately, many chlamydial infections, particularly in women, are difficult to diagnose clinically and elude detection because they produce few or no symptoms and because the symptoms and signs they do produce are nonspecific. The high prevalence of these infections in many parts of the world has thus resulted from inadequate laboratory facilities for their detection and eventual treatment, coupled with the nonspecific and minimal signs and symptoms chlamydial infections produce, the lack of familiarity clinicians have with these infections, and the lack of resources directed toward the development of programs for screening of high-risk patients, contact tracing, and treatment of infected partners.

Table 32-1. Clinical Parallels Between Genital Infections Caused by *N. gonorrhoeae* and *C. trachomatis*

	Resulting Clinical Syndrome	
Site of Infection	*N. gonorrhoeae*	*C. trachomatis*
Men		
Urethra	Urethritis	NGU, PGU
Epididymis	Epididymitis	Epididymitis
Rectum	Proctitis	Proctitis
Conjunctiva	Conjunctivitis	Conjunctivitis
Systemic	Disseminated gonococcal infection	Reiter's syndrome
Women		
Urethra	Acute urethral syndrome	Acute urethral syndrome
Bartholin's gland	Bartholinitis	Bartholinitis
Cervix	Cervicitis	Cervicitis, cervical metaplasia
Fallopian tube	Salpingitis	Salpingitis
Conjunctiva	Conjunctivitis	Conjunctivitis
Liver capsule	Perihepatitis	Perihepatitis
Systemic	Disseminated gonococcal infection	Reactive arthritis

EPIDEMIOLOGY

Chlamydial infections of the genital tract have a worldwide distribution and are prevalent both in the industrialized countries and in the developing world. The World Health Organization (WHO) estimated that 89 million new cases of genital chlamydial infections occurred worldwide in 2001.[1] In the United States, about 4–5 million cases of chlamydial infection occur annually at an estimated cost of $2.4 billion dollars.[2] Since chlamydial infections first became a reportable disease in the United States in 1986, the number of reported cases in both men and women have increased each year (Fig. 32-1).[3] The greater number of reported cases in women than men reflects current screening practices, which focus mainly on women. In 2004, 929,462 cases were reported, making *C. trachomatis* the most common reportable disease in the United States.[3] However, only a minority of cases are actually reported. In selected countries and in parts of the United States where intensive chlamydia control programs have been instituted, dramatic reductions in prevalence have been observed. In Sweden, for example, the number of cases of *C. trachomatis* infection was reduced by more than 50% over a 7-year period, falling from 38,200 in 1987 to 13,600 in 1994.[4] Similar declines have been seen in the Pacific Northwest (Region X in the

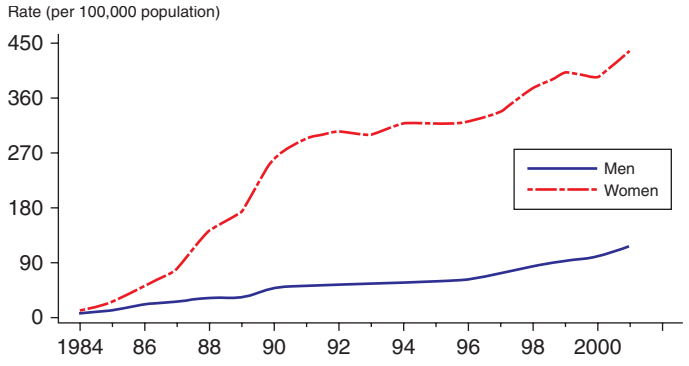

FIGURE 32-1. Reported cases of *C. trachomatis* infections in the United States by year and gender.

United States) and in Wisconsin after the institution of control programs. However, the prevalence of infection in these regions, namely, in Sweden, in Region X of the United States, and in Vancouver, British Columbia, Canada, has increased steadily each year since 1998 despite ongoing control program activities.[4,5] This phenomenon is discussed in more detail under prevention below.

Chlamydial infections of the genital tract are primarily caused by serovars D, E, F, G, H, I, J, and K.[5] A remarkably similar distribution of serovars has been observed worldwide, with the D, E, and F serovars (B class) being most prevalent and C class serovars less prevalent.[6] Infections caused by the former serovars are also associated with higher inclusion counts and with young age.[7] Among rectal infections in homosexual men, the D and G serovars are particularly prevalent for reasons as yet unexplained.[8] Several studies have suggested that the F and G serovars may produce less symptomatic and/or less inflammatory infections than strains of other serovars.[9,10] Paradoxically, variant F serotype strains have been seen more often in women with upper genital tract infection.[11]

Using molecular analyses of the chlamydial MOMP, it has become increasingly evident that polymorphism within the MOMP gene is common among isolates from patients who are highly sexually active and frequently exposed to chlamydial infection.[12] Allelic polymorphism, thus, may produce antigenic variation that provides the organism with the ability to evade the immune response. Less antigenic variation in MOMP has been observed in strains isolated from less sexually active populations.[13]

INFECTIONS IN MEN

The prevalence of chlamydial urethral infection has been assessed in populations of men attending general medical clinics, STD clinics, adolescent medicine clinics, and student health centers and ranges from 3–5% of asymptomatic men seen in general medical settings to 15–20% of all men seen in STD clinics.[5,14–17] Among military personnel, Podgore et al. found an 11% prevalence of asymptomatic urethral chlamydial infection compared with a 2% prevalence of urethral gonococcal infection.[18] Rates of chlamydial urethral infection of 13–15% have also been reported among sexually active boys attending adolescent medicine clinics.[19,20] Among men, the prevalence and site of mucosal infection appear to be strongly correlated with both age and sexual preference. Of 1221 patients screened for urethral infection in an STD clinic, 5% of homosexual men and 14% of heterosexual men had positive urethral cultures for *C. trachomatis*, and in both groups prevalence decreased in each 5-year period from age 19 to age 39 years (Fig. 32-2). This striking age-related prevalence has been demonstrated repeatedly in both men and women; age is thus the most potent risk factor for *Chlamydia* in both genders. In other studies, both nongonococcal urethritis (NGU) and postgonococcal urethritis (PGU) were caused by *C. trachomatis* less frequently in homosexual than in heterosexual men.[21] The prevalence of chlamydial infection generally has been higher in African Americans than in whites. In one screening study, 19% of nonwhite and 9% of white heterosexual males had urethral chlamydial infection.[17] Evidence of chlamydial infection has been infrequent in sexually inexperienced populations of men.

Chlamydial infection is a cause of acute proctitis in homosexual men who practice receptive rectal intercourse without condom protection.[22–24] Thus, both urethral and rectal chlamydial infections contributed to the high prevalence of serum antibody to *C. trachomatis* observed in homosexual men in the pre-AIDS era.

Pharyngeal infection with *C. trachomatis* has been demonstrated in 3–6% of men and women attending STD clinics and correlates with a history of recent orogenital contact.[25] Most such infections are asymptomatic. Among adolescents attending a teen clinic, only 1% were culture positive for *C. trachomatis* in the pharynx.[26] Earlier serologic studies suggesting an etiologic role for *C. trachomatis* in nonstreptococcal community-acquired pharyngitis have not been

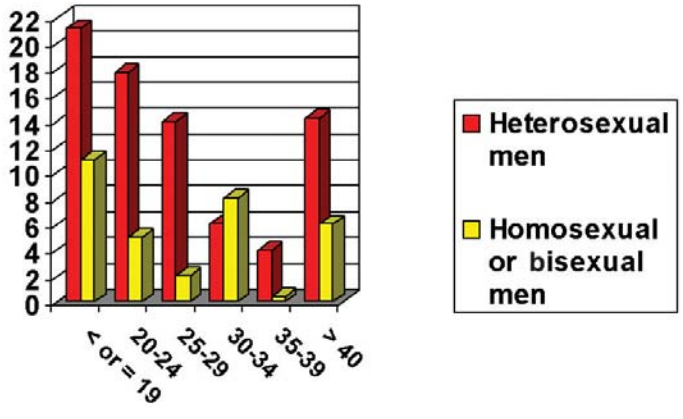

FIGURE 32-2. Prevalence of *C. trachomatis* urethral infection by age in men attending an STD clinic. *Open bars* = heterosexual men; *solid bars* = homosexual or bisexual men.

supported by more recent attempts to isolate *C. trachomatis* from patients with pharyngitis.[27,28] The earlier serologic studies most likely were measuring antibodies against *Chlamydia pneumoniae*.

The overall incidence of *C. trachomatis* infection in men has not been well defined, since in most countries these infections are not officially reported, are not microbiologically confirmed, and often may be asymptomatic, thus escaping detection. In the United States, the number of reported cases of chlamydial infection in men is thought to be artifactually low because of the infrequent use of chlamydia diagnostic tests in men (see Fig. 32-1). Recent population-based studies in the community utilizing nucleic acid amplification tests (NAATs) suggest a prevalence of about 2% in younger (<24 years of age) men, with lesser prevalences in older men.[29]

The transmissibility of genital chlamydial infections from females to males has not been extensively studied. In one study, male partners of women who had either chlamydial or gonococcal cervicitis were found to be infected with these agents 28% and 81% of the time, respectively.[30] Male partners of women with dual infections were also infected more often with gonorrhea than with chlamydia (77% and 28%, respectively).[30] Although this study suggests that *N. gonorrhoeae* is more transmissible than *C. trachomatis*, the differing lengths of incubation period of these two agents and differing efficiency of isolation from the urethra could explain the results. A more recent study by Quinn and colleagues utilized PCR rather than a culture to estimate rates of transmission and demonstrated that although 42% of male partners of infected women were urethral culture positive, 68% were PCR positive.[31] The genotypes of the chlamydial strains were identical in both partners as well. This study suggests that transmission from men to women and from women to men may be equally efficient.

INFECTIONS IN WOMEN

The prevalence of chlamydial infection has been studied in pregnant women, in women attending gynecology or family planning clinics, in women attending STD clinics, in college students, and in women attending general medicine or family practice clinics in school-based clinics and more recently in population-based studies. Prevalence of infection in these studies has ranged widely from 3% in asymptomatic women in community-based surveys to over 20% in women seen in STD clinics.[31–53] During pregnancy, 3–7% of women generally have been chlamydia positive, although a 21% prevalence in a population of inner-city African American women and a 26% prevalence among pregnant Native American women have been reported.[46–48] Demographic factors associated with an increased risk of chlamydial isolation in at least several studies include young age, nonwhite race, single marital status, use of oral contraceptives, and measures of sexual activity such as a new partner or multiple sexual partners.[31,35,44,45] The proportion of infected sexually active women has been highest for women aged 15–19 years and declines strikingly thereafter (Fig. 32-3). Sexually inexperienced populations (or women lacking the risk factors noted above) rarely exhibit chlamydial cervical infections. In a study evaluating a 50% sample of all sexually active Alaskan Inuit women living in remote villages, 114 (23%) of 493 had cervical infection with *C. trachomatis*.[53] As, in this study, has been demonstrated repeatedly that in sexually active populations in which little diagnostic testing and/or specific treatment is being used, the prevalence of infection may thus reach surprisingly high levels. This reflects the asymptomatic nature of chlamydial infection and the ability of the infection, when untreated, to persist for months or years.

The incidence of *C. trachomatis* genital infection has been defined in a few selected populations. Burstein and colleagues followed a cohort of 3860 women in Baltimore over 33 months and observed an incidence rate of 28/1000 person months in this largely African American inner-city population.[49] The increasing number of reported cases in the United States among women in recent years undoubtedly reflects increased use of diagnostic testing and more frequent screening of high-risk women (see Fig. 32-1).

As in men, transmissibility of chlamydia has also been poorly defined in women. A comparative study of partners of men with either chlamydial or gonococcal urethritis found

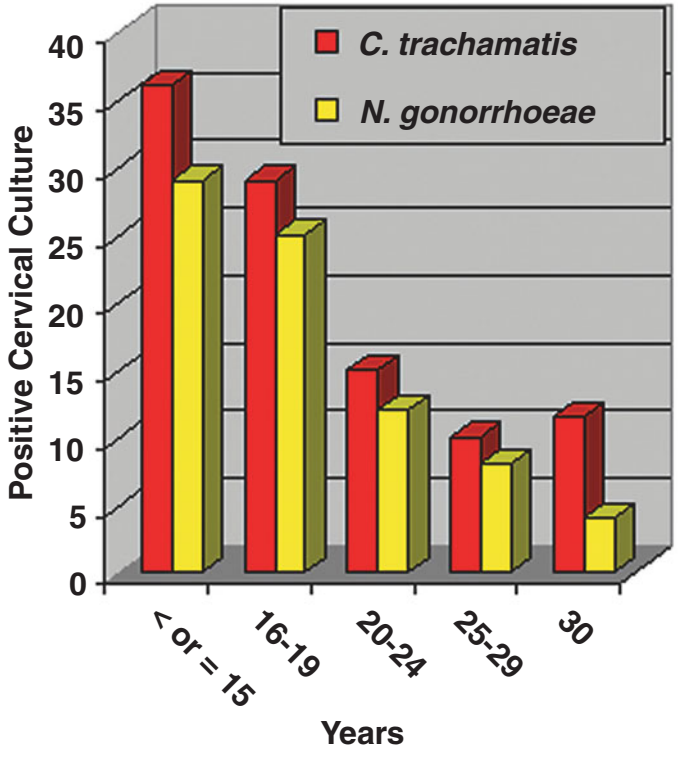

FIGURE 32-3. Prevalence of *C. trachomatis* and *N. gonorrhoeae* cervical infection by age in women attending an STD clinic. *Open bars = N. gonorrhoeae; solid bars = C. trachomatis*.

that these women were infected 45% and 80% of the time, respectively.[30] Among female partners of men with both infections, 45% had chlamydial infection and 64% had gonorrhea. Quinn and colleagues found that 57% of female partners of infected men were infected, as judged by culture, but 70% were positive, as judged by PCR.[31]

NATURAL HISTORY OF CHLAMYDIAL INFECTION

Several studies in the United States indicate that approximately 5% of neonates acquire chlamydial infection perinatally, yet antibody prevalence in later childhood before onset of sexual activity may exceed 20%.[54] The acquisition of infection during childhood has not yet been well documented but could occur from infected siblings (in whom infection acquired perinatally may persist for more than 1 year) or from parents or other adults via sexual abuse.[55] Childhood upper respiratory, eye, or middle ear infections with *C. trachomatis* might explain this rise in antibody prevalence between the neonatal period and adolescence, as could chlamydial genital infections acquired by children as a result of sexual abuse (see Chapter 72). Alternatively, cross-reacting antibody to *C. pneumoniae* strains producing upper respiratory infections during childhood could account for some or all of this apparent increase in the seroprevalence to *C. trachomatis* (see Chapter 15).

In adolescence, the incidence of culture-positive symptomatic genital chlamydial infections rises sharply, as does antibody prevalence. Asymptomatic infection also occurs commonly, and long-lived but unrecognized urethral, rectal, and cervical infections undoubtedly occur. Unrecognized, asymptomatic, or minimally symptomatic infections of the upper genital tract also occur and have been termed "silent salpingitis." Both rectal and urethral infections contribute to the high antibody prevalence found in homosexual men.

Much remains to be learned about the natural history of genital infections owing to *C. trachomatis*, but, on the basis of knowledge of the natural history of trachoma and of limited studies of untreated men, nonpregnant women, and children, subacute and chronic asymptomatic infection of genital mucosal surfaces undoubtedly occurs commonly.[32,56] Natural immunity in women, as measured by time to spontaneously clear infection, appears to take many months to develop.[57] The reported occurrence of chlamydial respiratory infection during immunosuppression suggests that impaired immunity may be followed by reemergence of symptomatic infection from a chronic latent focus.[58,59] Recrudescence of ocular trachoma years after leaving an endemic area has also been shown to occur during topical cortisone therapy.[60] Current evidence indicates that chlamydial infection has not been a clinically apparent problem in AIDS patients.[61] Similarly, the interactions between ocular trachoma, lymphogranuloma venereum (LGV), and non-LGV genital and perinatal infection have not been extensively studied in parts of the world where all of these strains are present in the same populations.[62] It is not known, for example, whether the epidemiology or clinical manifestations of genital chlamydial infections are altered in LGV or trachoma endemic areas.[62] Recent studies have called attention to the relatively high rate of recurrent infection with *C. trachomatis* in young, sexually active populations. In some studies, up to 20–30% of women have had evidence of recurrent infection within 6 months of an initial infection.[63,64] Recurrent infections may be with the same or a different serovar or genotype.[63] Mixed infections with two or more strains are evident in 3–8% of more highly sexually active populations.[65] It is likely that recurrences may be caused either by exogenous reinfection from a new or untreated sexual partner or by failure to eradicate an original infection.

CLINICAL MANIFESTATIONS

Genital infections caused by *C. trachomatis* closely parallel those due to *N. gonorrhoeae* in terms of clinical manifestations (see Table 32-1). Both organisms preferentially infect columnar or transitional epithelium of the urethra, with extension to the epididymis; the endocervix, with extension to the endometrium, salpinx, and peritoneum; and the rectum. Both organisms can produce extensive subepithelial inflammation, epithelial ulceration, and scarring. Rarely, both organisms can produce systemic manifestations. In general, infections caused by *C. trachomatis* tend to be less abrupt in onset and are more often characterized by no symptoms or by milder symptoms than is the case for gonococcal infections.

INFECTIONS IN MEN

URETHRITIS

Although Koch's postulates have not been specifically fulfilled, persuasive evidence suggests that *C. trachomatis* causes 35–50% of NGU in heterosexual men. In the 1970s and 1980s, the frequency of chlamydial isolation in men with recent onset of NGU was remarkably consistent from study to study, despite differences in patient population and methodology.[66–77] However, recent studies suggest that the proportion of NGU cases attributable to chlamydia may be declining in regions where chlamydia control programs have been in place.[78] When female partners of *C. trachomatis*-positive and *C. trachomatis*-negative men with NGU were examined, 60–75% of the former and 0–10% of the latter had chlamydial cervicitis, evidence that is consistent with

sexual transmission of *C. trachomatis* having resulted in NGU.[72–75] Immunotyping (or, more recently, genotyping) of isolates from both partners has shown concordance of immunotypes or genotypes in most couples.[31] Serum IgM antichlamydial antibody is found frequently in chlamydia culture-positive men with NGU but rarely in culture-negative men with NGU.[74] Finally, placebo-controlled treatment trials of men with NGU or therapeutic trials utilizing drugs such as spectinomycin, which have little effect on chlamydia, indicate that most men given placebo or ineffective therapy for *C. trachomatis* remain culture positive and symptomatic until effective treatment is given.[75–77] Elimination of chlamydia thus coincides with resolution of symptoms. Although *C. trachomatis* has not been experimentally inoculated into the human urethra, baboons and chimpanzees develop chlamydial urethritis accompanied by serologic evidence of infection after urethral inoculation.[79]

Clinically, chlamydia-positive and chlamydia-negative NGU cannot be differentiated on the basis of signs or symptoms.[76] Both usually present after a 7–21-day incubation period with dysuria and mild-to-moderate whitish or clear urethral discharge. Examination reveals no abnormalities other than the discharge in most cases; associated adenopathy, focal urethral tenderness, and meatal or penile lesions should suggest herpetic urethritis. Neither abnormal prostatic examinations nor prostatic inflammation has been convincingly linked to chlamydial urethritis.

C. trachomatis urethral infection is more often asymptomatic than gonococcal urethral infection, and, when symptoms occur, they are milder with chlamydial urethritis.[17,80] However, most men with asymptomatic chlamydial urethral infection exhibit ongoing inflammation, as defined by persistent urethral leukocytosis ($\gtrsim$ 4 polymorphonuclear leukocytes [PMNs] per 1000× field) on Gram stains of urethral secretions or persistent pyuria in a first-void urine. Leukocyte esterase testing can also be used to identify patients with asymptomatic chlamydial urethritis.[81,82]

PGU occurring in heterosexual men, like NGU, frequently results from infection with *C. trachomatis*.[83] These patients probably acquire gonorrhea and chlamydial infection simultaneously but, because of the longer incubation period of *C. trachomatis*, develop a biphasic illness if their original gonorrhea is treated with an agent that does not eradicate chlamydia. It is possible that acute gonococcal infection causes reactivation of a latent chlamydial infection, but there is little evidence to support this premise. Coinfection with these two agents occurs in from 15% to 35% of heterosexual men with gonorrhea but rarely in homosexual men. In areas where chlamydial control programs have been in place, the frequency of chlamydial coinfection among men with gonorrhea has declined to 5–10%. Of men infected with both chlamydia and *N. gonorrhoeae* who are treated with penicillin, ampicillin, gentamicin, or spectinomycin, 80% or more develop symptomatic PGU or urethral leukocytosis without symptoms.[66,68,83]

EPIDIDYMITIS

Berger and coworkers have shown that *C. trachomatis* causes most cases of what was previously termed idiopathic epididymitis in young, heterosexually active males.[84,85] In these and subsequent studies, chlamydial and gonococcal epididymitis usually was associated with urethritis caused by *C. trachomatis* and/or *N. gonorrhoeae* in patients who were less than 35 years of age and sexually active, whereas patients with epididymitis who were older than 35 years generally had gram-negative bacterial infections and a history of urologic disease or instrumentation (see Chapter 53). Currently, about 70% of acute epididymitis in young, sexually active men appears to be attributable to chlamydial infection (see Chapter 53). Clinically, chlamydial epididymitis presents as unilateral scrotal pain, swelling, tenderness, and fever in a young male who often has associated chlamydial urethritis (NGU). The urethritis, however, may often be asymptomatic and evident only as urethral inflammation on Gram stain. Men with chlamydial epididymitis improve rapidly with tetracycline treatment, supporting the causal role of *C. trachomatis*.[85]

C. trachomatis also produces mild epididymitis in monkeys after introduction of the organism into the vas deferens.[86] Antibody production, stimulation of cell-mediated immunity to chlamydial antigens, histologic findings, and subsequent recovery of *C. trachomatis* from the monkey's urethra support the causative role of *C. trachomatis* in this model.[86,87] However, the epididymitis is mild, organisms have not been recovered from the epididymis, and the effects of repeated inoculation have not been studied. Thus, animal experiments have not yet elucidated the pathogenic mechanisms operative in chlamydial epididymitis.

Despite continued study, the role of *C. trachomatis* in causing nonbacterial prostatitis remains controversial (see Chapter 54). Mardh and coworkers reported that only 13% of patients with nonbacterial prostatitis had antibodies to *C. trachomatis* in serum or in expressed prostatic secretions, and none had positive cultures from expressed prostatic secretions.[88] They speculated that negative cultures could have resulted from the antichlamydial effects of spermine and zinc in prostatic secretions.[89] Nilsson reported recovery of *C. trachomatis* from the expressed prostatic secretions of 26 men with acute NGU, all of whom were considered to have cytologic evidence of prostatitis.[90] Bruce and colleagues also reported frequent isolation of chlamydia from urine, prostatic fluid, and prostatic expressate of men with nonbacterial prostatitis.[91] However, these studies have not convincingly demonstrated the presence of chlamydia in the prostate itself, and the definition of prostatitis used is

disputed. Poletti and colleagues performed transrectal biopsies of the prostate in 30 men with known positive urethral cultures for *C. trachomatis* and a diagnosis of nonbacterial prostatitis based on prostatic tenderness or swelling on digital palpation; the organism was recovered from 10 of 30 prostatic specimens.[92] These studies require confirmation and, taken together, are inconclusive regarding the role of *C. trachomatis* in nonbacterial prostatitis. Further studies should utilize a careful case definition (including cell counts in expressed prostatic secretions), conventional histologic studies, immunohistochemical study of biopsied tissue, serologic studies, sensitive molecular techniques to assess the presence of chlamydia (i.e., PCR and in situ DNA hybridization) in the prostate, and evaluation of response to therapy.

PROCTITIS

The chronic, indolent form of LGV that results from secondary spread of *C. trachomatis* of the LGV immunotypes from the genitalia to the rectum, usually in women, is discussed in Chapter 17. *C. trachomatis* of non-LGV immunotypes has also been isolated from the rectal mucosa of infants, heterosexual women, and homosexual men. The clinical manifestations of rectal infection in infants and adult women have not been studied extensively. The manifestations in homosexual/bisexual men are described in Chapter 69.

Prospective evaluation of homosexual men indicates that *C. trachomatis* of either the genital immunotypes D to K or LGV immunotypes can produce proctitis.[22–25] The LGV immunotypes usually produce a primary ulcerative proctitis and a histopathologic picture of giant cell formation and granulomas similar to that seen in acute Crohn's disease. Non-LGV immunotypes produce milder infections, ranging from asymptomatic infection to symptomatic proctitis resembling gonococcal proctitis with rectal pain and bleeding, mucous discharge, and diarrhea. Most *C. trachomatis*-infected patients have abnormal numbers of PMNs in their rectal Gram stain, and, on sigmoidoscopy, those with symptoms exhibit friable rectal mucosa and often mucopus. In the pre-AIDS era, *C. trachomatis* appeared to be responsible for up to 15% of proctitis cases seen in homosexual males, and treatment with tetracycline promptly cured these patients.[93]

REITER'S SYNDROME

Both Reiter's syndrome (urethritis, conjunctivitis, arthritis, and characteristic mucocutaneous lesions) and reactive tenosynovitis or arthritis without the other components of Reiter's syndrome have been related to genital infection with *C. trachomatis*. Studies of untreated men with characteristic Reiter's syndrome using the microimmunofluorescent (micro-IF) antibody assay indicate that preceding or concurrent infection with *C. trachomatis* is present in more than 80% of cases (see Chapter 61).[94–96] Many men with Reiter's syndrome also exhibit marked lymphocyte stimulation by chlamydial antigens in in vitro blastogenesis assays.[95] Fluorescein-conjugated monoclonal antibodies have been used to demonstrate what appear to be *C. trachomatis* elementary bodies in the joint fluid and synovial biopsies of patients with Reiter's syndrome, suggesting dissemination of chlamydial antigen beyond the mucosal site of entry in such patients.[97] However, viable chlamydia cannot often be recovered from the joint fluid or synovium of these patients, and demonstration of chlamydial DNA in the joint fluid/synovium has been reported by some groups but not by others.[98–100] Cloned T cells from the synovium of patients with Reiter's syndrome have been demonstrated to recognize the chlamydial 57-kDa HSP and the chlamydial 18-kDa histone-like protein.[101]

Like postenteric (salmonella, shigella, and yersinia) arthritides, sacroiliitis, and spondylitis, Reiter's syndrome occurs with increased frequency in patients with the HLA-B27 haplotype.[102–104] Class 1 HLA-B27 haplotype appears to confer a 10-fold increased risk of developing Reiter's syndrome, and 60–70% of persons with the syndrome are HLA-B27 positive.[102–104] However, among a large series of HLA-B27-positive men with chlamydial urethritis, but with no other manifestations of Reiter's syndrome, none went on to develop Reiter's syndrome after onset of therapy with a tetracycline.[104]

INFECTIONS IN WOMEN

CERVICITIS

Although many women with chlamydia isolated from the cervix have no signs or symptoms of infection, at least a third generally have local signs of infection on examination.[105,106] Most commonly found are mucopurulent discharge (37% of women) and hypertrophic ectopy (19%). Hypertrophic ectopy refers to an area of ectopy that is edematous, congested, and bleeds easily (see Chapter 46). Cervical follicles can sometimes be visualized colposcopically in women with chlamydial infection of the cervix, but this finding has been uncommon in our experience and that of others.[41] Paavonen et al. reported that colposcopic features of immature squamous metaplasia of the zone of ectopy are associated with chlamydial infection.[106] The number of PMNs in cervical mucus is correlated with chlamydial infection of the cervix. Brunham et al. reported that >10 PMNs per 1000× field was best correlated, although this criterion has been extensively debated.[107] Attention to careful collection of the specimen, and to selective counting of PMNs in cervical mucus, rather than in areas containing vaginal epithelial cells, is important. Based on clinical experience and cumulative studies published to date, a cutoff of >30 PMNs per 1000× field in Gram-stained smears of cervical mucus appears best correlated with chlamydial (or gonococcal) cervicitis. There appears to be a wide range of normal leukocyte values in

women without cervical infection, likely owing to the influence of the menstrual cycle, contraceptive practices, sexual activity, and other infections. Women who exhibit signs of chlamydial cervicitis (mucopurulent discharge and hypertrophic ectopy) yield greater numbers of chlamydial inclusion-forming units on primary isolation in tissue culture than women who have chlamydial infection without cervicitis.[108] Whether infections associated with cervicitis have been more recently acquired has not been established but may be the case.

The prevalence of *C. trachomatis* infection is greater in women with ectopy than in those without ectopy.[109] Ectopy may predispose women to chlamydial infection by exposing a greater number of susceptible columnar epithelial cells, making infection more likely on exposure. Alternatively, ectopy may increase the shedding of *C. trachomatis* from the cervix, or *C. trachomatis* infection of the cervix may cause ectopy. Cervical ectopy is normally present in 60–80% of sexually active adolescents and then declines in prevalence in the third and fourth decades. This may help explain the high prevalence of cervical chlamydial infections in adolescents. Oral contraceptives have also been associated with an increased risk of cervical *C. trachomatis* infection, probably because their use promotes ectopy; the increased risk appears to be limited to oral contraceptive users with ectopy.[35,105]

Clinical recognition of chlamydial cervicitis depends on a high index of suspicion and a careful cervical examination. There are no genital symptoms that are specifically correlated with chlamydial cervical infection. As discussed previously, findings on examination suggestive of chlamydial infection include easily induced endocervical bleeding, mucopurulent endocervical discharge, and edema within an area of ectopy. The differential diagnosis of mucopurulent discharge from the endocervical canal in a young, sexually active woman includes gonococcal endocervicitis, salpingitis, endometritis, IUD-induced inflammation, or other causes (see Chapter 46). Gram stain of appropriately collected mucopurulent endocervical discharge from patients with chlamydial endocervicitis also usually shows greater than 30 PMNs per 1000× field, absence of gonococci, and only occasional other bacteria. Similarly, the observation of purulent (yellow or green)-colored cervical discharge on a cervical swab collected from such patients (a positive "swab test"; see Chapter 46) correlates with the presence of chlamydial and/or gonococcal infection.[107] Unfortunately, the majority of women with chlamydial infection cannot be distinguished from uninfected women either by clinical examination or by these simple tests and thus require the use of specific diagnostic testing.

Nearly all women with endocervical chlamydial infection have or develop antibodies to *C. trachomatis* in serum, as assessed by the micro-IF assay. Only 20–30% exhibit IgM antibody at the time of diagnosis, however, suggesting that many newly diagnosed cervical infections in women are not recent but long lived. Local cervical antibody has been reported in only 30–50% of cases, but, in our experience, over 70% of culture-positive women have local antibody.[109] Sequential culturing of untreated women has demonstrated that chlamydial infection of the cervix may persist for weeks or months without development of symptoms or may spontaneously resolve.[32,42]

The relation of chlamydial cervical infection to cytologic atypia, including reactive and metaplastic atypia and dysplasia, is discussed in Chapter 48. The cervical Pap smear frequently shows a characteristic pattern of inflammation in chlamydial infection, which can alert the cytopathologist and clinician to the need for further tests for chlamydia. The Pap smear itself, however, cannot be used as a sensitive or specific indicator of chlamydial infection of the cervix.

URETHRITIS

Screening studies in STD clinics suggest that of women cultured for *C. trachomatis* at both the cervix and the urethra, approximately 50% of positive women yield chlamydia from both sites and 25% from either site alone.[36,37,72] Paavonen reported that women who had *C. trachomatis* in their cervix and urethra were more likely to complain of dysuria than women with cervical infection alone. Isolated urethral infection, without cervical infection, appears to increase in prevalence with age.[37] Case reports have previously suggested that symptoms of dysuria and frequency occur in women with chlamydial urethritis, pyuria, and no bacteriuria or other urinary pathogens, and a prospective evaluation of young women with the acute urethral syndrome (dysuria and frequency without bacteriuria of $>10^5$ conventional uropathogens per mL of urine) has implicated chlamydia as an important cause of dysuria in young, sexually active women.[36,110] Of 16 women with sterile pyuria, 10 had cultural and/or serologic evidence of infection with *C. trachomatis*, compared with less than 10% of women from the same population who lacked urinary symptoms or had coliform cystitis.[36] Women with chlamydial infection who were given placebo remained culture positive and symptomatic until given active antimicrobial therapy, whereas those given doxycycline improved rapidly.[111]

Although urethral symptoms may develop in some women with chlamydial infection, the majority of female STD clinic patients with urethral chlamydial infection do not have dysuria or frequency. Even in women with chlamydial urethritis causing the acute urethral syndrome, signs of urethritis (urethral discharge, meatal redness, or swelling) are infrequent.[36] However, the presence of mucopurulent cervicitis in a woman with dysuria and frequency should suggest the diagnosis. *C. trachomatis* urethritis should be suspected in young, sexually active women with dysuria, frequency, and pyuria, especially if they have had a new sex partner within the last month or a sex partner with NGU. Other correlates of

chlamydial urethral syndrome include duration of dysuria of more than 7–10 days, lack of hematuria, and lack of suprapubic tenderness. An abnormal urethral Gram stain showing >10 PMNs per oil immersion field in women with dysuria but without coliform bacteriuria supports the diagnosis of chlamydial urethritis but is also found in women with gonococcal or trichomonal infection of the urethra.

BARTHOLINITIS

Like gonococci, *C. trachomatis* may produce an exudative infection of Bartholin's ducts. Davies et al. studied 30 women who had clinical evidence of bartholinitis and isolated *N. gonorrhoeae* and *C. trachomatis* from the ductal exudate of 24 and nine women, respectively.[112] Of the nine chlamydia-positive women, seven had concurrent gonorrhea, but two were sex partners of men with NGU and had no evidence of gonococcal infection. Purulent infections of Bartholin's ducts may thus be owing to chlamydial infection, either alone or with concurrent gonococcal infection.

ENDOMETRITIS

Histologic evidence of endometritis, often with immunohistologic and/or cultural evidence of *C. trachomatis*, is present in nearly one-half of patients with chlamydial mucopurulent cervicitis and can be demonstrated in nearly all patients with chlamydial salpingitis. The presence of endometritis in patients with chlamydial cervicitis also correlates with a history of abnormal vaginal bleeding (see Chapters 50 and 64).

It is now clear that *C. trachomatis* infection is associated with endometritis.[113–119] Mardh and coworkers first described two women from whom *C. trachomatis* was recovered by uterine aspiration, despite negative cervical cultures.[113] Both women exhibited signs of salpingitis and had serologic evidence of chlamydial infection. Concomitant endometritis probably explains the menorrhagia and metrorrhagia often seen in women with salpingitis. These studies, like previous evidence gathered in monkeys infected with *C. trachomatis*, indicate that chlamydia cervicitis probably spreads through the endometrial cavity to reach the fallopian tubes.[116] Subsequent studies have shown that chlamydial endometritis is characterized by infiltration of the endometrial stroma by plasma cells and infiltration of the endometrial superficial epithelium by PMNs. Besides nonpuerperal endometritis, Wager and coworkers have shown an association of intrapartum fever and late postpartum endometritis with untreated antenatal *C. trachomatis* infection.[120] Others have confirmed this association (see Chapter 64).

SALPINGITIS

The proportion of acute salpingitis cases due to *C. trachomatis* varies geographically and with the population studied. In Sweden, Mardh and colleagues found that 19 of 53 women with salpingitis had chlamydial infections of the cervix and that of those with cervical infection who had laparoscopy, six of seven grew *C. trachomatis* in a culture from the fallopian tube.[121] These authors found that 80% of 60 consecutive women with acute salpingitis had antibodies to *C. trachomatis*, with 37% exhibiting serologic evidence of acute chlamydial infection. Other serologic studies of women with salpingitis also suggest a prominent etiologic role of chlamydia.[122–124] Studies in Seattle in women with laparoscopically confirmed salpingitis and histologically confirmed endometritis indicate that 80–90% have proven chlamydial or gonococcal infection, usually confirmed in the upper genital tract, with the proportion having either chlamydial or gonococcal infection being approximately equal.[117,122] An interesting treatment study by Rees further supports the role of chlamydia in salpingitis.[125] Among 343 women randomly treated for gonorrhea with either penicillin or tetracycline, a significantly greater proportion of those who received penicillin went on to develop salpingitis; persistence of cervical *C. trachomatis* was associated with many but not all cases of salpingitis. As discussed in Chapters 49 and 50, and elsewhere, many cases of chlamydial salpingitis are associated with mild or absent symptoms or signs, despite progressive tubal scarring, resulting in pregnancy or infertility.[126–130] Such studies have given rise to the term "silent salpingitis" attributable to chlamydia. Studies in animal models (see Chapters 49 and 50) also demonstrate the causative role of chlamydia in salpingitis and in the production of tubal scarring and infertility.[131,132]

PERIHEPATITIS (FITZ-HUGH–CURTIS SYNDROME)

Since its original description by Fitz-Hugh and Curtis, perihepatitis occurring after or with salpingitis has been considered a complication of gonococcal infection. However, studies in the last 15 years suggest that chlamydial infection is, in fact, more commonly associated with perihepatitis than is *N. gonorrhoeae* (see Chapter 51), probably accounting for the majority of cases.[133–135] Perihepatitis should be suspected in young, sexually active women who develop right-upper-quadrant pain, fever, nausea, or vomiting. Evidence of salpingitis may or may not be present on examination. A recent study has demonstrated that perihepatitis is strongly associated with extensive tubal scarring, adhesions, and inflammation observed at laparoscopy, as well as with high titers of antibody to the 57-kDa chlamydial heat shock protein.[136]

OTHER CHLAMYDIAL INFECTIONS IN ADULTS

Since *C. trachomatis* causes a distinctive pneumonia syndrome in neonates (see Chapter 66), several studies have assessed the etiologic role of chlamydia in adults with pneumonia. Case reports and small studies suggest that *C. trachomatis* is an

occasional cause of pneumonitis in immunocompromised adults.[137,138] Tack and coworkers isolated *C. trachomatis* from the lower respiratory secretions of five immunosuppressed patients with pneumonia and from one patient with acute bronchitis.[137] *C. trachomatis* was also isolated from the eye and nasopharynx and from bronchial brushings in three of these patients. However, none of these six patients developed serologic evidence of *C. trachomatis* infection, and all had concomitant cytomegalovirus infection. On the other hand, Meyers and coworkers demonstrated sustained IgM and IgG antibody rises to *C. trachomatis* in three patients who developed interstitial pneumonia after marrow transplantation, but lung tissue examined by culture and fluorescent antibody techniques from these patients and from 63 other transplant patients with idiopathic pneumonia provided no evidence of chlamydial infection.[138] More recently, histologic or cultural evidence of *C. trachomatis* infection could not be demonstrated in 48 lung biopsies from AIDS patients with pneumonia.[61] Komaroff and coworkers reported serologic evidence of recent chlamydial infections in four out of 19 adults with community-acquired pneumonia not owing to other common bacterial or viral pathogens.[139] However, in retrospect, these likely represented antibodies to *C. pneumoniae* rather than to *C. trachomatis*. At this point, there is no evidence to suggest that *C. trachomatis* causes community-acquired pneumonia or other respiratory infections in adults.

C. trachomatis may on occasion produce culture-negative endocarditis, and serologic studies in one patient suggested that meningoencephalitis resulted from chlamydial infection.[140–142] Other uncommon infections reported in adults, including peritonitis and postmenopausal vaginitis, have been attributed to chlamydia.[143,144]

DIAGNOSIS

Chapter 74 discusses in detail the cytologic, cultural, antigen-detection, DNA hybridization, nucleic acid amplification, and serologic methods for diagnosis of *C. trachomatis* infections. Aspects relevant to deciding whom to test, what test to use, the collection of specimens, and the interpretation of results in adult patients are presented here.

Being an intracellular pathogen, *C. trachomatis* requires a cell culture system for propagation in the laboratory. Thus, cell culture was the gold standard test for the detection of *C. trachomatis* for years.[6] However, its stringent requirements in terms of both technical expertise and specimen collection and transport make cell culture impractical in settings in which neither a cold chain nor a cell culture system can be maintained. Further, a carefully collected sample of columnar epithelial cells from the cervix or urethra is necessary, and specimens composed purely of polymorphonuclear cells or mucopurulent discharge are not adequate.[6] For culture, specimens may be collected with a cotton-tipped swab (those with wooden sticks should not be used, as they are inhibitory to chlamydia). For endocervical specimens, a cytobrush may result in an increase in the sensitivity of culture as more cells are collected.[6] Specimens must be placed in specific transport media and refrigerated until they are inoculated within 24 hours onto cell culture plates.

Owing to the inadequacies, cost, and technical difficulties of cell culture, the development of nonculture tests has been a major research priority over the last 15 years. As a result, many nonculture diagnostic tests for *C. trachomatis* are now commercially available.[6,145] The first of these tests used antigen detection, generally of chlamydia lipopolysaccharide (LPS) or MOMP, as a means of detecting chlamydial elementary bodies or antigens in genital specimens. The most widely used of these assays are the DFA and enzyme immunoassay (EIA) tests. In general, when obtained from the cervix, these tests detect between 60% and 85% of infections relative to culture.[146,147] The DFA, when done by an experienced technician, has a sensitivity of 80–85%, but overall sensitivity depends both on the experience of the person performing the test and on collection of an adequate specimen.[147,148] Sensitivity of the EIAs generally are in the range of 60–80%, compared with culture, and vary by assay (see Table 32-1).[145–147,149] Although the DFA test is highly specific (>99%), the EIA requires a confirmatory assay with a blocking antibody or with DFA to eliminate false-positive results. Results of antigen detection tests can usually be obtained within 1–2 days. Several simplified rapid antigen detection tests that can be done on site and provide immediate results while the patient is in the clinic are also available. Unfortunately, the performance of these tests has been disappointing; most have yielded unacceptably low sensitivities relative to culture, and their use is discouraged until performance can be improved.[147,150]

The advantages of all of the nonculture tests in comparison with culture are their ease of use in settings where transport or maintenance of specimens at colder temperatures is problematic or where cell culture is not available and their low cost. However, the hope that they might be useful as a noninvasive means of diagnosing chlamydial infection by testing urine has not been realized. The sensitivities of these assays when applied to urine have been unacceptably low, often in the 40–50% range, as compared with culture.[151]

The most exciting development in chlamydial diagnostic testing has been that of automated methods for the detection of amplified *C. trachomatis* DNA or RNA. Initially, the two most widely used methods were LCR and PCR, both of which were used for cervical, urethral, and urine specimens from males and females. The specificity of these tests has consistently been above 99%.[6,147] Subsequently, the LCR assay was removed from the market because of problems with quality control. Another methodology, transcription-mediated amplification (TMA), amplifies chlamydial ribosomal RNA

and appears to have performance characteristics similar to LCR and PCR.[152] PCR assays target nucleotide sequences on the plasmid of C. trachomatis, which is present in multiple copies within each elementary body. The TMA assay targets a ribosomal RNA sequence. The lower limit of detection of these tests is in the range of one to 10 elementary bodies (as compared to 10,000 elementary bodies for EIA). Further details of additional diagnostic test methods are discussed in Chapter 74.

In order to define the performance of these newer highly sensitive amplification tests, a new gold standard other than cell culture must be utilized. The best approach now that several amplification assays are available is to confirm one amplification assay by comparing it with a second or third similar assay. Using this approach, LCR when applied to first-catch urine (FCU; the first 10–30 mL of stream) has a sensitivity of approximately 90–96% for the detection of chlamydial urethritis in males, and 69–96% for chlamydial urethritis and/or cervicitis in females.[153–157] Sensitivity of LCR performed on endocervical specimens has ranged from 81% to 100%.[155,158,159] Compared with the performance of cell culture or antigen detection assays, LCR generally detected 15–40% more infected persons, with a concomitant increase in estimated prevalence of 4–5%. These studies were the first to indicate that a NAAT (LCR) performed on endocervical specimens was consistently more sensitive than culture and that its performance on FCU was sensitive enough to provide a means of noninvasive testing for the diagnosis of chlamydial infection of the urethra and the cervix in women.

The performance of PCR in the diagnosis of chlamydial infection has also been evaluated, relative to the expanded gold standard described above. Among males, its sensitivity when performed on FCU has generally been 87–100%.[160–164] The test has detected up to approximately 40% more infections than urethral culture in some studies.[162] Among females, PCR performed on FCU has demonstrated a sensitivity of 82–93%.[162,165] Unexpectedly, performance of PCR on endocervical specimens has sometimes been variable, with sensitivities ranging from 60% to 92%.[162–165] The presence of inhibitors in endocervical mucous is thought to be responsible for this variability in PCR sensitivity, in one study effecting a reduction of sensitivity of 15%.[165] Of the NAATs that are currently available, the GenProbe Aptima CT assay, which utilizes target capture and RNA amplification, appears to be the most sensitive and specific assay.

In addition to the use of first-void urine, the newer amplification tests may make it possible to use other novel specimens for the diagnosis of *C. trachomatis* infection. In women, self-collected swabs of the vaginal introitus are as sensitive and specific as cerfical swabs for the diagnosis of chlamydial infection and may be the preferred specimen for either diagnosis or screening.

SEROLOGIC TECHNIQUES

Serologic tests have not been widely used for the diagnosis of chlamydial genital tract infections other than LGV. Several major problems have precluded their use. First, the baseline prevalence of antibody in populations of sexually active persons who are at risk of *C. trachomatis* infection is high, often ranging from 45% to 65% of persons tested. The high prevalence of seropositivity in culture-negative, asymptomatic patients presumably reflects either previous infection or persisting, chronic asymptomatic infection not easily detected with current assay techniques. Second, the lack of an abrupt onset of symptoms in many chlamydia-infected patients means that patients often are seen during periods when IgM antibody or rising or falling titers of IgG antibody cannot be demonstrated, and hence these serologic parameters of recently acquired infection often are absent. This particularly applies to women. Onset of symptoms is more abrupt in men with NGU, and seroconversion or IgM antibody can be documented in most men. Third, superficial genital tract infection (urethritis and cervicitis) generally produces micro-IF antibody titers in the range of 1:8 to 1:256, but rarely higher. Of men with NGU who were initially seronegative but later developed IgG antibody to chlamydia, 60% developed titers between 1:8 and 1:32, whereas 40% were between 1:64 and 1:256. Higher antibody titers (>1:256) have more often been seen in women with salpingitis and even higher titers (often >1:1024) in women with perihepatitis. Finally, cross-reacting antibody rises owing to *C. pneumoniae* may obfuscate serodiagnosis. These issues are discussed in more detail elsewhere in Chapter 31.

WHEN TO USE DIAGNOSTIC TESTING

All women suspected of having *C. trachomatis* genital infections on the basis of symptoms, signs, or exposure history, including women with suspected mucopurulent cervicitis, endometritis, pelvic inflammatory disease, acute urethritis, or acute proctitis, as well as women whose male partners have gonorrhea or NGU, should have specific diagnostic testing. As described in the preceding text, the diagnosis of many of these conditions is difficult to establish on clinical grounds alone, and the presence of a positive chlamydial test thus is of great value in confirming the suspected diagnosis. Although women in these categories should be empirically treated with antibiotics while test results are pending, the specific confirmation of *C. trachomatis* infection clarifies the diagnosis, improves the patients' understanding of their illness, probably enhances compliance with therapy, and facilitates management of sexual partners. Although "syndromic treatment" of women with chlamydia-associated syndromes (i.e., empiric treatment without testing) is an acceptable strategy, where

costs prohibit laboratory testing, the benefits attributable to testing argue for its use where affordable.

Second, unrecognized *C. trachomatis* infections should be identified by appropriate screening of asymptomatic women in high-risk groups.[158,163,168] Universal screening of all women attending STD clinics or other clinics (e.g., family planning clinics, juvenile detention centers, and abortion clinics), where the prevalence of infection exceeds 10–12%, appears to be an effective and cost-efficient strategy.[166–169] In other clinical settings where the overall prevalence of chlamydial infection is less than 5–6%, selective screening may be a more effective strategy. It has been recommended that all sexually active women under 25 years of age be screened, as well as older women who have specific risk factors, associated with chlamydial infections, including a new sexual partner, multiple sexual partners, and racial/ethnic backgrounds found to be at high risk in the local setting, and signs of cervicitis.[147,168] Strong consideration should be given to screening all unmarried pregnant women and all pregnant women with one or more of these risk characteristics, especially adolescents.

In men, given both the relative paucity of serious complications that arise from *C. trachomatis* infections and the considerably greater proportion of infections that can be accurately diagnosed on clinical grounds alone, both specific diagnostic testing and screening for *C. trachomatis* infections should be given a lower priority than in women.[168] Thus, when resources limit the numbers of tests that can be done (e.g., in public health clinics), the tests available should be used primarily for diagnosis and screening in women. However, knowledge of the etiologic role of *C. trachomatis* in NGU has prognostic implications (>90% cure rate for patients positive for *C. trachomatis*, compared with 50% for those who are pnegative) and fosters the need for more aggressive identification and treatment of female partners. Specific diagnostic testing thus provides a number of benefits, even though infected men with symptoms or signs of urethritis should be treated empirically before the test results are known.

Up to one-third of heterosexual men with *C. trachomatis* urethral infection attending STD clinics lack symptoms of urethritis.[17] Further, asymptomatic chlamydial urethritis is surprisingly prevalent (5–7%) among young men in inner-city high schools.[170] Screening of young men for asymptomatic *C. trachomatis* infection has been difficult because of the absence of a noninvasive and patient-acceptable diagnostic technique and because of the infrequency with which young men come into contact with health-care facilities. The availability of chlamydia testing on first-void urine using NAAT now makes screening of large numbers of young men possible in settings such as high schools or other clinics.[168] However, screening of sexually active asymptomatic young men has not been routinely recommended, as the health benefits of such screening for either heterosexual men or their partners have not been demonstrated and, in most areas, implementation of screening in young women is incomplete.[168] Asymptomatic partners of women with mucopurulent cervicitis, pelvic inflammatory disease, or asymptomatic chlamydial infection should be screened and then given empirical therapy. The use of empirical therapy without specific testing foregoes an opportunity to identify still other sexual contacts who should be evaluated and treated and thus fosters continuation of the epidemic and reinfection of the patient. In homosexual men with suspected proctitis, *C. trachomatis* testing should be done to confirm the suspected diagnosis. Tables 32-2 and 32-3 summarize diagnostic criteria for various C. trachomatis infections in men and women, respectively.

THERAPY

Although in vitro susceptibility testing for *C. trachomatis* has not been rigorously standardized, studies to date have found little strain-to-strain variation in minimum inhibitory concentrations of individual antimicrobials against chlamydia.[6] The most active drugs against *C. trachomatis* in tissue culture are rifampin and the tetracyclines, followed by macrolides, sulfonamides, some fluoroquinolones, and clindamycin.[6] Unlike gonococci, there has been no apparent emergence of antimicrobial resistance to *Chlamydia* isolated from humans. Tetracycline resistance has been observed in *C. suis* strains isolated from swine who had tetracycline in feed.[171]

The majority of clinical evidence regarding the effectiveness of various antimicrobials against *C. trachomatis* has been accumulated in men with NGU or gonococcal urethritis (Table 32-4). Two general principles have emerged from these studies: Penicillin, ampicillin, cephalosporins, and spectinomycin in single-dose regimens given for treatment of gonorrhea do not eradicate concomitant chlamydial infection, and 7 or more days of treatment with tetracyclines or macrolides eradicates *C. trachomatis* from nearly all men, at least as determined by short-term follow-up.[172–182] However, chlamydial infection recurs 3–6 weeks after treatment in 5–10% of these men and cannot be clearly designated as reinfection or relapse. Most such recurrences are of the same immunotype as the original infecting strain, and nearly all cause recurrent clinical evidence of urethritis.

In men with NGU, trials using either placebos or agents such as spectinomycin, which are ineffective against *C. trachomatis*, have clearly established the greater effectiveness of specific antimicrobial treatment in eliminating both signs and symptoms of infection and in eradicating chlamydia. Clinical trials indicate that tetracycline hydrochloride, doxycycline, minocycline, triple tetracycline, erythromycin, and trimethoprim-sulfamethoxazole all achieve comparable clinical cure rates of approximately 85–95% in men with chlamydial NGU (see Chapter 52). Of the newer fluoroquinolones, ofloxacin and levofloxacin also have reported cure rates in this range,

Table 32-2. Diagnosis of *C. trachomatis* Infections in Men

		Laboratory Criteria	
Associated Findings	**Clinical Criteria**	**Presumptive**	**Diagnostic**
NGU	Dysuria, urethral discharge	Urethral GS with 5 or more PMN/high-power (× 1000) field; pyuria on FVU	Positive culture or NAAT (urethra or FVU)
Acute epididymitis	Fever, epididymal or testicular pain, evidence of NGU, epididymal tenderness or mass	As for NGU	As for NGU; positive test on epididymal aspirate
Acute proctitis (non-LGV strain)	Rectal pain, discharge, bleeding; abnormal anoscopy (mucopurulent discharge, pain, spontaneous or induced bleeding)	Rectal GS with 1 or more PMN/high-power (× 1000) field	Positive culture or NAAT
Acute proctocolitis (LGV strain)	Severe rectal pain, discharge, hematochezia; markedly abnormal anoscopy (as above) with lesions extending into colon; fever lymphadenopathy	Rectal GS with 1 or more PMN/high-power (× 1000) field	Positive culture or NAAT complement fixation antibody titer

GS = Gram stain; PMN = polymorphonuclear leukocytes; NGU = nongonococcal urethritis; NAAT = nucleic acid amplification tests; FVU = first-void urine; LGV = lymphogranuloma venereum. Table 32-3. Diagnosis of *C. trachomatis* Infections in Women

		Laboratory Criteria	
Associated Findings	**Clinical Criteria**	**Presumptive**	**Diagnostic**
Mucopurulent cervicitis	Mucopurulent cervical discharge, cervical ectopy and edema, spontaneous or easily induced cervical bleeding	Cervical GS with greater than 30 PMN/high power (x 1000) field in nonmenstruating women	Positive culture or NAAT (cervix, FVU)
Acute urethral syndrome	Dysuria-frequency syndrome in young sexually active women; recent new sexual partner; often more than 7 days of symptoms	Pyuria, no bacteriuria	Positive culture or NAAT (cervix, or urethra or FVU)
PID	Lower abdominal pain; adnexal tenderness on pelvic exam; evidence of MPC often present	As for MPC; cervical GS positive for gonorrhea; endometritis on endometrial biopsy	Positive culture or NAAT (cervix, FVU, endometrium, tubal)
Perihepatitis	Right upper quadrant pain, nausea, vomiting, fever; young sexually active women; evidence of PID	As for MPC and PID	High-titer IgM or IgG antibody to *C. trachomatis*

GS = Gram stain; PMN = polymorphonuclear leukocytes; PID = pelvic inflammatory disease; MPC = mucopurulent cervicitis. Reproduced with permission from the *Annals of Internal Medicine.*

whereas ciprofloxacin has been associated with more frequent failures and should not be used for the treatment of NGU.[183–185] Although relatively ineffective against *C. trachomatis* in vitro and when administered as a single dose, amoxicillin, when given as 750 mg PO tid for 10 days, apparently eliminated chlamydia from six men with NGU followed for 24–48 days.[179] Pivampicillin in high dosage gave similar results.[172] Although symptoms usually subsided as cultures became negative in

Table 32-4. Summary of Selected Studies Evaluating Oral Antimicrobial Treatment of *C. trachomatis* Urethritis in Men

Regimen	Efficacy[a]	Reference
Minocycline, 200 mg stat., then 100 mg q 12 h for 6 days	11/12 (92%)	175
Tetracycline, 500 mg qid for 7 days	35/35 (100%)	76
Erythromycin stearate, 500 mg q 12 h for 2 weeks	30/31 (97%)	176
Doxycycline, 200 mg for 2 days, then 100 mg for 12 days	50/52 (96%)	177
Deteclo, qd for 7 days	11/12 (92%)	173
Deteclo, qd for 21 days	16/16 (100%)	
Minocycline, 200 mg stat., then 100 mg bid for 6 days	39/40 (98%)	178
Rifampin, 600 mg qd for 6 days	52/53 (98%)	
Erythromycin stearate, 500 mg q 12 h for 15 days	27/30 (90%)	180
Lymecycline, 300 mg q 12 h for 10 days	21/24 (88%)	
Lymecycline, 300 mg q 12 h for 20 days	18/21 (86%)	
Pivampicillin, 750 mg tid for 7 days	19/22 (86%)	172
Doxycycline, 200 mg for 1 day, then 100 mg for 6 days	56/57 (98%)	194
Trimethoprim-sulfamethoxazole, 160 and 800 mg bid, respectively, for 10 days	18/20 (90%)	
Erythromycin, 500 mg bid for 10 days	18/23 (78%)	
Trimethoprim-sulfadiazine, 160 and 500 mg, respectively, in 1 tablet bid for 14 days	18/19 (95%)	75
Tetracycline, 250 mg qid for 7 days	21/24 (88%)	181
Tetracycline, 500 mg qid for 7 days	33/36 (92%)	
Rosaramicin, 250 mg qid for 7 days	38/42 (90%)	
Amoxicillin, 750 mg tid for 10 days	6/6 (100%)	179
Ciprofloxacin, 750 mg bid for 7 days	11/20 (55%)	185
Ciprofloxacin, 1000 mg bid for 7 days	13/18 (72%)	185
Doxycycline, 100 mg bid for 7 days	15/16 (94%)	189
Minocycline, 100 mg qd for 7 days	19/19 (100%)	189
Doxycycline, 100 mg bid for 7 days	23/23 (100%)	78
Azithromycin, 1 g single dose	27/30 (90%)	78
Doxycycline, 100 mg bid for 7 days	29/29 (100%)	187
Azithromycin, 1 g single dose	34/34 (100%)	187

[a]Studies cited here generally performed chlamydia cultures before, just after, and 2–3 weeks following completion of treatment; efficacy, as expressed in this table, equals the number of patients with negative chlamydia cultures on visit 2 or 3 divided by the number of patients returning for follow-up visits 2 and 3. Eradication of chlamydia was usually, but not always, associated with clinical resolution of signs and symptoms.

these studies, the possibility cannot be excluded that latent chlamydial infection persisted after amoxicillin or pivampicillin treatment.

Azithromycin, with a half-life of 5–7 days, excellent intracellular and tissue penetration, and in vitro activity against *C. trachomatis* in the 0.25 μg/mL range, is an important, the only currently approved, single-dose agent for treatment of chlamydial infection.[186] Use of single-dose therapy is particularly attractive in potentially less compliant patients, such as adolescents or patients with few or no symptoms.[186–189] However, individuals treated with azithromycin should still abstain from sex for several days after receiving therapy; earlier resumption of sexual activity with use of single-dose therapy could theoretically result in transmission of an unresolved infection to sex partners. Despite the greater cost of azithromycin as compared with doxycycline ($9–15 vs. $1–2), cost-effectiveness analyses support the hypothesis that the compliance assured with single-dose therapy may make it a more cost-effective therapy, particularly in patients with poor compliance.[190,191] Wherever possible, directly observed single-dose therapy should be used, maximizing compliance. A recently published meta-analysis analyzed randomized clinical trials that compared azithromycin and doxycycline for *Chlamydia* genital infection and found equal efficacy (97% vs. 98%).[189]

The recommended length of therapy for NGU using tetracycline or doxycycline has ranged from 7 to 21 days. However, in two studies in which 7 days of therapy were compared with 21 days of therapy with tetracycline or minocycline, no difference was found.[174,175] Thus, there is as yet no evidence that prolongation of tetracycline or doxycyclinetherapy beyond 1 week is necessary, provided that sex partners are treated concurrently.

Fewer studies have assessed the effectiveness of antimicrobial treatment of uncomplicated cervical or urethral chlamydial infection in women (Table 32-5). Those data available suggest that tetracycline, 500 mg qid for 7 days, successfully eliminates *C. trachomatis* from the cervix through at least 3 weeks of follow-up.[182,192–197] Erythromycin, when given as 500 mg PO qid for 7–14 days, is also effective as is ofloxacin, 200 mg PO bid. A small double-blind, placebo-controlled trial indicates that doxycycline, 100 mg PO bid for 10 days, successfully eliminated *C. trachomatis* from the cervix and urethra of women with the acute urethral syndrome.[111]

Azithromycin given as a 1-g single dose was shown to be comparable to 7 days of doxycycline therapy for treatment of uncomplicated chlamydial infection of the cervix.[187] The advantages of single-dose directly observed therapy argue for its use in young women with uncomplicated cervical infection. Treatment options in pregnancy remain somewhat limited as neither doxycycline nor ofloxacin can be used. Erythromycin given as a 2-g daily dose achieves a cure in 84–94% of treated women, but up to half of women develop significant gastrointestinal side effects and cannot complete the course of therapy.[198–200] A 1-g daily dose for 7 days is better tolerated but less efficacious. The efficacy of azithromycin in pregnancy has now been studied sufficiently to recommend its routine use for treatment of *Chlamydia* in pregnant women.[197,201] The recently published CDC treatment guidelines recommended a 1-g dose in this circumstance.[197] Alternatively, Amoxicillin 500 mg orally three times daily for 7 days can be used. Amoxicillin, which has a cure rate approximately equal to that of erythromycin, causes less frequent gastrointestinal intolerance.[100,199,202] However, because the efficacies of all regimens in the pregnant patient may be low, a test of cure should be considered. .Test of cure, if using NAATs testing, should be done at least 3 weeks after the end of treatment to minimize false-positive results.

Treatment of other chlamydia-related syndromes is discussed in individual chapters on salpingitis, epidymitis, and so forth.

PREVENTION

Since many chlamydial infections are asymptomatic, it has become clear that effective control must involve periodic testing of individuals at risk.[168] As the cost of extensive screening may be prohibitive, various approaches to defining target populations at increased risk of infection have been evaluated. One strategy has been to designate patients attending specific high prevalence clinic populations for universal testing. Such clinics would include STD, juvenile detention, and some family planning clinics. This approach, however, fails to account for the majority of asymptomatic infections, since attendees at high prevalence clinics often attend because of symptoms or suspicion of infection. Consequently, selective screening criteria have been developed for use in various clinical settings.[204–208] Among women, young age (generally, <24 years) is a critical risk factor for chlamydial infection in almost all studies.[168] Other risk factors include the presence of mucopurulent cervicitis; multiple, new, or symptomatic male sex partners; and lack of barrier contraceptive use. These findings have given rise to criteria for selective screening of women. In some settings, screening based solely on young age (generally, <25 years) may be equally as sensitive as criteria that incorporate behavioral and clinical measures.[209,210]

The effectiveness of selective screening in reducing the prevalence of chlamydial infection in women has been demonstrated in several ecological studies. In the Pacific Northwest, where extensive screening began in family planning clinics, in 1988 and in STD clinics in 1993, prevalence declined from 10% to 12% in the late 1980s and 4% to 5% in 1995.[2] Similar trends have occurred in association with screening programs elsewhere.[211,212] However, Brunham et al. has pointed out that in British Columbia, Canada, as well as in

Table 32-5. Summary of Selected Studies Evaluating Antimicrobial Treatment of *C. trachomatis* Cervicitis in Women

Regimen	Efficacy[a]	Reference
Deteclo, 300 mg bid for 7 days	20/20 (100%)	192
Oxytetracycline, 250 mg qid for 14 days	49/50 (98%)	176

Erythromycin, 500 mg bid for 15 days	13/17 (76%)	180
Lymecycline, 300 mg bid for 10 days	18/20 (90%)	
Lymecycline, 300 mg bid for 20 days	14/14 (100%)	
Trimethoprim-sulfadiazine, 160 and 500 mg, respectively, in 1 tablet bid for 14 days	15/15 (100%)	75
Doxycycline, 100 mg bid for 10 days	15/15 (100%)	
Doxycycline, 200 mg stat., then 100 mg bid for 9 days	55/58 (95%)	194
Erythromycin, 500 mg bid for 10 days	36/39 (92%)	
Trimethoprim-sulfamethoxazole, 160 and 800 mg, respectively, in 1 tablet for 10 days	37/40 (93%)	
Tetracycline, 500 mg qid for 7 days	21/22 (95%)	196
Erythromycin, 250 mg qid for 7 days	12/12 (100%)	
Sulfisoxazole, 500 mg qid for 10 days	8/8 (100%)	
Ciprofloxacin, 500 mg bid for 7 days	30/35 (86%)	193
Pivampicillin, 700 mg bid for 7 days	26/26 (100%)	195
Doxycycline, 100 mg bid for 7 days	17/17 (100%)	189
Minocycline, 100 mg qD for 7 days	16/16 (100%)	189
Ofloxacin, 300 mg bid for 7 days	26/28 (93%)	184
Doxycycline, 100 mg bid for 7 days	22/22 (100%)	184
Doxycycline, 100 mg bid for 7 days	72/73 (99%)	187
Azithromycin, 1 g single dose	78/78 (100%)	187

[a]Studies cited here generally performed chlamydia cultures before, just after, and 2 to 3 wks following treatment efficacy, as expressed in this table, equals the number of patients with negative chlamydia cultures or visit 2 or 3 divided by the number of patients returning for those follow-up visits.

Region X in the United States, the low prevalence of infection in women screened for *Chlamydia* did not persist but rather was followed by rising prevalences each year since 1996.[5] This trend after earlier reductions in prevalence is worrisome and suggests that the use of female screening may have limitations in terms of long-term value. Brunham et al. postulates that women identified by screening and treated may develop only partial immunity and remain susceptible to reinfection.[5]

Evidence that screening can effect a reduction in upper genital tract disease has recently been published. In a study in Seattle, women in a large health-maintenance organization who satisfied selective screening criteria for chlamydial infection were randomized to one of two arms: an intervention arm in which women were tested for chlamydial cervical infection and a control arm characterized by standard care.[213] Subjects in the intervention (screening) arm experienced a marked reduction in the 1-year incidence of symptomatic PID, as assessed by clinical record review and patient report of symptoms compatible with PID (odds ratio, 0.44; 95% confidence interval, 0.20, 0.90). This finding was especially notable,

given that chlamydia prevalence in the study population was low (3.5%) and that chlamydia screening programs were already ongoing in the area.

The practical implementation of screening programs in settings with low-to-moderate *chlamydia* prevalence requires that the prevalence at which selective screening becomes cost effective relative to universal screening must be defined. Toward this end, a number of investigators have undertaken cost-effectiveness analyses. Most of these analyses have concluded that universal screening is preferred in settings with chlamydia prevalence above 3–7%.[166–168,203] Depending on the criteria used, selective screening is likely to be more cost effective when prevalence falls below these numbers.

Among asymptomatic males, risk factors for chlamydial infection have been less extensively explored, and the effectiveness of screening programs targeting males is not known.[168]

33 Lymphogranuloma Venereum

Walter E. Stamm

Lymphogranuloma venereum (LGV) is one of the sexually transmitted diseases caused by *Chlamydia trachomatis.* A sporadic disease in North America, Europe, and Oceania, LGV is highly prevalent in parts of Africa, Asia, and South America. It is also known variously as *tropical* or *climatic bubo*,[1] *strumous bubo*,[2] *poradenitis inguinalis*,[3] *Durand-Nicolas-Favre disease*,[3,4] *lymphogranuloma inguinale*, and the *fourth, fifth*, or *sixth venereal disease*.[5] LGV is preferred because it is less easily confused with granuloma inguinale.

LGV has a variety of acute and chronic manifestations. Three stages of infection, more or less analogous to those of syphilis, are recognized.[6] The primary lesion of LGV is a small, generally painless genital papule that may ulcerate rapidly. The secondary stage is characterized by acute lymphadenitis with bubo formation (the inguinal syndrome) and/or acute hemorrhagic proctitis following rectal intercourse (the anogenitorectal syndrome) together with fever and other symptoms caused by systemic spread of infection. The vast majority of patients recover from LGV after the secondary stage without sequels, but in a few patients the persistence of *Chlamydia* in anogenital tissue incites a chronic inflammatory response and the development of genital ulcers, fistulas, rectal strictures, and genital elephantiasis. Antibiotic treatment during the secondary stage prevents these late complications, which otherwise may require surgical repair.

LGV is usually caused by one of the three serovars of *C. trachomatis:* Ll, L2, and L3 (see Chapter 15). Other *C. trachomatis* strains occasionally have been isolated from infected tissue taken from patients who have symptoms compatible with genitoanorectal LGV.[7–9]

Throughout most of its history, LGV has been confused with other diseases, particularly with the lymphadenopathy of syphilis and genital herpes and the buboes of chancroid. Confusion was caused in part by the failure to recognize the common etiology of the different manifestations of LGV, which often were described as distinct clinical or pathologic entities. Durand, Nicolas, and Favre[4] established the disease as a clinical and pathologic entity in 1913, and Phylactos deduced a common etiology of climatic bubo and LGV in 1922,[10] but a major diagnostic advancement in the study of LGV was the development of a "specific" skin test by Frei in 1925.[11] This test established the etiology of LGV proctocolitis and rectal stricture.[12] In 1930, LGV *Chlamydia* were isolated from buboes by intracerebral inoculation of monkeys,[10] and LGV *Chlamydia* were grown in embryonated eggs in 1935.[13] The latter achievement made possible the commercial manufacture of large amounts of standardized antigen for Frei tests and serodiagnostic tests.

The first effective drugs for treatment of LGV were the sulfonamides, which were introduced in the late 1930s.[14] Although other drugs have since been developed for treatment of LGV[15] and both serodiagnostic and molecular tests have been refined to give greater specificity, we still do not understand the pathogenesis of this disease.

A more detailed review of the history of LGV is a study in itself and will not be undertaken here. The monograph on LGV published by Stannus in 1933[5] lists 933 references and, together with the excellent reviews published by Koteen in 1945[16] and Favre and Hellerstrom in 1954,[10] describes the historical evolution of the disease.

EPIDEMIOLOGY

LGV is a sporadic disease throughout North America, Europe, Australia, and most of Asia and South America. Occasional cases or clusters of cases suggest ongoing low-level transmission in these areas. It is endemic in east[17] and west Africa,[18] India,[19] parts of Southeast Asia,[20] South America,[21] and the Caribbean.[22] Few countries require official notification of LGV cases, and the lack of standard diagnostic criteria renders reported cases somewhat suspect. Since 1950 no country in Europe has reported more than a few dozen cases of LGV annually,[21] and the average for the United States was 595 cases per year, with slight increases during the wars in Korea and Vietnam.[23] By contrast, one municipal clinic in Ethiopia reports several thousand cases of acute LGV annually.[17] Most of the reported LGV cases in

nonendemic areas occur in travelers who acquire the infection while visiting or living in an endemic area.[20] Like other sexually transmitted diseases, LGV is more common in urban than in rural areas, among the sexually active, and among the lower socioeconomic groups.[22] Until recently, much of the reported epidemiology on LGV was based on cases diagnosed using clinical criteria or the results of serologic tests and/or Frei skin tests that were not specific for the disease.

Although cases of LGV are infrequent in Western Europe and the United States, recent outbreaks of LGV have been reported in homosexual and bisexual men many of whom are HIV positive and practice receptive rectal intercourse.[24,25] Most such men have presented with acute proctocolitis and only a few have had the more classic ulcer and bubo associated with LGV. Most of the infections have been with L2 strains, some with a unique molecular variant of LGV.[26,27]

Acute LGV is reported much more frequently in men than in women, with the ratio often reaching 5:1 or greater.[28] This is because symptomatic infection is much less common in women, who are usually diagnosed during early infection only if they develop acute proctocolitis or, less commonly, inguinal buboes. Late complications such as hyperplasia, ulceration and hypertrophy of the genitalia (esthiomene), and rectal strictures are reported to be more frequent in women than in men.[16,24]

The frequency of infection following exposure is unknown. LGV is probably not as contagious as gonorrhea. Primary ulcerative skin lesions, urethritis, cervicitis, proctocolitis, and chronic ulcerations are probably the most infectious forms of LGV. Although supporting evidence is limited, the endocervix is apparently the most common site of acute infection in women. The cervix may remain infected for periods of weeks or months, as has been demonstrated for other serovars of *C. trachomatis*.[29] Congenital transmission does not occur, but infection may be acquired by the infant during passage through an infected birth canal.

PATHOGENESIS AND PATHOLOGY

Chlamydia cannot penetrate intact skin but gains entry through minute lacerations and abrasions. Laboratory-acquired infections following sonication and inhalation of highly concentrated LGV cultures have been reported.[27]

LGV is predominantly a disease of lymphatic tissue.[30] The essential pathologic process is thrombolymphangitis and perilymphangitis with spread of the inflammatory process from infected lymph nodes into the surrounding tissue. The lymphangitis is marked by proliferation of endothelial cells lining the lymph vessels and the lymph channels in lymph nodes. Lymph nodes draining the site of primary infection rapidly enlarge and form small, discrete areas of necrosis surrounded by densely packed endothelial cells.[31] The necrotic areas attract polymorphonuclear leukocytes and enlarge to form characteristic triangular- or quadrangular-shaped "stellate abscesses." Inflammation mats the adjacent lymph nodes together by periadenitis, and as the inflammation progresses, abscesses coalesce and rupture, forming loculated abscesses, fistulas, or sinus tracts.

The inflammatory process lasts several weeks or months before subsiding. Healing takes place by fibrosis, which destroys the normal structure of lymph nodes and obstructs lymph vessels. The resulting chronic edema and sclerosing fibrosis cause induration and enlargement of the affected parts. Fibrosis also compromises the blood supply to the overlying skin or mucous membrane, and ulceration occurs. In the rectum, this results in destruction and ulceration of the mucosa, transmural inflammation of the bowel wall, obstruction of lymphatic drainage, and formation of a fibrotic, inflammatory stricture. Numerous adhesions form that fix the lower part of the sigmoid and rectum to the wall of the pelvis and neighboring organs.[31,32]

Although the primary pathologic process in LGV may be localized to one or two groups of lymph nodes, the organisms spread systemically in the bloodstream and can enter the central nervous system.[33] Dissemination and local extension of disease are limited by host immunity. Delayed hypersensitivity (as evidenced by positive skin tests) and LGV-specific *Chlamydia* antibody can be demonstrated 1–2 weeks after infection.[34] Chlamydial cytoplasmic inclusions can also be demonstrated within tissue phagocytes early in the course of infection.[13] Host immunity ultimately limits chlamydial multiplication but may not eliminate these organisms from the body, and a state of chronic infection ensues.[15] Viable *Chlamydia* has been isolated from late lesions as long as 20 years after initial infection.[35] Persistence of LGV in tissues or repeated infections by the same or related serovars of *C. trachomatis* may be important in developing systemic disease.[36] It is of interest that repeated subcutaneous or intravenous injections of Frei antigen were used to treat LGV in the 1930s with some success,[37] possibly by desensitizing the host to *Chlamydia*. Molecular and cellular aspects of pathogenesis are addressed in Chapter 31.

CLINICAL MANIFESTATIONS

PRIMARY LESION

The primary lesion of LGV may take one of four forms: a papule, an ulcer or erosion, a small herpetiform lesion, or nonspecific urethritis.[28] The most common is the nonindurated herpetiform ulcer that appears at the site of infection after an incubation period of 3–12 days or longer.[10,24,38,31] It may be asymptomatic and inconspicuous (although occasionally multiple and deeply erosive). It is found in 3–53% of patients,[39,40] heals rapidly, and leaves no scar.[28,31] The most common site of occurrence in men is the coronal sulcus,

followed by the frenum, prepuce, penis, urethral glans, and scrotum.[10] In women it appears most commonly on the posterior vaginal wall, the fourchette, the posterior lip of the cervix, and the vulva.[6,10,39] If located intraurethrally, the ulcer or erosion may cause nonspecific urethritis with a thin, mucous purulent discharge.[16,20] Other uncommon types of primary lesions are balanitis[38] and nodular ulcerations.[10,16,31] Following rectal intercourse acute colitis or proctocolitis is often seen as the main manifestation of primary infection. Increasingly, this presentation is the primary form seen in nonendemic countries.

Primary LGV lesions in men may be associated with a lymphangitis of the dorsal penis and formation of a large, tender lymphangial nodule, or *bubonulus*.[10] Bubonuli may rupture and form draining sinuses and fistulas of the urethra as well as fibrotic, deforming scars at the base of the penis.[41] Lymphangitis is very often accompanied by local and regional edema, which may produce varying degrees of phimosis in men and genital swelling in women[38] (Table 33-1).

Cervicitis and urethritis are probably more common manifestations of primary LGV than reported statistics indicate.[38] Urethritis is usually asymptomatic and follows a mild course. Cervicitis may extend locally and could conceivably cause perimetritis or salpingitis. Additional studies using modern molecular diagnostics would be valuable to assess the prevalence of LGV chlamydial infection at the urethral and cervical sites.

Table 33-1. Lesions of Lymphogranuloma Venereum

Early	Late
Inguinal syndrome	
Primary genital lesion(s)	Genital elephantiasis
Genital ulcers	Genital ulcers
Inguinal buboes	
Bubonulus	
Anorectal syndrome	
Proctitis	Rectal stricture
	Lymphorrhoids
	Perirectal abscesses
	Anal fistula
Other	
Urethritis	
Cervicitis	Frozen pelvis
Salpingitis	Infertility
Parametritis	
Conjunctivitis	

INGUINAL SYNDROME

Inflammation and swelling of the inguinal lymph nodes are the most common manifestations of the secondary stage of LGV in men[20,24] and are the reason that most patients seek medical attention.[28] Other lymph nodes may be involved; the likelihood of such involvement depends on the location of the primary lesion (Table 33-2). The incubation period for this manifestation is 10–30 days, but it may be delayed for as long as 4–6 months after infection.[35,39] It is important to note that LGV can also present as an acute systemic febrile infection without apparent lymph node localization or tissue reaction at the point of infection.

The inguinal bubo is unilateral in two-thirds of cases[16,24] (Fig. 33-1). It begins as a firm, slightly painful mass that enlarges over 1–2 weeks. The inguinal bubo was described by William Wallace[42] in 1833:

The skin becomes red and is then found to be adherent to the surface of the tumour, over which it could be previously moved. The bubo then for the most part increases with rapidity; the pain becomes of a throbbing kind; some degree of fever sets in, marked by an acceleration of pulse, an increase of heat, loss of appetite, imperfect sleep, with a general feeling of indisposition.

The constitutional symptoms associated with inguinal buboes may be associated with systemic spread of *Chlamydia.* During this stage of infection, LGV organisms have been recovered from the blood and the cerebrospinal fluid of patients both with and without symptoms of meningoencephalitis and abnormal cerebrospinal fluid.[33,43,44] Other manifestations of systemic spread are hepatitis,[45,46] pneumonitis,[28] and possibly arthritis.[47] Erythema nodosum,

Table 33-2. Site of Primary LGV Infection Determining Subsequent Lymphatic Involvement

Site of Primary Infection	Affected Lymph Nodes
Penis, anterior urethra	Superficial and deep inguinal
Posterior urethra	Deep iliac, perirectal
Vulva	Inguinal
Vagina, cervix	Deep iliac, perirectal, retrocrural, lumbosacral
Anus	Inguinal
Rectum	Perirectal, deep iliac

FIGURE 33-1. Early inguinal syndrome of LGV showing superficial, primary preputial erosion, dorsal penile lymphangitis, and right inguinal bubo.

erythema multiforme, and eyeground changes (papillary edema) are also reported.[16,38,44]

As the bubo enlarges, the male patient complains of severe pain in the groin. He may walk with a limp, bent at the waist in an attempt to limit pain. Within 1–2 weeks the bubo becomes fluctuant, and the skin overlying the bubo takes on a characteristically livid color ("blue balls") that predicts rupture of the bubo.[24]

Rupture through the skin usually relieves pain and fever.[16,44] Numerous sinus tracts are formed that drain thick, tenacious, yellowish pus for several days or weeks with little or no discomfort.[48] Healing takes place slowly, leaving callous and contracted scars in the inguinal region. The disappearance of the inguinal bubo usually marks the end of the disease in men, and the majority suffer no serious sequelae.[24,49] Bubonic relapse occurs in about 20% of untreated cases.[49]

Only about one-third of inguinal buboes become fluctuant and rupture; others slowly involute and form firm, slowly resolving inguinal masses without undergoing suppuration.[16,24] In about 20% of cases, the femoral lymph nodes are also affected and may be separated from the enlarged inguinal lymph nodes by Poupart's ligament; this process creates the "sign of the groove" that is said to be pathognomonic for LGV[28] (Fig. 33-2). Simultaneous involvement of the deep iliac lymph nodes occurs in about 75% of cases and may cause formation of a large pelvic mass that, fortunately, seldom suppurates.[38,44] Extragenital primary lesions produce lymphadenitis and bubo formation in the lymph nodes draining the lesions; these extragenital buboes do not differ symptomatically or pathologically from inguinal buboes.[16]

FIGURE 33-2. Early inguinal syndrome of LGV showing a small vesicular primary lesion and bilateral inguinal lymphadenitis with cleavage of the enlarged right inguinal and femoral lymph nodes by the inguinal ligament, the characteristic "groove" sign.

In large studies of LGV in women, only 20–30% present with the inguinal syndrome.[24,50] About one-third of female cases without proctitis, however, complain of lower abdominal and back pain, especially when supine.[44] This symptom is characteristic of involvement of the deep pelvic and lumbar lymph nodes and may be mistaken for acute appendicitis[28] or a tubo-ovarian abscess.[16,44] Numerous adhesions may form, fixing the pelvic organs together.[44]

Other infectious diseases causing inguinal lymphadenitis and bubo formation are plague, tularemia, cat scratch disease, and tuberculosis. More common causes of inguinal lymphadenitis without suppuration, which are frequently misdiagnosed as LGV, are genital herpes, syphilis, chancroid, and Hodgkin's disease.[38] Small skin lesions on the feet or lower extremities may cause significant inguinal adenopathy with bacterial superinfection, usually staphylococcal or streptococcal. In nonendemic areas, however, the syndrome is most frequently mistaken for an incarcerated inguinal hernia[51] or lymphoma.[52]

ANOGENITORECTAL SYNDROME

The subacute manifestations of this syndrome are proctocolitis and hyperplasia of intestinal and perirectal lymphatic tissue (lymphorrhoids). The chronic or late manifestations are perirectal abscesses, ischiorectal and rectovaginal fistulas, anal fistulas, and rectal stricture or stenosis.[22,38]

In men, the rectal mucosa can be inoculated directly with *Chlamydia* during receptive anal intercourse or by lymphatic spread from the male posterior urethra. In women, the rectal mucosa can also be inoculated directly with during anal intercourse, or it can be secondarily infected by migration of infectious vaginal secretions or by lymphatic spread from the cervix and posterior vaginal wall. The vast majority of

patients with the anorectal syndrome are women or homosexual men.[50,53–57]

The early symptoms of rectal infection are anal pruritus and a mucous rectal discharge caused by local or diffuse edema of the anorectal mucosa. The mucosa becomes hyperemic and friable after a period of several weeks and bleeds easily when traumatized.[53,56,57] Multiple, discrete, superficial ulcerations with irregular borders appear on the mucosa and are gradually replaced by granulation tissue. A chronic inflammatory process invades the bowel wall, and noncaseous granulomas and crypt abscesses form.[53,56] With secondary bacterial infection of the rectal mucosa, the discharge becomes mucopurulent. If left untreated, the granulomatous process progressively involves all layers of the bowel wall. The muscle layers are replaced by fibrous tissue.[32,53] In women the rectovaginal septum may be eroded and a rectovaginal fistula may be formed.[54] Contraction of the fibrous components of the granulation tissue over a period of months or years causes partial (stricture) or complete (stenosis) blockage of the rectum.[32,53,54]

Early symptoms of proctocolitis include fever, rectal pain, and tenesmus.[16,22,54] The lower left quadrant of the abdomen is tender, and the pelvic colon may be palpably thickened. The rectal mucosa feels granular on digital examination, and movable, enlarged lymph nodes may be palpated immediately under the bowel wall.[54] There are no pathognomonic sigmoidoscopic findings. The inflammatory process may be localized to one segment of bowel or may occur at several different levels concurrently, but it is usually limited to that portion below the peritoneal reflection.[22,32,54]

Additional symptoms that occur with rectal stricture are varying degrees of constipation, passage of "pencil" stools, attacks of ileus with colic and abdominal distension, and weight loss.[24,38,53,58] The stricture usually forms 2–5 cm above the anocutaneous margin, where the perirectal lymphatic tissue is the richest.[22,54] It is usually annular or tubular in shape[58] and its proximal margins are granular (Fig. 33-3). If the palpating finger can be introduced through the aperture of the nondistensible and rigid stricture, the mucous membrane above it has a normal consistency.[54] By contrast, the mucous membrane below the stricture generally shows ulcerative and granulomatous proctitis, which makes the digital examination very painful.[24] Although the stricture is often very narrow, complete bowel obstruction (rectal stenosis) is rare but strictures may cause bowel perforation and peritonitis, which is the usual cause of death in LGV.[38,59]

The rectal mucosa below the stricture and the skin around the anus are frequent sites for the formation of perirectal abscesses and anal fissures.[55,58] These may also occur as the only manifestation of chronic anogenitorectal LGV. Obstruction of the lymphatic and venous drainage of the lower rectum produces perianal outgrowths of lymphatic tissue that grossly resemble hemorrhoids but are called *lymphorrhoids*[60] or *perianal condylomas*.[58] Histologically, these anal tags are composed of dilated lymph vessels with perilymphatic inflammation.[16,24]

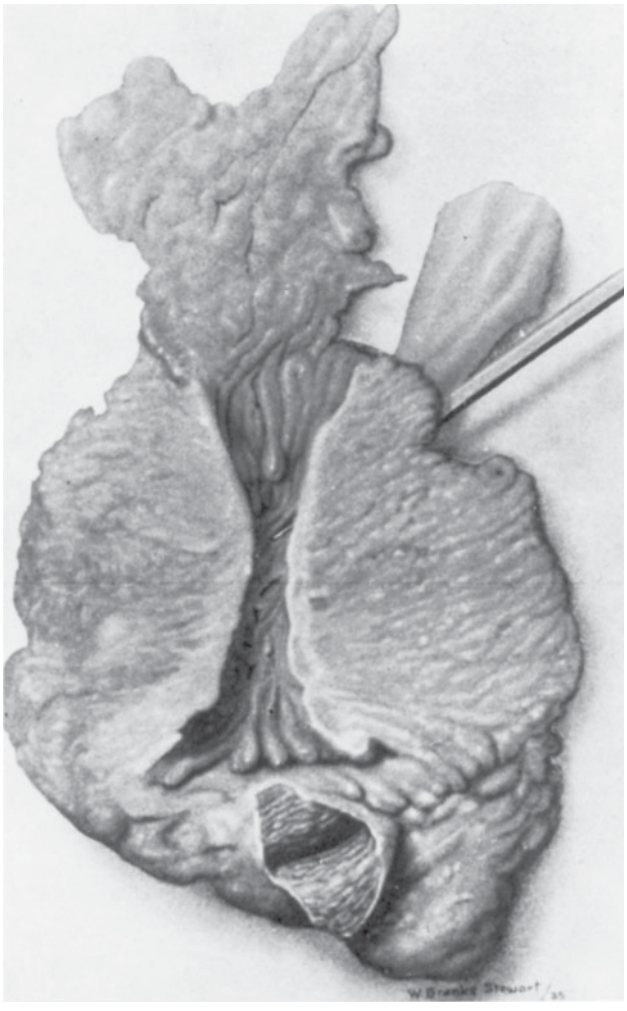

FIGURE 33-3. Necropsy specimen of an LGV rectal stricture containing an ileosigmoidal fistula. (With permission from Lichtenstein LL. Rectal stricture: A clinical analysis of 58 cases with observations on 154 Frei-positive cases of lymphogranuloma inguinale. *Am J Surg* 1936; 31: 111.)

The clinical and histologic picture of early LGV proctocolitis is very similar to that seen in inflammatory bowel disease,[61,62] and there has been considerable debate in the medical literature concerning a possible etiologic role for LGV in regional ileitis (Crohn's disease) and ulcerative colitis.[63] Schuller et al.[64] demonstrated specific LGV antibody in the sera of 38 of 55 patients with Crohn's disease, but subsequent studies showed no serologic evidence of *Chlamydia* infection in either Crohn's disease or ulcerative colitis.[65–67]

Several groups have isolated non-LGV *C. trachomatis* serovars from male homosexuals with proctocolitis.[9,56,57] The sigmoidoscopic and biopsy findings in these patients differ from those found in LGV infections; the inflammatory process is not as intense or as invasive as that caused by LGV serovars, and hypertrophic mucosal "follicles" predominate. Infection of the rectum with non-LGV strains generally

produces a far milder illness than does LGV, with lack of progression to suppurative sequelae or fibrosis.

The rectal stricture of LGV may resemble that caused by trauma, actinomycosis, tuberculosis, schistosomiasis, and malignancy.[22,38,58] It is most frequently mistaken for rectal cancer, and a biopsy should be taken to exclude this diagnosis. The incidence of rectal cancer in patients with LGV rectal stricture has ranged from 2%[68] to 5%.[69]

ESTHIOMENE

Esthiomene (Greek, "eating away"), a primary infection affecting the lymphatics of the scrotum, penis, or vulva, may cause chronic progressive lymphangitis, chronic edema, and sclerosing fibrosis of the subcutaneous tissues of these structures.[24,50] This results in induration and enlargement of the affected parts and, ultimately, in ulceration. In the earliest stages, the ulceration is superficial, but it gradually becomes more invasive and destructive. The vast majority of patients with esthiomene are women, and many authorities prefer to restrict the use of the term to this sex.

Chronic ulcerations are extremely painful. In women, they are most common on the external surface of the labia majora, on the genitocrural folds, and on the lateral regions of the perineum[38] (Figs. 33-4 and 33-5). The edema may extend from the clitoris to the anus and interfere with normal function. Urethral and vaginal[16,24,50] stenoses and fistula formation have been reported.

FIGURE 33-5. Elephantiasis of the labia and clitoris in a woman with late lymphogranuloma venereum. (*Courtesy of M.I. Unit, Ibadan University, Nigeria.*)

OTHER MANIFESTATIONS

There is a tendency for women to develop papillary growths on the mucosa of the urethral meatus; these growths cause dysuria, frequency, and urinary incontinence with some perimeatal ulceration.[50] Penile, scrotal, or perineal sinuses may develop with or without urethral stenosis.[18,50] Coutts[38] refers to this symptom complex as the *urethrogenitoperineal syndrome.*

Penoscrotal elephantiasis appears from 1 to 20 years after infection.[38] It may affect only the prepuce, the prepuce and the penis, the scrotum alone, or all the male external genitalia. The genital tissue is indurated and often deformed. The scrotum may reach monstrous size, but this is unusual.[24] Other conditions such as filariasis and mycosis must be considered in differential diagnosis.

Follicular conjunctivitis, often accompanied by lymphadenitis of the maxillary and posterior auricular nodes,[16] can occur at any stage of LGV. The conjunctiva is infected by autoinoculation of infectious genital discharge. This condition may be analogous to Parinaud's oculoglandular syndrome.[38]

Primary LGV lesions of the mouth and pharynx can occur as the result of fellatio or cunnilingus. This results in lymphadenitis of the submaxillary or cervical lymph nodes.[26] Cases of supraclavicular lymphadenitis with mediastinal lymphadenopathy and pericarditis have also been reported.[70,71] Coutts[47] has recovered LGV from the gallbladder wall (in cases of chronic cholecystitis) and from fibrous perihepatic (in cases of Fitz-Hugh-Curtis syndrome), abdominal, and pelvic adhesions.

Erythema nodosum and other skin manifestations occur in about 10% of LGV cases during the early stages of infection.[10] Their appearance may be precipitated by surgical

manipulation of infected lymph nodes.[16] The malnutrition associated with rectal stricture was a frequent cause of pellagra in the preantibiotic era.[24]

DIAGNOSIS

Mild leukocytosis with an increase in monocytes and eosinophils frequently accompanies early bubonic and anogenitorectal LGV.[20,22,25] A more significant polymorphonuclear leukocytosis is found routinely in patients whose LGV buboes are superinfected with pyogenic bacteria.[16] The only other clinical laboratory abnormality found with regularity is an elevated gamma globulin concentration due to an increase of IgA, IgG, and IgM immunoglobulins.[17]

The diagnosis of LGV is usually based on (1) a positive Frei skin test, (2) a positive complement-fixation (CF) or other serologic test for LGV, (3) isolation of LGV *Chlamydia* from infected tissue and secretions in mice, embryonated eggs, or tissue culture, (4) histologic identification of *Chlamydia* in infected tissue, or (5) demonstration of *Chlamydia* by polymerase chain reaction (PCR) or other nucleic acid amplification test (NAAT) in infected secretions or tissues.[72,73,74] Although histopathologic changes in LGV are not unique, they are sufficiently distinct to differentiate LGV buboes, bubonuli, and rectal strictures from similar lesions caused by other sexually transmitted agents.[24,31,75]

FREI TEST

While the Frei test is no longer produced commercially or used widely, it is of historical interest given its very important role in many early studies of LGV. The original Frei test antigen used pus obtained from unruptured buboes, diluted in saline, and sterilized by heating.[11] Not only was the risk of bacterial or viral contamination of this antigen considerable, but it could easily be inactivated by overheating, and standardization of its potency was impossible.[76] Nevertheless, a positive test in a patient with clinical findings compatible with LGV generally indicated present or past infection. The successful culture of LGV in large amounts in the yolk sacs of chick embryos led to the commercial manufacture of a standardized skin test antigen (Lygranum) in 1940.[77] The test consisted of intradermal injections of 0.1 mL Lygranum into the skin of one forearm and a similar volume of control yolk sac material into the other forearm. The test was read at 48 hours, and a positive result was the development of a papule at least 6 × 6 mm in the principal diameter, provided the papule produced by the control was 5 × 5 mm or smaller. The same antigen was also used in complement-fixation serodiagnostic tests for LGV[78] after Melczer and Sipos[79] demonstrated the complement-fixing property of LGV in 1937.

The Frei skin test usually becomes positive after the appearance of buboes 2–8 weeks after infection.[10,16,80] In the older literature it was said that the Frei test was positive in about 95% of patients with bubonic LGV and in about 90% of those with ulcerative genital elephantiasis.[6] The lack of sensitivity in the early stages of LGV is a distinct disadvantage.[46]

Since the Frei antigen is common to all *Chlamydia*, the specificity of a positive reaction has limited its diagnostic usefulness, particularly in the past two decades, when the prevalence of other chlamydial infections has risen considerably.[15] The Frei test usually remains positive for several years and possibly for life despite treatment.[80,81] Commercial manufacture of Frei antigen was discontinued in 1974.

COMPLEMENT-FIXATION SEROLOGIC TEST

CF antibody test is more sensitive and turns positive earlier than the Frei test.[16,38,43] There is no correlation between the CF antibody titer and the intensity of the Frei reaction,[16,82] although in a given patient there is often close agreement between the two.[80] Like the Frei test, the CF test may result in cross-reactions in infections caused by other chlamydial infections, and the antibody may persist in high or low titer for many years.[80,83] In general, active LGV infections have CF titers of 1:64 or greater,[28,80,82–84] but high CF titers are occasionally found in asymptomatic patients and those with other chlamydial infections. Titers below 1:64 in a patient suspected of LGV on clinical grounds should be interpreted with caution.

Although a rise in CF titer of two or more dilutions may occur in early LGV,[82] most patients with documented LGV initially have high CF titers that show little difference between serum specimens obtained during acute infection and at 6 weeks into convalescence.[46,82] Variations in CF titer can also be caused by changes in both the concentration of test antigen and the test procedure.

MICROIMMUNOFLUORESCENT (MICRO-IF) ANTIBODY TEST

The micro-IF test is considerably more sensitive and specific than the CF test[34,85,86]; although the micro-IF antibody reacts broadly with other *C. trachomatis* strains,[85] it is usually possible to demonstrate the antigenic type of the infecting strain by its pattern of reactivity in the assay.[9,17,34] In LGV, acute-phase serum usually contains very high titers of micro-IF antibody.[9,17,56] The major disadvantage of the micro-IF test is that it is technically very demanding and is hence used primarily in a few specialized research laboratories. It is not routinely available commercially.

ISOLATION OF LGV

Chlamydia can be isolated from infected tissue or secretions by inoculation of mouse brain, yolk sac, or tissue

culture.[15,16,87,88] The recovery rate depends on the method used and the source of the inoculum. Bubo pus is the most practical clinical material to obtain and inoculate.[28] Wall et al.[82] compared the recovery rate from bubo biopsy or pus in mice and yolk sac; *Chlamydia* were cultured from 85% of patients, with a higher recovery rate in mice (98%) than in yolk sac (78%). Other studies report much lower recovery rates.[46,89]

For the past 25 years, HeLa-229[90] and McCoy[1] tissue-culture cell lines have been used to isolate LGV *Chlamydia*. The reported recovery rate from buboes, genital tissue, or rectal tissue ranges from 24% to 30%,[17,34,46] which is lower than that reported for nongonococcal urethritis.[15,88]

CYTOLOGY

The elementary and inclusion bodies of *Chlamydia* can be visualized both outside and inside cells in secretions and infected tissues by using Giemsa, iodine, and fluorescent antibody staining methods.[38,88,91] Cytology has not been very successful for the diagnosis of LGV[31] often because of the frequent contamination of specimens by bacteria and other artifacts.

NUCLEIC ACID AMPLIFICATION TESTS

PCR technology was the first NAAT used to detect "signature" *C. trachomatis* nucleic acid specific for the organism in cases of urethritis, cervicitis, salpingitis, and other syndromes caused by this *agent*.

A prospective study of an epidemic of LGV in the Bahamas in 1990[92] involving 47 consecutive patients with genital ulcers seen at an STD clinic in Nassau demonstrated the advantage of the PCR test for diagnosis of LGV in an area where other causes of genital ulcers and lymphadenopathy, including HIV, are common. For non-LGV chlamydial infections, several different types of NAAT tests have been shown to be more sensitive and specific than chlamydial culture when used on urethral, cervical, vaginal, and urine specimens (see Chapter 31). More limited data indicate that NAAT tests can also be used on rectal swab specimens for testing Chlamydia although none of the assays have been FDA approved for this indication. As currently configured, the NAAT assays do not differentiate LGV and non-LGV chlamydia.

OTHER DIAGNOSTIC PROCEDURES

Various radiologic procedures have been used in LGV. Lymphography demonstrates the extent of lymph node involvement but does not outline buboes or reveal specific changes.[93] Rectal strictures caused by LGV are said to be characteristic when seen on barium enema and quite different from cancer: The LGV stricture is elongated, in contradistinction to the stricture produced by cancer; it produces little alteration in the mucosal pattern of the bowel; and it has a tendency to form fistulas that tend to reenter the lumen of the rectum.[94,95]

TREATMENT

A number of different drugs have been used to treat LGV, but few regimens have been studied in controlled clinical trials. A major problem in evaluating a given drug is the relative lack of criteria by which efficacy can be measured.[96] The natural history of LGV is highly variable and spontaneous remission is common.[44,49]

Sulfonamides were the first drugs to show efficacy in LGV by promoting reduction in the size of buboes and healing of fistulas.[14,75,97] However, lesions were not sterilized despite many months of therapy,[14] and CF titers often showed little or no change.[98] In experimentally infected mice, 20% remained infected with LGV despite the most extensive sulfonamide therapy.[97]

Penicillin and streptomycin were also found to be ineffective, although penicillin has some activity against *Chlamydia* in vitro.[97] The next antibiotics used were the tetracyclines, which proved to be quite effective in the management of the primary and secondary stages of LGV.[49,83,99] Similar effectiveness was found with chloramphenicol,[96] erythromycin,[100] minocycline,[19] and rifampin.[101] The regimens currently recommended by the Centers for Disease Control are doxycycline 100 mg twice a day for 21 days or erythromycin 500 mg four times a day for 21 days. Some experts recommend 1 g of azithromycin once weekly for 3 weeks, but this has been little studied.

BUBONIC LGV

Greaves et al.[49] attempted the only comparative treatment study of bubonic LGV. The relative effectiveness of oral chlortetracycline, oxytetracycline, chloramphenicol, or sulfadiazine was compared with patients treated symptomatically with aspirin. The tetracyclines and chloramphenicol were given in a dosage of 500 mg qid for 14 days following a loading dose of 1 gm. Sulfadiazine was given in a dose of 2 gm initially, followed by 4 gm daily in divided doses for 10–28 days. The relative effectiveness of each drug was measured by the duration of inguinal adenopathy and the occurrence of bubonic relapse, sinus formation, or skin lesions after completion of therapy. Unfortunately, the average number of patients treated with each drug was 6.5, which limits the statistical validity of the results.

The duration of the bubo after treatment was same in all drug-treated groups and was not significantly shorter compared with the duration of the bubo in those given symptomatic therapy. Although specific chemotherapy had only a minimal effect in shortening the duration of the bubonic lesion (31 vs. 69 days), there was a more frequent occurrence of complications among the symptomatically treated control group. There was a marked reduction in CF antibody titer in

drug-treated patients which suggests that the amount of LGV present in infected tissues was reduced, if not eliminated. Other workers have shown that lymph nodes that were proved to be infective before tetracycline were found to be negative after therapy.[102]

Minocycline, in a loading oral dose of 300 mg followed by 200 mg bid for 10 days, has been used with success to treat acute bubonic LGV and a limited number of cases of proctitis.[19] Only limited information is available on treatment of LGV with erythromycin.[100]

Although oral azithromycin in a 1-gm oral dose has been proven effective for treatment of chlamydial urethritis and cervicitis, its effectiveness in treating LGV is not known. Whereas it may prove to be effective for treatment of LGV in shorter courses, such short-course therapy should not be used until further supporting evidence is available.

Fever abates and patients usually experience prompt relief of bubo pain and tenderness and feel much improved 1–2 days after starting antibiotics.[17,20] The bubo seldom suppurates after therapy begins, but fluctuant buboes may require frequent needle-and-syringe aspiration to prevent rupture.[17]

ANOGENITORECTAL LGV

Banov[53] reported the immediate and long-term effects of chlortetracycline, oxytetracycline, chloramphenicol, and erythromycin in cases of rectal stricture. Criteria used to compare the different drugs were subjective, the patients were not randomly assigned treatments, and the dosage schedules were variable. With the exception of erythromycin (only three cases studied), all drugs were effective. Apparently these drugs reduced the inflammatory edema of the rectal stricture but had no effect on scar tissue. In contrast to bubonic LGV, antibiotics had no immediate effect on the titer of CF antibody. No case of anal or rectovaginal fistula was cured by drugs alone.

The response of proctocolitis to antibiotics is usually dramatic. Symptoms are completely relieved and the rectal mucosa heals within a few weeks after treatment.[22,56] However, occasional tetracycline treatment failures in proctocolitis have been reported.[22,57]

SURGICAL TREATMENT

Surgical treatment of the acute inguinal syndrome should be limited to aspiration of fluctuant lymph nodes and occasional incision and drainage of abscesses.[22] Before the advent of sulfonamides, surgical extirpation of buboes was recommended,[22,25] although it was probably a prominent factor in the development of postoperative elephantiasis of the genitals by further blocking normal lymphatic drainage.[39] Under antibiotic coverage there is little risk that incision or aspiration of fluctuant buboes will lead to formation of sinuses.[20,51]

Spontaneous resolution of a fibrous LGV rectal stricture never occurs, but the inflammatory process and the diameter of the stricture may be improved dramatically by antibiotic treatment.[22,53] Dilatation of the stricture using elastic bougies under direct vision may be necessary but poses a significant risk of bowel perforation. It should be limited to soft, short strictures not extending above the peritoneal reflection and should be abandoned if the stricture splits easily or if bleeding occurs.[22]

A variety of different surgical procedures may be required for advanced rectal stricture. The indications for operation are bowel obstruction, persistent rectovaginal fistula, and gross destruction of the anal canal, anal sphincter, and perineum.[22] Plastic operations on the vulva, penis, and scrotum may be required for esthiomene and genital elephantiasis.[38] None of these procedures should be attempted without antibiotic treatment, and if possible, antibiotics should be given for several months before the decision to perform surgery is made.[103]

PREVENTION

Prevention of LGV in nonendemic areas is predicated on identification and treatment of sexual contacts of proved or suspected cases. These contacts should receive prophylactic antibiotic treatment if recently exposed to infection so as to prevent reinfection as well as to eliminate a potential reservoir. The increasing prevalence of anorectal LGV in male homosexuals in Western Europe and the United States should be kept in mind when a young male presents with symptoms of proctocolitis.

Control of LGV in endemic areas presents a formidable problem.

The use of condoms and other safe sexual practices as outlined in Chapters 93–95 are the main prevention avenues to pursue.

ACKNOWLEDGMENTS

The original version of this chapter was prepared and coauthored with Peter Perrine, MD, whose extensive experience with and knowledge of lymphogranuloma venereum were instrumental in writing the chapter. Much of the chapter, especially those parts that deal with clinical presentations and complications reflect his expertise.

34 Biology of *Neisseria gonorrhoeae*

P. Frederick Sparling

Neisseria gonorrhoeae (gonococci) is the etiologic agent of gonorrhea and its related clinical syndromes (urethritis, cervicitis, salpingitis, bacteremia, arthritis, and others). It is closely related to *Neisseria meningitidis* (meningococci), the etiologic agent of one form of bacterial meningitis, and relatively closely to *Neisseria lactamica*, an occasional human pathogen. The genus *Neisseria* includes a variety of other relatively or completely nonpathogenic organisms that are principally important because of their occasional diagnostic confusion with gonococci and meningococci.

This chapter is concerned principally with the microbiology, genetics, and pathogenicity of gonococci. Chapter 35 is concerned with the clinical syndromes caused by gonococci and their treatment in adults; infections in children are discussed in Chapter 83. A discussion of the syndrome of urethritis in men is discussed in Chapter 59, and gonococcal and other related syndromes of the lower and upper genital tracts in women are discussed in Chapters 55 and 56.

HISTORY

Gonorrhea is one of the oldest known diseases of humans. There have been many reviews of the history of this disease, one of the best of which is the monograph by R.S. Morton.[1] Gonorrhea undoubtedly was known to the authors of the Bible. The Book of Leviticus describes a person with urethral discharge. Proclamations that infected persons were to keep themselves from others for 7 days may indicate that they already knew that the mean incubation period was 7 days. Biblical authors cautioned about transmission to social contacts and also about women copulating with afflicted men.

Hippocrates wrote extensively of gonorrhea in the fourth and fifth centuries B.C. He called acute gonorrhea "strangury" and understood that it resulted from "the pleasures of Venus." The Roman physician Celsus was well aware of gonorrhea and its complications, and was known to catheterize patients suffering from urethral stricture. In the second century, Galen coined the word *gonorrhea,* by which he meant "flow of semen." Other early Greco-Roman physicians prescribed various treatments for gonorrhea, including sexual abstinence and washing of the eyes of the newborn.

Knowledge of gonorrhea and other sexually transmitted diseases in Europe was scant until near the end of the Dark Ages. The term *clap,* which is still commonly used to refer to this disease, first appeared in print in 1378. The derivation of the word clap is unclear but possibly refers to the Les Clapier district of Paris in which prostitutes were housed in the Middle Ages. European writings of the late Middle Ages make it clear that the disease was associated with sexual intercourse.

After the arrival of syphilis in Europe in the late fifteenth century, considerable confusion existed regarding the relation between gonorrhea and syphilis. Great surgeons such as Ambroise Paré (sixteenth century) and John Hunter (eighteenth century) considered syphilis and gonorrhea to be different manifestations of a single disease. Hunter's conclusions were the result of a famous experiment in which he inoculated himself with material from a patient with gonorrhea; he acquired syphilis as a result. Distinction between these diseases was first clearly achieved by Philippe Ricord, but real understanding was only achieved after Neisser's description of *N. gonorrhoeae* in 1879 and Leistikow's and Lõffler's cultivation of the organism in 1882.

The twentieth century brought new, safe, highly effective therapy for gonorrhea, replacing the sometimes horrific therapies used for centuries, including urethral astringents, soundings, and other mechanical devices. Sulfonamides were first introduced in 1936 and penicillin in 1943 for gonorrhea therapy. The second great development of the twentieth century concerned the revolution in our understanding of the pathogenic mechanisms of this fascinating organism, which started with the demonstration by Kellogg and his colleagues in 1963 that there are differences in virulence of gonococci with different colonial morphology.[2] These developments enable better understanding of how gonococci cause repeated infections in the same individual and may lead to development of an effective vaccine.

EPIDEMIOLOGY

TRANSMISSION

Humans are the only natural host for gonococci. Gonococci survive only a short time outside the human body. Although gonococci can be cultured from a dried environment such as a toilet seat up to 24 hours after being artificially inoculated in large numbers onto such a surface, there is virtually no evidence that natural transmission occurs from toilet seats or similar objects. Gonorrhea is a classic example of an infection spread by contact: immediate physical contact with the mucosal surfaces of an infected person, usually a sexual partner, is required for transmission. (The single exception is the occasional epidemic among prepubescent females living together and sharing bath towels and similar objects.)

STRAIN TYPING

For epidemiologic studies, it is useful to differentiate one strain from another. Several techniques have been developed that can be used successfully for this purpose.

Auxotypes

A relatively cumbersome system for differentiating gonococcal strains based on their ability to grow on chemically defined media was developed that classified strains as to whether they could grow without certain amino acids, purines or pyrimidines, or other specific nutrients.[3] A strain unable to grow on chemically defined media lacking proline was designated Pro^-, and a strain unable to grow without arginine was Arg^-. Naturally occurring gonococcal isolates exhibit remarkable diversity in their biosynthetic capacities, probably reflecting the biochemically rich environment of their human host, which provides the organisms with most of the compounds needed for growth. The auxotyping system was used successfully in a variety of epidemiologic studies.[4] The Arg^- Hyx^- ($hypoxanthine^-$) Ura^- ($uracil^-$), or AHU^-, auxotype typically was associated with multiple other properties, including resistance to killing by normal human serum; propensity for causing asymptomatic male urethral infection; increased likelihood for causing bacteremia; and others.[5] The auxotyping technique is not widely used in clinical laboratories today.

Serotyping

Investigators tried to develop a practical serotyping scheme for decades. A useful and formerly widely available technique for this purpose was based on monoclonal antibodies specific for various epitopes on outer membrane protein I (P.I, or Por).[6] Por occurs in two immunochemically distinct serogroups: PI.A and PI.B, each of which is an allelic form of the *porB* gene. By employing a set of monoclonal antibodies against PI.A strains and another set against PI.B strains, one can subdivide each of the serogroups into a wide variety of serovars (e.g., P.IA-6, P.IB-1), differing in their ability to react with certain members of the panel of monoclonal antibodies. Many dozens of specific serovars have been defined by these techniques.[4,6] By a combination of auxotyping and serotyping with anti-Por monoclonal antibodies, gonococci can be divided into over 70 different strains; the number may turn out to be much larger. The technique is now little used because of exhaustion of the supply of the crucial monoclonal antibodies. It has been replaced largely for research purposes by hybridization with sets of specific oligonucleotides for variable loops of the *porB* gene, or by DNA sequencing of *porB* ("porin genotyping"), which serves much the same purpose.[7,8] The technique has been used to follow evolution of strains in communities over time[9] and also to document mixed infection by different strains.[8]

Antimicrobial susceptibilities

Another method to strain type gonococci is based on antimicrobial susceptibilities. This may be employed as an adjunct to the *porB* genotyping scheme, but by itself it is of little use.

Genotyping

Although it is impractical to undertake full genomic sequencing, it is possible to use various tools of molecular biology to rapidly assess differences in DNA sequences. Several techniques have been tried, most of which are no longer considered useful. A technique termed Opa typing used *opa*-based PCR primers to generate DNA from each of the approximately 11 *opa* genes. These were then subjected to restriction enzyme digestion, and the resultant pattern of restriction fragment length polymorphisms (RFLP) was used to compare identities of strains.[10] Used in conjunction with other strain-typing systems, Opa genotyping offered additional and powerful resolving power. The most sophisticated technique for research purposes compares the DNA sequence of a variety of housekeeping genes (multilocus sequence typing, or MLST), which are not thought to be subjected to evolutionary pressures by the immune response to infection.[9] The same technique has proven very useful in studies of the epidemiology of meningococcal infection,[11] but it is only employed by large research groups. Pulsed field gel electrophoresis (PFGE) is another research tool for differentiation of strain differences.

BIOLOGY

COLONY MORPHOLOGY

Gonococci are gram-negative diplococci, nonmotile and non spore forming, which characteristically grow in pairs (diplococci) with adjacent sides flattened. In 1963, Kellogg showed that gonococci occur in multiple colony types when grown

on a clear agar medium and viewed with obliquely transmitted light.[2] Small convex glistening type 1 and type 2 colonies were easily distinguished from the larger, flatter type 3 and type 4 colonies. The small colonies are now known to be piliated and are designated P^+; large colonies are nonpiliated (P^-) (Fig. 34-1). Colony types are variable, and although fresh isolates from patients usually are P^+, unselected transfer in vitro usually results in conversion to P^-.[2,12] Some P^- colonies are capable of subsequent reversion to P^+. Using human male prison volunteers as experimental subjects, Kellogg and his coworkers showed that after 69 in vitro passages, P^+ "type 1" colonies retained virulence but the P^- "type 4" colonies did not.[2]

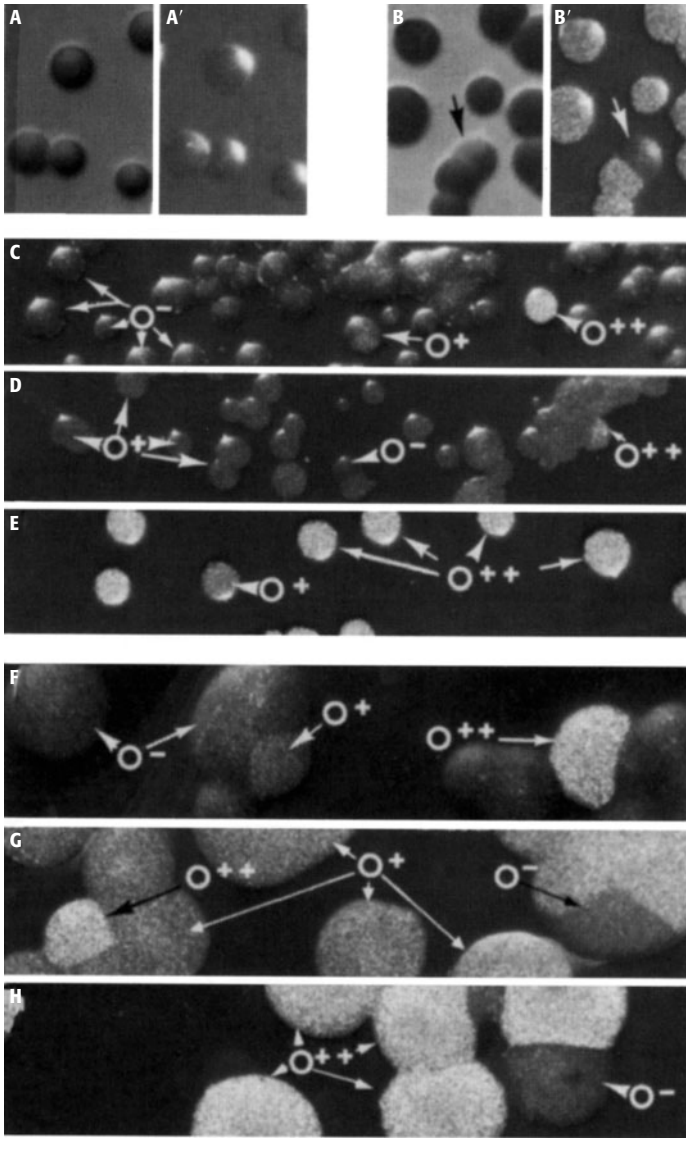

FIGURE 34-1. Gonococcal colonial morphologies. A variety of sizes and forms are present in gonococci cultivated on clear medium, in vitro. Small colonies with darkly rimmed borders (**A–E**) contain heavily piliated organisms, whereas large colonies (**F–H**) are constituted of nonpiliated gonococci. Colonies of both piliated and nonpiliated organisms display variation in their color and opacity characteristics. Use of a diffusing substage reflector allows visualization of colony color (**A** and **B**) and is depicted here for very light (**A.**) and very dark (**B.**) colonies. Use of a polished substage mirror allows differentiation of colonial opacity variants (**A′, B′, C–H**). Transparent colony (O^-) populations are regularly "contaminated" by variants of intermediate (O^+) or marked (O^{2+}) colonial opacities (**C.**) Similarly, O^- and O^{2+} colonies are found in O^+ preparations (**D.**), and colonies of lesser opacity (O^- or O^+) appear in O^{2+} colony populations (**E.**) These variants can also be found in otherwise homogeneous O^- (**F.**), O^+ (**G.**), and O^{2+} (**H.**) populations of nonpiliated gonococcal colonies. *(Courtesy of J. Swanson and L. Mayer.)*

A second type of morphologically visible colonial variation concerns relative opacity of the colonies when viewed through a low-power microscope on clear media in appropriate lighting.[13,14] Opaque (Op) colonies are darker and more granular than transparent (Tr) colonies (see Fig. 34-1). The Op and Tr colony types undergo rapid reversible variations in vitro. The biochemical basis of the opaque–transparent colony variation is owing to variation in expression of a family of outer membrane proteins formerly designated protein II (P.II) but now designated Opa; Op colonies contain cells expressing Opa, whereas most transparent colonies contain cells that are not expressing Opa.[15]

MEMBRANE STRUCTURE

When gonococci are viewed in cross section by transmission electron microscopy (TEM), they are seen to have a typical gram-negative outer membrane overlying a relatively thin peptidoglycan layer and cytoplasmic membrane. Meningococci contain a true polysaccharide capsule that is important to virulence, whereas gonococci lack such a structure. Frequently small blebs of outer membrane may be seen in TEM. Unlike *Escherichia coli* and many other enteric bacteria, gonococci are prone to release fragments of membrane into their surrounding environment; this may deliver toxic membrane components to distant sites and antigenic fragments that bind host antibodies.

Pili

The most important parts of the gonococcus from the pathogenic point of view concern surface molecules that are involved in attachment to, or invasion or injury of, the host or that serve as targets for host immune defenses. Among the best-studied surface molecules are pili. Viewed by electron microscopy, pili are arranged in individual fibrils or fibrillar aggregates and cover virtually the entire outer cell surface of the organism (Fig. 34-2). Fibrillar pili actually are polymers composed of perhaps thousands of a subunit of about 18 kDa. A great deal is now known about the structure of the pilin subunit, as assessed by x-ray crystallography.[16] Pili are known to increase adhesion to host tissues.[17] The cell receptor for binding pili is under intense study and subject to some dispute; it may involve the CD46 molecule.[18,19]

Antigenic and phase variation

Pili undergo two types of variations at relatively high frequency: antigenic variation, in which strains shift the

antigenic type of their pilus; and phase variation, in which strains switch between P^+ and P^- states. Immune sera raised in animals against a single purified pilus react relatively weakly with pili prepared from unrelated clinical isolates.[20] The pilus expressed by a single gonococcal strain is known to be able to undergo extensive antigenic variation, either during passage on agar plates, during growth in subcutaneous chambers implanted into experimental animals, or during natural infection of humans.[21-23] The genetics of pilin variation, and the DNA sequence of expressed pili in several strains are well established.[23-26] There is a common N-terminal region and several variable domains in the midportion or carboxy terminus of the protein (Fig. 34-3). Several relatively invariant or common regions are scattered amid the variable domains, including two cysteines at amino acids 121 and 151 that form a disulfide bridge. The amino terminus is nearly identical in all type 4 pilus expressing bacteria, including gonococci, meningococci, and several other organisms including *Bacteroides nodosus, Moraxella bovis,* and *Pseudomonas aeruginosa.*

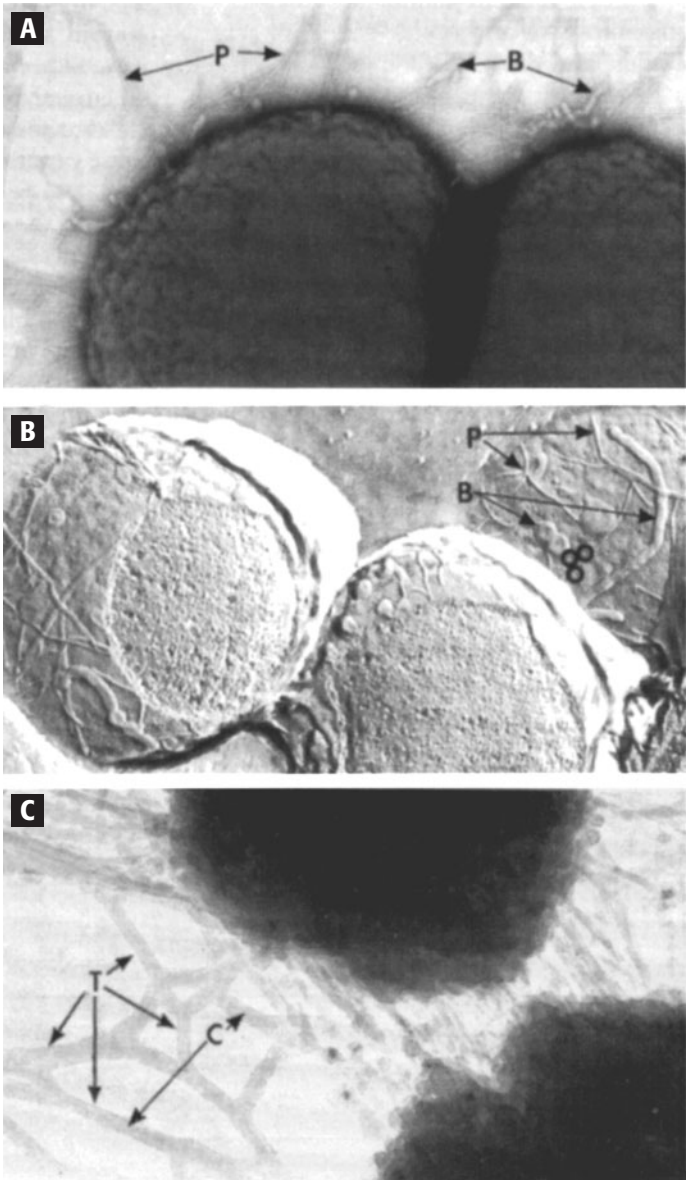

FIGURE 34-2. Electron microscopic appearances of gonococcal surface constituents. Different methods of preparing gonococci for electron microscopic examination yield strikingly different views of these organisms' surface constituents. In negatively stained preparations (**A**), pili (P) appear as thin (approx 8 nm) structures that are clearly differentiated from evaginated *blebs* (B) of the outer membrane. These blebs occur as elongated, sausagelike forms or as small vesicles. The actual surfaces of gonococci have a rugose appearance that is poorly resolved in this micrograph. After freeze-fracture freeze-etching (**B**), both pili (P) and outer membrane blebs (B) are seen lying against the organisms' surfaces. The "pebbled" appearance of the gonococcal surface is punctuated by pits (examples encircled). *(Courtesy of J. Swanson and L. Mayer.)*

Molecular mechanisms

The mechanisms of pilus phase (P^+) ↔ (P^-) and antigenic ($P^+\alpha$) ($P^+\beta$) variation have been studied extensively. There are one or sometimes two complete pilin genes on the chromosome.[25–30] The intact gene "expression site" contains an intact promoter region and ribosome-binding site and encodes an unusual short 7 amino acid signal sequence and the 159–160 amino acids of the mature pilin subunit. There are six to eight "silent" regions scattered at various locales around the chromosome. Each silent locus contains various amounts of pilin sequences, but lacks a promoter region, and the 5' end of the pilin structural gene. In some of these silent sites, there are many different copies of incomplete pilin gene sequences arranged in a head-to-tail tandem repeat order, and many of these variant copies of pilin sequences are slightly different from each other. Nonreciprocal recombination events may move one of these silent variant copies of pilin sequence into the expression site, resulting in expression of an antigenically variant but fully functional pilus (antigenic variation). On occasion, the variant copy of silent pilin DNA encodes a faulty peptide that when expressed results in a pilin that cannot be processed, assembled, secreted ("long pilin"), or anchored ("small" or secreted pilin) into a mature pilus, and the cell becomes P^- as a result.[28] Reversion back to a P^+ state in these instances occurs when a functional pilin sequence is moved from another variant silent copy into the expression site, replacing the faulty pilin sequences (phase variation) (Fig. 34-4).

Movements of pilin sequences between the silent and the expression sites are mediated by the homologous sequences

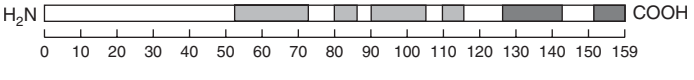

FIGURE 34-3. Schematic diagram of variability of pilin structure as revealed by DNA sequencing of expressed *pil* genes in multiple clinical isolates of a single epidemic strain. In the semivariable regions (hatched), single amino acid substitutions were found. In the hypervariable regions (black), there frequently were insertions or deletions of one to several amino acids. White areas are constant regions. Results are typical of those found in vitro in three laboratory strains. Numbers refer to amino acid residues of mature pilins. (From Sparling PF, et al. *J Infect Dis* 1986; 153: 196).

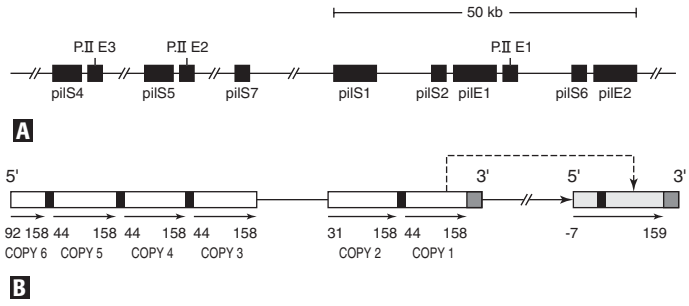

FIGURE 34-4. Molecular basis of pilus variations. In (**A**) the approximate chromosomal organization of known loci for pilin (*pil*) or opacity proteins (*opa*, or P.II) is shown. In strain MS11, there are two complete ("expression") *pil* genes (*pil*E1, *pil*E2) and multiple incomplete ("silent") loci (e.g., *pil*S1) containing copies of the 3′ end of *pil* genes. In some instances, *opa* (P.II) genes are adjacent to *pil* loci (e.g., P.II E1), each encoding a complete Opa protein. In (**B**) is shown the organization of one silent locus (*pil*S1), which contains six slightly variant copies of the 3′ end of *pil* genes. Numbers below the bars indicate pilin amino acids encoded by the DNA. Solid bars or striped areas indicate constant regions in or around the *pil* genes; other constant DNA regions are omitted for simplicity. The dotted line and arrow refer to movement by recombination of DNA from one silent copy into an expression locus (*pil*E1), which is facilitated by homology between the constant regions. This may result in phase or antigenic variation, as described in the text. (Adapted principally from data of Haas R, Meyer TF. *Cell* 1986; 44: 107.)

that flank or are located at intervals within the pilin DNA at the silent and the expression sites and depend on a functional recombination system.[31] Occasionally a recombinational event results in deletion of the entirety of the 5' and upstream regions of the structural gene in the expression site.[32] When this happens, the organism becomes permanently nonpiliated since the necessary information to restore the pilus expression site is not contained within any of the silent copies.

Existence of three promoters for each pilin structural gene (*pilE*) suggests complex mechanisms for transcriptional control of pilus expression.[33] Indeed a *pilA pilB* sensor regulator system has been described that either induces or represses expression of *pilE*; it is not yet known which environmental factors affect the activity of this system.[34] An additional factor (integration host factor, or IHF) was described that also affects transcription of *pilE*.[35] Presumably, these complex systems serve to provide fine control of the amount of expressed pili, although the biological advantage of such controls is unclear.

Pilus-associated proteins

A vary active area of research concerns the structure and function of a number of pilus-associated proteins.[36] One of them, designated PilQ, is a major outer membrane protein composed of 12 subunits, through which the assembled pilus fibril passes from inside to outside the bacterial outer membrane; it is thus a member of the secretin class of proteins.[37,38] Recent evidence shows that PilQ also is a porin, through which antibiotics, transforming DNA, and heme pass under certain conditions.[37,38] PilC is a hydrophobic outer membrane protein that is the product of two genes (*pilC1* and *pilC2*), each of which produces slightly different forms of the protein. In the presence of a fully assembled pilus fibril, PilC apparently is bound to the pilus, and may be the adhesin that binds gonococci to the host cell.[39,40] PilT is a minor protein that serves to retract the assembled pilus, thereby giving the cells their characteristic twitching motility,[41] and serving to pull gonococci closer to the host cells to which they are rather loosely attached by the initial contact by pili. This in turn triggers several changes in the host cell, and promotes host cell survival.[42] Other minor pilus associated proteins are involved in assembly and expression of pili.

Porin protein (Por)

When outer membrane proteins are examined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), the most prominent protein is a 34–36-kDa protein formerly designated P.I but now designated Por. Por is exposed on the surface of the outer membrane and in its native state in the membrane is a trimer.[43] It is physically proximate to the lipooligosaccharide (LOS) and also to reduction modifiable protein (Rmp).[44,45] Por fulfills many functions for the gonococcus, including forming an anion-specific channel through the lipid-rich outer membrane.[46,47] Por exists in two major chemically and immunologically distinct classes designated P1.A and P1.B; a given strain produces one or the other, but never both. They are the product of the *porB* gene; a separate *porA* gene which is expressed in meningococci is a pseudogene (mutant, not expressed) in gonococci.

The DNA sequence of multiple *porB* genes has been determined.[48,49] The amino acid sequence and predicted structure is similar to that of porin proteins in other gram-negative bacteria. Comparison of the sequence of P1.A and P1.B proteins reveals certain regions that are common to both proteins and others where there is considerable variation.[50] The regions of variability represent areas of antigenic diversity. The P1.A and P1.B proteins are products of allelic variants of a single *porB* locus.[50]

Opacity proteins

The opacity-associated protein family designated Opa (formerly protein II, or P.II) comprises a family of closely related proteins involved in cell adhesion that share the property of heat modifiability.[13–15] These proteins vary in size from about 24 to about 28 kDa and when heated to 100°C take on a different conformation and exhibit a higher apparent molecular mass in SDS-PAGE. A given strain has the capacity to produce at least 10 different variants of the Opa family, as judged by sizes and antigenic properties of the expressed Opa proteins.[51] A strain may express none of these or up to four or five different members of the Opa family simultaneously.[51] The Opa family undergoes both phase variations ($Opa^+ \leftrightarrow Opa^-$) and antigenic variation (OpaA → OpaB → OpaC → ...), analogous to pilus variations.

Some Opa proteins promote adherence of cells in a colony and also promote adhesion of gonococci to neutrophils and epithelial cells.[52,53] Most Opa proteins result in increased colony opacity, whereas all Opa⁻ clones are transparent. The very high frequencies in variation of Opa proteins can easily be seen by examining colony morphologies under appropriate lighting; many colonies exhibit sectors varying in opacity, which reflects the variability in expression of Opa (see Fig. 34-1).

Mechanisms of Opa variations

The genetic basis for phase and antigenic variation of the Opa family is now quite well understood and is different from that used to control the expression of pilus proteins. When Southern hybridizations are performed with the cloned *opa* gene, up to 12 *opa*-related restriction fragments of chromosomal DNA are visualized, indicating that there is a family of *opa* genes in the chromosome.[54–57] Each of the *opa* genes is a complete gene with its own promoter, and each is transcribed into RNA at all times.[55,56] Variation in expression of these genes is achieved by varying the number of an identical pentameric (CTCTT) repeat unit located immediately downstream from the ATG start codon, within the DNA that encodes the hydrophobic signal sequence, and upstream from the sequences coding for the mature structural protein.[55-57] When the number of these repeat units is evenly divisible by three (e.g., 9, 12, 15, ...), the gene is translationally in-frame and an Opa protein is expressed. Any other number of the pentameric repeat (e.g., 8, 10, 11, 13, 14, ...) results in transcription of a gene that is translationally out-of-frame, and no Opa is expressed. The number of the pentameric repeat undergoes high-frequency variation, and this results in regulation of expression at the level of translation. Each *opa* gene contains two hypervariable domains, which may recombine with similar domains in other *opa* loci. Thus variable expression of *opa* genes results in antigenic variation, because of differences in structures encoded by different *opa* genes.

Reduction modifiable protein

All *pathogenic Neisseria*, including all gonococci, contain an antigenically conserved Rmp protein (formerly designated Protein III, or P.III) of about 30–31 kDa that is characterized by its altered apparent molecular mass on SDS-PAGE under reducing conditions. The structural gene *rmp* was cloned and sequenced.[58] This protein is of interest in pathogenesis because many blocking antibodies that prevent serum bactericidal activity are directed against this antigen, as discussed in the following.

H.8 Proteins

A monoclonal antibody (MAb) designated H.8 reacts with a conserved antigen found on all gonococci and meningococci, and on *N. lactamica* and *Neisseria cinerea*, but not on other nonpathogenic *Neisseria*.[59] In gonococci and meningococci, there are at least two proteins containing an H.8 MAb-binding epitope. One is a lipoprotein containing five imperfect repeats of the peptide AlaAla-Glu-Ala-Pro (AAEAP) at the N-terminal region and an azurinlike sequence at the C-terminal region.[60,61] The azurins are copper-containing proteins that may be involved in electron transport. The second H.8 MAb-binding protein does not have azurin-related sequences and is made up primarily of 13 repeats of the AAEAP peptide. The azurin protein Laz is involved in defense against oxidative stress and copper toxicity.[62]

Iron- or oxygen-repressible proteins

Although all of the proteins discussed in the preceding with the possible exception of pili are expressed under all growth conditions, a variety of other proteins are expressed only under certain conditions, including iron starvation, anaerobic growth, or other limited-growth situations.[63–66] The iron-repressible proteins (Irps) include a 37-kDa protein and several in the approximate range of 65 to over 100 kDa.[63,64,67] The 37-kDa protein is designated ferric-binding protein (Fbp) because it contains iron and is involved in iron transport.[68] Virtually all gonococci and meningococci express an antigenically conserved Fbp.[69] A 70-kDa protein formerly designated FrpB on the outer membrane also is common to virtually all gonococci and meningococci. It has been renamed FetA in recognition of its function in low-affinity binding of the phenolate siderophore ferric enterochelin.[70] Gonococci do not produce siderophores, and the precise role of FetA in gonococcal physiology is unclear. Many of the other Irps are receptors for iron ligands, either for transferrin (Tf), lactoferrin (Lf), or hemoglobin (Hb).[71–73] These receptors bind ligand (either Tf, Lf, or Hb) with great specificity, and binding is required before iron is stripped from the ligand and transported into the cell. Unlike FetA, which is composed of a single integral outer membrane protein, the Tf, Lf, and Hb receptors are composed of a loosely surface-tethered lipoprotein and an integral membrane protein that appear to work together; the function of all of the iron-ligand receptors is dependent on transmission of energy to the outer membrane receptor by the inner membrane protein TonB.[74]

Virtually all gonococci produce a functional Tf and Hb receptor, although about half of gonococci do not produce a functional LF receptor.[72] The Hb receptor undergoes phase variation in expression (either translationally "on" or "off") by means of slipped-strand mispairing of a short DNA repeat within the *hpuA* gene, analogous in mechanism to that employed by Opa proteins in their phase variation.[75] Women are more likely to express a Hb receptor in the expressed "on" phase in the first 2 weeks of the menstrual cycle, as compared to the latter half of the cycle or to isolates from men, suggesting that availability of Hb in the form of menstrual blood is a

selective advantage to gonococci in vivo.[76] Studies in male human volunteers established that either of the Tf or Lf receptors is essential for experimental infection of the anterior urethra[77,78]; presence of both the Lf and Tf receptors imparts a selective advantage in the male urethra.[78] Thus both the Tf and Lf receptors appear to be functionally important to mucosal infection. It is unclear what advantage is imparted by loss of the Lf receptor; there appears to be some advantage to loss of the Lf receptor under certain circumstances, since there is evidence of horizontal transmission of a unique deletion of the *lbpAB* genes among clinically isolated gonococci.[78]

Iga$_1$ proteases

All gonococci and meningococci but not other nonpathogenic Neisseria produce a protease that recognizes both serum and secretory IgA_1 (but not IgA_2) as a substrate.[79] There are two genetically and biochemically distinct variants of the gonococcal IgA_1 protease, and there is a correlation between auxotype, Por serogroup, and the class of IgA_1 protease expressed by the strain.[80] Each of the IgA_1 proteases cleaves IgA_1 at the hinge region, resulting in release of Fab and Fc fragments.[79] Since secretory IgA is the principal arm of antibody-mediated defenses at mucosal surfaces, the *Neisseria* IgA_1 protease presumably is important in inactivation of mucosal immune defenses. Surprisingly, loss of IgA_1 protease limits ability of gonococci to grow within epithelial cells, apparently because IgA_1 protease normally cleaves an intracellular protein (LAMP1) involved in phagosomal compartmentalization.[81] Loss of IgA_1 protease does not reduce infectivity of gonococci for human volunteers (personal communications, J. Cannon, M. Cohen, et al.).

IgA_1 protease is synthesized as a precursor protein of about 169 kDa, and then is proteolytically cleaved twice to create a 45-kDa outer membrane protein and the mature 106-kDa IgA_1 protease molecule. The 45-kDa protein forms a channel through the membrane that allows export of the IgA_1 protease to the exterior.[82]

Lipooligosaccharide

All gonococci express LOS on their cell surface, similar to the lipopolysaccharide (LPS) of other gram-negative bacteria. Gonococcal LOS contains a lipid A moiety and a core polysaccharide consisting of ketodeoxyoctanoic acid (KDO), heptose, glucose, galactose, and glucosamine, and/or galactosamine.[83] The two-dimensional structure of gonococcal LOS is now well established.[84] Unlike other gram-negative bacteria, gonococci do not express a long polymeric sugar attached to this core, and thus the gonococcal LOS is considerably smaller than typical LPS of other bacteria. By both chemical and immunologic criteria, there is intrastrain and interstrain variation in the nature of the core sugar antigens of LOS.[83,85,86] A single strain may make up to six variants of LOS, varying in apparent molecular mass from 3 to 7 kDa. Since the core sugars of LOS form antigens that are important in immune bactericidal reactions, phenotypic variation of these antigens may be pathogenically important.[87,88] Gonococci with "short" LOS are serum sensitive but able to invade eukaryotic cells, whereas gonococci with "long" LOS are serum resistant but noninvasive.[89–92] Many genes involved in LOS core sugar assembly undergo high-frequency phase variation by a mechanism similar to that involved in *opa* variations.[93] The terminal lacto-*N*-neotetraose (LNnT) moiety on gonococcal LOS mimics the structure of certain human glycosphingolipids, which may help immune evasion.[83]

Variation in LOS core sugar chain length has several important implications for pathogenesis. Gonococci vary in their ability to undergo sialylation of LOS (addition of host neuraminic acid to LOS by means of a bacterial sialyltransferase), because the site of sialylation is on a near-terminal LOS sugar that is variably expressed.[89,94] "Short" LOS is unable to be sialylated, whereas full-length LOS is readily sialylated.[90–92] Sialylated gonococci are at least partially protected ("masked") from antibodies against both LOS and the closely neighboring Por molecule.[95]

Other surface structures

Gonococcal peptidoglycan is similar to that of other gram-negative bacteria, containing a backbone of muramic acid and *N*-acetylglucosamine, but is rather unusual in the degree of its *O*-acetylation.[96] This may be relevant to the susceptibility of peptidoglycan fragments to biodegradation and to its inflammatory and other biological properties.[97]

Gonococci do not express a true polysaccharide capsule despite several early reports to the contrary. Gonococci do produce a surface polyphosphate, however, that may serve some of the functions of a polysaccharide capsule, including provision of a hydrophilic and negatively charged cell surface.[98] Gonococci also bind charged polyanions including DNA to certain Opa proteins, which alters the surface charge of the cell and also the ability to be killed by normal human serum.[99] Gonococcal structures involved in pathogenesis are summarized in Table 34-1 and shown in Fig. 34-5.

METABOLISM

Gonococci have complex growth requirements.[3] They utilize glucose, lactate, or pyruvate as sole sources of required carbon but cannot use other carbohydrates.[3] This forms the basis for the carbohydrate utilization tests used for decades to speciate neisserial organisms. When grown in media supplemented with serum, they exhibit different outer membrane proteins and altered attachment to human neutrophils.[100] The factor that seems to stimulate these phenotypic variations is lactate.[101] Human neutrophils release lactate as an end product of metabolism, with the result that gonococci growing in vivo

Table 34-1. Some Gonococcal Structures Involved in Pathogenesis

Structure (Abbreviation)	Function in Infection
Por	Insertion into host cell membranes Target for bactericidal, opsonic antibodies
Opa	Adherence
Rmp	Target for blocking antibodies
Pili	Adherence
	Resistance to neutrophils
Lipooligosaccharide	Tissue toxin
	Target for bactericidal, chemotactic antibodies
Peptidoglycan	Tissue toxin
Iron-repressible proteins	Iron uptake from transferrin, lactoferrin, hemoglobin
IgA_1 protease	(?) Escape from mucosal IgA_1

might encounter lactate as a principal carbon source.[101] All gonococci (as well as other *Neisseria*) rapidly oxidize dimethyl- or tetramethyl-phenylenediamine, and this turns colonies pink and then black, forming the basis of the oxidase test.

Gonococci are capable of growth under anaerobic conditions if nitrite is provided as an electron acceptor.[102] Their growth is stimulated by 5% gaseous CO_2 or if additional bicarbonate is added to liquid or solid growth media. They produce abundant catalase, which undoubtedly helps to promote growth in the presence of otherwise toxic peroxides, but unlike most aerobes they do not produce appreciable amounts of superoxide dismutase. It has been postulated that they grow in vivo under relatively anaerobic conditions,[65] although they ordinarily are grown in vitro under aerobic conditions.

Growth media

Gonococci do not tolerate drying and ordinarily must be plated onto appropriate media immediately on sampling patient secretions. As an alternative, gonococci may be put into one of several available transport media, in which they survive for up to 24 hours prior to being plated on definitive culture media. Growth is optimal at 35–37°C in a 5% CO_2 atmosphere, at a pH of about 6.5–7.5. When grown at relatively low pH (6.0–6.5), outer membrane composition is altered; below pH 6.0, no gonococci survive. (Vaginal secretions are quite acidic, but gonococci grow in the endocervix, where the pH is neutral.) Although certain nonpathogenic *Neisseria* grow at room temperature, gonococci do not grow well below 30°C, and they do not survive above 40°C.

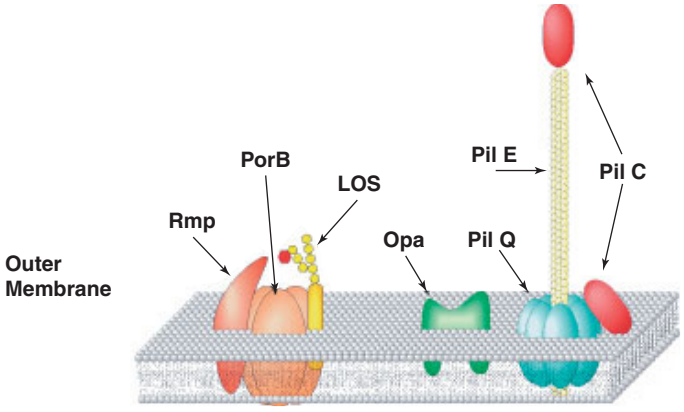

FIGURE 34-5. Illustration of gonococcal outer membrane depicting many of the antigens described in the text. Rmp, reduction modifiable protein; Por B, porin protein; LOS, lipooligosaccharide–the branched and phase variable LOS polysaccharide chain is depicted as being bound by sialic acid, designated by a red hexagon; Opa, opacity protein; PilQ, pilin accessory protein Q, a secretin through which the assembled pilus extrudes; PilE, pilin, the subunits which are assembled into the alpha helical pilus fibril; PilC, the outer membrane protein PilC, which is proposed to be presented by the pilus fibril as a tip adhesin. *(Courtesy of C.E. Thomas.)*

A complex growth medium is required. Ordinarily this is in the form of either chocolate agar or similar complex agar containing inorganic iron and supplemental glucose, vitamins, and cofactors. Many less fastidious microorganisms also found in the same ecological niches (pharynx, cervix, and rectum) grow more readily than gonococci, and relatively selective media have been devised that use antibiotics to inhibit growth of nonpathogenic *Neisseria*. Vancomycin, colistin, and nystatin were widely used for this purpose, but some gonococci are quite sensitive to the concentrations of vancomycin used in the selective media. Other formulations now have been developed in which vancomycin is replaced with lincomycin or other antibiotics.

GENETIC SYSTEMS

There are two principal systems for performing genetic analysis of gonococci: transformation and conjugation. There are no known bacteriophages for gonococci (or meningococci), and a drug-resistance transposon system that functions well within the gonococcus has not been discovered. No presently available transposon is suitable for generalized chromosomal mutagenesis of the gonococcus. Seifert and colleagues developed a shuttle mutagenesis system that is extremely useful for genetic studies, in which a chloramphenicol acetyltransferasegene *cat* (or other antibiotic-resistance genes) replaces β-lactamase (penicillinase) in a derivative of the transposon Tn3.[103] Other analogous shuttle mutagenesis systems have been developed.[104]

Transformation

Gonococci are quite unusual in their constitutive expression of competence for transformation by exogenous DNA. In competent gonococci, virtually every cell is competent at all stages of growth, quite unlike many other transformable species in which competence is restricted to certain phases of the growth cycle. However, only piliated (P^+) gonococci are competent for transformation.[105] The association between competence for transformation and expression of pili suggests that pili are involved directly in recognition or entry of transforming DNA. Mutations in *pil*E or in certain pilus-accessory genes dramatically reduce competence for transformation.[106] DNA enters through the secretin protein PilQ[37] and requires not only Pili but also PilT and PilC.

Although most P^+ gonococci are highly competent, they only take up their own (homologous) DNA into the cell.[107,108] The structural basis for specificity in recognition of homologous DNA is uncertain. A 10 base pair sequence was described that is largely responsible for selective entry.[109,110]

Because gonococci are piliated (competent) in vivo and are highly autolytic and release transforming DNA in a biologically active form, transformation may be used in nature to transfer genes between different gonococcal strains.[111] This might be important in transfer of chromosomal antibiotic-resistance genes or pilin silent genes, among others. Indeed, Spratt has shown that gonococci probably are transformed in nature by DNA from other species, creating novel hybrid genes; this probably is important to evolution of the species, which exhibits a plastic, nonclonal structure.[112,113] A complete genomic map of the gonococcal chromosome (strain FA1090) is available. Sequencing of other strains showed that there are blocks of DNA, not present in the genome of FA1090, apparently acquired by horizontal exchange from other bacterial species.[114] These genetic or pathogenicity islands probably contribute to the ability of certain gonococci to invade host cells, secrete DNA, and other properties.[114]

Conjugation

Many gonococci contain a 36-kb conjugal plasmid that efficiently mobilizes sexual transfer of certain other non-self-mobilizable plasmids such as the 4.5- or 7.2-kb penicillinase (Pc^r) plasmids.[115,116] The 36-kb conjugative plasmids also mobilize their own transfer with high efficiency, but they do not detectably mobilize chromosomal genes for transfer between gonococci.[117]

Mutagenesis

Although gonococci are highly variable in certain properties (particularly expression of pili, Opa, and LOS), they are relatively nonmutagenic. They are very susceptible to ultraviolet light but lack photoreactivation and error-prone repair systems and do not undergo ultraviolet mutagenesis under ordinary conditions.[118] A gonococcal *rec*A gene has been cloned and mutated.[119] The gonococcal *rec*A mutants show reduced frequencies of chromosomal transformation and of pilin antigenic variation, as expected.[31]

Restriction and modification systems

Gonococci are known to contain multiple restriction endonucleases and their corresponding methylases.[120] Transformation by plasmid DNA is markedly reduced when plasmids are introduced into gonococci across restriction barriers, but chromosomal transformation seems to be little influenced by restriction barriers.[121] Gonococci have DNA methylases for which there is no corresponding restriction endonuclease, which suggests that DNA methylation might be important to other biological functions including gene regulation.[120]

Plasmids

Many gonococci contain a 36-kb conjugal plasmid. Slightly larger derivatives of the 36-kb plasmid have been isolated that contain the tetracycline resistance (Tc^r) *tet*M transposon.[122] A variety of gonococcal β-lactamase (penicillin resistant, Pc^r) plasmids have been isolated and characterized. The two most frequent plasmids are either about 5.3 or 7.2 kb.[123] The Tc^r and Pc^r plasmids are discussed in the following under "Antimicrobial Susceptibility."

Most gonococci also contain a 4.2-kb plasmid of unknown function (*cryptic plasmid*). The DNA sequence of this plasmid has been determined.[124] Occasional gonococci can be isolated that do not contain the freely replicating (cytoplasmic) 4.2-kb cryptic plasmid, but they appear biologically normal.[125]

PATHOGENESIS

Clinical correlations

Consideration of clinical manifestations of gonorrhea suggests many facets of the pathogenesis of the infection. Since gonococci persist in the male urethra despite hydrodynamic forces that would tend to wash the organisms from the mucosal surface, they must be able to adhere effectively to mucosal surfaces. Similarly, since gonococci survive in the urethra despite close attachment to large numbers of neutrophils, they must have mechanisms that help them to survive interactions with polymorphonuclear neutrophils. Since some gonococci are able to invade and persist in the bloodstream for many days at least, they must be able to evade killing by normal defense mechanisms of plasma, including antibodies, complement, and transferrin. Invasion of the bloodstream also implies that gonococci are able to invade mucosal barriers in order to gain access to the bloodstream. Repeated reinfections of the same patient by one strain

strongly suggest that gonococci are able to change surface antigens frequently and/or to escape local immune mechanisms (Table 34-2).[126] The considerable tissue damage of fallopian tubes consequent to gonococcal salpingitis suggests that gonococci make at least one tissue toxin or gonococci trigger an immune response that results in damage to host tissues.[127] There is evidence to support many of these inferences.

Model systems

Studies of pathogenesis are complicated by the absence of a suitable animal model. A variety of animal models have been developed, each of which has certain utility, but no animal model faithfully reproduces the full spectrum of naturally acquired disease of humans. Considerable evidence about antigenic variation and interactions with neutrophils has been obtained from inoculation of subcutaneous chambers in guinea pigs or other animals. Gonococci survive in the female genital tract of mice for up to several weeks, which has provided the basis to demonstrate the importance of many gonococcal gene products to local mucosal infection in the mouse.[128] However, the mouse model lacks many of the critical receptors including complement receptor 3 (CR3), CD46, and the carcinoembryonic antigen related family of cell adhesion molecules (CEACAM, or CD66) found on human tissues[129] and thus does not fully reproduce the physiology of human infection. The mouse model has been used for studies of immunogenicity of various vaccine candidates,[130] and for early studies of experimental vaccines. The best model system for many in vitro studies is organ culture of human tissues, particularly the fallopian tube system exploited successfully by McGee and colleagues.[127] Cultures of human cells including primary male urethral epithelial cells[131] provides means to study attachment and invasion.

Investigators have used male human volunteers for critical studies of pathogenesis.[132] Evidence in human volunteers confirms high frequency of in vivo variation of LOS, pili, and Opa,[23,132,133] and the apparent necessity of expression of either a transferrin or lactoferrin receptor.[77,78] Expression of full-length LOS appears essential for maximal infectivity.[134] These studies in human volunteers are hopefully the prelude to efficient, rational, and safe tests of gonococcal vaccine candidates, although after at least two decades of intense research, no vaccine candidates are on the horizon.

Adherence

Two adherence ligands are well documented to be important: pili and Opa. Porin and LOS are also involved in adherence. Different adherence ligands are involved in binding different receptors, which vary in their presence in different human cells and organs. Piliated gonococci adhere better to human columnar epithelial cells than to squamous cells and to human cells better than to nonhuman cells. Isolated pili adhere in vitro, and certain pilus antigenic variants exhibit selective ability to attach to particular cells under defined conditions in vitro.[135] Antibodies against pili decrease adherence of piliated gonococci to epithelial cells and red blood cells.[136–138] Similar evidence supports the role of Opa proteins in adherence: gonococci expressing certain Opa proteins adhere better than Opa^- (transparent) gonococci to various cells, and a monoclonal antibody raised against one Opa protein inhibits adherence.[52,53,138] Antigenic variation of both pili and Opa may be biologically advantageous not only for escape from specific immune responses but also by providing specific adherence ligands for attaching to different niches in vivo.[139] There are claims for the importance of CD46 for adherence mediated by pili, although this is quite controversial,[18,19] and both CEACAM and heparin-like glycosaminoglycans have been identified as host-cell receptors for Opa.[140,141] Studies from Apicella's laboratory have shown that CR3 is a receptor in female genital cells and tissues for binding both pili and PorB[129]; another important receptor is the asialoglycoprotein (ASGP-R) for binding LOS. The interactions between various adhesins and their receptors, and the consequences for attachment and invasion of various cells, have been reviewed recently.[129]

Pilus adhesins

Polyclonal sera raised against synthetic pilin peptides were studied for ability to block adherence of two unrelated P^+ gonococci to epithelial cells, and only sera against pilin peptides from amino acids 41 to 50 and 69 to 84 were effective.[142] These peptides are from relatively invariant regions of pilin.[143] However, many monoclonal antibodies that recognize specific or unique epitopes on pilin are more active in blocking adherence than monoclonal antibodies directed at common epitopes, which suggests that the pilin domain(s) involved in adherence actually are in variable region(s).[138] This is consistent with pilus vaccination studies of human volunteers, in whom protection extended only to the homologous isolate from which the pilus vaccine was prepared.[144]

In *E. coli* and other gram-negative bacteria, pili (or fimbriae) are associated with increased adherence, but the adhesin is not the pilin subunit but rather a minor pilus-related protein.[145] Difficulties in identifying the gonococcal pilus adhesin might be owing to focusing research efforts entirely on pilin subunits. Gonococci contain several pilus-related proteins other than pilin.[146] At least one of these (PilC) has been proposed to be an adhesin independent of pili.[39,40] PilC undergoes high-frequency phase variation in its expression, like so many gonococcal cell surface molecules. PilC may be located on the tip of the pilus and may be a tip-adhesin since antibodies against PilC decrease adherence.[39] PilC seems to play an important but still not fully defined role in gonococcal attachment.

Opa undoubtedly are important in infection since almost all isolates taken from patients are opaque or Opa expressing; the only exception is isolates taken from the female cervix near menses when most isolates are transparent.[147] Binding (adherence) to host cells is facilitated in an additive fashion by both Opa and Pili. Once host cells have bound an Opa^+ Pil^+ gonococcus, they appear to undergo increased expression of the ASGP cell-surface receptor for gonococcal LOS, thus presumably increasing the force and perhaps the frequency of attachment of other gonococci.[148]

Interactions with leukocytes

Gonococci were formerly referred to as *Neisseria intracellulare* because Gram-stain smears from human infections sometimes showed neutrophils covered with gonococci, which were assumed to be inside the cell. Pili are known to increase adherence of gonococci to human polymorphonuclear neutrophils, but they also increase resistance to phagocytosis and killing. In contrast to nonpiliated gonococci, which are readily ingested and killed by neutrophils, piliated gonococci attach well but are ingested relatively poorly.[149,150] Antipilus antibodies increase phagocytosis ("opsonization").[151,152] Thus pili increase epithelial cell adherence and decrease neutrophilic killing, and antipilus antibodies block epithelial adherence and increase phagocytic killing. Attachment to neutrophils is also increased by certain members of the Opa family.[53,129,153]

The majority of gonococci taken up by neutrophils are killed, but at least 2% of gonococci survive ingestion by neutrophils.[154,155] Work in Smith's laboratory has identified a 20-kDa gonococcal protein that seems to play an important role in resistance to intracellular killing by neutrophils.[156] Porin acts to inhibit phagosome maturation and inhibits neutrophil function, and down-regulates expression of the opsonin-dependent receptor CR3.[157] Porin also modifies myeloperoxidase-mediated oxidative killing.[158]

Neutrophils possess both oxidative and nonoxidative methods for killing intracellular bacteria. Oxidative killing depends on enzymes contained within the specific and nonspecific granules of neutrophils, whereas the nonoxidative mechanisms depend on a variety of cationic or basic lysosomal proteins. Gonococci are sensitive to damage by the oxidative products generated intracellularly during the neutrophilic respiratory burst, but are also killed efficiently by neutrophils from patients with chronic granulomatous disease that lack the oxidative killing mechanism.[159] One neutrophilic protein involved in nonoxidative killing of gonococci is cathepsin G.[160] Gonococci containing certain alterations in penicillin-binding proteins show increased susceptibility to cathepsin G, which may explain the clinical observation that gonococci with low-level chromosomal resistance to penicillin are uncommonly isolated from the bloodstream.[160]

Invasion

Biopsies from patients with gonorrhea show gonococci partially embedded within the cell surface (Fig. 34-6). Gonococci also can be seen within the epithelial cell, sometimes surrounded by cellular membranes. Shaw et al. employed a continuous culture of a human endometrial carcinoma cell to study variables affecting gonococcal invasion in vitro and found that invasion was increased when gonococci were grown in an iron-supplemented medium.[161] Other laboratories confirmed this observation.[162] Gonococci adhere selectively to mucus-secreting nonciliated cells of the fallopian tube and are gradually enfolded by pseudopods and engulfed by the host epithelial cell.[127,163–165] Gonococci appear to be able to multiply and divide intracellularly, although they do not invade laterally between cells.[127,166] Eventually some gonococci exit from the basal surface of the cell by a process termed exocytosis.[166] Once inside the epithelial cell, gonococci are immune to attack by antibody, complement, or neutrophils; their ability to survive to some degree inside epithelial cells suggests that they might be considered facultative intracellular parasites. As discussed in the preceding and subsequently, invasion also is favored by expression of PI.A and certain Opa proteins and also by expression of "short" (nonsialylated) LOS.

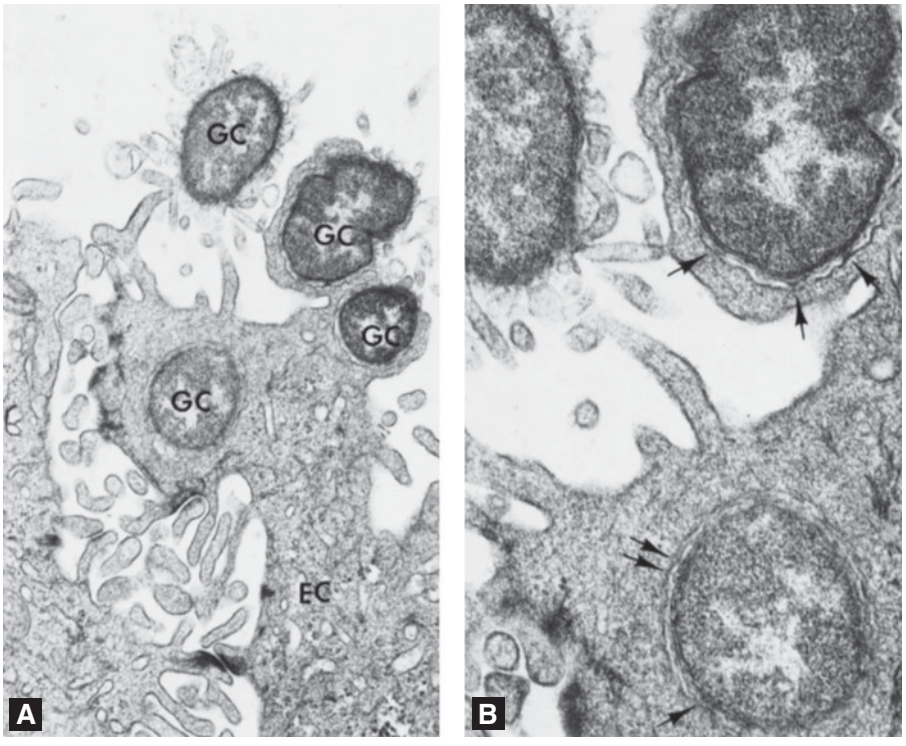

FIGURE 34-6. Gonococcal–epithelial cell relation in cervical biopsies from a woman with acute gonorrhea. One of the exocervical epithelial cells (EC) seen in this electron micrograph (**B** is an enlarged portion of **A**) has closely adherent gonococci (GC). Some of the bacteria appear to be partially or completely endocytosed by the epithelial cells. Pili are not visible in this thin section and, in general, are usually difficult to visualize in thin-section preparations. Note the close apposition of gonococcal outer membrane and epithelial cell plasmalemma (arrows) and the apparent enfolding of the bacteria by the host's cervical cells. (Courtesy of D. Eschenbach and K. Holmes.)

Is Por a "trigger" for invasion?

Invasion is associated with a variety of cell-signaling events, and changes in epithelial cell morphology, as summarized recently.[129] Several observations suggest that Por may play a role in invasion. Incubation of radiolabeled gonococcal membranes or whole bacteria with red blood cells results in transfer of the gonococcal porin from the bacterial cell surface into the red cell membrane.[167] No other protein is translocated into the red cell membrane. Using phospholipid bilayers or so-called black lipid membranes to quantitate rates of transfer of porin protein, Lynch et al. showed that gonococci containing P.IA transfer Por into membranes more readily than gonococci containing P.IB.[168] Since gonococci with P.IA are more likely to cause disseminated disease than gonococci with P.IB (see Chapter 35), these results are consistent with the hypothesis that translocation or spiking of host cells by Por may be an important step in invasion of the host cell. Por translocation is accompanied by calcium flux and other changes in host-cell physiology.[169] Once inside the cell, Por associates with mitochondria[170] and either potentiates or depresses apoptosis, depending on the cell system studied.[169–172] Porin channel activity is regulated during gonococcal growth in intact epithelial cells.[171]

Tissue damage

Gonococci produce a variety of extracellular products that might damage host cells including enzymes (phospholipase, peptidases, and others), but no true extracellular protein toxin has been identified. Tissue damage appears to be owing to two structural components of the cell surface: LOS and peptidoglycan.

Although gonococci do not attach to ciliated cells of fallopian tubes in organ culture, diminished beating of cilia is evident within hours after infection.[127] Electron micrographs demonstrate extrusion of ciliated cells, even though attached gonococci are only visible on adjacent nonciliated cells (Fig. 34-7). Similar effects are evident after purified gonococcal LOS is added to the fallopian tube model.[173] The toxic portion of LOS almost certainly is the lipid A portion, as would be expected.[173] Perhaps damage to ciliated cells results when membrane blebs containing lipid A are released from gonococci attached to nonciliated cells.

In addition to the unequivocal evidence that lipid A is a tissue toxin for gonococcal infections, there is also excellent evidence that fragments of the cell wall or peptidoglycan are capable of inducing damage in the human fallopian tube organ culture model.[174] Gonococcal peptidoglycan fragments also may be involved in the pathogenesis of inflammatory arthritis after bacteremic disease,[175] similar to the role of peptidoglycan fragments in a well-studied animal model of poststreptococcal arthritis.[176]

Dissemination

Serum resistance. The ability to resist the killing activity of antibodies and complement in normal human serum is closely related to the ability of gonococci to cause bacteremic illness with or without septic arthritis. A complex literature has evolved relating to the mechanisms of gonococcal resistance to serum antibodies and complement.

FIGURE 34-7. Scanning electronic microscopy studies of normal, uninfected human fallopian tube mucosa showing (**A**) ciliated cells and nonciliated cells (the latter are covered with microvilli) and (**B**) human fallopian tube mucosa 20 hours after infection with a piliated clone of *N. gonorrhoeae.* In (**B**) note morphologically intact ciliated cells (far right and top), two sloughing ciliated cells (center), and gonococci attached almost exclusively to the microvilli of nonciliated cells but not attached to a sloughing ciliated cells, ×4000 magnification. (With permission from McGee ZA, et al. Pathogenic mechanisms of *Neisseria gonorrhoeae*: Observations on damage to human fallopian tubes in organ culture by gonococci of colony type I or type 4. *J Infect Dis* 1981; 143: 413.)

Most gonococci isolated from the bloodstream of patients are resistant to killing by serum from normal previously uninfected volunteers, whereas approximately two-thirds of isolates from mucosal infections are sensitive to killing by normal human serum.[5] Presumably the bactericidal activity of normal human serum for many gonococci results from previous exposure to common antigens shared by gonococci and other commensal bacteria. The nature of these common antigens and the bacteria on which they are carried are unknown.

Some gonococcal isolates are resistant to normal human serum on first isolation from mucosal surfaces, but rapidly lose serum resistance on in vitro cultivation. This probably is owing to sialylation of full-length LOS in vivo, which results in phenotypic serum resistance. Nearly every isolate from patients with bacteremic disease exhibits stable serum resistance in vitro, which strongly suggests that unstable (phenotypically reversible) serum resistance is not biologically relevant to clinical gonococcal bacteremia.[5] The remainder of this discussion refers to stable (genotypic) serum resistance or serum sensitivity.

In normal human serum, the principal bactericidal activity against serum-sensitive gonococci is found in the IgM fraction.[87,177] Bactericidal antibodies of the IgG class also occur in pooled human serum globulins or in convalescent sera. The antigens against which bactericidal complement-fixing antibodies are directed include LOS, although IgM and IgG bactericidal antibodies apparently recognize different epitopes on LOS.[87] Equal amounts of the complement "attack complex" are bound to the surface of both serum-sensitive and serum-resistant gonococci, suggesting that serum-resistant gonococci somehow are able to resist the otherwise lethal action of a fully formed complement attack complex.[178,179]

The interaction between serum antibodies, complement, and antigenic targets on LOS is complicated by the presence in many individuals of other non-complement-fixing IgG antibodies that recognize epitopes on Rmp. These *blocking antibodies* inhibit the ability of otherwise bactericidal IgM antibodies in normal human sera to effectively recognize their target on LOS.[177,180] The killing activity of sera frequently depends on the balance between non-complement-fixing blocking antibodies and complement-fixing bactericidal antibodies. Presumably the close physical proximity between Rmp and LOS accounts for the ability of anti-Rmp antibodies to block access of other antibodies to LOS. Recent evidence suggests that Rmp may be important not only for resistance to the bactericidal effects of human serum (and therefore for invasiveness) but also for successful transmission to the mucosal surfaces of sexual partners. Women with preexisting antibodies to Rmp were more likely to acquire infection from their infected partners than were other women who lacked antibodies to Rmp.[181] Presumably, antibodies to Rmp in genital secretions blocked otherwise protective antibodies in genital secretions.

The structure of Por is also important to serum resistance. Early work established several genetic loci that were important to serum resistance (*sac-1*, *sac-3*), and each was very tightly linked to the *por* structural gene.[182] Subsequent genetic studies showed that creation of intragenic *por* hybrids, in which a

crossover event occurred within *por*, markedly altered serum bactericidal resistance.[50] Thus the *sac* loci may well have represented alterations of Por, undetectable by the means available when those studies were conducted. Subsequently, two serum factors that inhibit complement deposition and activation have been identified that bind to particular surface-exposed loops of Por: C4bp and factor H, conclusively documenting the role of Por in serum bactericidal resistance.[183,184] Species-specific ablility to bind C4bp helps to determine whether gonococci are able to infect different animal hosts.[185]

Chemotaxis

Serum resistance of gonococci may also relate to the pathobiological potential of infection at mucosal sites. Serum-resistant gonococci that cause bacteremia frequently cause asymptomatic relatively noninflammatory infections at the mucosal surface; this correlates with their relative inability to trigger a chemotactic response for neutrophils. In contrast, serum-sensitive isolates that rarely cause bacteremic disease but that frequently cause a marked inflammatory response at the mucosal surface elicit a much stronger chemotactic response in vitro.[186] Antibodies that elicit the C5 a-dependent chemotactic response are directed against LOS antigens.[186] Since severe pelvic inflammatory disease is correlated with relatively high-level sensitivity to serum killing in vitro, local tissue damage may reflect the ability of some gonococci to trigger a chemotactic response, resulting in increased local inflammation and tissue damage.[187]

DIAGNOSIS

Diagnostic procedures are discussed fully in Chapter 35, but the principles can be outlined briefly here.

The standard procedure for diagnosing symptomatic disease in men with urethritis is the Gram stain. In asymptomatic men or in women with genital infection, the Gram stain is less useful, however, and cultures or nucleic acid amplification tests (NAATs) are necessary. A variety of NAATs have been developed, and they are the principal means of diagnosing gonococcal infection in most clinics in the United States at present.[188] Cultures are particularly useful whenever one is considering the possibility of an antibiotic-resistant gonococcal strain. Lack of culture in most locations has the effect that antibiotic sensitivity testing is rarely carried out except in certain locations that are part of the nation-wide gonococcal isolate sensitivity profiling (GISP) network established by the Communicable Diseases Center.

A variety of tests were developed to detect gonococcal antigen in genital secretions, including enzyme immunoassays with polyclonal sera against gonococcal antigens, monoclonal antibodies against gonococcal antigens, and a Limulus amoebocyte gelation test for lipid A, but none of these is in current use. Unfortunately, good diagnostic serologic tests have never been developed. Approximately one-half of infected persons develop antipilus antibodies in serum during convalescence, but the sensitivity of the test is not sufficiently high for its use in high-prevalence populations, and the specificity is too low to use as a screening test in low-prevalence populations. A unique test that once had clinical promise used competent piliated gonococci as a test system to detect gonococcal transforming DNA in patient secretions.[189] The principle of this test was that gonococci can be transformed only by their own DNA and that virtually every gonococcal infection leaves residual amounts of biologically active transforming DNA in the environment. It has never been developed as a clinically useful test however.

ANTIMICROBIAL SUSCEPTIBILITY

Gonococci are inherently quite sensitive to antimicrobial agents, compared with many other gram-negative bacteria. However, there has been a gradual selection for antibiotic-resistant mutants in clinical practice over the past several decades, first by accumulation of chromosomal mutations that generally resulted in low-level resistance to penicillins and tetracyclines, and subsequently plasmids that mediate relatively high-level Pc^r and TC^r. The consequence of these events has been to make penicillin and tetracycline therapy ineffective in most areas. Antibiotics such as spectinomycin, ciprofloxacin, and ceftriaxone generally are effective but more expensive than penicillin G and tetracycline. Resistance to ciprofloxacin emerged in SE Asia and Africa in the past decade and has spread gradually throughout much of the world. The epidemiologic trends in prevalence of antibiotic-resistant gonococci and proper treatment of antibiotic-susceptible and antibiotic-resistant gonococcal infections are discussed in Chapter 35. The biochemical and genetic basis for antibiotic resistance is discussed in this chapter.

Penicillin

Isolates obtained in the 1940s typically were inhibited by 0.01 μg/mL penicillin G or less. A gradual increase in prevalence and extent of resistance to penicillin occurred over the subsequent several decades; this was shown to be owing to the accumulation of several independent chromosomal mutations that affect cell surface structure. Three genetic loci resulting in low-level resistance to penicillin have been well studied.[190] One of them (*pen*A) results in alteration of penicillin-binding protein two (PBP2), decreasing the affinity of PBP2 for penicillin. The gene for altered gonococcal PBP2 was cloned and sequenced, with the interesting suggestion that it might be the result of gene transfer from another related species in nature, leading to a hybrid PBP2.[112] The other loci (*mtr* and *penB*) result in low-level resistance to many antibiotics in addition to penicillins. The *mtrR* locus has been shown to encode a repressor of an *mtrCDE* efflux-pump that, when fully expressed,

reduces intracellular concentrations of antibiotics.[191–193] The *penB* locus involves point mutations of *porB*, the structural gene for the major porin protein, altering net entry of antibiotics through the porin channel when the *mtr* mutation of the efflux pump also is present.[48] Introduction of *penA*, *mtr*, and *penB* into a sensitive gonococcal strain results in an increase in the minimum inhibitory concentration (MIC) of penicillin G from 0.01 to about 1.0 μg/mL. There have been a number of reports of gonococci with chromosomally mediated resistance to penicillin in which the MIC for penicillin is 2–4 μg/mL.[126] This fourth-step mutation was recently shown to be due to a point mutation in the secretin protein PilQ.[38]

In 1976, a new type of gonococcal resistance to penicillin was first documented: the production of β-lactamase owing to the presence of plasmids that encoded production of a TEM-1 type of β-lactamase.[194] The first Pc^r (penicillinase-producing) gonococci contained either a 5.3- or a 7.2-kb plasmid. These two Pc^r plasmids are very closely related, and each carries approximately 40% of the common gram-negative μ-lactamase transposon Tn2.[195,196] Based on the molecular structure of the gonococcal and *Haemophilus ducreyi* Pc^r plasmids, there is strong suspicion that gonococci acquired the Pc^r plasmids from *H. ducreyi*.[197,198] The gonococcal Pc^r plasmids can be mobilized efficiently by the 36-kb gonococcal conjugal plasmid, helping to explain how Pc^r plasmids are spread to new gonococcal strains.[199]

Tetracycline

Resistance to tetracycline also has increased owing either to the additive effects of several chromosomal mutations or to acquisition of a TC^r plasmid. Chromosomal loci mediating low-level resistance to tetracycline have been designated *mtr*, *penB*, and *tet*; two of these also are involved in low-level, non β-lactamase mediated Pc^r.[190] The chromosomal *tet* gene encodes the 30 S ribosomal protein S10.[200] In aggregate, these three loci result in an increase in the tetracycline MIC from about 0.25 to 2–4 μg/mL. Much higher levels of resistance (tetracycline MIC ≥ 64 μg/mL) are found in gonococci containing a 38-kb TC^r plasmid, which is a derivative of the 36-kb conjugal plasmid. Hybridization studies show that the Tc^r plasmid contains *tetM*, which is carried on a transposon found in a variety of gram-positive and gram-negative microorganisms including many genital pathogens (*Gardnerella, Ureaplasma*).[122] The Tc^r plasmids contain *tetM* in a position that does not inactivate conjugal function, and Tc^r gonococci can transfer this plasmid as well as Pc^r plasmids efficiently into other antibiotic-sensitive gonococci. The mechanism of resistance mediated by *tetM* involves production of a cytoplasmic protein that protects ribosomes from the action of tetracycline. Resistance to penicillins and tetracyclines remains common in most parts of the world.[201,202]

Spectinomycin

For many years, there were only rare reports of gonococci exhibiting high-level resistance to spectinomycin (Spc), but in areas where this antibiotic has been used frequently because of the prevalence of Pc^r gonococci, Spc^r isolates are more common.[203] Single-step, high-level resistance to Spc can be obtained relatively easily in the laboratory, and biochemical and genetic studies of Spc^r mutants and of naturally occurring Spc^r isolates show that they are virtually identical. The genetic locus *spc* maps within a cluster of chromosomal ribosomal genes and results in alteration of the ribosomal target on which Spc acts.[190]

Other antibiotics

Streptomycin (Str) is not frequently used for therapy of gonorrhea at present, but many gonococci exhibit high-level resistance to Str. A locus for resistance to Str (*str*) maps near *spc*, and both are closely linked to those for resistance to tetracycline (*tet*), rifampin (*rif*), and others.[190]

Resistance to nalidixic acid and related DNA gyrase inhibitors is obtained easily in the laboratory with mutation frequencies of approximately 1×10^{-8}. In contrast, Spc^r mutants arise with a frequency of about 1×10^{-10} to 1×10^{-11}. Resistance to fluoroquinolones is increasing, and now has become a general problem in many areas of the world.[204,205] Resistance to fluoroquinolones is due either to mutations in gyrA or parC.[205–207]

HOST-IMMUNE RESPONSE

Naturally acquired gonococcal infection results in serum antibodies against many gonococcal antigens including Pil, Por, Opa, Rmp, and LOS.[208,209] As would be expected, serum antibody responses are greater in patients who have bacteremia or salpingitis than in those who have uncomplicated mucosal infection. Studies of mucosal secretions demonstrate that uncomplicated genital infection often results in serum and mucosal IgA and IgG antibodies against the homologous isolate,[210,211] although some studies found a very poor local antibody response and almost complete lack of inflammatory cytokines IL-1, IL-6, and IL-8.[212] The duration of the serum and mucosal antibody responses after natural infection are quite brief, however.[210] There is an innate response at the mucosal surface, with production of certain defensins.[213]

Cytokine responses in experimental and natural gonorrhea are generally less than in other genital infections.[212] The paucity of immune response is consistent with the ability of gonococci to dampen the response, as has been suggested for many other bacterial and viral pathogens. Work from two research groups has shown that gonococci expressing certain members of the Opa family do down regulate immune responses by T cells[214] and B cells,[215] although the mechanisms may be different in the different target cells. In B cells,

there appears to be an apoptotic response,[215] whereas in T cells there is no apparent cell death.[214] This is a very exciting recent development, and in combination with the well-worked theme of antigenic variation, provides entirely plausible reasons for the inability of local uncomplicated natural infection to result in an effective protective immune response.

There also is a cellular immune response to natural gonococcal infection, although the cellular immunology of gonorrhea has been studied much less extensively than the humoral response.

VACCINES

The principal efforts to stimulate protective immunity to date have focused on use of P.I as an antigen. Intramuscular or subcutaneous inoculation with purified Pil results in both serum and mucosal antibodies that have antiadherence and opsonizing properties.[136,144,151] Limited in vitro studies of male volunteers vaccinated with a single antigenic type of pilus showed that there was partial protection against urethral challenge with the homologous strain.[216] Although the level of protection was modest, with only a 10–30-fold increase in the 50% infectious dose, this conceivably could result in clinically significant protection. Unfortunately, challenge of vaccinated volunteers with a heterologous strain resulted in no protection (C.C. Brinton, presented at the International Pathogenic *Neisseria* Meeting, Montreal, 1982). A single antigenic type of pilus was used to vaccinate American military in a clinical trial, with the perhaps expected result that there was no protection against the diverse antigenic types of gonococci found in clinical practice.[144] It remains possible that a polyvalent pilus vaccine would be more effective or that a common pilin domain or pilus-related protein antigen will be discovered that is more broadly protective against mucosal and/or systemic gonococcal infection.

Other vaccines (including PorB and TbpA/B) are also under active investigation.[217] Advantages of the recombinant partial protection against reinfection by the same Por serovar was demonstrated in a large study in Africa.[218] However, this result was not confirmed in another differently designed study.[219] Studies of recombinant PorB and genetic vaccines expressing PorB in the mouse model of genital gonorrhea have not shown protection (W. Zhu, C.-J Chen, C. E. Thomas, A. Jerse, P.F. Sparling, et al., unpublished studies). A genetic vaccine composed of *porB* expressed from a Venezuelan Encephalitis virus replicon particle (VRP-PorB) showed some protection in the same moel, but it appeared to be entirely due to the proinflammatory Th1 response elicited by the VRP vector, and not due to the expressed PorB (W. Zhu, C-J. Chen, C.E. Thomas, R. Johnston, N. Davis, A. Jerse, and P.F. Sparling, unpublished data).

Understanding of the pathogenesis of gonorrhea is now quite extensive. There is reason for some hope that this new information can be translated into protection against this common and sometimes serious infection. It remains for the future to determine whether this hope can be realized. Few are working on a vaccine for gonorrhea, and no vaccine is in immediate sight.

35 Gonococcal Infections in the Adult

Edward W. Hook, III, and H. Hunter Handsfield

HISTORY

The major clinical manifestations of gonorrhea in men were described in ancient Chinese, Egyptian, Roman, and Greek literature as well as in the Old Testament.[1] The current term for the clinical syndrome referred to as gonorrhea (Greek, "flow of seed") is attributed to Galen (130 A.D.), who is said to have believed that the urethral exudate in males with gonorrhea was semen. However, there is little recorded evidence of awareness that urethral discharge in men was linked with morbidity for women until relatively recently. In 1879, *Neisseria gonorrhoeae* was demonstrated by Neisser in stained smears of urethral, vaginal, and conjunctival exudates,[2] making the gonococcus the second identified bacterial pathogen following the discovery of *Bacillus anthracis*. *N. gonorrhoeae* was first cultured in vitro by Leistikow in 1882, and effective antimicrobial therapy in the form of sulfonamides was first applied in the 1930s.[3] In 1962, the availability of Thayer-Martin medium[4] greatly facilitated the diagnosis of gonorrhea and may have contributed to subsequent increases in numbers of cases of gonorrhea reported in women. Since the mid-1960s, knowledge of the molecular basis of gonococcal–host interactions and of gonococcal epidemiology has increased to the point where it is amongst the best described of all microbial pathogens.

N. gonorrhoeae initially infects noncornified epithelium, most often of the urogenital tract and secondarily of the rectum, oropharynx, and conjunctivae. It is an exclusively human pathogen, which is transmitted primarily by sexual contact or perinatally. Infection most often remains localized to initial sites of inoculation. Ascending genital infections (salpingitis, epididymitis) and bacteremia, however, are relatively common and account for most of the serious morbidity due to gonorrhea. These complications are most common in populations that lack ready access to effective diagnosis and therapy.

EPIDEMIOLOGY

INCIDENCE

Relatively few countries have reporting systems that permit accurate estimation of true gonorrhea incidence. Figure 35-1 shows the reported annual incidence of gonorrhea in the United States, Canada, and Sweden from 1970 through 2005.[5–7] Gonorrhea is rare in Canada and much of Western Europe and, despite recent declines in reported cases, remains relatively common in the United States as well as in much of the developing world. In the United States, recent changes in gonorrhea incidence reflect the influence of multiple, sometimes opposing, trends for members of certain risk groups. At least part of the decline in gonorrhea in developed countries (including the United States) has been attributed to the impact of behavioral changes made to reduce risks of infection with human immunodeficiency virus (HIV). However, these changes have not occurred uniformly within the population. Although national data are not available, studies from several North American and European cities[8,9] suggest that gonorrhea rates in homosexual or bisexual men declined precipitously in the 1980s and 1990s, but has again increased early in the twenty-first century[5]; it is not clear that rates in other groups have changed substantially. In addition, U.S. gonorrhea rates appear to have changed more for whites than for blacks and more among older age groups than in the young.[5]

The incidence of gonorrhea varies with age (Fig. 35-2). Seventy-five percent of reported cases in the United States in 2005 occurred in persons aged 15–29 years, with the highest rates occurring in the 15–19-year-old group. The incidences in 15–19-year-old and 20–24-year-old women were 625 and 581 cases per 100,000 population, respectively. However, it is estimated that only about 50% of 15–19-year-old women in the United States were sexually experienced, compared with

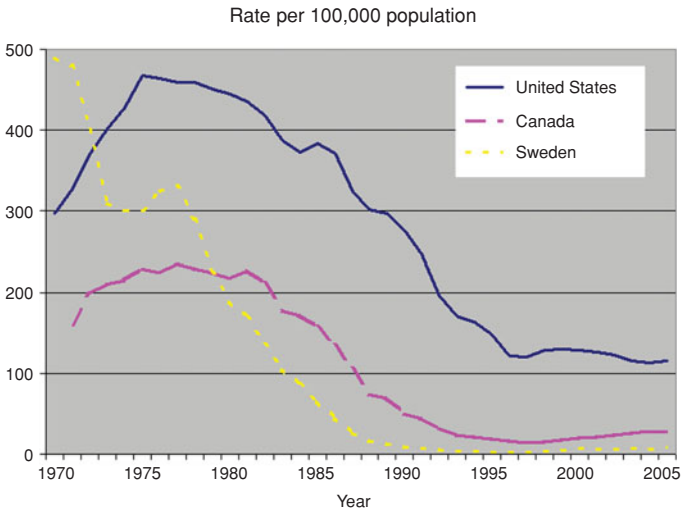

FIGURE 35-1. Reported annual incidence of gonorrhea in the United States, Canada, and Sweden, 1970–2005.

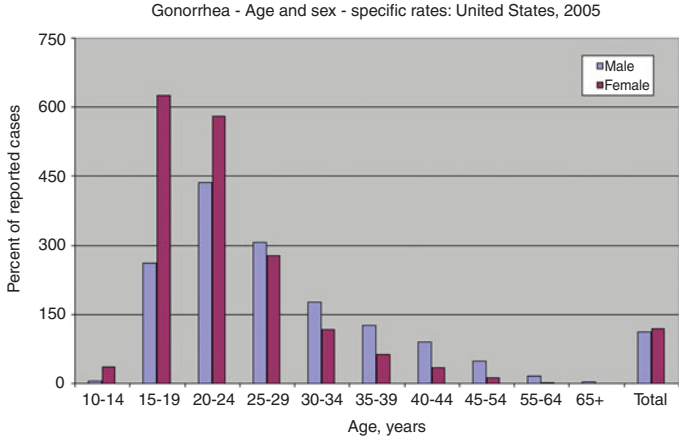

FIGURE 35-2. Age and sex distribution of reported cases of gonorrhea in the United States, 2005.

over 90% of the 20–24-year-old group. Thus, despite similar overall rates, the reported incidence of gonorrhea was almost twice as high for sexually active adolescents as for sexually active women in the 20–24-year-old group.[5]

In the United States in 2005, reported cases of gonorrhea were more than 18-fold higher in African Americans than in whites, a difference only partly explained by greater attendance of nonwhites at public clinics, where reporting is more complete than in other health care settings.[5,10] Other demographic risk factors for gonorrhea include low socioeconomic status, early onset of sexual activity, unmarried marital status, and a history of past gonorrhea.[10,11] Studies in Seattle documented that about 25% of sexually active 16–18-year-old black females living in low socioeconomic level urban census tracts in 1986–1987 acquired gonorrhea each year.[12] Since 1980s, illicit drug use and prostitution have also become increasingly associated with enhanced risk of gonorrhea, syphilis, and probably other sexually transmitted diseases (STDs) as well. In the past decade, male homosexuality has become less associated with gonorrhea because of changing sexual practices among many homosexual men as a consequence of concerns regarding AIDS. Despite this trend, the incidence of gonorrhea in men who have sex with men (MSM) may still be higher than in exclusively heterosexual persons.[13]

The incidence of gonorrhea in the United States is seasonal: the highest rates occur in late summer, whereas the lowest are in late winter and early spring, with nadirs tending to be about 20% lower than peaks.[10,14,15] The antimicrobial susceptibility of *N. gonorrhoeae* appears to fluctuate similarly,[15] possibly as a consequence of seasonal variation in antibiotic usage. Seasonal variations in sexual activity, access to health care, changing commitments in schedules of the young individuals at highest risk for gonorrhea, or other factors also may be involved in these seasonal fluctuations.

The efficiency of gonorrhea transmission depends on anatomic sites infected and exposed as well as the number of exposures. The risk of acquiring urethral infection for a man following a single episode of vaginal intercourse with an infected woman is estimated to be 20%, rising to an estimated 60–80% following four exposures.[16] The prevalence of infection in women named as secondary sexual contacts of men with gonococcal urethritis has been reported to be 50–90%,[16,17] but no published studies have carefully controlled for number of exposures. It is likely that the single-exposure transmission rate from male to female is higher than that from female to male, in part because of retention of the infected ejaculate within the vagina. The risk of transmission by other types of sexual contact is less well defined. Gonorrhea transmission through insertive or receptive rectal intercourse presumably is relatively efficient, and pharyngeal gonorrhea is readily acquired by fellatio.[18,19] Transmission of pharyngeal infection to other sites has been thought to be rare, but in one study this route of exposure accounted for 26% of urethral gonorrhea in MSM.[13] It is possible that changing sexual practices among MSM in response to AIDS, specifically an increasing frequency of oral sex and decreased anal intercourse, have changed the population attributable risk of oral sex for urethral gonorrhea.

In women, use of hormonal contraception may increase the risk of acquiring gonorrhea,[20,21] and use of the diaphragm has a protective influence.[22] Transmission by fomites or through nonsexual contact is extremely rare, but may account for rare cases of gonorrhea in infants.

Symptoms and the behavioral response to them also influence the transmission of gonorrhea. Previous reports saying that 80% of women with gonorrhea were asymptomatic were most often based on studies of women who were examined in screening surveys or referred to STD clinics because of sexual contact with infected men.[23] Symptomatic infected women who sought medical attention were thus often excluded from

such surveys. However, as might be expected, more than 75% of women with gonorrhea attending acute care facilities such as hospital emergency rooms are symptomatic.[24] The true proportion of infected women who remain asymptomatic undoubtedly lies between these extremes. Appreciation of symptomatic infection in infected women is more difficult than in men because the clinical syndromes may be mistakenly attributed to other infectious processes, including urinary tract or vaginal infections.

Asymptomatically infected males and females contribute disproportionately to gonorrhea transmission, because symptomatic individuals are more likely to cease sexual activity and seek medical care. However, the presence of urogenital symptoms does not ensure that transmission will not occur. In a study of patients attending STD clinics in Baltimore, 38% of men and 46% of women presenting for symptom evaluation reported continued sexual activity after the onset of the symptoms that brought them to the clinic.[25] The reasons for continued sexual activity despite the presence of symptoms may include the relative lack of severity of symptoms early in the course of disease, denial, and for women, the nonspecificity of urogenital symptoms. The observation that many transmitters of gonorrhea (and other STDs) do not spontaneously cease sexual activity and seek care emphasizes the importance of taking active steps to bring the partners of infected persons to treatment.

Asymptomatic infections occur in men as well as women, and the percentage of infected men who are asymptomatic probably varies with duration of infection. In a cohort of 81 men who acquired urethral infection at a defined time, the mean time to development of symptoms was 3.4 days, and only 2 (2.5%) remained asymptomatic for 14 days[26] (Fig. 35-3).

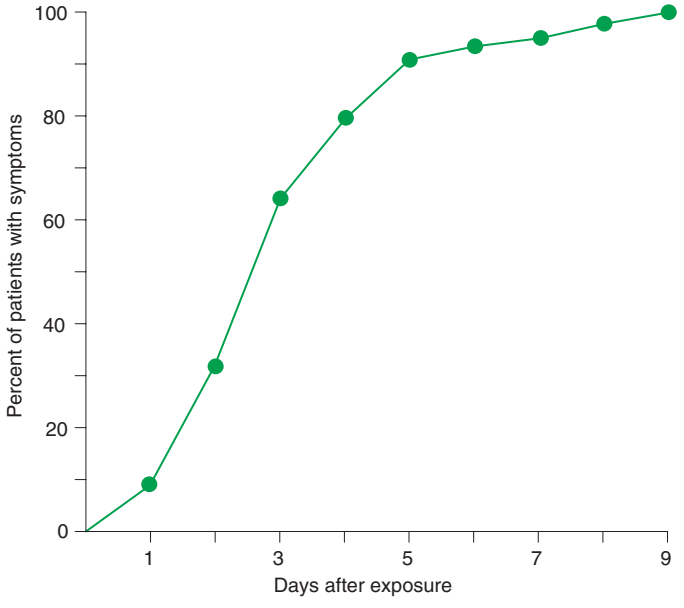

FIGURE 35-3. Incubation period in 44 men with symptomatic gonococcal urethritis. (From Harrison WO, et al. A trial of minocycline given after exposure to prevent gonorrhea. *N Engl J Med* 1979; 300: 1074.)

Although this study was performed in a geographic area where the strains of *N. gonorrhoeae* most likely to cause asymptomatic urethral infections were uncommon, the incidence of asymptomatic urethral gonococcal infection in the general population also has been estimated at approximately 1–3%.[27] The prevalence of asymptomatic infection may be much higher, approaching 5% in some studies, because untreated asymptomatic infections may persist for considerable periods.

PREVALENCE

The prevalence of gonorrhea within communities tends to be dynamic, fluctuating over time, and influenced by a number of interactive factors. Mathematical models for gonorrhea within communities suggest that gonorrhea prevalence is sustained not only through continued transmission by asymptomatically infected patients but also by "core group" transmitters who are more likely than members of the general population to become infected and transmit gonorrhea to their sex partners.[28–30] Although members of the core group described in these mathematical models share a number of characteristics including geographic clustering (usually within inner cities) and low socioeconomic status, the core group actually comprises a number of heterogeneous subgroups whose membership may change over time. These include persons with repeated episodes of gonorrhea, those who fail to abstain from sex despite the presence of symptoms or knowledge of recent exposure, and patients who practice high-risk behaviors such as illegal drug use, prostitution, or prostitute patronage.[12,25,29] Finally, because the core group is defined primarily on behavioral grounds, membership in a core group is not a stable characteristic of an individual, but may change over time. Several studies have provided empirical observations that support mathematical models of core-group transmission.[12,25,29]

While providing the focus for continued endemnicity of gonorrhea, core groups are not solely responsible for gonorrhea prevalence within communities. In terms of social behavior, disease prevalence is due to infections transmitted by both core-group and non-core-group members, the interaction between these two groups, and the movement of patients from one group to another. These factors fluctuate with changes in normative social behavior, disease-control efforts, and other epidemiologic factors. At present, gonorrhea prevention and control efforts are heavily invested in the concept of vigorous pursuit and treatment of infected core-group members and asymptomatically infected individuals. Because about 40% of asymptomatically infected men and many women who are asymptomatic indeed have clinical findings compatible with gonorrhea,[24,27] patient education designed to modify the behavior or response to mild symptoms also is an important albeit largely unexplored

part of gonorrhea control. In addition, however, efforts to access the often-difficult-to-reach core-group transmitters are needed to assist in gonorrhea control. Mathematical models of core transmission theory suggest that because gonorrhea transmission is not 100% efficient, and because spontaneous cures occur, without hyperendemic transmission by core-group members, gonorrhea prevalence would decline, perhaps ultimately to zero.[28,30]

EPIDEMIOLOGIC CORRELATES OF GONOCOCCAL TYPES

A number of methods for gonococcal typing have been developed, as discussed in Chapter 31. Auxotyping,[31] protein I–serotyping,[32] and the two used in combination have been used most widely to study gonococcal epidemiology. Auxotyping classifies gonococci on the basis of stable nutritional requirements for a variety of amino acids and nucleosides, alone or in combination.[31] Examples of common auxotypes are strains that require arginine (Arg), proline (Pro), uracil (U), methionine (M), or Arg, hypoxanthine, and uracil (AHU) for growth. Gonococci requiring none of the substrates are termed *prototrophic* (Proto) or are referred to as *wild type* by some authors. Protein I serotyping is based on the stable antigenic diversity of protein I, the protein present in largest quantity in the gonococcal outer membrane.[32] Protein I is divided into two mutually exclusive classes, protein IA and protein IB, each of which can be further subdivided into serovars in coagglutination assays using panels of protein IA-or protein IB-specific monoclonal antibody reagents. Each serovar is designated by its protein I type (IA or IB) and a numeral based on its coagglutination pattern (e.g., IA-4, IB-3). Using both auxotyping and serovar analysis, gonococci can be divided into a large number of auxotype/serovar (A/S) classes (e.g., AHU/IA-1, Pro/IB-3, Proto/IB-12), providing a highly discriminative tool for study of gonococcal epidemiology.[33] In recent years, however, the antibodies for protein I (Por) serotyping have largely been exhausted and are no longer available. Strain typing based on differences in Por can now be accomplished in certain laboratories based on the DNA sequence of the *por* gene ("genotyping"),[34] as discussed more fully in Chapter 34.

Relatively large numbers (>50) of gonococcal A/S classes usually are present in most communities simultaneously,[33,35] and new strains can be detected over time. The distribution of isolates within A/S classes tends to be uneven, with a few A/S classes contributing disproportionately to the total number of isolates. These predominant A/S classes generally persist within communities for months or years. In most studies, many more A/S classes are detectable only intermittently or even only once during a sampling interval and then not detected again. The factors that determine which A/S classes will become predominant and which will be seen only transiently may include biologic characteristics of the strain or the host. Alternatively, epidemiologic factors such as transmission by commercial sex workers or drug users and importation by travelers may be important.

By allowing individual strains of *N. gonorrhoeae* to be tracked, A/S classification has helped elucidate how gonococci are introduced and spread in communities. For example, during a 12-week study of consecutive patients with gonorrhea seen at a Seattle STD clinic,[33] 489 isolates were collected from 390 patients. These isolates could be divided into 57 different A/S classes. Some A/S classes were isolated only from heterosexual men and women (e.g., AHU/IA-1, AHU/IA-2), whereas others were isolated almost exclusively from homosexual or bisexual men (e.g., Arg/IB-2, Proto/IB-20). During the study, one strain (Proto/IB-3) was not detected until week 6 and over the next 2 weeks was isolated from 1 woman, 1 homosexual man, and 10 heterosexual men. During the next few weeks, isolates of this A/S class from heterosexual men continued to far outnumber those from women, and over the subsequent year, this strain became one of the predominant gonococcal A/S classes throughout the city. Interviews of the patients infected by the Proto/IB-3 strain early in the outbreak identified one infected female who acknowledged over 100 different sexual partners over the preceding 2 months, suggesting that she may have played an important role in the introduction and establishment of this gonococcal strain in the community. Thus the Proto/IB-3 strain may have become common in Seattle not because of specific biologic factors but because of its chance of transmission to members of a core population by a high-frequency transmitter.

Some gonococcal strain types are associated with specific clinical manifestations of disease[35]. In Seattle during the early 1970s, AHU/IA-1 and AHU/IA-2 strains caused more than 90% of asymptomatic urethral infections in men[36] and the majority of cases of disseminated gonococcal infections (DGIs).[37] However, these A/S classes were less common in symptomatic men and in women with gonococcal salpingitis.[38] AHU/IA-1 and AHU/IA-2 strains grow more slowly than many other gonococci, are particularly susceptible to the penicillins and tetracyclines, and tend to be resistant to the complement-mediated bactericidal activity of normal human serum.[39] Since the 1970s, the prevalence of AHU/IA strains in Seattle has diminished markedly, as have the numbers of cases of DGI and asymptomatic urethral gonorrhea in men.[40] These changes occurred shortly after institution of contact tracing for gonorrhea and with routine treatment of asymptomatic male sexual partners of infected women. Thus it seems that AHU/IA strains may have accumulated in the population because of their ability to cause asymptomatic infection in men. When this selection pressure was reduced through partner notification and treatment of asymptomatic men, the prevalence declined.

PATHOLOGY

In adults, only mucous membranes lined by columnar or cuboidal, noncornified epithelial cells are susceptible to gonococcal infection. The initial event in gonococcal infection is the adherence of *N. gonorrhoeae* to mucosal cells in a process mediated by pili, Opa, and perhaps other surface proteins.[41,42] In fallopian tube organ culture models, the organism is then pinocytosed by the epithelial cells, which transport viable, sometimes dividing gonococci from the mucosal surface to subepithelial spaces.[43,44] Simultaneous with attachment of gonococci to nonciliated epithelial cells, gonococcal lipooligosaccharide (endotoxin) impairs ciliary motility and contributes to destruction of surrounding ciliary cells.[44] This process may promote further attachment of additional organisms. Progressive mucosal cell damage and submucosal invasion are accompanied by a vigorous polymorphonuclear leukocytic response, submucosal microabscess formation, and exudation of purulent material into the lumen of the infected organ. In untreated infections, polymorphonuclear leukocytes are gradually replaced by mononuclear cells, and abnormal round cell infiltration has been reported to persist for several weeks or months after gonococci can no longer be isolated.[43] The molecular mechanisms of gonococcal invasion and infection are more fully discussed in Chapter 34.

CLINICAL MANIFESTATIONS: UNCOMPLICATED GONOCOCCAL INFECTIONS

Despite the focus of many patients and even some clinicians on symptomatic local infections, clinical gonorrhea is manifested by a broad spectrum of clinical presentations including asymptomatic and symptomatic local infections, local complicated infections, and systemic dissemination. Figure 35-4 estimates the relative proportion of individuals with each of the major clinical syndromes and shows the interrelations between them in a simplified form.

URETHRAL INFECTION IN MEN

Acute anterior urethritis is the most common manifestation of gonococcal infection in men. The incubation period ranges from 1 to 14 days or even longer; however, the majority of men develop symptoms within 2–5 days, as was the case in 36 (82%) of 44 men with uncomplicated gonorrhea in one of the few studies in which the time of exposure could be clearly defined[26] (see Fig. 35-3). The predominant symptoms are urethral discharge or dysuria. Although initially scant and mucoid or mucopurulent in appearance, in most males the urethral exudate becomes frankly purulent and relatively profuse within 24 hours of onset[43,44] (Fig. 35-5). Dysuria usually begins after onset of discharge. Variable degrees of

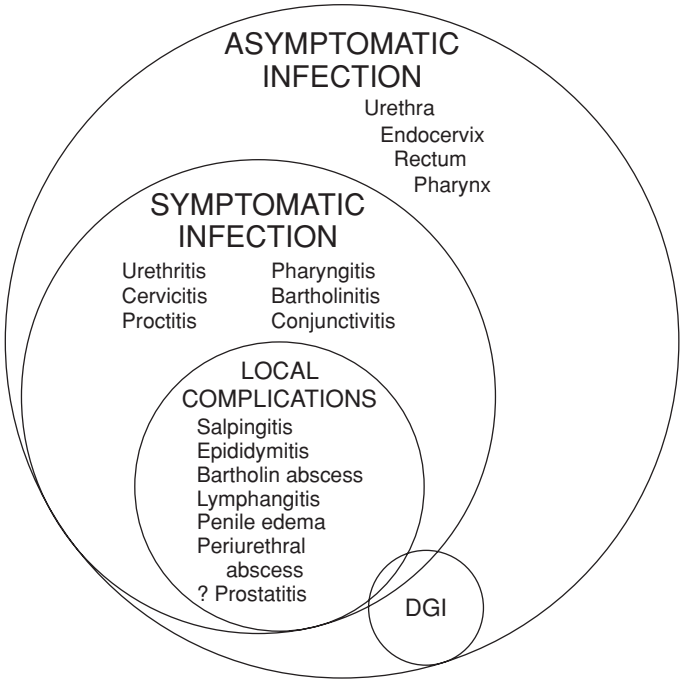

FIGURE. 35-4. Clinical spectrum of gonococcal infection (DGI, disseminated gonococcal infection).

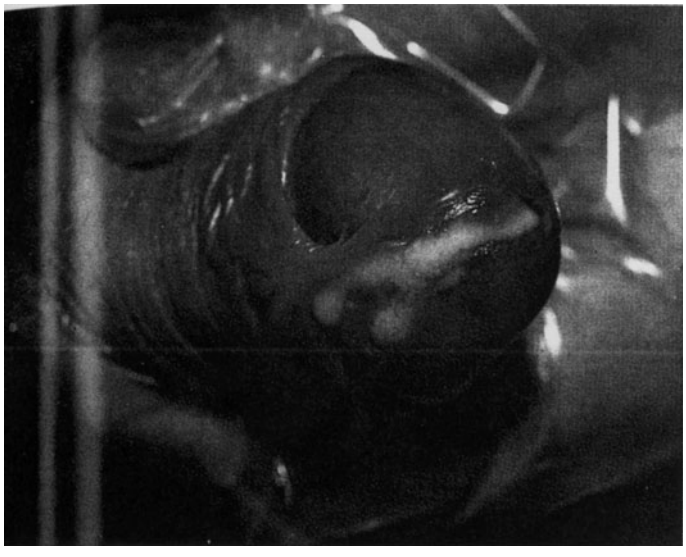

FIGURE 35-5. Purulent urethral discharge and penile edema in a patient with gonococcal urethritis.

edema and erythema of the urethral meatus commonly accompany gonococcal urethritis. Approximately one-quarter of patients develop only a scant or minimally purulent exudate, grossly indistinguishable from that associated with nongonococcal urethritis,[45,46] and a minority never develop overt signs.[27,28] The severity of symptoms is partly determined by the infecting strain of *N. gonorrhoeae*,[44] as discussed above. Without treatment, the usual course of gonococcal urethritis is spontaneous resolution over a period of several weeks, and before the development of effective antimicrobial therapy, 95%

of untreated patients became asymptomatic within 6 months.[43] Subsequent asymptomatic carriage of *N. gonorrhoeae* may occur but probably is exceptional.

Complications of gonococcal urethritis include epididymitis (see Chapter 60); acute or chronic prostatitis (see Chapter 61); so-called posterior urethritis, which may be associated with stranguria and urinary urgency; seminal vesiculitis; and infections of Cowper's and Tyson's glands. These have been documented infrequently using modern diagnostic techniques and are now rare in industrialized societies.

UROGENITAL INFECTION IN WOMEN

The endocervical canal is the primary site of urogenital gonococcal infection in women. Urethral colonization is present in 70–90% of infected women,[47–49] but is uncommon in the absence of endocervical infection. However, after hysterectomy, the urethra is the usual site of infection.[50] Infection of the periurethral (Skene's) gland or Bartholin's gland ducts is also common, but probably is rare in the absence of endocervical or urethral infection.

The incubation period for urogenital gonorrhea in women is less certain and probably more variable than in men, but most who develop local symptoms apparently do so within 10 days of infection.[51,52] The most common symptoms are those of most lower genital tract infections in women (see Chapter 55) and include increased vaginal discharge, dysuria, intermenstrual uterine bleeding, and menorrhagia, each of which may occur alone or in combination and may range in intensity from minimal to severe.[24,53] Although the physical examination may be normal, many infected women have cervical abnormalities that include purulent or mucopurulent cervical discharge, erythema and edema of the zone of ectopy, and mucosal bleeding that is easily induced by swabbing the endocervix.[53] Purulent exudate occasionally may be expressed from the urethra, periurethral glands, or the Bartholin's gland duct (Fig. 35-6). The clinical assessment of women for gonorrhea is often confounded, however, by the nonspecificity of these signs and symptoms and by the high prevalence of coexisting cervical or vaginal infections with *Chlamydia trachomatis, Trichomonas vaginalis, Candida albicans*, herpes simplex virus, and a variety of other organisms (see Chapter 55).

The manifestations of gonorrhea during pregnancy are not significantly different from those in nonpregnant women except that pelvic inflammatory disease (PID) is probably less common and pharyngeal infection appears to be more prevalent than in nonpregnant women.[54] Reported complications of genital gonorrhea in pregnancy include spontaneous abortion, premature rupture of fetal membranes, premature delivery, and acute chorioamnionitis (see Chapter 80), as well as ophthalmia neonatorum, pharyngeal infections, and other syndromes in the newborn (see Chapter 82).

FIGURE 35-6. Purulent exudate expressed from the Bartholin's gland duct of a woman with gonococcal Bartholin's gland abscess. (From JA Davies et al. Isolation of *Chlamydia trachomatis* from Bartholin's ducts. *Br J Vener Dis* 1978; 54: 409.)

RECTAL INFECTION

The rectal mucosa is infected in 35–50% of women with gonococcal cervicitis and is a frequent site of infection in homosexual men; it is the only site of infection in approximately 5% of women with gonorrhea and 40% of homosexually active men studied prior to recognition of the HIV epidemic.[47–49,55–59] In a study of MSM in 1993 and 1994, rectal infection was documented in 26 (25%) of 105 men infected at any anatomic site.[13] In women, rectal gonorrhea is usually asymptomatic, although some cases, especially in MSM, are associated with overt proctitis. Among MSM, rectal gonorrhea is due to direct inoculation through receptive rectal intercourse. In contrast, most rectal infections in women occur without acknowledged rectal sexual contact and are assumed to result from perineal contamination with infected cervical secretions. The prevalence of rectal infection in women is positively correlated with the duration of endocervical infection,[56] further supporting the thesis that infection is usually due to perineal contamination by cervicovaginal secretions. Rectal infection occurs rarely, if ever, in strictly heterosexual men.

Many rectal infections are asymptomatic. When present, the symptoms of rectal gonococcal infection range from minimal anal pruritus, painless mucopurulent discharge (often manifested only by a coating of stools with exudate), or scant rectal bleeding, to symptoms of overt proctitis, including severe rectal pain, tenesmus, and constipation.[56–58] External inspection of the anus only occasionally shows erythema and abnormal discharge, but anoscopy commonly reveals mucoid or purulent exudate (often localized to the anal crypts), erythema, edema, friability, or other inflammatory mucosal changes.[57] Several studies have suggested that fewer than 10% of rectal gonococcal infections in men and women are symptomatic, but many of these studies may have ignored or failed to elicit more subtle or ill-defined symptoms. Moreover, most studies have been affected by sample bias, failing to distinguish among patients being screened for gonorrhea, those attending spontaneously because of symptoms, and those responding to epidemiologic investigation of infected partners. One study[57] found that among MSM examined because they were sexual contacts of men with gonorrhea, 87 (57%) of 152 infected men had rectal symptoms, compared with 66 (41%) of 162 men from whom *N. gonorrhoeae* was not isolated ($p = 0.01$). However, infection with other pathogens was not investigated. A prospective study that was controlled for the reason for the visit showed that while a history of recent exposure to a sexual partner with gonorrhea was common in asymptomatically infected patients, in patients attending the clinic for other reasons, *N. gonorrhoeae* was isolated from 31 (27%) of 114 symptomatic men but from only 6 (9%) of 64 asymptomatic men ($p < 0.01$).[58]

PHARYNGEAL INFECTION

Among patients with gonorrhea, pharyngeal infection occurs in 3–7% of heterosexual men, 10–20% of heterosexual women, and 10–25% of homosexually active men. In studies performed prior to the AIDS era, the pharynx was the sole site of infection in less than 5% of patients irrespective of gender or sexual orientation.[18,56,60–62] Among MSM, shifting prevalence of pharyngeal and rectal infection, as well as other published data, suggests that the frequency of fellatio has increased while the frequency of anal intercourse has declined in response to the HIV/AIDS epidemic. Gonococcal infection is transmitted to the pharynx by orogenital sexual contact and is more efficiently acquired by fellatio than by cunnilingus.[63]

Anecdotal reports suggest that gonococcal infection may cause acute pharyngitis or tonsillitis and occasionally is associated with fever or cervical lymphadenopathy, but over 90% of pharyngeal infections are asymptomatic.[18,60,61] Evaluation of pharyngeal symptoms is confounded, however, by the intriguing observation that among clients of STD clinics, sore throat and perhaps overt pharyngitis are correlated with a history of fellatio but not with isolation of *N. gonorrhoeae* or other sexually transmitted organisms.[18,63] Cunnilingus has not been associated with pharyngeal symptoms.

The clinical and epidemiologic significance of pharyngeal gonococcal infection may be greater than previously appreciated. The occasional occurrence of symptomatic pharyngitis and a possible increased risk of DGI in persons with pharyngeal gonorrhea[18] are countered by the usual absence of symptoms and a spontaneous cure rate that approaches 100% within 12 weeks of infection.[64,65] In addition, the transmission of pharyngeal gonorrhea to sex partners has been thought to be inefficient and relatively rare. However, in one study,[13] 17 (26%) of 66 MSM with urethral gonorrhea acknowledged insertive oral sex but not insertive anal sex in the preceding 2 months. In this study, insertive oral sex was independently associated with both the urethral gonorrhea (odds ratio of 4.4, 95% confidence interval of 1.4, 9.4). Thus, pharyngeal infections may now be an important source of urethral gonorrhea in MSM.

UNCOMPLICATED INFECTION OF OTHER SITES

Gonococcal conjunctivitis is rare in adults; it is most often seen in patients with concomitant anogenital gonorrhea, presumably due to autoinoculation.[66] Accidental conjunctival infection has been emphasized as a hazard for laboratory personnel working with *N. gonorrhoeae.*[67,68] An outbreak of 13 cases of gonococcal conjunctivitis was attributed to the cultural practice of ocular irrigation with urine.[69] Although usually described as a severe infection with a high risk of sequelae, mild or asymptomatic conjunctival gonorrhea infection occurs as well.

Primary cutaneous infection with *N. gonorrhoeae* has been reported rarely[70–72] and usually presents as a localized ulcer of the genitals, perineum, proximal lower extremities, or finger. In many reports, simultaneous infection with other etiologic agents such as herpes simplex virus, *Haemophilus ducreyi,* and other pyogenic organisms was not excluded, and primary gonococcal infection could not be differentiated from secondary colonization of a preexisting lesion. Gonococcal infection of a congenitally patent median raphe duct of the penis is an uncommon but well-documented occurrence.[71] Such infections usually occur in patients with anogenital gonorrhea, but exceptions have been reported.[72]

DIFFERENTIAL DIAGNOSIS OF UNCOMPLICATED GONORRHEA

In males, gonococcal urethritis usually causes more florid signs and symptoms than nongonococcal urethritis and has a more abrupt onset, more prominent dysuria, and a urethral

discharge that is more profuse and more purulent in appearance.[45,46] Additionally, the incubation period for gonorrhea usually is shorter than that of nongonococcal urethritis. Nonetheless, there is sufficient overlap in all these features that clinical differentiation is sometimes unreliable and must be corroborated by laboratory tests.[45] For the diagnosis of urogenital infection in women and for anorectal or pharyngeal infections, clinical differentiation of gonococcal from other causes is even less reliable than for urethritis in men, and laboratory diagnosis is mandatory. Nonetheless, a careful history and use of clinical predictors of infection for directing presumptive therapy in populations at increased risk are appropriate and desirable because expeditious therapy is likely to reduce complications and reduce further transmission of infection. Differential diagnosis is discussed more completely in Chapters 55, 56, and 59–61.

COMPLICATED GONOCOCCAL INFECTIONS

LOCAL COMPLICATIONS IN MEN

In men, the most common local complication of gonococcal urethritis is epididymitis (see Chapter 60), a syndrome that occurred in up to 20% of infected patients prior to the availability of modern antimicrobial therapy.[43] At present, the most common causes of acute epididymitis in patients under age 35 are *C. trachomatis, N. gonorrhoeae*, or both organisms.[73] Patients with acute epididymitis tend to present with unilateral testicular pain and swelling, and most patients with gonococcal epididymitis have overt urethritis when they present.

Penile lymphangitis, sometimes associated with regional lymphadenitis, is an uncommon minor complication of gonococcal urethritis, as is penile edema ("bull-headed clap"), a syndrome that also may accompany nongonococcal urethritis or genital herpes.[74] The pathogenesis of penile edema is unclear; swelling resolves with successful therapy and most such patients lack palpable cords or other clear signs of penile thrombophlebitis or lymphangitis. Postinflammatory urethral strictures were common complications of untreated gonorrhea in the preantibiotic era but are now rare.[43] Many such strictures, however, probably were related to repeated infection or due to the caustic urethral irrigations used for treatment, and stricture is rare today if effective systemic antimicrobial therapy is instituted promptly. Periurethral abscesses also are rare.

LOCAL COMPLICATIONS IN WOMEN

Pelvic inflammatory disease

In acute PID, the clinical syndrome comprised primarily of salpingitis, and frequently including endometritis, tubo-ovarian abscess, or pelvic peritonitis is the most common complication of gonorrhea in women, occurring in an estimated 10–20% of those with acute gonococcal infection.[75,76] PID is the most common of all complications of gonorrhea, as well as the most important in terms of public-health impact, because of both its acute manifestations and its long-term sequelae (infertility, ectopic pregnancy, and chronic pelvic pain). Patients with gonococcal salpingitis usually present with various combinations of lower abdominal pain, dyspareunia, abnormal menses, intermenstrual bleeding, or other complaints compatible with intraabdominal infection.[77] On physical examination, these patients usually are found to have lower abdominal, uterine, or adnexal tenderness, cervical motion pain, abnormal cervical discharge, and sometimes an adnexal mass or tubo-ovarian abscess.[77] Gram-stained smears of cervical secretions may show gram-negative intracellular diplococci. However, as in women with uncomplicated gonococcal cervicitis, the Gram stain is negative in 40–60% of women with gonococcal PID. Other findings that may or may not be present include fever, leukocytosis, elevation of the erythrocyte sedimentation rate, and increased levels of C-reactive protein.[77] Women with gonococcal salpingitis often appear more acutely ill than women with nongonococcal salpingitis, are more often febrile (74 vs. 22%), and are more likely to present during the first 3 days of symptoms (32 vs. 15%).[77] Despite the apparently greater clinical severity of gonococcal PID, laparoscopic studies show that the severity of tubal disease is similar in women with gonococcal or nongonococcal salpingitis.[77] The pathophysiology, differential diagnosis, and clinical spectrum of acute salpingitis are more fully discussed in Chapter 56.

Apart from PID, Bartholin's gland abscess is the most common urogenital complication of gonorrhea in women. *N. gonorrhoeae* was isolated from the Bartholin's gland ducts of 52 (28%) of 183 women with urogenital gonorrhea, 10 of whom (6%) had enlargement and tenderness of the gland.[78] Other bacteria, including *C. trachomatis*, are responsible for many cases of bartholinitis, but tests for gonococcal infection are indicated for all women with this syndrome.

SYSTEMIC COMPLICATIONS: DISSEMINATED GONOCOCCAL INFECTION

Disseminated gonococcal infection, usually manifested by the acute arthritis-dermatitis syndrome, is the most common systemic complication of acute gonorrhea. The syndrome has been estimated to occur in 0.5–3% of patients with untreated mucosal gonorrhea, although the higher estimates were made in settings where the prevalence of gonococcal isolates likely to disseminate was high.[79–81] DGI results from gonococcal bacteremia and is most often manifested by acute arthritis, tenosynovitis, dermatitis, or a combination of these findings. Patients with these clinical manifestations

are often stratified on the basis of culture results into proven, probable, and possible DGI.[82] Patients with positive cultures from blood, joint fluid, skin lesions, or otherwise sterile sources constitute less than 50% of DGI cases and are considered to have proven DGI.[79–82] In more than 80% of DGI patients, *N. gonorrhoeae* may be cultured from the primary mucosal site(s) of infection (anogenital or pharyngeal cultures) or from a sexual partner[79–82]; in the absence of positive blood or other sterile-site cultures, these patients are usually referred to as having probable DGI. Patients with an appropriate clinical syndrome and the expected response to therapy but with negative cultures for *N. gonorrhoeae* are referred to as having possible DGI. However, recognition of patients with DGI is sometimes delayed, or even overlooked, because of the wide variety of clinical findings associated with this syndrome and the mistaken assumption that patients with gonococcal bacteremia have genitourinary signs and symptoms, high fever, marked leukocytosis, or other signs of clinical toxicity.

The most common clinical manifestations of DGI are joint pain and skin lesions. Although the "classic" skin lesion of gonococcal dermatitis is a tender, necrotic pustule on an erythematous base, in many patients skin lesions also may evolve from, or present as, macules, papules, pustules, petechiae, bullae, or ecchymoses.[79–82] The skin lesions tend to be located on distal portions of the extremities and usually number fewer than 30.[80,82] Many patients with gonococcal dermatitis have arthralgia or tenosynovitis early in the disease, and frank arthritis with effusion tends to occur somewhat later. Approximately 30–40% of patients with DGI have overt arthritis.[79–82] Any joint may be involved, although DGI most often involves wrist, metacarpophalangeal, ankle, and knee joints. Synovial fluid cultures are rarely positive in patients with synovial fluid leukocyte counts of less than 20,000 per mm^3, whereas cultures are often positive in patients with more than 40,000 white blood cells per mm^3.[81,82] The manifestations of gonococcal arthritis and differentiation of this process from other acute arthritides are more fully discussed in Chapter 67.

Proving infection in patients with DGI is sometimes difficult. The bacteremia associated with DGI is not continuous, and positive blood cultures become less common as the duration of clinical signs and symptoms increases. Overall, only 20–30% of DGI patients have positive blood cultures.[79–82] In some areas, AHU/IA-1 and AHU/IA-2 strains of *N. gonorrhoeae* cause most cases of DGI; these strains also tend to be associated with asymptomatic urogenital infection, increased susceptibility to penicillin G, and resistance to the complement-mediated bactericidal activity of normal human serum.[80,81] Although most gonococci isolated from patients with DGI exhibit such "serum resistance," isolates from patients with suppurative arthritis are less resistant than those from patients with tenosynovitis or dermatitis.[81,83] These organisms also are more likely to be inhibited by the concentrations of vancomycin contained in selective media for gonococcal isolation from mucosal sites (e.g., modified Thayer-Martin medium) and by the sodium polyanethiosulfonate anticoagulant used in many blood culture media.[84–86] These problems may be overcome through the use of alternative media; however, use of alternative media is relatively uncommon because of lack of knowledge of their availability. In addition, DGI is often not included in the differential diagnosis of acute, asymmetric arthritis or dermatitis in young, sexually active patients because of the erroneous expectation that patients with DGI are likely to have signs and symptoms of urogenital infection. Mucosal infection in patients with DGI often is asymptomatic. All these problems contribute to underdiagnosis.

DGI is probably more common in women than in men.[79–82] In most cases, bacteremia probably begins soon after infection; in about half of the women with DGI, the onset of symptoms occurs within 7 days following menstruation.[79–82] Several studies also have cited pregnancy and pharyngeal gonorrhea as risk factors for DGI.[18,79–82] Deficiency of complement either due to inherited complement deficiency or due to episodic complement deficiency in association with clinical flares of other diseases such as lupus erythematosus may predispose individuals to gonococcal or meningococcal bacteremia.[80,81,87] Only a small percentage of patients with DGI, however, have complement deficiency syndromes, and routine screening of DGI patients for complement deficiency is probably not indicated. Such screening should be performed, however, in patients with second episodes of systemic gonococcal or meningococcal infection.[81,87]

The characteristic response to appropriate antimicrobial therapy has been interpreted as evidence of DGI in patients from whom *N. gonorrhoeae* could not be isolated.[82] Over 90% of patients are subjectively improved within 48 hours of initiating therapy, and more than 90% of febrile patients become afebrile over the same period.[82] DGI due to PPNG[88] or gonococci with chromosomally mediated antibiotic resistance[89] has become apparent with failure to respond clinically to penicillin therapy; ceftriaxone or other antibiotics with proven activity against antibiotic-resistant gonococci should be used rather than penicillin for all patients with suspected DGI.

Gonococcal endocarditis and meningitis

Gonococcal endocarditis is an uncommon complication of gonococcal bacteremia, occurring in an estimated 1–3% of patients with DGI.[79,80] Nonetheless, recognition of gonococcal endocarditis among patients with DGI is essential because of the possibility of rapidly progressive valvular

damage with life-threatening consequences. The aortic valve appears to be infected most often in patients with gonococcal endocarditis, and in the preantibiotic era, most patients died of aortic valve incompetence and acute heart failure within 6 weeks.

Fewer than 25 cases of gonococcal meningitis have been reported. Case reports of this complication describe patients with typical presentations of acute bacterial meningitis, usually without typical findings of DGI.[90,91] *N. gonorrhoeae* is indistinguishable from *N. meningitidis* on Gram's stain of cerebrospinal fluid.

MENINGOCOCCAL INFECTIONS

Several reports have documented that infection or colonization with *N. meningitidis* may occur at all mucosal sites compatible with sexual transmission. Although rare in comparison with gonorrhea, meningococcal infections may mimic nearly all the clinical manifestations of gonorrhea. Pharyngeal colonization with *N. meningitidis* was documented in 17.2% of 2224 patients attending an STD clinic from 1970 to 1972,[18] a rate comparable with that in the general population.[92] However, subgroups of patients attending STD clinics have been found to have differing rates of carriage. Among 398 STD clinic patients with gonorrhea, *N. meningitidis* was isolated from the oropharynges of 44 (52%) of 85 MSM, compared with 58 (19%) of 313 heterosexual men and women ($p < 0.0001$). In addition, *N. meningitidis* was isolated significantly less frequently from heterosexual African Americans than from heterosexual whites ($p < 0.0001$).[93] These prevalences parallel the relative frequencies with which these population groups acknowledge oral sex (MSM > heterosexual whites > heterosexual African Americans).[94] Other investigators reported a similar prevalence (42.5%) of pharyngeal meningococcal colonization in 815 homosexual men attending an STD clinic.[62]

Genital and anorectal colonization with meningococci also occurs. In studies conducted in STD clinics in the 1970s, the prevalence of urethral colonization with *N. meningitidis* was 0.2–0.4% in heterosexual men, but was up to 1% in MSM.[95–98] In MSM, meningococci accounted for 15 (13%) of 114 urethral isolates of oxidase-positive, gram-negative diplococci, compared with 4 (1.1%) of such 368 urethral isolates from heterosexual men.[98] Similarly, 37 (21%) of 175 such isolates from the rectums of MSM were *N. meningitidis*.[98] In women, the prevalence of cervical, urethral, or rectal colonization with *N. meningitidis* was similar to that of urethral infection in heterosexual men.[92,95–98] However, in London, England, in the late 1980s, meningococci were isolated from only 11 (0.2%) of 5571 urethral specimens in MSM, and only 4% of oxidase-positive, gram-negative diplococci were *N. meningitidis*.[99] In the same study, no meningococci were isolated from almost 25,000 urethral or cervical specimens from women or heterosexual men. Thus, it is likely that the prevalence of anogenital meningococcal colonization varies geographically and over time. All suspicious anorectal or urethral isolates from homosexual men, as well as pharyngeal isolates from all patients, should be tested to distinguish *N. gonorrhoeae* from *N. meningitidis*.

The pathogenicity of anogenital meningococcal infection and the frequency with which it produces clinical disease are unclear, and no systematic studies have been performed to determine its mode of acquisition or the prevalence of infection in the sex partners of colonized patients. However, 50–80% of meningococcal isolates in this setting are serogroupable and hence presumably pathogenic; serogroups B, C, X, and Y account for most anogenital isolates.[62,93,95,96] Several case reports have linked meningococcal isolation to urethritis, epididymitis, vaginal discharge, acute salpingitis, and DGI-like syndromes.[40,92,95,96,99–102] Therapy has not been formally studied, but symptomatic rectal or genital meningococcal infections have been cured in small numbers of patients receiving treatment with regimens recommended by the Centers for Disease Control and Prevention (CDC) for gonorrhea. Thus, the preponderance of evidence suggests that genital meningococcal infection sometimes is sexually transmitted and, when detected, should be managed in the same manner as gonorrhea.

LABORATORY DIAGNOSIS

The laboratory diagnosis of gonococcal infections depends primarily on identification of *N. gonorrhoeae* at infected sites by microscopic examination of stained smears, by culture, or increasingly by immunochemical or genetic detection of the organism. Principals of several techniques are discussed in Chapter 34 and details of several techniques, and particularly culture, are included in Chapter 52.

IDENTIFICATION OF *NEISSERIA GONORRHOEAE* IN SECRETIONS

Culture

While culture for *N. gonorrhoeae* detection from urogenital sites has been supplanted, in large part by nonculture methods in North America and Western Europe, isolation remains the diagnostic standard for gonococcal infections and continues to be used in many locations. Currently available antibiotic-containing selective media (e.g., modified Thayer-Martin medium) have diagnostic sensitivities of 80–95% for promptly incubated specimens, depending in part on the anatomic site being cultured (Table 35-1). For urethral specimens from symptomatic men, cultures on selective and nonselective media are equally sensitive, because the concentration of gonococci in the urethra usually exceeds that of other

Table 35-1. Frequency of Isolation of *Neisseria Gonorrhoeae* by Site from Patients with Uncomplicated Gonorrhea[a]

	N	Total Positive Number (%)	Only Site Positive, Number (%)

flora. In contrast, selective media are preferred for culturing the endocervix, rectum, and pharynx, where other, less fastidious bacteria often outnumber *N. gonorrhoeae*.[85,86] The highest yield from all sites probably results when both selective and nonselective media are inoculated simultaneously with specimens obtained using separate swabs.[4,85,103,104] However, the incremental yield is small, and this procedure is not sufficiently cost-effective to be recommended for routine use.

For women, single cultures on most selective media detect 80–90% of endocervical infections.[47,48,85,104] Although the urethra, Bartholin's gland ducts, and Skene's glands are commonly infected, they are rarely the sole site of infection in women with intact cervices and therefore are not usually cultured. In women who have undergone hysterectomies, however, urethral culture gives highest yield.[50] *N. gonorrhoeae* may be isolated from the anal canal of 35–50% of women with gonorrhea, and this is the sole site of infection in up to 5%.[47,48,55] Similarly, the pharynx is infected in about 5–20% of women with gonorrhea, but is the sole site of infection in fewer than 5%.[18,47,48] The increased yield from sampling sites in addition to the cervix results in part from reduced sampling error. Thus the proportion of women found to have a positive culture from the anal canal or pharynx alone might be still lower if duplicate endocervical specimens were cultured routinely.[85,104] Accordingly, for women, cultures of the urethra, accessory gland ducts, anal canal, and pharynx should be considered optional, depending on symptoms, sites exposed, culture methods employed, and available resources.

The sites to be cultured in men also depend on sexual orientation and the anatomic sites exposed. For symptomatic heterosexual men, culture of urethral exudate alone is usually sufficient, but pharyngeal cultures may be useful for men with pharyngitis who practice cunnilingus or for men who have performed cunnilingus with a woman known to have gonorrhea.[18] Although screening of asymptomatic men for urethral gonorrhea has been recommended in the past, in many areas the prevalence of the AHU/IA strains that cause most asymptomatic infections has declined, and the yield of culture may be low enough to permit discontinuation of this practice. For example, at the Seattle-King County STD clinics in 1993 and 1994, *N. gonorrhoeae* was isolated with urethral cultures from only 6 (0.12%) of 5179 men who had no symptoms of urethritis, no discharge on examination, and were not contacts of women with gonorrhea (authors' unpublished data). Similarly, only 34 (1%) of 3271 men seen at a Birmingham, AL, STD clinic between January 1, 1994 and June 30, 1995 with positive cultures for *N. gonorrhoeae* were not treated at the time of their initial presentation to the clinic (authors' unpublished data). Among MSM, the rectum is infected almost as frequently as the urethra, although the actual

yield depends on patients' specific sexual practices.[59,62,104] Isolated pharyngeal infection occurs in about 5% of infected homosexual men.[13,18,59,61,105] Although gonococcal urethritis is common, asymptomatic urethral infection is rare in this population.[59,62] Thus, in screening asymptomatic MSM for whom all three sites are potentially exposed, anorectal culture gives the highest yield, and pharyngeal cultures are desirable. However, these issues have not been thoroughly reexplored since the mid-1980s, when many urban homosexually active men made major changes in sexual behavior in response to the AIDS epidemic.

Several reports have documented failure of vancomycin-containing selective culture media to support growth of vancomycin-sensitive gonococci.[84,106] The prevalence of such strains is highly variable, but in 1970s it accounted for up to 30% of gonococcal isolates in some geographic areas.[84,86,106] The ability to culture these organisms also is inoculation dependent, with greater inhibition occurring with smaller inocula.[84,86,106]

Stained smears

Gram's stain, methylene blue, acridine orange, and several other dyes have been used to prepare clinical material for microscopic examination for gonococci, but Gram's stain has been the most extensively studied. For examination of clinical material, a smear is considered positive for gonorrhea when gram-negative diplococci with typical morphology are identified within or closely associated with polymorphonuclear leukocytes (Fig. 35-7); it is considered equivocal if only extracellular organisms or morphologically atypical intracellular gram-negative diplococci are seen; and it is considered negative if no gram-negative diplococci are present. Nonpathogenic *Neisseriaceae* other than *N. meningitidis*, which are morphologically indistinguishable from *N. gonorrhoeae*, are generally not cell associated. *Acinetobacter* spp are bipolar-staining gram-negative bacilli that, contrary to earlier reports, are easily distinguished from *N. gonorrhoeae* by experienced microscopists. Table 35-2 shows the sensitivity and specificity of Gram-stained smears for various categories of genital and rectal infection relative to isolation of *N. gonorrhoeae.*

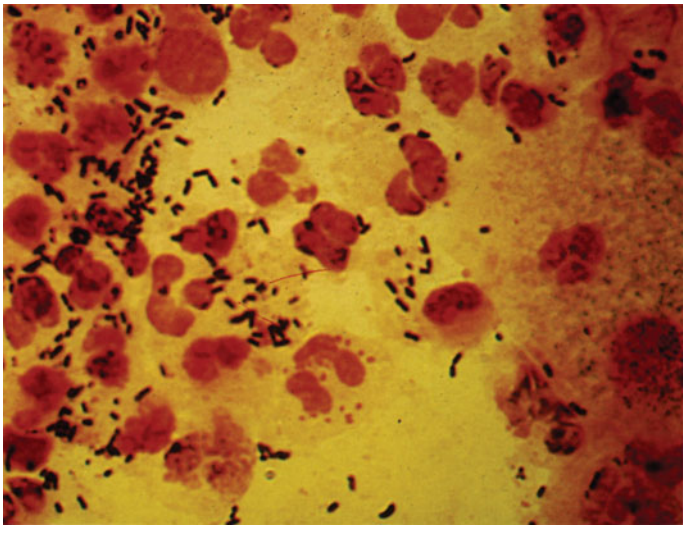

FIGURE 35-7. Gram-sained smear showing polymorphonuclear leukocytes with intracellular gram-negative diplococci in urethral exudate from a man with gonococcal urethritis (× 1000).

For evaluation of men with symptoms or signs of urethritis, the urethral smear is sufficiently sensitive and specific that additional testing may be considered optional for routine care.[107] In some settings such as for monitoring of antimicrobial susceptibility, culture remains an important initial step. The performance of stained smears and culture likewise each depend in part, however, on specimen collection technique and the experience of the microscopist. Smears from the endocervix or rectum are less sensitive than those from the urethra, although positive smears of properly collected specimens are highly specific when examined by experienced personnel, and they facilitate expeditious therapy of infected patients, especially when the index of suspicion is high.[75,107,108] On the other hand, in most clinical settings where the prevalence of gonorrhea is relatively low even among women with cervicovaginal complaints, the yield and predictive value of stained smears of cervical secretions, and thus the utility of the test, is low. Stained smears should be used as an adjunct to, but not replacement for, more specific tests. The sensitivity of anorectal smears for evaluation of patients with symptoms of proctitis is enhanced when the exudate is obtained by direct visualization using an anoscope rather than blindly,[109] even though anoscopy does not apparently improve the sensitivity of culture.[110] Smears are not commonly obtained from the urethra or accessory gland ducts of women, but should be performed if abnormal exudate is expressed or the patient has had a hysterectomy. The Gram's stain smear has not been studied in pharyngeal gonococcal infection, but is generally believed to be both insensitive and nonspecific; it is not recommended.

Nonculture diagnostic techniques

A major impediment to use of culture for gonorrhea diagnosis in many clinical settings are the time, expense, and logistical limitations such as specimen transport to laboratories for testing, a process that may take several days and result in temperature variation or other circumstances that can jeopardize culture viability.[111] In recent years, reliable nonculture assays for gonorrhea detection have become available and are being used increasingly. In 2001, it was estimated that about 25 million tests for gonorrhea diagnosis were performed in the United States, of which approximately over 75% were nonculture tests.[112] Given that these tests are likely somewhat more sensitive than culture for diagnosis of urogenital infection, their continuing promotion by manufacturers, and the fact that specimens collected for gonorrhea diagnosis with these tests also can be frequently

Table 35-2. Sensitivity and Specificity of Gram-Stained Smears for Detection of Genital or Anorectal Gonorrhea

Site and Clinical Setting	Sensitivity[a]	Specificity[b]
Urethra		
Men with symptomatic urethritis	90–95	95–100
Men with asymptomatic urethral infection	50–70	95–100
Endocervix		
Uncomplicated gonorrhea	50–70	95–100
Pelvic inflammatory disease	60–70	95–100
Anorectum		
Blind swabs	40–60	95–100[c]
Anoscopically obtained specimens	70–80	95–100[c]

[a]Sensitivity–percent of patients with positive cultures who have positive Gram-stained smears.

[b]Specificity–percent of patients with negative cultures whose Gram-stained smears also are negative.

[c]The studies showing 95–100% specificity for anorectal smears did not report whether meningococcal infection was distinguished from gonorrhea. Until further data are available, a positive anorectal smear should be considered highly specific for either gonococcal or meningococcal infection.

used to simultaneously test for *C. trachomatis,* their utilization is likely to continue to increase. At the same time, there is an increasing need for culture-based regional monitoring of gonococcal antimicrobial susceptibility to guide therapeutic choices (see below).

Nonamplified DNA probe tests (e.g., Gen-Probe Pace 2) are often used as nonculture tests for gonorrhea. Compared to culture, this test, based on a single-stranded DNA probe designed to hybridize to *N. gonorrhoeae* rRNA, has sensitivities of 89–97% and specificity of 99%, has performed comparably to culture on selective media, and is often available for costs similar to culture.[113–115]

More recently, nucleic acid amplification tests (NAATs) for gonorrhea diagnosis have become widely available.[116,117] Assays based on polymerase chain reaction (PCR), transcription-mediated amplification (TMA), and other nucleic acid amplification technologies have been developed. As a group, commercially available NAATs are more sensitive than culture for gonorrhea diagnosis and specificities are nearly as high as for culture. NAATs have additional advantages of providing performance similar to that of urogenital swabs when voided urine or, for women, vaginal swabs are used as specimens. This simplified specimen collection has permitted gonorrhea screening for men and women in settings where genital examinations are impractical, but disease prevalence may be high. In addition, like the nonamplified tests mentioned above, a single specimen collected for most NAATs can be tested for both *N. gonorrhoeae* and *C. trachomatis*. Although not currently approved for these specimens, studies underway evaluating the performance of NAATs for diagnosis of pharyngeal and rectal infection suggest that they will perform well at nonurogenital sites of infection.

Fluorescein-conjugated antibodies have occasionally been employed to detect *N. gonorrhoeae*, but this method has not proved sufficiently sensitive or specific for routine use.[118] Immunologic or biochemical detection of gonococcal antigens or metabolic products, including surface proteins, endotoxin, and oxidase or other enzymes, also has been investigated in the past but currently seem less promising than nucleic acid detection.

Collection of clinical specimens

Urethral exudate from men may be obtained by passage of a small swab 2–4 cm into the urethra[28] or by collecting the first 15–30 mL of voided urine.[118,119] Although the latter method obviates the discomfort of passing a urethral swab or loop, collection and culture of urine are time consuming, depend in part on the ability of the patient to provide a proper specimen, and require prompt processing for culture because the urine from some individuals is rapidly bactericidal for *N. gonorrhoeae*.[120] Similar specimen handling and transport have far less effect on NAAT performance. For collection of endocervical specimens, the cervix should be cleansed of external exudate or vaginal secretions and a swab inserted 1–2 cm into the external os and rotated gently for up to 10 seconds.[121] When personal or logistic constraints preclude speculum examination, a vaginal specimen may be obtained by a clinician or the patient using a swab or a tampon.[122] With this technique, the sensitivity of NAATs are excellent, whereas there is a modest reduction in culture sensitivity and a marked reduction in the sensitivity of Gram-stained smears.

Nucleic acid amplification assays have been studied for clinical specimens from sites other than the urogenital tract. Emerging data suggest that most currently available NAATs are substantially more sensitive for gonorrhea detection than conventional culture. The specificity of NAATs for diagnosis of extragenital gonorrhea is slightly less than that for culture, although the most appropriate gold standard for nonculture diagnosis remains an area of controversy which may impact performance estimates.

Anorectal specimens from patients without symptoms of proctitis may be obtained by blindly passing a swab 2–3 cm into the anal canal, using lateral pressure to avoid entering any fecal mass. If gross fecal contamination of the swab occurs, it should be discarded and another specimen obtained. For symptomatic patients, anorectal specimens should be obtained under direct vision using anoscopy, which increases the sensitivity of the smear.[109,110] Pharyngeal specimens are obtained by swabbing the posterior pharynx, including the tonsillar areas and faucial pillars.

SEROLOGIC DIAGNOSIS

Serologic tests have been developed to detect antibodies to *N. gonorrhoeae* or its components using complement fixation, immunoprecipitation, bacterial lysis, immunofluorescence, hemagglutination, latex agglutination, enzyme-linked immunoabsorbance, and other techniques.[123] Many of these methods have proved useful for studies of the immune response and pathogenesis of gonorrhea. However, most reported serodiagnostic tests have sensitivities of about 70% and specificities of about 80% for patients with uncomplicated gonorrhea and thus are not useful for screening, case finding, or diagnosis, or other clinical purposes in the United States.[124,125]

THERAPY OF GONOCOCCAL INFECTIONS: ANTIMICROBIAL SUSCEPTIBILITY OF *N. GONORRHOEAE* AND DEVELOPMENT OF RESISTANCE

While the majority of gonococci remain susceptible to a variety of antimicrobial agents, selection of strains with relative or absolute resistance is readily accomplished both in the laboratory and in the real world, and in vivo development of resistance continues to dictate changes in recommended therapy for gonorrhea. The prevalence of resistance varies geographically, and it is important to know the sensitivities of isolates from the region in which one practices. In general, the resistance is mediated through either the cumulative effect of chromosomal mutations or by single-step acquisition of plasmids that encode for high-level resistance. Since many patients with gonorrhea are treated syndromically and formal agar dilution MIC determination for *N. gonorrhoeae* is time consuming and not widely available, recommendations for gonorrhea therapy usually only consider regimens with efficacy of 95% or greater.[126] To accomplish this, both the United States and the World Health Organization use sentinel surveillance systems (see below) to monitor susceptibility and guide their gonorrhea treatment recommendations.

Prior to the mid-1930s, when sulfanilamide was introduced, gonorrhea therapy involved local genital irrigation with antiseptic solutions such as silver nitrate or potassium permangate.[3,43] By 1944, however, many gonococci had become sulfanilamide resistant, and infection persisted in about one-third of patients treated with maximal doses. Fortunately, in 1943 the first reports of the near 100% utility of penicillin for gonorrhea therapy were published,[127] and by the end of World War II, as penicillin became available to the general public, it quickly became the therapy of choice. Since then, continuing development of antimicrobial resistance by *N. gonorrhoeae*[128,129] led to regular revisions of recommended gonorrhea therapy. From the 1950s until the mid-1970s, gradually increasing chromosomal penicillin resistance led to periodic increases in the amount of penicillin required for reliable therapy. Similar trends in MICs were also observed for macrolide and tetracycline antibiotics, the other two major antibiotics used at the time.[129] In 1976, however, strains of *N. gonorrhoeae* with high-level penicillin resistance due to plasmid-mediated β-lactamase production were reported initially as having originated in West Africa and the Far East.[130] Thus, for the first time, through single-step plasmid acquisition, gonococci had become impervious to clinically useful doses of penicillin. About 10 years later, gonococci with high-level, plasmid-mediated resistance to tetracycline were first described,[131] further reducing the utility of the tetracycline family of drugs for gonorrhea treatment. As a consequence, by the late 1980s, penicillins and tetracyclines were no longer recommended for gonorrhea therapy.

In addition to resistance to penicillin, tetracyclines, and erythromycin, in 1987, clinically significant chromosomally mediated resistance to spectinomycin—another drug recommended for gonorrhea therapy—was described in U.S. military personnel in Korea.[132] In Korea, because of the high prevalence of PPNG, in 1981, spectinomycin had been adopted as the drug of choice for gonorrhea therapy. By 1983, however, spectinomycin treatment failures were beginning to occur in patients with gonorrhea, and over the next 2 years, the prevalence of spectinomycin-resistant *N. gonorrhoeae* increased. Following recognition of the outbreak of spectinomycin-resistant gonococci in Korea, ceftriaxone became the drug of choice for treatment of gonorrhea in U.S. military personnel in that country.[132] Sporadic cases of spectinomycin-resistant gonorrhea have been reported elsewhere, but such strains remain rare in the United States, possibly related to relatively low utilization of this relatively expensive therapeutic agent.[133,134]

Beginning in 1993, fluoroquinolone antibiotics were recommended for therapy of uncomplicated gonorrhea in the United States These drugs were effective in single-dose, oral regimens, were unrelated to β-lactam antibiotics and thus could be administered to persons with penicillin allergy, and were well tolerated. These appealing characteristics contributed to their extensive use for gonorrhea therapy over the subsequent decade. By 2007, however, U.S. antimicrobial surveillance revealed that the prevalence of gonococcal strains with diminished fluoroquinolone susceptibility had exceeded 5% nationally, sparing no region and with particularly high prevalences in Hawaii, in the Western U.S., and among MSM nationwide. As a result, in 2007 the CDC opted to no longer recommend fluoroquinolone antibiotics for therapy of uncomplicated gonorrhea. This change meant that ceftriaxone and other cephalosporin antibiotics had become the sole class of antibiotics recommended as first-line therapy for gonorrhea.

In 1986, as the problems of antimicrobial resistance in *N. gonorrhoeae* in the United States were becoming apparent, the CDC reinstituted sentinel surveillance of the antimicrobial susceptibility of *N. gonorrhoeae.*[135] In 2005, data from the systematic monthly testing of gonococcal isolates from 27 U.S. cities demonstrated that nearly 20% of isolates have one form or another of antimicrobial resistance.[136] The CDC sentinel surveillance system continues to document the substantial geographic diversity of antimicrobial-resistant *N. gonorrhoeae.*[135,136]

CHOICE OF TREATMENT REGIMENS FOR *N. GONORRHOEAE*

The choice of antimicrobial agents for gonorrhea therapy is influenced by a variety of factors in addition to the antimicrobial activity of drugs for *N. gonorrhoeae.*[137] Pharmacokinetic studies demonstrated that serum levels of penicillin equal to or greater than three times the MIC of the infecting strain of *N. gonorrhoeae* for 8 hours were needed to reliably cure uncomplicated infection[138]; similar relationships between antimicrobial pharmacokinetics and gonococcal susceptibility are presumed to be operative for other antimicrobial agents. In general, single-dose, observed therapy is preferred for gonorrhea in order to overcome problems of patient compliance. In addition, the choice of antimicrobial agents for therapy is influenced by the probability that patients with acute gonococcal infection are coinfected or have been exposed recently to other STD agents. Among coinfecting agents for patients with gonorrhea in the United States, *C. trachomatis* is preeminent. Up to 10–20% of men and 20–30% of women with acute urogenital gonorrhea are coinfected with *C. trachomatis.*[10,46,76,139–141] In addition, substantial numbers of women with acute gonococcal infection have simultaneous *T. vaginalis* infections. For several decades, it was recommended widely that therapy for gonorrhea would also be effective against incubating syphilis. However, more recent data suggest that incubating syphilis is relatively rare in gonorrhea patients in the United States and the choice of treatment has no measurable effect on the frequency of syphilis.[142] However, activity of selected agents against *Treponema pallidum* may remain an important consideration in some settings. Similarly, in Africa and other areas where chancroid is prevalent, patients may have been exposed to *H. ducreyi* at the time of contraction of gonorrhea.

Since 1985, the treatment recommendations published by the CDC for the United States have recommended single-dose therapy with medications effective for eradication of *N. gonorrhoeae*, followed by therapy expected to eradicate *C. trachomatis* infections (currently either azithromycin or doxycycline). This approach has been shown to be effective for the therapy of both the infections.[139,140]

For over two decades, ceftriaxone—a third-generation cephalosporin—has been the most reliable single-dose regimen used for gonorrhea worldwide.[141] The dose of ceftriaxone currently recommended for therapy of uncomplicated gonorrhea by the CDC is a single intramuscular injection of 125 mg,[140,143] although in some settings 250 mg, the lowest unit dose commercially available, continues to be used. Either dose is highly effective for rectal and pharyngeal, as well as genital, gonorrhea.[144] Although a small percentage (<1%) of patients treated with ceftriaxone fail antimicrobial therapy, clinically significant ceftriaxone resistance has not been reported through 2005.[136,141] The major drawbacks of ceftriaxone therapy for gonorrhea are the requirement for parenteral administration and the potential (albeit low) for reactions of patients allergic to β-lactam antibiotics. Cefixime, an orally absorbed cephalosporin with MICs for *N. gonorrhoeae* that are similar to ceftriaxone, provides a useful oral alternative to parenteral ceftriaxone and also was recommended by the CDC for gonorrhea in its *2006 STD Treatment Guidelines.*[141] However, at the time of writing, cefixime tablets are not commercially available in the United States.[141]

In 1984 a report was published describing the utility of norfloxacin, the first widely available fluoroquinolone antibiotic for treating gonorrhea.[145] Enthusiasm for gonorrhea therapy with earlier quinolones (nalidixic acid and rosoxacin) had been tempered by the tendency of gonococci to rapidly become resistant to the former and by the unacceptable neurotoxicity (primarily vestibular) of the latter.[146] Since that time, a number of other newer fluoroquinolones, including ciprofloxacin, ofloxacin, levofloxacin, and several others, have been evaluated as single-dose regimens with promising results.[142,146] However, as early as 1988, there were reports of quinolone resistance among gonococcal isolates from the Philippines[147] and Southeast Asia, where some quinolone antibiotics are inexpensive and widely available, and by the mid-1980s quinolones were no longer reliable in

some Pacific and Asian countries. By 2006, surveillance in the United States showed that the prevalence of quinolone-resistant gonococci had increased to exceed 5% in heterosexual men and 35% among MSM, leading the CDC in 2007 to no longer recommend this class of antibiotics for therapy of uncomplicated gonorrhea.[148]

Thus, there are currently few well-studied therapeutic alternatives to ceftriaxone for gonorrhea treatment. Limited data and ongoing studies suggest that cefpodoxime, cefuroxime, or other oral cephalosporins may be effective alternatives to ceftriaxone. A single 2-g dose of azithromycin has also been found to be effective for gonorrhea therapy,[149] although gastrointestinal side effects (nausea, vomiting) are relatively common with this regimen and there is reason for concern for the potential for *N. gonorrhoeae* to rapidly develop clinically significant resistance.

Each of the currently recommended treatment regimens has specific advantages and disadvantages that should be used to individualize therapy for gonorrhea. For example, single-dose oral regimens are desirable in terms of convenience and reduced risk for needle-stick exposures in health-care workers. For treatment of MSM with gonorrhea, the ceftriaxone regimen is preferred over other regimens. The strains of gonococci that occur in homosexual men are more likely to harbor the antibiotic resistance mutation (mtr),[150] which makes these organisms somewhat more resistant to antibiotics and thus results in higher treatment failure rates when alternate regimens are used. Similarly, while efficacious for anogenital gonorrhea, spectinomycin hydrochloride often fails to cure pharyngeal gonorrhea[151] and is not recommended in homosexual men. Moreover, spectinomycin is not readily available in the United States at present. Finally, particularly in settings such as public clinics where large numbers of patients are treated and funds are limited, cost considerations may lead to choice of one agent over another.

In addition to currently recommended regimens for treatment of uncomplicated gonorrhea, there are a substantial number of other antibiotics that have been demonstrated to be effective for gonorrhea therapy.[141,149] However, compared with the CDC-recommended ones, these drugs may not have any advantage over recommended regimens.[141]

FOLLOW-UP

Because all recommended regimens have cure rates that approach 100%, repeat cultures for test of cure are no longer recommended for all patients with gonorrhea.[141] However, test-of-cure often is warranted if an atypical regimen is used or if medication compliance is uncertain. Even when recommended regimens are used, as for persons with chlamydial infections, 10–20% of heterosexual men or women treated for gonorrhea become reinfected in the next several months.[151] Thus, a diagnosis of gonorrhea identifies a person at increased risk for reinfection. As a result, rescreening for acquisition of gonorrhea or other STDs is now recommended for persons with gonorrhea approximately three months following their initial diagnosis.[141]

MANAGEMENT OF SEX PARTNERS

Most authorities recommend treatment of all recent sex partners of patients with gonorrhea, prior to the availability of culture results, in order to prevent complications and curtail the transmission ("epidemiologic treatment").[141,152] The definition of *recent* depends on the clinical and epidemiologic settings; in most instances, all partners exposed within the preceding 60 days prior to the onset of symptoms or to diagnosis of the index case should be treated. For patients with asymptomatic gonococcal infection, however, extending contact tracing to may prove useful for prevention efforts. There is considerable evidence that expedited partner therapy is beneficial to partners and the index case as well (see Chapter 54).

PREVENTION

Properly used condoms provide a high degree of protection against acquisition and transmission of genital infection.[26,153] The diaphragm and cervical cap also may reduce transmission and acquisition of endocervical infection.[20,154,155] Topical spermicidal and bactericidal agents have been shown recently to clearly reduce the probability of infection by both *N. gonorrhoeae* and *C. trachomatis* in patients using these gels. However, nonoxynol-9 containing spermicides have been shown to increase risk for HIV infection in studies conducted in high-risk women (commercial sex workers); hence nonoxynol-9-containing spermicides are no longer recommended for STD prevention.[20,21,142] Urinating, washing, and douching after intercourse are assumed by many to be beneficial in prevention of gonorrhea, but controlled data are lacking. In addition, certain practices such as douching are now increasingly being associated with harmful outcomes. Prophylactic administration of antibiotics immediately or soon after sexual exposure clearly reduces the risk of infection (see Chapter 51).[26] However, this practice is likely to select and facilitate transmission of antibiotic-resistant strains of *N. gonorrhoeae*. In addition, except in very high-risk settings, routine antibiotic prophylaxis is unlikely to be cost-effective.

36 Biology of Treponemes

Sheila A. Lukehart

Syphilis and related infections have long fascinated clinicians and scientists who marvel at the ability of the fragile bacterial agents of these diseases to cause lifelong infection in the untreated host. The nature of the waxing and waning clinical course, the ability of the bacteria to evade the host immune response for decades, and the refractory nature of the bacteria to manipulation in vitro have been the topics of research for decades, without resolution today. Nonetheless, much has been learned about the *Treponema,* and the molecular genetic tools that have been developed have had a marked impact on our knowledge of these organisms. This chapter reviews our current understanding of these organisms and the mechanisms employed by the bacteria and the host in the intimate interactions that we call infection.

CLASSIFICATION

The treponemes are members of the family Spirochaetaceae within the order Spirochaetales. This family includes several important human pathogens (e.g., the agents of syphilis and the endemic treponematoses, Lyme disease, and relapsing fever), animal pathogens, as well as symbionts. A second family, Leptospiraceae, includes the agents of leptospirosis; a proposed third family, Brachyspiraceae, includes several species associated with gastrointestinal illness in humans and other mammals. All members of the Spirochaetales are characterized by their spiral shape, corkscrew motility, and the existence of periplasmic flagella (endoflagella); their phylogenetic relationships have been extensively investigated by 16S rDNA analysis.[1,2] All members of the genus *Treponema* are thought to be host-associated, with a wide variety of natural hosts including humans and other primates, rabbits, cattle, dogs, and termites. An extensive review of the pathogenic treponemes has recently been published.[2]

TREPONEMAL PATHOGENS OF HUMANS

Treponemal infections of major public health importance include venereal syphilis (called syphilis hereafter), yaws, and bejel ("endemic syphilis"). Three morphologically identical subspecies of *Treponema pallidum* have been classified as the agents of these infections: *T. pallidum* subsp. *pallidum* (syphilis), *T. pallidum* subsp. *pertenue* (yaws), and *T. pallidum* subsp. *endemicum* (bejel). *T. carateum* is the agent of pinta, a related treponemal infection that is rarely reported today. This uncultivable treponeme is thought to be very closely related to the *T. pallidum* subspecies listed above and should probably be listed as a fourth subspecies of *T. pallidum*. Each of these infections is transmitted by direct contact: usually sexual contact for syphilis and skin-to-skin or mucous membrane contact for yaws, pinta, and bejel. All cause early skin or mucous membrane lesions, followed by disseminated and sometimes recurring lesions and chronic asymptomatic infection, occasionally leading to disfiguring and destructive late manifestations after many years. These infections are described more fully in Chapters 37 and 38.

Many phylogenetically distinct treponemes have been identified in the gingival pockets of persons with periodontal disease.[3,4] This very common condition is characterized by a shift in the oral flora from gram-positive to gram-negative, by chronic or recurring gingival inflammation, and alveolar bone resorption with loss of dentition. Although periodontal disease is characterized as polymicrobial, approximately 40% of bacteria found in periodontal pockets are treponemes.[5] A number of oral treponemes can be cultivated in vitro, and the best-studied oral treponeme is *T. denticola*. A group of noncultivable oral treponemes, called PROS (pathogen-related oral spirochetes), have some antigenic similarity to *T. pallidum* and have been highly associated with several types of periodontal disease.[6–8]

RELATED ANIMAL PATHOGENS

Several treponemal infections have been recognized in nonhuman mammals. A natural venereal infection of rabbits is caused by *T. paraluiscuniculi*, a noncultivable treponeme that is morphologically identical, yet antigenically distinct from *T. pallidum* but is not infectious for humans.[9–12] Another

treponeme was isolated from baboons in Guinea, a yaws-endemic region, and was determined by immunological studies to be more closely related to *T. pallidum* subsp. *pertenue* than to *T. pallidum* subsp. *pallidum*[13,14]; recent work has shown that this treponeme is genetically distinct from the three known *T. pallidum* subspecies.[15] One study suggests that this organism is infectious for humans.[16]

A newly identified group of treponemes, including *T. brennaborense,* is highly associated with papillomatous digital dermatitis (PDD) and ulcerative mammary dermatitis in cattle and sheep.[17–20] Like periodontal disease, these polymicrobial infections are primarily associated with anaerobic gram-negative bacteria and a preponderance of treponemes. The PDD treponemes are closely related genetically to oral treponemes.[21]

INTESTINAL TREPONEMAL SYMBIONTS

Several symbiotic treponeme species have been identified in digestive tracts of cattle and termites. In both cases, these organisms appear to be important for host nutrition. Members of a widely diverse treponemal flora in the hindgut of termites[22] have H_2/CO_2-acetogenesis and dinitrogen fixation capabilities that contribute to the health of their hosts.[23] In cattle, organisms such as *T. saccharophilum* are thought to be important in the digestion of ingested plant material.

GENETICS OF TREPONEMES

TREPONEMA PALLIDUM GENOME

Perhaps because of the inability to culture *T. pallidum* in vitro, *T. pallidum,* Nichols strain, was one of the first bacteria for which the genome sequence was determined.[24] This achievement in 1999 opened the door to understanding the metabolic capabilities of *T. pallidum* and spawned a number of molecular studies of potential virulence factors. The circular chromosome contains 1,138, 006 base pairs containing 1041 predicted open reading frames, making its genome approximately one-fourth the size of *Escherichia coli*. The lack of metabolic capability revealed in the *T. pallidum* genome sequence is consistent with the strong host-dependence of this organism for survival. Although there is still no method for genetic modification of *T. pallidum,* the availability of the genome sequence has largely overcome the problem of obtaining large numbers of treponemes from infected animal tissues by permitting targeted amplification and identification of genes of interest. This has greatly facilitated studies of individual genes, gene families, and metabolic pathways.

COMPARATIVE GENOMICS

In addition to *T. pallidum,* the genome of *T. denticola* has also recently been sequenced.[25] The genome of this cultivable organism is 2.5 times larger than *T. pallidum* and contains genes for much of the metabolic machinery lacking in *T. pallidum.* Comparative analysis of these genomes suggests that the divergence of these two treponeme species was very ancient compared to that for other bacterial groups. Although two-third of *T. pallidum* genes have homologues in the *T. denticola* genome, there is very little synteny. Minimal genome sequence (limited primarily to 16S DNA sequence) is available for the noncultivable oral treponemes; these fall across the phylogenetic spectrum, but many are closely related to *T. vincentii* and *T. medium*.[26]

In the 1950s, a "nature versus nurture" debate raged in which Hudson[27] and Hackett[28] argued whether the clinical differences among the treponemal infections were due to genetic versus environmental factors, respectively. Recently, a molecular approach has been used to compare gene sequences from the three *T. pallidum* subspecies. The gene sequences for some of the major antigens and proteins of the subspecies have demonstrated either complete identity (TpN15,[29] TpN17[30]) or minor changes (*tpf-1*,[31] 16S rDNA,[32] and Tp92[33]) between the *pallidum* and non-*pallidum* (*pertenue, endemicum*) subspecies. For some molecular signatures, rapid restriction site analysis of coding (glycerophosphodiester phosphodiesterase[34]) and noncoding[35] regions can be used to differentiate the *pallidum* from non-*pallidum* subspecies, but none of these molecular targets can be used to differentiate *T. pallidum* subsp. *pertenue* from *T. pallidum* subsp. *endemicum*.

More dramatic differences between the *pallidum* and non-*pallidum* subspecies were identified through examination of a family of putative virulence factors (the *T. pallidum* repeat [Tpr] family of proteins, discussed again below). At one locus, *tprD*, the non-*pallidum* subspecies and approximately 50% of the tested *pallidum* strains have a sequence (called *tprD2*) that differs significantly from the *tprD* sequence present in the Nichols strain genome sequence[36]; the remaining 50% of *pallidum* strains have the Nichols *tprD* sequence. It was subsequently found that the *tprD*-containing strains have an identical sequence at the *tprC* locus, while the *tprD2*-containing strains have *tprC* sequences that differ significantly from each other and from the Nichols prototype *tprC/D* sequence.[37] Even this major sequence difference, however, could not be used to identify *T. pallidum* subsp. *pertenue* versus *T. pallidum* subsp. *endemicum*, and the "nature versus nurture" debate was unresolved.

Newly published data[15] show for the first time that the three subspecies can be differentiated by molecular signatures within the *tpr* family. The functional significance of these sequence differences is not yet known but may involve tissue tropism or invasive capability, two characteristics that distinguish syphilis from the nonvenereal treponemal infections. This and several other analyses[33,34,38] have also demonstrated that *T. paraluiscuniculi* is more distantly related compared to

the three subspecies of *T. pallidum*. Although molecular differences have been defined among the three subspecies, the specific genes and gene products responsible for different clinical diseases (see Chapter 38) have not been identified.

Rothschild[39] suggests that *T. pallidum* subsp. *pertenue* was the most ancestral of the three subspecies and was present in Africa at the time of the origin of modern humans; the two remaining subspecies are suggested to have evolved from *pertenue*, with the *pallidum* subspecies evolving in the New World (the Columbian theory) within the past 2000 years. Baker and Armelagos[40] revised the Columbian theory and proposed a scenario in which *T. pallidum* subsp. *pallidum* (venereal syphilis) evolved in Europe within the past 500 years. More recently, Armelagos and colleagues[41] reviewed the molecular literature on the pathogenic treponemes and concluded that there is a no molecular distinction among the subspecies. In contrast, Gray et al.[38] performed an extensive comparison of six *tpr* genes (*tprC, D, I, K, G*, and *J*) from multiple strains of each of the *T. pallidum* subspecies, demonstrating that there is clear molecular evidence to support the existence of the three subspecies and suggesting that the divergence of the three subspecies was distant in time, certainly not within the past 500 years as proposed by Baker and Armelagos.[40] Investigation of additional genes and additional strains will be needed to resolve these divergent views.

STRUCTURE AND PHYSIOLOGY OF TREPONEMES

CELL STRUCTURE

Treponemes are motile spiral-shaped bacteria that are seen by darkfield or phase contrast microscopy but they are difficult to visualize by routine light microscopy because their long and very thin dimensions (approximately 10–14 µm in length and 0.1–0.2 µm in diameter) place them below the resolution of the light microscope. Their cell architecture is similar to gram-negative bacteria, in that they have a cytoplasmic membrane, a thin peptidoglycan cell wall, and a periplasmic space underlying the outer membrane. The motility organelles are termed periplasmic flagella or endoflagella (EF) because they are located within the periplasmic space. A cross section of *T. pallidum* is shown in Fig. 36-1; the EF are readily visible in the periplasmic space. Approximately three EF filaments are inserted at each end of the treponeme and they wrap around the cell body toward the center of organism.

The outer membrane of *T. pallidum* differs from most gram-negative bacteria in two major respects: it lacks lipopolysaccharide (LPS)[42,43] and it has a dearth of integral membrane proteins.[44,45] Immunological studies have suggested that binding of antibody to the surface of *T. pallidum* is very limited and requires long incubation periods.[46–48] It had been suggested that the surface of the bacterium is covered by a mucopolysaccharide "slime layer"[49,50] or by host-derived proteins,[51] thus blocking the binding of specific antibodies to surface antigens.[47] An alternative explanation resulted from freeze–fracture electron microscopy studies from two laboratories: these studies independently showed that the number of visible "particles" (thought to represent integral outer membrane proteins) on the surface of *T. pallidum* was significantly lower (by 90%) compared to cultivable treponemes and other spirochetes.[44,45] This finding led to the coining of the term "stealth pathogen" to describe the relative antigenic inertness of the *T. pallidum* surface.[52] In contrast, the inner membrane contains numerous visible particles (see Fig. 36-2). Although the number of surface antigens may be small in *T. pallidum*, there is ample functional evidence that such antigens exist, and a number of surface-exposed proteins have been proposed. Several of these are discussed below in the discussions of attachment to host cells and antigenic variation. The search for surface-exposed proteins has been significantly hampered by the exquisite fragility of the *T. pallidum* outer membrane and there continues to be controversy in the field about the identity of such proteins.

MOTILITY

T. pallidum is actively motile, moving with a corkscrew motion, with bending and flexing, but with little translational movement. These characteristics are used to differentiate *T. pallidum* from other treponemes during darkfield microscopic examination of specimens from patients with suspected syphilis. The structure of *T. pallidum* EF is unique, consisting of four gene products: FlaA (outer sheath) and three flagellar

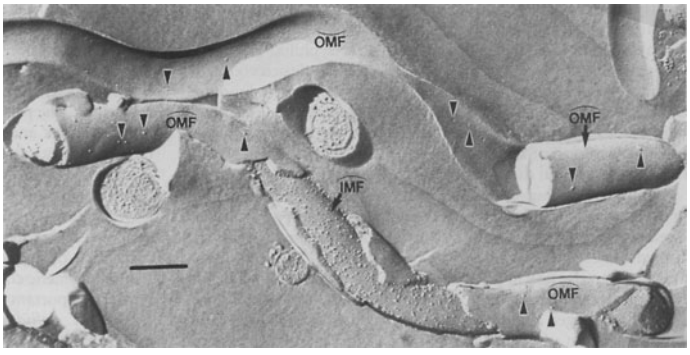

FIGURE 36-2. Membrane architecture of *T. pallidum* subsp. *pallidum*, as demonstrated by freeze–fracture electron microscopy. The concave and convex outer membrane fracture (OMF) faces, corresponding to the outer and inner leaflets of the outer membrane, respectively, contain a very low concentration of intramembranous particles (*arrowheads*). In contrast, the convex inner membrane fracture (IMF) face, corresponding to the inner leaflet of the inner membrane, has a high concentration of intramembranous particles. (*Courtesy of Eldon M. Walker*.)

core proteins, FlaB1, FlaB2, and FlaB3.[24] Studies of nonmotile EF knock-out mutants of cultivable treponemes indicate that the helical shape of the treponeme is maintained even when the EF are not produced.[53] Motility of the treponemes is enhanced by increased viscosity of the medium, suggesting that the bacteria are capable of motility in body fluids in the eye and joints. Motility results from the rotation of the EF from their insertion points, similar to flagella from other bacteria, and is mediated by a rotary motor apparatus. An important role for motility in syphilis pathogenesis has long been suspected but has not been rigorously proved because there is no genetic system for creating nonmotile EF mutants in *T. pallidum.*

■ CHEMOTAXIS

Most motile bacteria have chemotactic capability, and *T. pallidum* is no exception. Approximately 5–6% of the genome is devoted to genes associated with directed (chemotactic) movement.[54] Interestingly, the genomes of *T. pallidum* and other pathogenic spirochetes, including *Borrelia burgdorferi*, are predicted to contain orthologs of the well-recognized CheW-CheR chemotaxis components. The chemotaxis machinery is thought to assist *T. pallidum* as it navigates throughout the body during dissemination, and recent microarray studies indicate that a number of chemotaxis genes are upregulated during early active syphilis infection.[55]

METABOLISM AND SURVIVAL IN VITRO

Studies of the metabolism of *T. pallidum* have been hampered for many years by contaminating rabbit tissue that was contained in *T. pallidum* suspensions. It was not until the publication of the *T. pallidum* genome that investigators fully appreciated the metabolic limitations of the organism. Although *T. pallidum* contains the genes for the complete Embden–Meyerhof pathway, it lacks genes for the Krebs cycle and lacks the heme proteins involved in electron transport.[24] This suggests that *T. pallidum* is able to generate only two molecules of ATP per glucose molecule through glycolysis, compared to 36–38 molecules for bacteria with "complete" metabolic capability, perhaps accounting for its significantly slower growth rate (generation time of ~30–33 hours,[56,57] compared to *E. coli's* 30 minutes). Furthermore, *T. pallidum* lacks the genes required to synthesize most amino acids, purines, pyrimidines, and lipids de novo. As expected for an organism with such limited biosynthetic capability, there are 18 putative transport systems including ATP-Binding Cassette (ABC) transport systems.[24] The predicted targets of *T. pallidum* transporters include amino acids, carbohydrates, and cations. *T. denticola,* which has much more complete metabolic machinery, has 106 ABC transporter systems compared to four for *T. pallidum*[25] Many of *T. denticola*'s transporters appear to be specific for amino acids, consistent with the high number of proteases produced by *T. denticola*, suggesting that proteolysis of host tissue may provide a major source of nutrients (via amino acid fermentation) for that organism.

It has long been recognized that *T. pallidum* survival is diminished in atmospheric oxygen, and most cultivation attempts in the past 30 years have employed reduced-oxygen conditions in recognition of the microaerophilic nature of the organism. Aerotolerant bacteria have enzymes, such as superoxide dismutase, catalase, or peroxidase, which can protect them from the toxic effects of oxygen radicals. The genome sequence confirmed that *T. pallidum* lacks genes for these enzymes,[24] thus explaining its sensitivity to oxygen. However, the organism survives better in microaerophilic rather than anaerobic conditions, and several other genes for oxygen protective enzymes were identified. Hazlett and colleagues[58] described neelaredoxin, which reduces superoxide to peroxide, and proposed a scheme in which alkyl hydroperoxide reductase C reduces the peroxide to water (substituting for the activity of catalase). Neelaredoxin is thought to be regenerated by reduction with rubredoxin. Rubredoxin is then reduced by NADH oxidase, the only *T. pallidum* enzyme to require molecular oxygen and perhaps accounting for the microaerophilic nature of *T. pallidum.* Although this pathway appears to provide some level of protection against oxygen toxicity, it is likely less effective than superoxide dismutase and catalase.

Many attempts have been made to cultivate *T. pallidum* in vitro. Limited success was described by Fieldsteel and colleagues in 1981[59] in which *T. pallidum* was shown to undergo limited multiplication (up to a 50-fold increase or five generations) during coculture with rabbit epithelial cells under reduced oxygen concentration with dithiothreitol. Although others have reproduced these findings,[60,61] significant

advances have not been reported, and it is still not possible to achieve multiplication after subculture. The inability to cultivate *T. pallidum* is a major stumbling block in research on syphilis, as the development of tools for genetic manipulation of the organism requires cultivation.

NATURAL HISTORY OF SYPHILIS

The natural history of syphilis is described in detail in Chapter 37, but a brief discussion is warranted here as a context for the following discussion of animal models and pathogenesis of syphilis.

Syphilis is a chronic infection that progresses over decades, with alternating active clinical disease (primary, secondary, and tertiary stages) and asymptomatic periods (called latency).

EARLY SYPHILIS

Infection occurs by direct, usually sexual, contact with an infectious lesion (i.e., primary chancre or secondary mucocutaneous lesions). The bacteria are thought to penetrate intact mucosal surfaces[62] or via microscopic abrasions of skin where they multiply locally with a generation time of ~30 hours. Within the first hours-to-days of infection, some organisms gain access to the circulation (including lymphatics) and disseminate widely, often including the central nervous system (CNS) and, in pregnant women, the fetus. The primary lesion, called a chancre, appears at the site of infection and is caused by the host cellular infiltration triggered by the presence of large numbers of treponemes; regional lymphadenopathy is common. The chancre resolves without treatment (see "Acquired Immunity and Bacterial Clearance" section) and the untreated individual may manifest the secondary stage after a period of weeks to several months or, in some cases, concurrently with the healing of the primary lesion. The secondary stage is characterized by skin lesions (usually a maculopapular rash) on the trunk, extremities, palms and soles, as well as mucous membrane lesions (mucous patches) and hypertrophic lesions in moist body crevices (condylomata lata). These are often accompanied by systemic lymphadenopathy. The rash and lymphadenopathy resolve spontaneously due to the host's immune response. Less common symptoms and signs of secondary syphilis include alopecia, subclinical or clinically apparent hepatitis, and uveitis; symptomatic or asymptomatic CNS involvement is common during this stage. After resolution, patients enter the latent stage. Secondary lesions may reappear, usually during the first year of infection, and latent (asymptomatic) syphilis of <1-year duration is called "early latent" syphilis.

LATE SYPHILIS

Late syphilis (>1-year duration) is asymptomatic ("late latent" stage) in most untreated individuals. The bacterial burden, though systemically distributed, is thought to be relatively low. Even in the preantibiotic era, most untreated persons with syphilis failed to develop further clinical manifestations during the remainder of their lives.[63] This observation, coupled with the reversion to seronegativity in the cardiolipin-based tests available at the time, led some to postulate that spontaneous cure occurs in a proportion of persons with untreated late latent syphilis. There is no microbiological evidence for cure, and some VDRL nonreactive persons develop tertiary syphilis. Therefore, it should be assumed that infection is chronic in untreated individuals. Late active disease (termed "tertiary syphilis") ultimately appeared in ~30% of infected persons in the preantibiotic era and was most frequently manifested as gummatous tissue destruction, cardiovascular involvement (aortitis, aortic aneurysm), or symptomatic late neurosyphilis (tabes dorsalis, paresis, optic atrophy).[63]

ANIMAL MODELS OF TREPONEMAL INFECTIONS

The rabbit is the standard experimental model for syphilis, although other mammals, including nonhuman primates, can be infected with *T. pallidum* subspecies.[64] Whereas the mouse is the preferred experimental host for many infections, *T. pallidum* fails to induce disease in this animal although organisms can be recovered from tissues of inoculated mice.[65] There is reportedly some host "preference" among the *T. pallidum* subspecies, and hamsters appear to be better hosts for subspecies *pertenue* and *endemicum*[64,66] in terms of the development of clinical disease. *T. carateum* will grow only in nonhuman primates.[67]

The rabbit is the most widely used animal model because infection results in disease that closely resembles human infection in terms of clinical manifestations, histopathology, and immune responses. Intradermal infection of rabbits results in development of chancres that enlarge, ulcerate, and heal as in humans. If the backs of such rabbits are kept clipped, a proportion of animals will subsequently develop disseminated lesions that mimic human secondary syphilis. Disseminated lesions will also appear on the clipped back following inoculation by the intravenous route, although immunologically this is considered a disseminated primary infection. Organisms are most readily propagated by intratesticular infection, and bacteria can be extracted from testis tissue during peak orchitis. Rabbits, like humans, have persistent latent infection (demonstrated by the ability to isolate *T. pallidum* from rabbits that have been infected for years), although symptomatic tertiary disease is not recognized. Extensive pathological studies of rabbits with longstanding syphilis suggested a number of abnormal findings; however, the specificity of these findings to syphilis is unclear.

Nonhuman primates are the only species in which symptomatic tertiary syphilis has been described.[68]

Congenital syphilis, a major cause of human neonatal morbidity and mortality worldwide, has been replicated in guinea pigs and rabbits in limited studies.[69–71]

PATHOGENESIS AND IMMUNE RESPONSES

ATTACHMENT, INVASION, AND DISSEMINATION

One of the requirements for infection is the attachment of the pathogen to host cells. *T. pallidum* readily attaches to eukaryotic cells and has been demonstrated to be fairly promiscuous in its attachment to a variety of cell types,[72–74] perhaps reflective of its ability to disseminate to and infect many tissues. Bacterial adhesin(s) and the cognate eukaryotic cell surface receptor(s) have not been identified for *T. pallidum,* although it is recognized that immune serum (collected from infected rabbits) will inhibit attachment of the organisms to eukaryotic cells in vitro.[73,74] This area of research was inactive for two decades until recent work by Cameron and colleagues[75,76] applied molecular and informatics approaches to identifying adhesins of *T. pallidum.* Through their work, the individual proteins that specifically bind the extracellular matrix (ECM) components laminin[75] and fibronectin[76] have been identified and characterized. Fibronectin and other ECM molecules are frequently used by bacterial pathogens as an early step in attachment in which the ECM molecules, which also have cell-binding domains, serve as a bridge between the host cell and the bacterial cell. Fibronectin and laminin are widely distributed in serum and in tissues and may play a role in the ability of *T. pallidum* to disseminate. Laminin is also abundant in the basement membranes that lie beneath endothelial and epithelial cells, and the ability of *T. pallidum* to bind to laminin may facilitate initial infection through the epithelial surfaces and dissemination by guiding bacterial migration into the vasculature. Specifically, Tp0155 and Tp0483 bind to fibronectin,[76] and Tp0751 binds to laminin.[75] In each case, antibodies raised against the recombinant proteins effectively inhibit binding of *T. pallidum* to the respective ECM component in vitro. Antibodies to these proteins are also induced by active infection, demonstrating that the proteins are expressed in vivo, and it is assumed that antibody-mediated inhibition of binding may also occur in the host after the acquired immune response develops. The demonstration that these proteins function in attachment of *T. pallidum* to ECM implies that they are surface exposed on the intact treponeme. While formal proof of their outer membrane location has not been provided, the existing data are most consistent with surface exposure. Other than the ECM-binding proteins, no other putative *T. pallidum* adhesins have been identified at the molecular level.

It is well recognized from the clinical course of syphilis that early and widespread dissemination occurs. The organism can rapidly pass through intact genital mucosa[62] and can be identified in regional lymph nodes within hours of intratesticular inoculation in rabbits.[77] In vitro models have demonstrated *T. pallidum* traversing an endothelial monolayer via intercellular junctions,[78] although this may not be the only route. It is widely assumed that the active motility of the organism is essential for invasion and dissemination; this is supported by the fact that 5–6% of the *T. pallidum* genome is devoted to putative chemotaxis and motility-related genes.

INNATE HOST RESPONSE

The role of the innate immune response to infections has become an area of intense research in recent years. The previously held belief that the primary defensive function of epithelial surfaces of the body was to serve as a passive physical barrier to pathogens has been modified by the recognition that toll-like receptors (TLR) can be expressed on many epithelial surfaces (reviewed in 79). In response to common pathogen components (e.g., LPS, lipoteichoic acid, CpG DNA, flagellin), epithelial cells can be triggered to produce proinflammatory cytokines and chemokines. These serve to attract professional antigen presenting cells (APC) that also express TLR, thus amplifying the proinflammatory signal in the host.

Unlike most gram-negative bacteria, *T. pallidum* lacks LPS[42,43] and thus does not activate cells through TLR4. Radolf and coworkers showed that the lipid portions of treponemal lipoproteins (e.g., Tp47, Tp15, Tp17) serve to activate cells through TLR2/TLR1 heterodimers.[80–82] Because these lipoproteins are not on the surface of *T. pallidum,* the organisms may be able to escape immediate detection by the innate immune system, thus providing time for initial multiplication and dissemination. Although we know that an inflammatory response is eventually triggered by *T. pallidum*, the precise mechanics of signaling are still unresolved. Lipoproteins may be released from dying treponemes in vivo, thus allowing their interaction with TLR2 on the surface of epithelial, endothelial, or APC. Invasion of tissues by *T. pallidum* would also bring the bacteria into direct contact with dendritic cells, macrophages, and other known APC, which would ingest and process the antigens, thus releasing the lipoproteins for recognition by TLR expressed inside the phagocytic vacuole. In either case, APC containing *T. pallidum* antigens travel to the draining lymph nodes where T lymphocytes initially become sensitized. These *T. pallidum*-sensitized T cells then traffic to the sites of infection and high bacterial concentration, thus establishing a potent and very effective acquired immune response.

ACQUIRED IMMUNITY AND BACTERIAL CLEARANCE

Syphilis is a disease in which the clinical manifestations appear to be caused by the inflammatory and immune responses rather than by any direct cytotoxic effect of *T. pallidum*. Extraordinarily high ratios of *T. pallidum* to mammalian cells are necessary for any evidence of direct cytotoxicity in vitro,[83] and the genome of *T. pallidum* does not contain orthologs of known bacterial toxins. The induration of the primary chancre is due to the infiltration of the site by large numbers of lymphocytes and macrophages; the tissue destruction seen in the ulceration of the primary chancre and in late gummatous syphilis is due to endothelial proliferation in local capillaries, with occlusion of the lumen resulting in localized tissue necrosis. Similarly, in congenital syphilis, damage to the fetus is not apparent until the fetal immune response is sufficiently mature to respond to the presence of the bacteria.[84] As mentioned above, the inflammatory effects of *T. pallidum* are mediated primarily by the lipid moiety of the lipoproteins (e.g., Tp47, Tp17, Tp15). Numerous *T. pallidum* antigens, including the lipoproteins listed above, the endoflagellar proteins (e.g., FlaA, FlaB1, 2, 3), and the Tpr protein family (e.g., TprA-TprL), have been shown to stimulate T-cell responses, including interferon-gamma (IFN-γ) production, in the rabbit model.[85–87]

BACTERIAL CLEARANCE

Studies of experimental syphilis have shown that T-cell infiltration occurs as early as day 3 following infection and continues to increase in magnitude in parallel with *T. pallidum* numbers.[88,89] Macrophages next infiltrate the site and, within days of significant macrophage infiltration, the number of treponemes in the tissue declines precipitously (termed "bacterial clearance"). With smaller inocula or in natural infection in humans, the same process occurs, albeit with a longer time frame.

The observations that bacterial numbers decline rapidly after macrophage infiltration, coupled with the demonstration that macrophages can phagocytize opsonized *T. pallidum* in vitro,[90] strongly suggest that the major mode of bacterial clearance and lesion resolution is phagocytosis of treponemes by macrophages.[88,89] Subsequent studies by Baker–Zander and coworkers demonstrated that *T. pallidum* are killed following ingestion by macrophages in vitro,[91] and that this is dependent upon the presence of opsonic antibody. Interestingly, a small subpopulation of treponemes escapes active clearance in early lesions and Baker–Zander demonstrated that these surviving organisms are refractory to phagocytosis.[92] This resistance may be due in part to antigenic variation, discussed below.

The T lymphocytes that infiltrate early syphilitic lesions in humans[93–96] and rabbits[96a] include both $CD4^+$ and $CD8^+$ cells. The cytokine profile of the cellular infiltrates, in rabbits[96b] and humans,[97] is skewed very heavily toward the Th1 type, with IFN-γ predominating. IFN-γ production parallels the bacterial number in syphilis lesions (Fig. 36-3). Little to no IL-4 (a Th2 cytokine) is produced. IFN-γ can be produced by both $CD4^+$ and $CD8^+$ lymphocytes, and IFN-γ is consistent with the hypothesis that activated macrophages are the primary effector cell in the resolving early lesion.

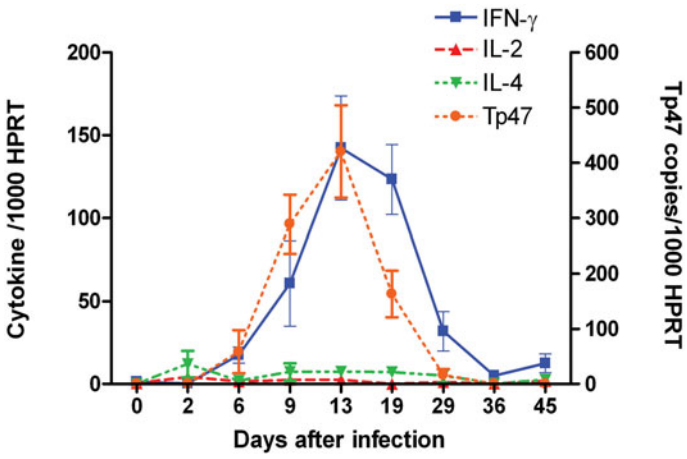

FIGURE 36-3. Quantitation of interferon-gamma (IFN-γ), interleukins 2 and 4, and *T. pallidum* (represented as Tp47) during progression and healing of chancres in rabbits, as measured by quantitative reverse transcriptase polymerase chain reaction. Copies of message for cytokines and Tp47 are normalized to 1000 copies of a housekeeping gene, hypoxanthine phosphoribosyl transferase (HPRT). IFN-γ is the most abundant cytokine and its level parallels the bacterial load, as measured by Tp47. (Unpublished data).

The presence of both activated T lymphocytes and macrophages at the site of an ulcerative lesion (primary chancre) may explain the well-recognized association of syphilis with higher rates of acquisition and transmission of HIV.[98–100] HIV has been isolated from swabs of genital ulcers, including primary syphilis chancres.[101,102] Stimulation of macrophages by treponemal lipoproteins upregulates both HIV-1 gene expression[103] and expression of CCR5 (a coreceptor for HIV) on peripheral blood mononuclear cells.[104]

ANTIBODIES IN SYPHILIS

Antibodies are produced during syphilis infection, and detection of antibodies is a major tool in diagnosis and screening for syphilis. As described in Chapter 63, serodiagnosis of syphilis is based upon antibodies to lipid antigens in the VDRL and RPR (so-called "nontreponemal") tests and to predominantly protein antigens in the FTA-ABS, TPPA, and TPHA ("treponemal") tests. The functions of the antibodies measured by these tests are not known, except that anti-VDRL antibodies can opsonize *T. pallidum* for phagocytosis by macrophages and, thus, comprise a portion of the opsonic capacity of immune serum.[105]

An early serological test for syphilis (the "*T. pallidum* immobilization," or TPI, test) measured the ability of serum

antibodies to render *T. pallidum* immobile in the presence of complement.[106] Bishop and Miller demonstrated that antibodies and complement can neutralize, or render noninfectious, *T. pallidum* following a long incubation in vitro,[48] although molecules that are the targets of these immobilizing and neutralizing antibodies have not been defined. Recent work by Blanco and coworkers demonstrates, for the first time, that a monoclonal antibody with specificity for a phosphorylcholine moiety putatively located on the surface of *T. pallidum* is highly effective in immobilizing and neutralizing *T. pallidum.*[107] It should be noted that phosphorylcholine is a component of the VDRL/RPR lipid antigen mentioned above that induced opsonic antibody. The role of immobilizing and neutralizing antibodies in the infected host is unclear. It is recognized that there are large numbers of circulating treponemes in the host during early syphilis, even after the development of measurable immobilizing antibody. Further, the successful immunization studies of Miller (described below) demonstrated complete protection of immunized rabbits against *T. pallidum* challenge even in the absence of measurable immobilizing antibody.[108]

The identities of protein targets of opsonizing antibody remain controversial and are embroiled in the discussion about the nature of outer membrane proteins in *T. pallidum.* Centurion-Lara[109] and colleagues reported that TprK (TP0897) is a target of opsonic antibody, but Hazlett et al. failed to reproduce these results.[110] Cameron and coworkers provided evidence that Gpd (Tp0257)[111] and Tp92 (TP0326)[33] are located in the outer membrane and are targets of opsonic antibody, but Shevchenko et al. reported that GPD (called GlpQ in their report) is entirely subsurface.[112] Thus, although it is well recognized that opsonizing antibodies are induced by infection, the identities of their specific molecular targets is unclear at this time.

EVASION OF HOST IMMUNITY AND ESTABLISHMENT OF LATENT INFECTION

Despite the dramatic clearance of billions of treponemes from early syphilitic lesions and the development of opsonizing, neutralizing, and immobilizing antibodies, syphilis is a chronic infection in which treponemes persist in the host for decades. Administration of large quantities of high-titer antibodies from infection-immune rabbits only partially protects recipients from infectious challenge.[113–116] A number of hypotheses have been proposed to explain this persistence, including localization within host cells,[117] masquerading by coating the bacterial surface with host proteins,[51] relative lack of surface exposed protein antigens,[44,45,52] and specific or generalized immunosuppression.[118,119] Of these, only the relative lack of surface proteins is currently considered to be a major factor in persistence. As discussed above, *T. pallidum* does have a paucity of integral outer membrane proteins and lacks LPS. Thus, it can effectively avoid triggering an immediate inflammatory response, and discernible cellular infiltration (even in immunized animals) occurs only in response to a large bacterial number ($\geq 10^6$). Thus, the organism has evolved very successful mechanisms for evading the immune response.

One of the most intriguing discoveries in syphilis pathogenesis is the recent description of antigenic variation in *T. pallidum.* The gene encoding TprK, a putative target of opsonic antibody, was demonstrated to have seven sequence-variable regions (V regions); this sequence variation was demonstrated between *T. pallidum* isolates and even within a given isolate.[120,121] Subsequent studies by Centurion–Lara elegantly demonstrated that the mechanism of sequence variation is gene conversion, with new sequences being derived from discrete donor sites elsewhere in the genome.[122] Development of clonal populations of *T. pallidum* (with a homogenous *tprK* sequence) permitted the demonstration that sequence change occurs at a very rapid rate in some strains, and that accumulation of variant sequences within a host is more impressive in the setting of specific immunity.[122,123]

Correlative immunological studies by Morgan and coworkers clearly demonstrated that the V region peptides are the targets of infection-induced antibodies, while the intervening constant regions of the protein are T-cell epitopes.[124] LaFond et al. demonstrated that anti-V region antibodies are exquisitely specific, and that even minor changes in amino acids can abrogate reactivity of the antibodies.[125] Thus, changing the amino acid sequence of the antibody epitope even slightly permits the bacterium to escape the activities of anti-TprK antibodies that are induced during infection. This antigenic variation mechanism likely permits some treponemes to escape the local bacterial clearance during resolution of early lesions and contributes to the long-term survival of *T. pallidum* during latent syphilis and chronic infection.

PROTECTIVE AND LONG-LASTING IMMUNITY

Antibodies and specifically sensitized T lymphocytes can be demonstrated even after many years of infection, suggesting a significant long-term memory response, persisting after penicillin therapy. The role of this immunological memory in prevention of reinfection is unclear. STD clinicians recognize that individuals can have multiple episodes of syphilis. Thus, infection per se does not produce lifelong immunity to reinfection. Controlled studies in the rabbit model have demonstrated that the degree of acquired resistance to reinfection is dependent upon the length of the initial syphilis infection: rabbits infected with *T. pallidum* for 3–6 months, then treated with penicillin, are resistant to symptomatic reinfection with that same strain of *T. pallidum*, while those infected for shorter periods before treatment are susceptible to reinfection.[48,64] Cross-immunity between strains is less complete,

even following long-term infection.[64] Infectious challenge of rabbits with untreated latent infections does not result in symptomatic reinfection. Protective immunity was examined in humans by Magnuson and coworkers[126] who inoculated prisoners at Sing Sing Prison with the Nichols strain of *T. pallidum*. Those subjects who had been treated for syphilis in the past were susceptible to infectious challenge: symptomatic reinfection or increase in antibody titer was seen in those previously treated for early syphilis and in half of those previously treated for late latent syphilis. The only individuals who showed no change following infectious challenge were five persons with *untreated* late latent syphilis and half of those previously treated for late latent syphilis. These studies demonstrate that immunity to syphilis is very slow to develop, is often incomplete except in untreated syphilis, and may be strain specific.

Grassly and colleagues, using modeling methodology, recently proposed that the periodicity of syphilis epidemics is due to developing immunity that appears after "recovery from syphilis."[127] The definition of "recovery from syphilis" is key to the validity of this hypothesis. If "recovery" means those patients who have been treated for latent syphilis, then the level of established immunity in most individuals would be dependent upon duration of infection prior to treatment and would, in many cases, be insufficient to prevent reinfection, particularly with a different strain of *T. pallidum*. If, on the other hand, "recovery" indicates those in whom early lesions have resolved and who now have *untreated* latent infection, developing immunity may in fact contribute to reduced susceptibility to symptomatic reinfections. These individuals would be "dead ends" in terms of transmission. This situation is somewhat reminiscent of the hypothesis of Brunham et al.[128] regarding immunity in chlamydia: does prompt identification and treatment of chlamydia infections within a population prevent the development of meaningful immunity to reinfection in that population? The very long duration of syphilis infection needed to develop functional immunity suggests that a situation similar to that being postulated for chlamydia might also be relevant to syphilis.

IMMUNIZATION AND LIKELIHOOD OF A VACCINE

PROOF OF CONCEPT

The slow establishment of significant immunity during natural infection suggests that development of a vaccine for syphilis is likely to be a very difficult endeavor. In the premolecular era, numerous investigators (reviewed in 129) used standard approaches to antigen preparation (e.g., formalin-fixation and heat-killing) in the hope of creating an effective syphilis vaccine. None of these vaccines was successful, probably because immunity is largely dependent upon an effective cellular immune response rather than the antibody-focused response induced by killed organisms. In now-classic studies, however, Miller[108] hypothesized that there is a fragile, low concentration of protective antigen on the surface of intact *T. pallidum* and that this antigen must be preserved for effective immunization. He attenuated *T. pallidum* by exposure to high levels of gamma-irradiation and, coupled with a strenuous immunization schedule (60 intravenous inoculations of motile, freshly irradiated *T. pallidum* over a 37 week period), was able to demonstrate complete and long-lasting immunity in rabbits to inoculation with the immunizing strain of *T. pallidum*. These studies serve as proof of concept for development of a syphilis vaccine and provide encouragement to those investigators who are searching for an effective immunization protocol.

Many issues remain for development of a human vaccine, including the question of cross-protection among strains, the impractical nature of the attenuation and immunization protocol used by Miller, and the contamination of *T. pallidum* suspensions with rabbit tissue because of the need to propagate *T. pallidum* in rabbits. Today's investigators are examining the effectiveness of immunizing with purified single antigens or antigen combinations in the hope of overcoming these difficulties. To date, these studies have resulted in partial protection at best.

RECOMBINANT PEPTIDE ANTIGENS

Since the advent of recombinant DNA technology, syphilis researchers have produced recombinant *T. pallidum* proteins in *E. coli* and have immunized rabbits using a variety of adjuvants. Many of these studies were unsuccessful and are unpublished; others yielded partial protection (resulting in infection following challenge of immunized rabbits but with significant alteration in lesion development compared to control infections). None has provided complete protection. Recent studies, summarized in the review by Cullen and Cameron,[130] demonstrate that those proteins with putative outer membrane localization and surface exposure (e.g., TprK, Tpr subfamily I members, ECM-binding proteins, Tp92) are generally most successful in inducing measurable, though not complete, resistance to infection. In many of these immunized animals, erythema and induration ("lesions") developed at the challenge sites but they contained few or no demonstrable treponemes, and the lesions failed to progress to ulceration. If a similar "partially protective" vaccine were to be approved for use in humans, it would not protect the host from infection but might impact syphilis transmission by limiting treponeme burden and ulceration. Efforts are continuing to modify antigens, adjuvants, and immunization protocols to increase the level of protection achieved.

LIPIDS AS IMMUNOGENS

Lipid antigens have long been recognized in syphilis and have served as the basis for the original Wassermann test as well as for the VDRL and RPR tests that are currently used for serodiagnosis. The outer membrane of *T. pallidum* contains a paucity of integral membrane proteins, and the lipid membrane comprises the majority of the surface that is exposed to the host. Antibodies raised against the cardiolipin-lecithin-cholesterol VDRL antigen are opsonic, and animals immunized with this antigen are partially protected against infection with *T. pallidum.*[105] The antiphosphorylcholine monoclonal antibody described by Blanco[107] has very potent treponemicidal activity in vitro and in vivo. While these results may suggest the use of lipid antigens in a future syphilis vaccine, care must be taken to ensure that autoimmune responses are not induced. This is particularly important because *T. pallidum* lacks the capability to synthesize its own lipids and derives its membrane lipids from the host. Thus, immune responses resulting from lipid immunization may be misdirected to affect normal host tissue.

CONCLUSIONS

Just as syphilis has fascinated and perplexed clinicians for centuries, the causative agent, *T. pallidum*, continues to challenge investigators who strive to unravel its mysterious nature. Significant challenges lie ahead in terms of in vitro cultivation, genetic manipulation, identification of surface antigens, and the means for inducing protective immunity. Each of these goals is formidable, and the shrinking number of investigators who devote their research efforts to syphilis does not bode well for major advances in *T. pallidum* research. Despite this, the availability of the genome and the development of a number of new molecular methodologies have resulted in significant new information in the past 10 years. However, until an effective syphilis vaccine is developed, control of syphilis will continue to depend on reduction of risk-taking behavior, prompt identification and tracing of contacts, and the continued efficacy of penicillin therapy. Unfortunately, without new tools, the same tired approaches may yield the same high levels of infection that have been seen globally for the past 50 years.

37 Clinical Manifestations of Syphilis

P. Frederick Sparling, Morton N. Swartz, Daniel M. Musher, and Bernadine P. Healy

INTRODUCTION

Syphilis is one of the most fascinating diseases of humans. Untreated infection typically evolves through several stages, termed primary, secondary, and tertiary, each separated for variable times by no clinical evidence of infection, which is termed latency. The interval between primary and secondary stages typically is only weeks to a few months, but the interval between secondary stage and tertiary syphilis typically is many years. This remarkably variable and long-drawn-out course raises many unanswered questions about the nature of the host–parasite interaction. These issues are discussed in Chapter 36 by Lukehart, and the natural history of the disease in studies from the preantibiotic era is discussed in more detail in earlier editions of this book.[1]

The disease has been of great historical importance not only for the practice of medicine but also because of its effect on many persons who played important roles in the history of the Western world. It was an extremely common infection only a few decades past, with prevalence in various autopsy series in the first half of the twentieth century of 5–10%.[2,3] In certain groups of low socioeconomic status studied in the prepenicillin era, syphilis affected 25% or more of the U.S. population. Widespread use of antibiotics after World War II reduced the incidence of early syphilis to manageable proportions, and recognized new cases of late syphilis decreased. However, late syphilis (particularly neurosyphilis) remains an important problem in the Western world, and congenital syphilis is an occasional problem as well. Syphilis remains a very common problem in many other parts of the world, especially Southeast Asia and sub-Saharan Africa. Since syphilis is also an important risk factor for HIV transmission throughout the world,[4] this ancient disease still is highly deserving of our complete attention.

ORIGINS

THE COLUMBIAN THEORY

Syphilis was epidemic in late fifteenth-century Europe, and the early stages apparently were often unusually severe by contemporary standards. The rapid spread and considerable effects of the disease throughout Europe in the last decade of the fifteenth century caused it to be termed the Great Pox, in contrast to another scourge, smallpox. The disease received its present name from the poem by Fracastoro in 1530 about the afflicted shepherd, Syphilis. The late complications of syphilis were recognized early and were frequently mentioned by many Elizabethan authors.

The late fifteenth-century European epidemic coincided with the return of Columbus from America in 1493, causing many to assume that the disease was acquired from natives in the West Indies and carried back to a nonimmune (and therefore particularly susceptible) population in Europe. Certainly, if this did occur, conditions were ripe for rapid transmission, because Europe was engaged in wars at that time, and the movement of the troops and their camp followers created a perfect vehicle for rapid spread of a sexually transmitted disease. On the other hand, there are Biblical and ancient Chinese writings that are consistent with descriptions of late cutaneous syphilis, although other illnesses such as tuberculosis or leprosy could have caused similar descriptions to be written. An illness suggestive of syphilis apparently was not described in early American natives. These and other considerations led some to speculate that venereal syphilis did not arise suddenly in Europe after 1493 but may have been endemic already, only to become more widespread and severe as a consequence of the wars that coincided with the return of Columbus and his men.

TRANSMISSION

The disease is usually acquired by sexual contact, with the obvious and important exception of congenital syphilis, where the infant acquires the infection by transplacental transmission of *T. pallidum.* Transmission by sexual contact requires exposure to moist mucosal or cutaneous lesions of primary or secondary syphilis. Patients with untreated disease may apparently recover only to relapse over a period of up to 2 years. Therefore, a person may be able to transmit syphilis during the first year or two of untreated infection.

The rate of acquisition of syphilis from an infected sexual partner during a single sexual contact has been estimated at about 30%, based on a placebo-controlled study of the efficacy of various antibiotics in aborting syphilis in known contacts within the previous 30 days of patients with primary or secondary syphilis.[5] The dose of the rabbit-adapted Nichols strain of *T. pallidum*, which infects 50% of human volunteers by intracutaneous inoculation, is about 60 organisms, similar to that for rabbits.[6] If the ID_{50} for humans of native or "street strains" of *T. pallidum* on mucosal surfaces is similar, exposure to a relatively few organisms suffices to initiate infection. Syphilis is a systemic disease; treponemes spread via the blood stream beginning during the incubation period,[7] and women may transmit infection to their fetus in utero shortly after onset of infection.[7] Transmission to the fetus in utero has been documented as early as the ninth week of pregnancy.[8] Women remain potentially infectious for the fetus for many years, although the risk of infecting a fetus declines gradually during the course of untreated illness; after about 8 years there is little risk even in the untreated mother.

EPIDEMIOLOGY

Reported syphilis peaked in the Western world in the years around World War II but declined dramatically thereafter, coincident with the general availability of penicillin. In the United States, a significant resurgence of early syphilis occurred in the 1980s, owing to successive waves of disease, first in homosexual males and then in drug-abusing persons. The peak of this epidemic occurred in 1990 and was followed by a steady decline in primary and secondary syphilis, as well as congenital syphilis. Between 1991 and 1995, total reported U.S. cases of primary and secondary syphilis declined from 43,500 to 17,000 and, by 2000, to 6000. Almost all states recorded decreases; incidence remained highest in the south and, nationwide, among African Americans. This decline in early infectious syphilis led some to speculate about elimination of syphilis. Such speculation was not new, but, once again, it proved to be premature, given the increases that followed in subsequent years. A national syphilis elimination effort was launched in 1999, focused on African American heterosexuals in the southern United States.

Between 2000 and 2004, there was a resurgence of early syphilis in the United States, with 8000 cases in 2004, mainly due to an increase in men who have sex with men (MSM).[9] Rates remained highest in the southern states and, especially, among African Americans, where they were five times higher than among whites. This increase coincided with outbreaks of acute HIV infection among college-age men who used the Internet as a means to contact sex partners.[10] In some cities, coincident acute HIV and early syphilis outbreaks were noted in MSM, and behavioral data showed that rates were highest in HIV patients who were taking antiretroviral therapy.[11,12] The conclusion was inescapable that MSM were adopting riskier behaviors, perhaps in the belief that HIV was now a treatable disease. Public health authorities were urged to adopt Internet-based interventions targeted at MSM.[10]

Rates of infectious syphilis are higher in many other areas of the world than in Western Europe and the United States. For instance, rates of early syphilis rose dramatically in the 1990s in certain cities of the former USSR, attributed to a breakdown in public health systems.[13] Infectious syphilis is relatively common in much of sub-Saharan Africa, and in Southeast Asia, including China; the World Health Organization (WHO) estimates that about 4 million new cases occur yearly in each of Southeast Asia and sub-Saharan Africa.[14] Syphilis has resurged in China in recent years and is now epidemic.[15] The prevalence of syphilis in the population in some African communities is 5–10%. Clearly, this infection has not disappeared in the antibiotic era, as some thought it would.

EPIDEMIOLOGIC TREATMENT OF CONTACTS

Because *T. pallidum* has a relatively long doubling time, approximately 33 hours for each cell division, the incubation period before onset of infectious lesions is relatively long also, averaging 3 weeks, but extending as long as 90 days. This allows a window of opportunity for treatment of sexual contacts exposed within the past 90 days to partners with early syphilis (early latent and primary and secondary syphilis), which practice has been crucial to controlling syphilis in the United States. As incidence wanes, resources allocated to public health personnel for finding and treating named contacts often have been cut back, resulting in waves of disease. In less affluent countries, there are few funds for such epidemiologic tracing initiatives, which may help to explain, in part, national disparities in incidence and prevalence of syphilis.

THE STAGES OF SYPHILIS

PRIMARY

The initial lesion of syphilis is a papule that appears at the site of venereal contact, 10–90 days (average 3 weeks) after exposure. The papule grows to a size of 0.5–1.5 cm in diameter and after about a week ulcerates, producing the typical chancre of primary syphilis, a round or slightly elongated ulcer, 1–2 cm across, with an indurated margin (Fig. 37-1). The ulcer has a clear base, without an exudate. It is remarkable that genital ulcers of 1–2 cm in diameter are painless; this feature contributes importantly to the natural history of the infection. Modest enlargement of inguinal lymph nodes, frequently bilaterally, is observed in the majority of patients who have genital lesions. Although

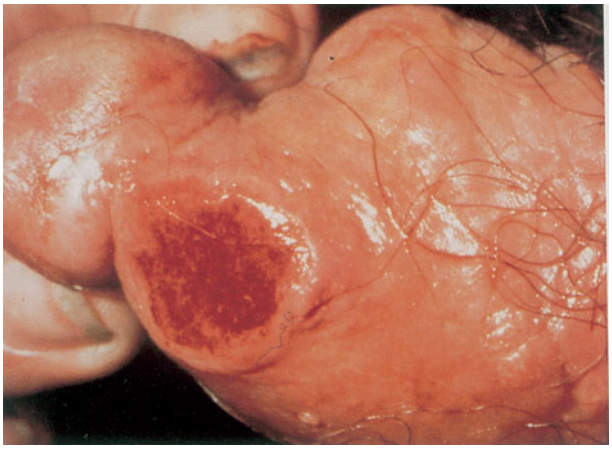

FIGURE 37-1. Primary syphilitic cancre of the penis. Note the rolled edges of the ulcer, the indurated button-like appearance, and the clean ulcer base.

FIGURE 37-2. Primary perianal chancre in a homosexual man.

solitary lesions are often thought to be typical, multiple lesions frequently occur. Primary lesions in nongenital sites are particularly likely to have an atypical appearance, especially in the anal area (Fig. 37-2).

Because of their venereal origin, primary syphilitic chancres most frequently occur in the genital, perineal, or anal area; however, any part of the body may be affected (Fig. 37-3). Most chancres are found on the penis of men and on the labia, fourchette, or cervix of women. Therefore, syphilis is usually diagnosed in its primary stage in heterosexual men. In contrast, because the chancre is not visible in women and is also painless, syphilis is often not diagnosed in women until the secondary stage. The same applies to chancres in the anus or rectum, which are particularly common in homosexual men. Although these lesions may cause pain on defecation or rectal bleeding, becoming confused with hemorrhoids or even a neoplasm, they often go unnoticed, as do those on the labia and cervix.

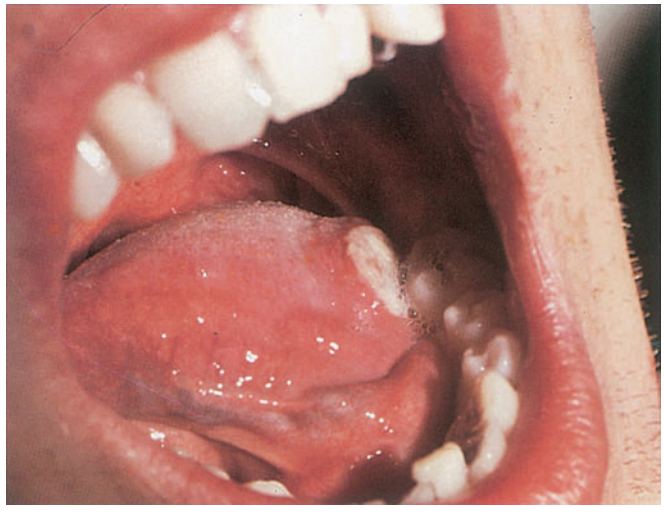

FIGURE 37-3. Primary chancre of the tongue.

In the absence of treatment, syphilitic chancres heal spontaneously within 3–6 weeks. The immune mechanism for healing is obscure but presumably involves both cellular and humoral mechanisms (see Chapter 36).

Differential diagnosis

As a general rule, syphilis should be considered as a possible cause of any ulcerating lesion of the genitalia or other erogenous zone and in any cutaneous area exposed to infectious lesions. Differentiating a syphilitic chancre from chancroid, the lesion caused by *Haemophilus ducreyi*, may be impossible on clinical grounds, although a great degree of tenderness, a jagged border, a yellow exudate, or striking inguinal lymphadenopathy, especially if the overlying skin is thin and shiny, is suggestive of chancroid. A chancre that is smaller, but otherwise indistinguishable from that caused by syphilis, may be transiently present in lymphogranuloma venereum. Simple trauma to the penis or a fixed drug eruption may cause lesions resembling a chancre. It is usually not a problem to distinguish lesions of herpes simplex virus (HSV) infection from those of syphilis, because HSV produces multiple small lesions on which a vesicle might be seen. However, coinfection by *T. pallidum* and HSV may occur, and secondary bacterial infection of a limited vesicular eruption may produce coalescent lesions that can be confused with syphilitic chancres. Moreover, recurrent HSV may present with a single ulcer. Even experienced clinicians are not able to diagnose the etiology of genital ulcer on clinical grounds alone, with more than 60–70% accuracy.

In some regions of the world, genital ulcer may also be due to *Calymmatobacterium granulomatis*, the cause of Donovanosis. A multiplex single-tube polymerase chain reaction (PCR) assay has been devised to diagnose genital ulcers, including *T. pallidum*, HSV, *H. ducreyi*, and *C. granulomatoisis*, with good specificity but less than optimal sensitivity.[16]

SECONDARY

Within a few weeks or months (or less commonly, coincident with the primary lesion) a variable systemic illness develops, characterized by low-grade fever, malaise, sore throat, headache, adenopathy, and cutaneous or mucosal rash.

Evolution of secondary lesions is a manifestation of widespread hematogenous and lymphatic dissemination of *T. pallidum*, as evidenced by the infectious transfer of disease to susceptible animals with blood, lymph nodes, liver biopsy, and cerebrospinal fluid (CSF).[7] At least 25% of patients with secondary syphilis have abnormal CSF, with increased cells, protein and presence of *T. pallidum* by animal transfer or PCR.[17] This spread to the central nervous system is not usually accompanied by neurological signs, and standard therapy for early syphilis in persons without HIV infection appears equally effective for patients with or without abnormal CSF, as discussed below, under treatment.

The initial finding in disseminated syphilis is an evanescent copper-colored macular rash that is usually overlooked by the patient and not observed by the physician. A few days later, a symmetric papular eruption appears, involving the entire trunk and the extremities, including palms of the hands and soles of the feet. The papules are red or reddish brown, discrete, and usually 0.5–2 cm in diameter. They are generally scaly, although they may be smooth, follicular, or, rarely, pustular. Except for the involvement of palms and soles (Fig. 37-4), syphilis may be difficult to distinguish from pityriasis rosea or psoriasis. Vesicles and bullae do not occur except in congenital syphilis of the newborn, although pustular lesions are seen on the palms or soles. Circular (annular) lesions occur on the face of dark-skinned persons. Hypo- or hyperpigmentation may be seen. Alopecia occurs in some cases. Mucosal lesions, either small, superficial, ulcerated areas with grayish borders that resemble painless aphthous ulcers or larger gray plaques, also are common (Fig. 37-5). Erosive gastritis has been documented in rare instances.

Condyloma lata is a term used to describe large, raised, whitish or gray lesions found in warm, moist areas. These lesions were originally described as a manifestation of secondary syphilis, resulting from the effects of local skin breakdown in warm, moist areas; most frequently, the axilla and groin were involved (Fig. 37-6). Today, it is more common to observe condyloma in an area adjacent to a primary chancre, generally in the perineum or around the anus, possibly resulting from direct spread of treponemes from the primary lesion. These lesions appear before or soon after the appearance of the generalized lesions of secondary syphilis.

FIGURE 37-4. Secondary syphilitic rash on palm and sole.

FIGURE 37-5. Mucus patches involving the tongue in secondary syphilis.

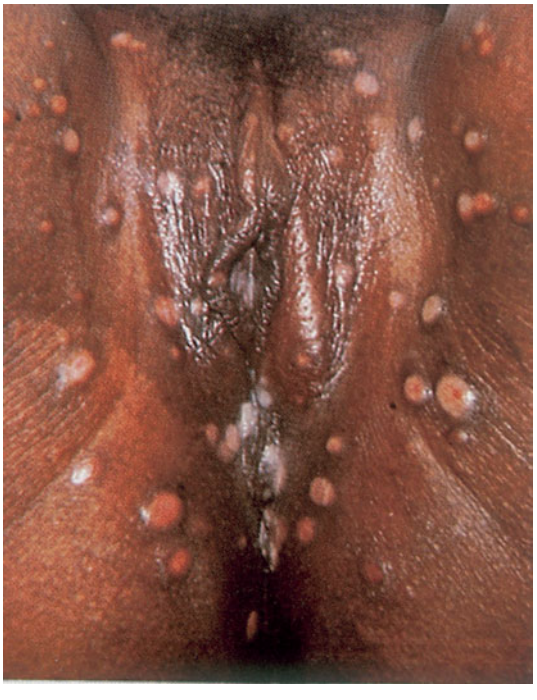

FIGURE 37-6. Perivulvar and perianal condyloma latum in secondary syphilis.

Secondary syphilis is a systemic disease, and interest in the dermatologic manifestations should not blind the physician to the presence of other symptoms, such as malaise, sore throat, headache, weight loss, low-grade fever, or muscle aches Pruritus is not uncommon, and it may be severe. Lymph node enlargement is present in the majority of patients. In one prospective study, 75% of infected persons had palpable inguinal nodes, and 38% had axillary, 28% posterior cervical, 18% femoral, and 17% epitrochlear nodes.[18] Periosteal inflammation was said to be clinically apparent in one-fourth of cases in the pretreatment era, with the skull, tibia, sternum, and ribs being involved most often. In a more recent study, technetium bone scan found lesions in a measurable proportion of cases, but these were asymptomatic; symptomatic bone involvement occurs only very rarely. Subclinical hepatitis can be detected by laboratory studies revealing elevated liver enzymes (particularly alkaline phosphatase) in about one-fifth of cases and is supported by histologic findings; occasionally, symptomatic hepatitis results.[20]

Circulating immune complexes are uniformly present in secondary syphilis, and their deposition is thought to play a prominent role in the pathogenesis of syphilitic lesions. When iritis, anterior uveitis, and glomerulonephritis or nephrotic syndrome occur in secondary syphilis, they are probably mediated entirely by deposition of complexes.[17,21]

Differential diagnosis

The skin rash of secondary syphilis may be confused with pityriasis rosea, psoriasis, especially if it is scaly, erythema multiforme, or a drug eruption. The sore throat, fever, and adenopathy suggest infectious mononucleosis and similar syndromes, including acute HIV infection. In this setting, clinical hepatitis and jaundice occasionally may be observed. The meningitis of secondary syphilis suggests many other causes of lymphocyte-predominant aseptic meningitis, as discussed below under syphilis of the central nervous system. Unless lesions are present on the palms or soles, any cause of a generalized papular eruption may be confused with secondary syphilis. It may be difficult to diagnose syphilis in its secondary stage once the disease is considered, but far more commonly, the physician has simply forgotten to entertain the diagnosis. For these reasons, serological tests for syphilis should be included in evaluations of sexually active adults who have a generalized skin eruption, and syphilis and acute HIV should be considered in any mononucleosis-like syndrome.

LATENCY

By definition, persons with historical or serological (see below) evidence for syphilis who have never received treatment for this disease and who have no clinical manifestations are said to have latent syphilis. The diagnosis of latency formally requires examination of the CSF to rule out asymptomatic neurosyphilis, although most clinicians do not do a lumbar puncture in every patient with probable latent syphilis, as discussed below. Latency has been somewhat arbitrarily divided into early latency and late latency, on the basis of the time when untreated individuals are likely to have spontaneous mucocutaneous (infectious) relapses. In the Oslo study of untreated syphilis at the turn of the twentieth century, secondary relapses occurred in 25% of patients whose infection had become latent, with most relapses occurring in the first year.[22] The U.S. Public Health Service therefore defines early (potentially infectious) latency as 1 year from onset of infection.

TERTIARY

The principal morbidity and mortality of syphilis in adults in past years were due to the late manifestations of illness involving the skin, bones, central nervous system, or viscera, particularly the heart and great vessels. There may be an interval of 1 to over 20 years from the acute infection to clinical onset of the late or tertiary stages of disease, long after the lesions of early syphilis have been forgotten. Studies in the preantibiotic era suggested that about one-third of untreated infections were followed by tertiary complications, of which neurosyphilis was most common, but gummas and cardiovascular disease were also prevalent.[22] In the antibiotic era, all but neurosyphilis are now curiosities in the developed world, probably because of the effects of intermittent antibiotics on the development of gummas and cardiovascular disease.

SYNDROMES OF TERTIARY SYPHILIS

Tertiary syphilis occurs in many clinical syndromes, most conveniently divided into three main groups: neurosyphilis, cardiovascular syphilis, and late benign syphilis.

NEUROSYPHILIS

Abnormalities in the CSF have been noted in 13% of patients with untreated primary syphilis, and 25–40% of patients with untreated secondary syphilis.[23,24] *T. pallidum* has been demonstrated by animal inoculation or PCR in the CSF of 15–40% of patients with untreated primary and secondary syphilis, even in the absence of other abnormalities.[7,18,25]

After the initial spirochetal invasion of the CNS during early syphilis, untreated infection may resolve spontaneously, persist as asymptomatic syphilitic meningitis, or progress to symptomatic acute syphilitic meningitis. Progression of early asymptomatic or symptomatic meningeal infection may lead to meningovascular syphilis (usually 5–12 years after primary infection) or the later forms of neurosyphilis such as tabes or paresis (usually 18–25 years). The progression often represents a continuum of changes rather than a series of discrete steps. It is unclear why some patients never develop neurosyphilis in the absence of treatment, whereas others do.

Table 37-1. Classification of Neurosyphilis

Asymptomatic	31[a]
Early	
Late	
Meningeal	20
Acute syphilitic meningitis	6
Meningovascular	11[b]
Cerebral	
Spinal form	3
Parenchymatous	48
General paresis	12
Tabes dorsalis	30
Taboparesis (mixed)	3
Optic atrophy	3[c]
Gummatous	1
Cerebral form	
Spinal form	
Total	100

[a]Distinction between early and late asymptomatic syphilis could not be made.

[b]"Deafness," comprising 1% of cases in Merritt et al.[26], was included in this category.

[c]"Optic neuritis," comprising 3% of cases in HH Merritt et al.[26], was included in this category.

Data from Merritt HH, et al. *Neurosyphilis.* New York: Oxford, 1946.

A helpful scheme for classifying syndromes of CNS syphilis as seen in the preantibiotic era was provided by Merritt and colleagues (Table 37-1).[26] Although this classification emphasizes individual forms of neurosyphilis, features of several of the entities commonly coexist, producing, for example, combinations of meningitis and vasculitis or tabes and paresis.

Early neurosyphilis: asymptomatic

By definition, there are no clinical manifestations of asymptomatic neurosyphilis; rather, this condition is defined by the presence of abnormalities in the CSF in the absence of other findings of neurologic disease. The usual abnormalities include 10–100 WBC/mm^3 (nearly all of which are lymphocytes), a protein of 50–100 mg/dL and, in 90% of cases, a reactive nontreponemal antibody (Venereal Disease Research Laboratory [VDRL]) test in the CSF. Blood serology (VDRL or rapid plasma reagin [RPR]) is usually but not invariably positive.

The likelihood of finding CSF abnormalities in persons with untreated syphilis increases until 12–18 months after initial infection, and the likelihood that neurosyphilis will develop increases in proportion to the extent of the abnormalities.[27] Conversely, a completely normal CSF examination after 2 years of latent untreated syphilis affords reasonable assurance that neurosyphilis will not develop. Thus, because asymptomatic neurosyphilis tends, in the absence of therapy, to resolve or to progress, its frequency tends to decrease with the passage of time.[28] In the absence of treatment, 87% of persons who had persistent CSF abnormalities for 5 years after infection went on the develop neurosyphilis.[29]

Acute syphilitic meningitis

Acute syphilitic meningitis was relatively rare even before antibiotics became available, accounting for 6% of all cases of neurosyphilis.[26]

Symptoms and signs. The incubation period in the majority of patients with syphilitic meningitis is less than 1 year. In about one-quarter of these patients, meningitis is the first clinical manifestation of syphilis. A small percentage of patients still have a secondary rash at the time of the meningitis.[30] The clinical presentations of acute syphilitic meningitis may be divided into several patterns, but these categories overlap extensively. The principal neurologic manifestations include cranial nerve palsies (seen in 40% of cases) and signs of increased intracranial pressure. The involvement of multiple cranial nerves, particularly the third, sixth, seventh, and eighth, is consistent with an extensive basilar meningitis. Sensorineural deafness occurs in about 20% of patients, commonly in association with other cranial nerve palsies.[31] Deafness is often preceded by tinnitus and may develop rapidly, for example, over 1 or 2 weeks. The hearing loss primarily involves higher frequencies; vestibular involvement is uncommon. Involvement of the eighth cranial nerve may be an isolated finding, and the CSF may be entirely normal. Thus, early acquired syphilis is a cause of potentially reversible, rapidly progressive, or sudden sensorineural deafness and must be considered in diagnosis, even in the absence of clinical findings of secondary syphilis or of overt lymphocytic meningitis.

Acute syphilitic meningitis was relatively common in patients who received inadequate doses of antisyphilitic therapy. Ehrlich documented this association and called the condition neurorecurrence. In the 1990s, this same constellation of symptoms and signs was noted in HIV-infected patients, especially after penicillin treatment, leading to the concept that such disease occurred after treatment of immunologically normal hosts with inadequate antimicrobials or treatment of immune-compromised hosts with ordinarily excellent antibiotics.

Acute syphilitic hydrocephalus was seen in one-third of the cases of syphilitic meningitis reported by Merritt et al.[30]

Symptoms usually develop 3–7 months after primary infection, but they can appear as many as 6 years later. The principal symptoms and signs are those of increased intracranial pressure; fever is only low-grade or may be absent.

Laboratory findings. The CSF changes include elevated pressure, mononuclear pleocytosis of 10–200 cells per cubic millimeter (but occasionally as high as 1000–2000 cells per cubic millimeter), elevated protein concentration (up to 200 mg/dL), elevated globulin level, and a modest reduction in glucose in 45% of cases. The VDRL test on CSF is reactive in most but not all cases. Patients with isolated involvement of the eighth cranial nerve are likely to have a normal CSF with a nonreactive VDRL test.

Pathologic changes. The inflammatory process involves not only the meninges but also the ependyma (granular ependymitis). The meningeal infiltrate consists of lymphocytes and plasma cells located particularly in perivascular spaces. Progressive inflammatory changes produce an endarteritis, which may result in thrombosis, vascular occlusion, and cerebral infarction. This process underlies the focal cerebral signs (aphasia and hemiplegia) and seizures that occur in some patients with acute syphilitic meningitis. Acute syphilitic hydrocephalus develops as a result of obstruction, by organizing exudate, of CSF flow either from the posterior to middle cranial fossa (communicating hydrocephalus) or from the fourth ventricle (obstructive hydrocephalus). Cranial nerve abnormalities result from compression by basilar exudate and fibrous organization or as a consequence of increased intracranial pressure.

Diagnosis and differential diagnosis. Diagnosis of acute syphilitic meningitis is based on the clinical picture of aseptic meningitis, and reactive blood and CSF serology. A history of a recent chancre or secondary rash or the presence of generalized lymphadenopathy may suggest the diagnosis, but meningitis may be the first clinical manifestation of syphilitic infection, especially in HIV-infected patients.

Differential diagnosis includes the various causes of a lymphocytic meningitis, including enteroviruses, HSV, HIV, other spirochetes (*Leptospira or Borrelia* [Lyme disease]), mycobacteria, fungi, drug reactions, malignancy, and autoimmune diseases. Syphilis is likely to be accompanied by reactive serology, which does not, a priori, exclude any other diagnosis. Each of these other conditions may have some unique epidemiologic, clinical, and laboratory features pointing to the correct diagnosis. Acute syphilitic hydrocephalus may suggest the diagnosis of brain tumor, and the presence of low-grade fever and signs of increased intracranial pressure might raise the question of brain abscess.

The clinical features, particularly the distinctive skin lesion, and epidemiology of Lyme disease serve to distinguish it from secondary syphilis. When Lyme disease occurs in the absence of extrameningeal findings, the distinction between the two processes becomes more difficult. The sera and CSF of patients with the neurologic involvement of Lyme disease have been said to be nonreactive in nontreponemal tests.[32] However, 11% of patients with Lyme disease have a reactive fluorescent treponemal antibody (FTA) test after absorption (ABS) with nonvirulent treponemes (FTA-ABS).[33] Furthermore, patients with syphilis show serologic reactivity with *Borrelia burgdorferi*: five of 18 patients with various stages (primary, secondary, latent, and late) of syphilis had positive ELISA tests for Lyme disease, and 11 had positive FTA tests.[32] Utilizing the clinical and epidemiologic features of the two diseases as well as VDRL reactivity and *B. burgdorferi* antibody testing of serum and CSF, distinction between the two spirochetal diseases usually can be made. Western blots may help to resolve serological ambiguity.

Meningovascular syphilis

Vascular neurosyphilis may involve any part of the central nervous system.[34] The common denominator is infarction secondary to syphilitic endarteritis. The process is almost invariably a meningovascular one, stemming from the chronic meningitis that underlies all forms of central nervous system syphilis. In the series of Merritt et al., 10% of patients had this form of neurosyphilis.[26] This disease usually occurs 5–12 years after initial syphilitic infection, which is earlier than the occurrence of paresis or tabes, and most patients are 30–50 years of age. Cerebrovascular neurosyphilis may occur concurrently with, or progress to, general paresis or tabes and may be accompanied by Argyll Robertson pupils in the absence of these complications.

Symptoms and signs. The most common manifestations are hemiparesis or hemiplegia (83% of cases), aphasia (31%), and seizures (14%). Among 241 patients with neurosyphilis studied at the Medical College of Virginia, adult-onset seizure disorders were prominent in 24%.[35] The most common involvement, by far, is the territory of the middle cerebral artery, but any other artery on occasion may be occluded.

The onset of symptoms may be abrupt. However, about 50% of patients have premonitory symptoms of headache, dizziness, insomnia, memory loss, or mood disturbances lasting for weeks or months, probably consistent with diffuse arterial involvement. Psychiatric manifestations (personality and behavioral changes and slowing of mentation and speech) may be so prominent as to suggest the diagnosis of general paresis initially, until the onset of a stroke syndrome.[26,34]

Laboratory findings. Serum RPR is positive in meningovascular syphilis. The CSF VDRL test is positive in most but not all cases, and there is a lymphocytic pleocytosis in the CSF. Angiographic changes include diffuse irregularity and "beading" of anterior and middle cerebral arteries and segmental dilatation of the pericallosal artery.[36] In contrast to the short, irregular sites of atherosclerotic disease, the areas of arterial narrowing in cerebrovascular syphilis tend to be

longer and smoother. Vascular neurosyphilis, rather than atherosclerosis, is also suggested when angiographic changes occur in the supraclinoid portion of the internal carotid artery and the proximal portions of the anterior or middle cerebral arteries, in the absence of stenotic changes at the carotid bifurcation. Computed tomography (CT) shows low-density areas with variable degrees of contrast enhancement, consistent with multifocal infarctions. Magnetic resonance imaging shows focal regions of high signal intensity on T2-weighted sequences, compatible with foci of ischemia.[37]

Pathologic changes. The characteristic histologic changes of the arteritis of cerebrovascular neurosyphilis consist of infiltration by lymphocytes and plasma cells of the vasa vasorum, the adventitia, and, ultimately, the media of large- and medium-sized arteries. Occlusion of the vasa vasorum results in destruction of the smooth muscle and elastic tissue of the media. Concentric proliferation of subintimal fibroblasts narrows the lumen progressively until it is occluded by thrombus formation.

Diagnosis and differential diagnosis. The possibility of meningovascular syphilis should be considered when cerebrovascular accidents occur in a young adult, especially one who has none of the usual risk factors such as uncontrolled hypertension or findings suggestive of embolic cardiac disease. In the older age group, the diagnostic problem is compounded by the greater likelihood of coexisting cerebral atherosclerosis, which may also be responsible for a stroke, even though the patient has, e.g., meningeal (asymptomatic) neurosyphilis.

Differential diagnosis includes other causes of stroke syndromes such as hypertension (lacunar strokes), atherosclerotic vascular disease, cerebral emboli, or various types of cerebral vasculitis. Angiographic changes in cerebral vessels in systemic lupus erythematosus may be indistinguishable from those of syphilitic arteritis, and those in polyarteritis nodosa may be somewhat similar.

Meningovascular syphilis of the spinal cord

Meningovascular syphilis of the spinal cord consists principally of syphilitic meningomyelitis (the most common form) and spinal vascular syphilis (acute syphilitic transverse myelitis).[38] Spinal syphilis has always been rare, representing only about 3% of cases of neurosyphilis. It is almost always associated with cerebral involvement, but the disease of the cord may be preeminent. The basic underlying process is chronic spinal meningitis, which may result in parenchymatous degeneration of the cord directly or as a result of vascular thrombosis.[38]

Symptoms and signs. Syphilitic meningomyelitis usually occurs after a latent period of 20–25 years. The onset is gradual. The earliest symptoms are weakness or paresthesias of the legs, progressing to paraparesis or paraplegia, which is often asymmetric. Urinary and fecal incontinence and variable sensory disorders (pain and paresthesias) in the legs are prominent. On examination, the legs are weak and spastic, and deep tendon reflexes are hyperactive; ankle clonus is present. The most frequent sensory abnormalities are loss of position and vibratory sense in the lower extremities, with a sensory level in about one-third of patients. The clinical picture may be more complex when meningomyelitis develops in the course of tabes or general paresis, or when spinal artery thrombosis supervenes, changing the spastic paraparesis to a flaccid paraplegia. The classic manifestations of spinal vascular syphilis are those of a transection of the spinal cord, usually at a thoracic level, with abrupt onset of flaccid paraplegia, a sensory level on the trunk, and urinary retention.

Laboratory findings. Blood serologic tests are regularly positive and CSF examination discloses the same abnormalities seen in other forms of syphilis (including a positive VDRL test), except in burned-out or old, treated cases.

Diagnosis and differential diagnosis. The diagnosis of syphilitic spinal thrombosis is made when flaccid paraplegia develops abruptly in a patient who has consistent CSF abnormalities and reactive blood and CSF serologies. Other causes of acute transverse myelitis must be distinguished.

General paresis

General paresis (also known as paretic neurosyphilis, dementia paralytica, and general paralysis of the insane) is a meningoencephalitis associated with direct invasion of the cerebrum by *T. pallidum*. The clinical illness is a chronic process that evolves over many years and declares itself in middle-to-late adult life. This form of late syphilis develops 15–20 years after initial infection. Prior to World War II, patients with this disease made up 5–10% of all first admissions of psychotic patients to psychiatric hospitals.[39,40] Although this disease is now rare, it accounted for 10% of cases of neurosyphilis in the first two decades of penicillin therapy.[41]

The clinical picture is that of a combination of psychiatric manifestations and neurologic findings that may mimic almost any type of psychiatric or neurological disorder. The illness is commonly insidious in onset but may occasionally become suddenly evident. The early features are usually of a psychiatric nature, and the course of illness is that of a dementing process (Table 37-2). As the disease progresses, these symptoms are magnified and others appear, including defects in judgment, emotional lability, delusions, and inappropriate social or moral behavior. Grandiose delusions and megalomania, although dramatic manifestations, occur in only 10–20% of cases.[42] Depression may be the predominant presenting feature and the most common initial diagnosis in patients with paresis.[41] Adult-onset seizures, noted in 15–20% of patients, may be the initial manifestation of paresis.[42] Although rare,

Table 37-2. Symptoms of General Paresis

Early	Late
Irritability	Defective judgment
Memory loss	Emotional lability (depression, agitation, and euphoria)
Personality changes	Lack of insight
Impaired capacity to concentrate	Confusion and disorientation
Carelessness in appearance	Delusions of grandeur
Headache	Paranoia
Insomnia	Seizures

Data from Merritt HH, et al. *Neurosyphilis.* New York: Oxford, 1946.

congenital syphilis may present with a paresis-like picture in adolescence, resulting in poor performance in school and behavioral abnormalities.

The most common neurologic findings in general paresis are pupillary abnormalities; flattening of the facial lines, tremors of the lips, tongue, facial muscles, and fingers; and impaired handwriting and speech. Pupillary abnormalities are common in paresis and may be present in other forms of neurosyphilis. The pupils may be large, unequal, and sluggishly reactive to light and accommodation. Over the course of months, normal pupils may change to the Argyll Robertson type defined by the following characteristics: (1) the retina is sensitive (i.e., the eye is not blind); (2) the pupils are small and fixed and do not react to strong light; (3) the pupils react normally to convergence accommodation; (4) mydriatics (atropine) fail to dilate the pupils fully; and (5) the pupils do not dilate on painful stimuli. Argyll Robertson pupils are observed more frequently in tabes than in paresis.

The duration of untreated paresis ranges from a few months, in cases of sudden onset, to 4 or 5 years until death. Uncommonly, spontaneous but transitory remissions have occurred. The shorter the duration and the milder the symptoms at the institution of therapy, the better is the prognosis.

Communicating hydrocephalus has complicated a few cases of general paresis and may account for either lack of clinical improvement or progressive deterioration after treatment.[43] The patients have had gait apraxia, akinetic mutism, incontinence, and pyramidal tract signs along with severe dementia. Isotope cisternograms have shown early ventricular entry of the radionuclide and absence of parasagittal radioactivity. CSF shunting has produced immediate improvement in several cases.

Laboratory findings. Nontreponemal serologic tests of blood and CSF are usually but not invariably positive in cases of paresis.[26,42,44] Other CSF findings are typical of those in neurosyphilis. The CSF may be normal in a patient whose neurosyphilis has been arrested by treatment.

Specific antitreponemal antibody tests of CSF, such as FTA-ABS or micro-hemagglutination assay for *T. pallidum* (MHA-TP), have been studied as a tool to diagnose neurosyphilis in cases in which the CSF VDRL is nonreactive.[45–47] These tests are more sensitive, but they may be reactive as a result of diffusion of serum immunoglobulins into the CSF; for this reason they should probably not be done routinely, although some advocate their use of these to help rule out neurosyphilis.[48–50]

Another approach is to examine intrathecal antibody synthesis of antitreponemal antibodies using the CSF-IgG index, obtained by dividing the CSF to serum IgG ratio by the CSF to serum albumin ratio. A result >0.7 is indicative of IgG synthesis within the CNS, but this finding is consistent with a variety of infectious or inflammatory processes.[51,52] Better evidence for intrathecal antitreponemal antibody synthesis may be obtained if the CSF:serum ratio of *T. pallidum* hemagglutination assay (TPHA) is at least four times higher than the corresponding ratio for some other unrelated but ubiquitous antibody, such as adenovirus hemagglutinating antibody. CSF *T. pallidum*-specific IgM antibody levels have been studied for their utility in diagnosing CNS syphilis[53,54] but have not found widespread use in practice. An increase in proportions of B cells in CSF may help diagnose neurosyphilis.[55] A PCR test on CSF for *T. pallidum* has been reported to be modestly sensitive and specific diagnosing neurosyphilis[18,56] but, to date, has not been applied in clinical practice.

Computerized tomography in parenchymatous neurosyphilis may show extensive regions of decreased attenuation of the cerebral white matter, particularly in the frontal lobes and paraventricular areas of the parietal lobes, together with enlargement of cortical sulci and associated ventricular dilation; such changes are similar to those seen in demyelinating disorders.[57] Cortical atrophy and multiple areas of hypodensity in both cerebellar hemispheres and in the brainstem, consistent with infarctions, may also be seen. Multiple nodular enhancing lesions were observed at the base of the brain in one patient with meningovascular syphilis and cleared completely within 3 months after a 10-day course of intravenous penicillin.[58] Both enhancing lesions (gummas) and generalized cortical and subcortical atrophy have been observed in patients with neurosyphilis.[59]

What should the physician conclude concerning an older adult with a history of prior treated early syphilis who years later has a reactive serum treponemal test, atypical neurologic or psychiatric findings, and CSF abnormalities such as minimal pleocytosis and slightly elevated protein with a negative CSF VDRL? Is this a patient whose treponemal test reactivity

merely represents prior infection and whose current neurologic syndrome has a nonsyphilitic etiology, or does he/she have active neurosyphilis in the absence of serum and CSF VDRL reactivity? This may be a very difficult diagnostic dilemma.

Pathologic changes. Grossly, the brain in general paresis shows varying degrees of thickening of the meninges, consistent with chronic meningitis and fibrosis. Cerebral atrophy is prominent, particularly in the frontal pole and the tips of the temporal lobes. Demyelination of cerebral white matter is often present. Granular ependymitis, formed of whorls of subependymal astrocytes, is characteristic.

Diagnosis and differential diagnosis. The diagnosis is based on the clinical picture, which is readily recognizable in its full-blown form but is more difficult to define when atypical or incomplete, together with characteristic spinal fluid abnormalities. Moreover, other diseases including alcoholic brain disease may mimic paresis, and if they occur in a patient with positive serologies for syphilis, a mistaken diagnosis of paresis may be made. The findings on CT scan, the presence of pupillary changes, and a history of alcohol abuse are helpful in correct diagnosis. Hallucinations are prominent in delirium tremens but are rare in general paresis.

Tabes dorsalis

In the prepenicillin era, tabes dorsalis accounted for about one-third of patients with neurosyphilis. Among several hundred patients with neurosyphilis treated in neurologic clinics in Poland from 1956 to 1965, tabes was the most frequent diagnosis (44%), although in the majority; the process appeared to have "burned out," that is, the disease no longer progressed and CSF abnormalities were absent, either spontaneously or as a result of the incidental use of antibiotics.[60] In a study of late complications of syphilis involving about one-third of the population of Finland between 1963 and 1968, 66 cases of neurosyphilis were identified; of these, two-thirds involved tabes dorsalis.[61] In the 1960s, 30 cases of neurosyphilis (10 of tabes) were seen in one regional neurological center in England over a 3.5-year period. Over the next 8.5-years, only 16 cases, including four of tabes, were encountered.[62] This condition is now a rarity in most of the developed world.

Symptoms and signs. The onset of symptoms of tabes occurs in the majority of untreated patients after a latent period of 20–25 years. The early clinical features are lightning pains, paresthesias, diminished deep tendon reflexes, and poor pupillary responses to light. In more advanced stages, other symptoms and signs become prominent (Table 37-3). Lightning pains are sudden paroxysms of severe stabbing pains lasting for a few minutes at a time. These pains usually occur in the lower extremities but may be felt anywhere. They may occur at long intervals or may persist in attacks lasting for several days at a time. Treatment with carbamazepine or related drugs may be effective.[63] Paresthesias are frequently felt on the legs or trunk. Hyperesthesia may be present in the areas involved by lightning pains; such areas may serve as trigger zones that precipitate bouts of pain when touched.

Table 37-3. Symptoms and Signs of Tabes Dorsalis

	Percent
Symptoms	
Lightning pains	75
Ataxia	42
Bladder disturbances	33
Paresthesias	24
Visceral crises	18
Visual loss (optic atrophy)	16
Rectal incontinence	14
Signs	
Pupillary abnormalities	94
Argyll Robertson pupils	48
Absent ankle jerks	94
Absent knee jerks	81
Romberg's sign	55
Impaired vibratory sense	52
Impaired position sense	45
Impaired touch and pain sense	13
Ocular palsies	10
Charcot's joints	7

Data from Merritt HH, et al. *Neurosyphilis*. New York: Oxford, 1946.

Visceral crises are related to lightning pains, tending to recur in attacks of marked severity that may mimic acute surgical emergencies. The most common form is a gastric crisis consisting of intense epigastric pain, nausea, and vomiting. Intestinal crises (abdominal pain and diarrhea), rectal crises (painful tenesmus), and laryngeal crises (pain in the larynx, hoarseness, and stridor) are rare.

Loss of vibration sense and inability to feel passive movement in joints are among the first detectable signs. Other sensory abnormalities include loss of deep pain perception and development of patchy areas of hypalgesia and hypesthesia over the trunk and extremities. Knee and ankle reflexes are almost always reduced or absent, whereas muscle strength is usually well preserved until the late stages. Plantar responses are flexor; Babinski's reflex indicates the coexistence of meningovascular

syphilis, general paresis, or some unrelated disorder of the CNS. Ataxia of gait is evident, and results of heel-to-shin and finger-to-nose testing are abnormal. In addition to the broad-based, stamping gait, which becomes worse when patients try to walk in the dark, abnormal findings include diminished vision owing to optic atrophy, Charcot's joint (unstable, painless, uninflamed, and markedly enlarged joint with overproduction of bone owing to repeated trauma to this anesthetic structure, especially involving the knee), and mal perforans (a painless penetrating trophic ulcer on the plantar surface at the base of a toe). The spine (particularly the lumbar spine) may be the site of Charcot changes, characterized by dense irregular sclerosis, large parrot-beak osteophytes, scoliosis, and disk-space narrowing. Although the lesion itself is painless, distressing pain may be produced by impingement of the hypertrophic bone or by a disk protruding on posterior nerve roots.

Sluggish pupillary reactivity to light is an early finding in tabes; true Argyll Robertson pupil is a later feature of the disease. Involvement of cranial nerves (particularly the second, third, and sixth) is often overlooked in tabes. Primary optic atrophy appears as sharply defined, grayish white optic disks with conspicuous physiologic cupping, visible lamina cribrosa, and narrowed retinal arteries. If untreated, visual loss progresses to irreversible blindness over months to years. Ptosis and flabbiness of facial muscles probably contribute in a large measure to the so-called tabetic facies. Divergent strabismus may also result from third cranial nerve palsy. Oculomotor weakness is attributed to basilar meningitis, accounting for its occasional improvement after penicillin therapy. Eighth cranial nerve involvement (hearing loss with or without accompanying vestibular abnormalities) is not uncommon.

The time from the onset of tabes to the development of ataxia may be 6 months to 25 years; the longer the duration of the preataxic phase, the slower the subsequent course. In the prepenicillin era, far-advanced tabes was observed with complete incapacitation owing to joint deformity, loss of bladder control, blindness, ataxia, and deafness. Tabes may burn out with time, even in the absence of treatment. Lighting pains may persist even when early treatment has been successful; their presence, therefore, does not indicate continued syphilitic infection. Antibiotic treatment cannot reverse the extensive changes of advanced disease.

Laboratory findings. The laboratory findings in tabetic neurosyphilis are variable, depending on the stage of tabes, whether partial or full treatment has been administered in the past and whether the process has spontaneously burned out. In the prepenicillin era, negative blood serologic reactions were reported in 12–42% of cases. In a 1972 study of seven patients with long-standing tabes, the blood nontreponemal serology was negative in six patients, all of whom had been treated repeatedly but continued to have lightning pains and other manifestations of tabes.[63]

The CSF findings among 100 patients with tabes, including a large number of patients with old, arrested cases, were (1) lymphocytic pleocytosis in 50% (practically all untreated cases), (2) elevated protein concentration (45–100 mg/dL) in 50%, and (3) reactive nontreponemal serologic test in 72%.[26]

Diagnosis and differential diagnosis. A clinical diagnosis of tabes is most likely in a patient with lightning pains and ataxia who exhibits findings of absent deep tendon reflexes, Argyll Robertson pupils, and a positive Romberg sign. Early and atypical cases present greater problems in diagnosis, and only the results of serologic testing and spinal fluid examination may lead to the correct diagnosis. A mixed clinical picture of taboparesis may also be a source of diagnostic confusion.

Differential diagnosis includes a variety of neurologic disorders. Although knee and ankle jerks may be lost in meningovascular syphilis of the spinal cord, lightning pains and pupillary changes are not usually present; ultimately, hyperactive reflexes and extensor plantar responses develop. Adie's syndrome (absent deep tendon reflexes and myotonic pupil) can be distinguished from tabes by the fact that the pupil is not miotic. This syndrome also lacks the lightning pains and ataxia of tabes; serologic tests are negative and CSF examination is normal. Diabetic neuropathy may mimic tabes (diabetic pseudotabes) by producing sluggish pupillary reactivity, ptosis, pains, and ataxia and by absent deep tendon reflexes. However, in diabetic and other types of peripheral neuropathy, the pain is burning in character rather than shooting, as is typical of tabes, and the serologic findings are negative. Combined system disease is similar to tabes in producing ataxia and bladder disturbances, but lightning pains are not a feature. Extensor plantar responses are found in combined system disease but not in tabes.

Optic atrophy and ocular syndromes

Syphilitic optic atrophy, which often is seen in tabes, may appear as an isolated manifestation of neurosyphilis.[64] Other ocular manifestations may also be the first sign of neurosyphilis, including uveitis; clinicians suspecting late syphilis should inspect the eyes carefully and refer patients for ophthalmologic evaluation including slit lamp examination. The usual symptoms of optic atrophy are those of progressive visual loss involving first one eye and then the other. As in cases of tabes, CSF abnormalities are usually present in the untreated patient. Optic atrophy may also result from prior syphilitic optic neuritis. The visual evoked response may make it possible to distinguish primary from postneuritic optic atrophy on the basis of a normal latency in the former.[65] Penicillin treatment can usually prevent further progression of visual loss.

Gummas of the nervous system

Cerebral gummas. Intracerebral gummas are extremely rare.[26] The features are those of a cerebral neoplasm, brain abscess, or tuberculoma. CSF findings are the same as in other forms of neurosyphilis but include increased CSF pressure. CT scan may reveal a low-density nonenhancing area, and angiography may show a hypervascular blush zone surrounding the focal area of gummatous necrosis.[66] The diagnosis may only be made when the patient is operated on for a suspected intracranial mass lesion. Recent literature contains anecdotal accounts of cerebral gummas, mostly in HIV-infected persons.[67]

Atypical presentations of neurosyphilis in HIV infection?

As the incidence of neurosyphilis has continued to decline in the antibiotic era, atypical presentations of this disease have been noted.[35,68,69] One reason may simply be decreased familiarity with the full range of manifestations of neurosyphilis. It is also possible that the clinical features and the course of neurosyphilis have been modified by antibiotic treatment of intercurrent illnesses during the latent stage of syphilis, or by concomitant presence of HIV infection. In a retrospective study, 1.5% of all patients attending a clinic for HIV-related disease had been diagnosed as having neurosyphilis.[70] Holtom et al. screened 312 entrants to an AIDS clinic and found 71 with reactive RPR and MHA-TP tests.[71] Of these, 33 consented to have a lumbar puncture; three (10%) had reactive VDRL in the CSF. Thus, prevalence of neurosyphilis was at least 1% (three of 312). Dowell et al. found that when 13 asymptomatic HIV-infected patients with serum RPR $\geq$1:4 submitted to a lumbar puncture, the CSF VDRL was reactive in seven (54%); five of these subjects had increased white blood cells in their CSF and six had elevated protein, as well.[72] Since many clinics that provide care for HIV-infected patients find that 5–10% of all patients have serum RPR reactive at $\geq$1:4, these data are all consistent with a prevalence of asymptomatic neurosyphilis exceeding 2% in HIV-infected patients.[71,72]

Neurosyphilis often occurs in persons whose HIV infection has not yet progressed to cause AIDS.[73] The diagnosis of HIV infection may be made first when a patient presents with neurosyphilis. Considering its rarity in the non-HIV-infected population, the diagnosis of neurosyphilis should strongly suggest the coexistence of HIV infection. Failure to treat asymptomatic neurosyphilis in HIV-infected persons may be followed by progression to symptomatic neurosyphilis, generally manifesting itself as a cerebrovascular accident. Recognition of the rapid progression to meningovascular syphilis in HIV-infected persons was probably the first recognition of the coexistence of these diseases.[74] Anecdotes of the dangers of progression to neurosyphilis after apparently adequate penicillin therapy of HIV-positive patients are not uncommon, although large treatment studies of HIV-positive and HIV-negative subjects have not found differences in clinical response overall.[18] Serological responses may be slower or less complete in patients with HIV.[18,75,76]

CARDIOVASCULAR SYPHILIS: CLINICAL MANIFESTATIONS OF ACQUIRED CARDIOVASCULAR SYPHILIS

Syphilis of the cardiovascular system becomes clinically manifest after a latent period of 15–30 years. Most patients are between 40 and 55 years of age at onset, and men are affected three times as often as women. Reasons for the male predominance are unclear, and some have speculated that susceptibility was increased in persons undergoing hard physical labor for prolonged periods. There really is no clear evidence as to why some develop neurosyphilis, others develop cardiovascular syphilis, and others—the majority of untreated patients—never develop symptomatic late disease. Penicillin and other antibiotics appear to have nearly eliminated late cardiovascular syphilis, even in AIDS patients. It is unclear why this is so.

Cardiovascular syphilis may lead to aortic aneurysms, aortic insufficiency, coronary artery stenosis, and, rarely, myocarditis. Its clinical presentation is characterized by the functional disorder resulting from cardiac involvement, and, at times, it may be difficult to distinguish cardiovascular syphilis from other more common varieties of cardiac disease.[77]

Pathology and pathophysiology

The cardiovascular system is not clinically affected in the early stages of syphilis, but older pathology studies suggest that such involvement was common in tertiary-stage disease.[78] However, clinical manifestations of cardiovascular syphilis occurred in only 10% or less of patients with tertiary disease. Aortic, coronary ostial, valvular, and myocardial lesions have been described, but aortitis was the most common lesion, accounting for the majority of clinical manifestations.[79–81]

T. pallidum presumably spreads to the heart during the early stages of syphilis, possibly via the lymphatics, and the organisms lodge in the aortic wall, where they remain dormant for years. The spirochetes appear to have a predilection for the vasa vasorum of the aorta, particularly the proximal aorta, producing transmural inflammatory lesions resulting in endarteritis of these vessels. The proximal portions of the coronary arteries near the ostia sometimes are involved by the obliterative endarteritis. This inflammatory process, which is rich in perivascular lymphocytes and plasma cells, continues for years, long after evidence of early syphilis has passed. This suggests that the lesions of late cardiovascular syphilis have an immunologic basis, as has been proposed for other forms of tertiary syphilis.

Although the initial insult is primarily to the small nutrient vessels of the aorta, all three layers of aortic wall are affected by

the process. Probably because of obliteration of the lumen of the vasa vasorum, the aortic media develops patchy necrosis with subsequent focal scarring. The medial destruction is also associated with the destruction of the important elastic tissue of the media, which sets the stage for subsequent aortic dilation and aneurysm formation. The adventitia, which contains the prominently inflamed vasa vasorum, undergoes fibrous thickening. The overlying aortic intima becomes diffusely diseased, with atherosclerotic changes involving virtually the entire intimal surface of the affected aorta. The extensive plaque formation has been described as "tree barking," and the calcification accompanying these complicated atherosclerotic plaques accounts for the eggshell calcification of the proximal aorta that is often evident radiographically (Fig. 37-7).

Aortic aneurysm

Syphilitic aneurysms, the most common manifestations of tertiary syphilis, virtually always involve the thoracic aorta, particularly the ascending aorta immediately at and above the sinuses of Valsalva. Over 60% involve the ascending portion of the thoracic aorta; 25% involve the transverse arch.[82] Rarely, syphilitic aneurysms of the innominate artery present with cerebral emboli.[82] These aneurysms are typically fusiform or saccular in type. Syphilitic aneurysms do not dissect, probably because of the medial scarring and wall thickening of the chronic inflammatory process.[79]

Characteristically, syphilitic aneurysms remain asymptomatic for many years, before they are detected. Symptoms eventually develop when an aneurysm encroaches on surrounding structures or ruptures. In some cases, aneurysms erode through the chest wall and present as a chest wall mass. More typically, the patient presents with persistent chest pain or with symptoms of a mass lesion compressing adjacent structures, such as hoarseness from recurrent laryngeal nerve pressure. A rare presentation may be with the superior vena cava syndrome and, in association with cough, dyspnea, dysphagia, and hemoptysis, may be misdiagnosed as lung cancer.[83] If aortic insufficiency is not present, there may be no detectable abnormalities on cardiac examination. The chest radiograph may be normal or show a mediastinal mass with typical eggshell calcification outlining the aneurysm (see Fig. 37-7). This finding, however, may also be seen in severely atherosclerotic aortas or aortas from patients of advanced age and is not specific for syphilis. The precise definition of the aneurysm is achieved by aortic root angiography.

Management is largely dictated by symptoms. If a patient presents with evidence of an expanding aneurysm or with chest pain or symptoms of encroachment on adjacent tissue, surgical resection would be appropriate therapy.

FIGURE 37-7. Chest radiograph, after barium swallow, of a 56-year-old man with a history of incompletely treated syphilis. Marked calcification can be seen within the aneurysm of the ascending aorta (*arrow*). (*Courtesy BW Gayler.*)

Coronary artery disease

The coronary arteries may be primarily involved in syphilis, but almost always only the ostia or the most proximal few millimeters of the coronary arteries are affected. The pathogenesis of the coronary arterial disease is an obliterative endarteritis. When the luetic process significantly narrows the coronary ostia, it may lead to ischemic heart disease, including angina pectoris or sudden death.[84] Ordinarily, the acute coronary occlusion would involve such an extensive mass of left ventricular myocardium that the patient would not likely survive long enough to evolve a clinically apparent myocardial infarct. The diagnosis of syphilitic coronary disease should be considered in a patient who has been shown, by coronary angiography, to have isolated right or left main coronary ostial narrowing without atherosclerosis in the rest of the coronary tree and who has a history of syphilis or other signs of cardiovascular syphilis.

Aortic regurgitation

Pure aortic regurgitation without stenosis formerly was a common cardiovascular manifestation of syphilis, occurring in roughly 30% of patients with tertiary syphilis of the cardiovascular system. Aortic regurgitation appears to be due to aortic root dilation with stretching of the aortic valve, leading in many cases to widening of the aortic valve commissures, thickening of the aortic valve leaflets, and a variable amount of aortic valve incompetence.[79] The degree of insufficiency may range from mild to severe and largely determines both the clinical course and its management.

Physical findings of luetic aortic insufficiency include diastolic blowing along the lower left sternal border, increased aortic second sound, and if the aortic insufficiency has been severe enough, a prominent left ventricle that is both hypertrophied and dilated. A tambour-like quality of the second heart sound has been commonly described in syphilitic aortic valve disease, probably owing to the aortic root dilation. If aortic stenosis also is present, the cause is highly unlikely to be syphilic.

The differential diagnosis of chronic pure aortic insufficiency (i.e., without a component of stenosis) includes healed infective endocarditis, congenitally malformed valves, Marfan's syndrome, ankylosing spondylitis, Reiter's syndrome, trauma with cusp dehiscence, or aging and aneurysm in a sinus of Valsalva. Cardiovascular syphilis can usually be distinguished from these other conditions by findings including aortic root disease, a tricuspid aortic valve with normality of the other cardiac valves, and the absence of stigmata of metabolic and connective tissue diseases.

Management of syphilitic aortic insufficiency is dictated by the symptoms and hemodynamic status of the patient. Congestive heart failure and chest pain are indications for valve replacement. Unfortunately, symptoms often develop at a time when the heart has already been hypertrophied and dilated, and, despite valve replacement, a secondary valvular myocardiopathy remains. Technical aspects of surgery for syphilitic aortic insufficiency are generally no more difficult than for rheumatic valvular disease; the area of the sinuses of Valsalva and the most proximal aortic root tend to be scarred and thickened and therefore provide a good foundation for valve implantation. The state of the aorta should be carefully assessed both before and after valve replacement. Progressive thoracic aortic dilatation can occur after aortic valve replacement for syphilitic aortic valve disease and may require surgical repair, as well.[85]

LATE BENIGN SYPHILIS

Late benign syphilis or gumma is a proliferative granulomatous inflammatory process that may be destructive of affected tissues. Most lesions occur in the skin and the bones, with a lesser frequency in the mucosae and certain of the viscera, muscles, and ocular structures. In some ways, the classification is misleading, since gumma of the myocardium, brain, spinal cord, or trachea with stenosis may be anything but benign.[86]

Incidence

In the preantibiotic era, gummas were common, but, for unclear reasons, in the United States, they became much less common in the decade before the introduction of penicillin and all but vanished by 1960. A critical review of the Oslo study, originally conducted in the late nineteenth century, showed that 15.8% of 1147 patients "sooner or later" developed late lesions of the skin, mucous membranes, or bones and joints.[22] Twenty-five percent of men and 35% of women had recurrent episodes.[22] In contrast, a search of medical records at Vanderbilt University and Nashville General Hospitals by the late Dr. Rudolph Kampmeier disclosed only a single case during a 15-year period in the 1970s and 1980s. The literature post-1990, however, contains scattered anecdotes of gummatous lesions of many organs (brain, bones, skin, and others) mainly in HIV-infected persons.[87–89] Thus, physicians still must be aware of this relatively rare form of syphilis.

Pathogenesis

The gumma is thought to represent an inflammatory response to a few organisms. The demonstration of *T. pallidum* in lesions was difficult; animal inoculation rarely was successful, and silver stains usually were unrewarding. The best evidence in support of hypersensitivity was provided by Magnuson et al., who inoculated volunteers in Sing Sing Prison with the Nichols strain of *T. pallidum*. Gummas developed only in persons with a history of previous syphilis.[6] Magnuson et al. concluded that superinfection in a sensitized patient may explain gumma formation.

Pathology

Syphilitic inflammation is generally relatively mild but chronic, and slow destruction of tissue leads to eventual fibrosis. The early inflammatory nodule has a granulomatous character closely resembling the lesion of tuberculosis. Grossly, gummas are nodules that may be found in any tissue or organ and may vary from microscopic size to many centimeters in diameter. The necrotic material in the larger nodules is of a gummy consistency, hence the term gumma. The histologic picture shows coagulative necrosis surrounded by lymphocytes and mononuclear cells; multinucleated giant cells appear only rarely. The lesion is encapsulated by proliferating connective tissue, with vascularized connective tissue extending outward from the necrotic area. When the skin or mucous membrane is involved, an ulcer develops. Deep scarring accompanies the healing of gummas.

Clinical manifestations

The presence of any chronic inflammation, tumefaction or tumor, or destructive lesion of any tissue or organ of the body suggests that syphilis be considered in the differential diagnosis.

Skin. Two forms may appear: a nodular or noduloulcerative and a solitary lesion.

Nodular and noduloulcerative lesions. The nodular lesion is a deep indurated nodule that varies from pinhead to pea size and is brownish red in color. The multiple nodules are distributed

usually in an arciform pattern with predilection for the face, the scapular and interscapular areas, and the extremities. They may remain for weeks or months and may heal without breaking down but still may show scarring. If nodular lesions break down to the noduloulcerative form, they heal leaving an atrophic noncontractile scar (Figs. 37-8 and 37-9). If untreated, they will heal, but over time (up to years) new nodules appear at the margins of the previous site, advance in a serpiginous fashion, and may eventually cover by scar an area as large as the whole back. These lesions resolve promptly with effective treatment.

The solitary gumma. The solitary gumma is a subcutaneous process that involves the skin secondarily. It is more common on the thighs, buttocks, shoulders, forehead, and scalp. As it becomes necrotic, it has the characteristics of a "cold abscess," as in other granulomatous diseases. It may drain through one or more areas (Fig. 37-10).

Skeleton. Tertiary syphilis of bones was about as common as gumma of the skin. Although the gumma is a destructive process, it may be hidden by the osseous or perosteal reaction. The radiographic manifestations include periostitis, gummatous osteitis, and sclerosing osteitis. The clinical characteristics include pain (especially nocturnal), tenderness, swelling, bony tumor, stiffness, and limited motion. Less common symptoms are heat, redness, and draining sinuses. Gumma of skeletal muscle is recognized by biopsy or by resolution of the tumor under therapy.

Recognition of skeletal involvement by congenital syphilis may come late in life; one of the authors (M.N.S.) has seen an elderly patient who presented with fractures of the leg bones thought to be secondary to osteomyelitis until it was recognized that periostial elevation typical of congenital syphilis was seen in many long bones as well as the cranium.

Upper respiratory tract, mouth, and tongue. Gummatous osteitis of the nasal bones, hard palate, and nasal septum, as well as perichondritis of the latter used to be relatively common (Figs. 37-11 and 37-12).

Digestive system. The clinical picture of the rare gumma of the esophagus suggests carcinoma. Esophagoscopy may reveal an ulcer, tumor, or stricture. Gastric syphilis may mimic either a malignant or a benign gastric ulcer clinically and radiologically. Gumma of the liver was the most

frequent type of gastrointestinal tertiary syphilis. Some patients remain asymptomatic. However, there may be symptoms of low-grade fever, weight loss, and epigastric pain and tenderness.

Myocardium. Myocardial gummas, especially of the left ventricle and commonly asymptomatic, have been reported on occasion. Rarely, complete heart block resulted from gummatous involvement of the atrioventricular bundle.

DIAGNOSIS

The principal challenge in diagnosing syphilis is remembering to include it in the differential diagnosis.

DARKFIELD EXAMINATION

The most specific and sensitive method for verifying the diagnosis of primary syphilis is the finding of treponemes with characteristic appearance by darkfield microscopic examination of fluid obtained from the surface of the chancre. *T. pallidum* is slender, actively motile with sudden bending motions, and has pointed tips and about 16 coils. This test result is nearly always positive if a good specimen is provided to an experienced observer, provided that there has been no prior therapy with antibiotics or application of ointments that render the reading difficult. If no exudate is present, abrading the chancre and adding a drop or two of saline yields an adequate specimen. False-positive readings do not occur if trained observers are doing the study, even if the material has been obtained from oral lesions. Although treponemes can be detected in secondary lesions, it is much more difficult to prepare the sample, and almost no one uses this technique for diagnosis in secondary syphilis, except in cases of condyloma lata. Darkfield examination has no place in diagnosing late syphilis.

CULTURE

No method has been developed for culture outside of animals, despite years of trying by many investigators. *T. pallidum* can be grown in animals, and isolation in rabbits has been used in test of clinical materials[18] (see Chapter 36).

MOLECULAR AMPLIFICATION

PCR-based tests have been developed and used in research studies to diagnose either the invasion of the CSF[18,90] or the cause of genital ulcers,[16] but they are not available for routine clinical use.

SEROLOGICAL TESTS

Serologic tests for syphilis fall into two broad categories. Those in the first category, initially described by Wassermann 100 years ago, measure antibody to diphosphatidylcholine or cardiolipin, a component of mammalian cell membranes that is incorporated and, presumably, modified by *T. pallidum*. Subsequent modifications include the VDRL test, developed at the Centers for Disease Control and Prevention, and the RPR. The VDRL test is the test that is still done on CSF, whereas the RPR is a card assay that tests for anticardiolipin antibody in serum. The level of antibody is reported as the greatest dilution of CSF or serum at which the test is still positive. In general, the height of the RPR antibody correlates with the activity of the syphilitic infection.

The second category of serologic tests for syphilis is the one that detects surface-exposed proteins of *T. pallidum* after adsorption to remove cross-reacting antibodies to common, shared bacterial antigens. Until the late 1970s, the standard test was the FTA-ABS. This test was highly specific for *T. pallidum* and very sensitive but required a fluorescent microscope and highly trained personnel. It has largely been replaced by a card assay that uses hemagglutination as the endpoint (MHA-TP or TPHA). A variation on this test now widely used is the *T. pallidum* particle agglutination test. These tests are reported without titration, and the result is positive or negative. Once this antibody appears, it usually persists for life; thus, a positive test indicates present or prior infection with *T. pallidum*. A Western blot test has been studied as an additional method to validate specificity[91] but is not widely used.

Historically, serologic tests for antibody to cardiolipin have been called nontreponemal or nonspecific, whereas those to surface-exposed proteins have been called treponemal or specific tests. Antibody to cardiolipin is, in some senses, an autoantibody, which explains chronic (>6 months) positivity of this test in certain autoimmune diseases, including lupus

erythematosus and the antiphospholipid syndromes—and in the aged. Antibody to cardiolipin also appears transiently (<6 months) in other acute infections, most notably EB virus infection and chicken pox—and after immunizations.

In primary syphilis, the RPR is positive in about 80% of patients at the time they come to medical attention, often at a relatively low level (≤1:16). The MHA-TP is positive in about 90% of such patients. In secondary syphilis, the RPR is always positive and at titers ≥1:16, as is the MHA-TP. In latency, the titer of anticardiolipin antibody falls, although the test is likely to remain positive at a low level. In neurosyphilis, the RPR rises in some, but not all forms, as noted above. The RPR may also be positive at only a low level in cardiovascular syphilis, because weakening of the aortic wall may continue after active disease has burned itself out. In gummatous disease, the RPR is positive at a high level, as might be expected from the immunologic nature of the reaction.

It is important to understand that, although these serologic tests are both sensitive and specific, they are likely to support but not establish a diagnosis of syphilis. For example, a positive MHA-TP with a negative RPR in a patient with a genital ulcer could be consistent with syphilitic chancre. But the MHA-TP may remain from a prior syphilitic infection, and the genital lesion may be due to another organism altogether, e.g., *H. ducreyi*. The same may apply even if both tests are positive. This is why the search for treponemes by darkfield examination should be undertaken whenever possible, even though it is time consuming and requires trained personnel, and why tests should be routinely done for other causes of genital ulcer. A high-titered MHA-TP in the presence of a skin rash strongly supports a diagnosis of secondary syphilis. Nevertheless, *the most reliable use of the MHA-TP test is to use a negative result to exclude the diagnosis of anything other than the earliest stage of primary syphilitic infection.* A negative MHA-TP excludes the diagnosis of syphilis in a patient with a rash that might be secondary infection (so does a negative or low-titer RPR, although the prozone phenomenon rarely may give a false-negative reaction) and also excludes the possibility that neurologic or cardiovascular disease may be syphilitic.

Since, as noted above, RPR reactivity reflects activity of disease, levels are expected to subside after treatment, and the results of this test are followed in order to assess the efficacy of such therapy. After treatment for primary or early secondary syphilis, the RPR generally returns to nonreactive over a period of 1–2 years. The longer the disease persists before treatment, the more likely it is that the test will remain positive at a low level throughout life—the so-called serofast state. Treatment of latent or late syphilis generally is followed by persistence of a positive RPR.

The serofast state may indicate that treatment failed to eradicate treponemes from the body. Treponemes may persist in lymph nodes and the CNS of treated patients and experimental animals.[92,93]

SYPHILIS AND HIV INFECTION

Few published data support the contention that the manifestations of primary and secondary syphilis are altered by HIV infection, and, in fact, prospective studies provide results that refute this notion. In contrast, concurrent HIV infection, whether before or after a diagnosis of AIDS has been made, appears to have an impact on neurologic involvement in syphilis.[94] Cases of therapeutic failures have been described after conventional doses of penicillin for primary or secondary syphilis. Numerous individual case reports have documented the apparently rapid progression of early syphilis to neurosyphilis, manifested as meningitis or cranial nerve defects (most commonly optic neuritis or deafness).[94–97] The term "quaternary neurosyphilis" has been revived to describe necrotizing encephalitis in an HIV-infected patient.[98] In many cases, concurrent HIV infection has been documented for the first time only when neurologic complications appeared. Risk of neurosyphilis is increased substantially—three- to fivefold—in HIV-infected patients with RPR titers ≥1:32 or in whom CD4 counts are <350.[90]

TREATMENT OF SYPHILIS

PRIMARY OR SECONDARY SYPHILIS, NO HIV INFECTION

A single dose of 2.4 million units of benzathine penicillin appears to produce a clinical cure of primary or secondary syphilis. For patients who are unable to take penicillin, ceftriaxone (1 g) intravenously or intramuscularly every day for 10 days[99–102] should provide identical results. Tetracycline 500 mg, four times daily or doxycycline 100 mg twice daily for 14 days[103] may be just as effective. Azithromycin has been used successfully[104–107] to treat syphilis and has the advantage of apparently being curative in primary- and secondary-stage illness after a single oral dose of 1 or 2 g, even in HIV-infected patients.[106] However, clinical failures after single-dose azithromycin therapy have been noted on the West coast of the United States,[108] which has been correlated with mutation of the ribosomal RNA target for macrolide antibiotics.[109,110] As of early 2007, the prevalence of resistance to azithromycin among *T. pallidum* isolates is largely unknown, due to lack of routine testing for resistance, but the extent of documented resistance suggests that use of azithromycin is unwise.[111]

With successful antibiotic treatment for primary or secondary syphilis, lesions disappear within days and the RPR test returns to negative over 1 to 2 years in nearly all cases, declining more slowly in secondary disease. Serologic failure must be differentiated from recurrent (new) infections after treatment for the initial infection. The rarity of tertiary

syphilis in the United States in the past three decades argues that, in practice, recommended doses of penicillin have been remarkably successful in curing syphilis. Some patients who are cured of their secondary syphilis retain low-grade VDRL or RPR reactivity throughout life (serofast state), which does not respond to repeat therapy with the same or other antibiotics.

Patients who fail therapy, as measured by clinical relapse or a fourfold or greater rise in RPR titers, should be retreated, usually with benzathine penicillin in a dose of 2.4 MU IM weekly for 3 weeks. Their HIV status should be rechecked, and a lumbar puncture should be strongly considered.

After treatment for primary or secondary syphilis, about one-third or two-thirds of patients, respectively, have a reaction characterized by chills, fever, arthralgias, headache, and transiently increased prominence of lesions. This is called a Jarisch–Herxheimer reaction (discussed in more detail below).

LATENT SYPHILIS, NO HIV INFECTION

Latent syphilis presents a problem. The diagnosis is based on a reactive RPR and MHA-TP tests in an asymptomatic subject. In the majority of instances in the United States today, this serologic result reflects previously treated rather than active infection. The official recommendation in the 2006 Treatment Guidelines from the CDC[112] is that a single injection of benzathine penicillin, 2.4 million units, be given in early latent syphilis (less than 1 year), but that three injections be given at weekly intervals for late latent syphilis or syphilis of unknown duration.

An important question is whether to perform a lumbar puncture in every patient with presumed latent syphilis, in order to exclude asymptomatic neurosyphilis. In cases where suspicion of untreated or inadequately treated syphilis is high, lumbar puncture should be done. An alternative approach is to do no spinal tap unless neurological disease is present, treating with three doses of benzathine penicillin at weekly intervals, a therapeutic regimen that once was standard for neurosyphilis and in which failures were documented very infrequently. Careful follow-up is mandatory.

The response of latent syphilis to therapy is difficult to assess. Since the patient is free of symptoms, the only possible response, barring the appearance of symptomatic tertiary syphilis, is a change in serologic test results. The RPR titer often remains unchanged (serofast state), or it may decline, but it usually does not return to negative. Rising titers suggest therapeutic failure, in which case a CSF examination must be done and the patient must receive either a repeat of the initial therapy or a more aggressive therapy, as for instance intravenous penicillin for neurosyphilis (see below).

TREATMENT OF PRIMARY AND SECONDARY SYPHILIS IN HIV-INFECTED PATIENTS

Most reports show that HIV infection does not markedly affect response to benzathine penicillin therapy.[112] Concomitant use of probenecid to boost serum levels after oral amoxicillin therapy did not improve response to therapy of early syphilis, regardless of HIV status.[18] The U.S. Public Health Service continues to recommend a single dose of 2.4 million units benzathine penicillin in this situation.[112]

Concern remains, however, that benzathine penicillin may not prevent the progression to early neurosyphilis in HIV-infected persons, based on numbers of individual cases in which treatment of primary or secondary syphilis with benzathine penicillin was followed by rapid progression to neurosyphilis, along with evidence of persisting treponemes in the CSF of HIV-infected patients after treatment.[92,113–115] Those who recommend a single dose of benzathine penicillin state that the percentage of treated cases that fail is so small that they cannot recommend an increased penicillin dose for everyone. Some authorities, in contrast, believe that minimum therapy for primary or secondary infection without neurologic involvement in HIV-infected patients should be three doses each of 2.4 million units benzathine penicillin at weekly intervals.[112] However, there are no data to show that progression to neurosyphilis, the principal concern in this situation, is reduced by the more aggressive therapy.[18] The same may be said for injection of 2.4 million units daily of procaine penicillin plus oral probenecid 500 mg every 6 hours or of 1 g ceftriaxone daily for 10 days.[76,101] There are no data to support use of doxycycline in this situation. Azithromycin appears to be equally efficacious in HIV—positive and negative—subjects,[105,106] but worries about azithromycin resistance raise serious concerns, as discussed above. Additional reservations about the macrolides stem from the facts that the evidence favoring their use in syphilis never was strong and they plainly do not readily cross the blood–brain barrier. Clearly, careful serological and clinical follow-up after treatment is especially important in the patient with early syphilis who is also HIV infected.

TREATMENT OF LATENT SYPHILIS IN HIV INFECTION

Unlike the situation in non-HIV-infected persons, a substantial proportion (5–50%) of HIV-infected persons who have no clinical signs of syphilis, but who have a positive RPR, especially if the titer is ≥1:8, has CSF abnormalities that suggest the diagnosis of neurosyphilis.[99,116] Accordingly, in such cases, lumbar puncture is highly desirable. Odds of finding evidence of neurosyphilis on examination of CSF are increased about sixfold in HIV-infected persons if their RPR is ≥1:32, and about threefold if the CD4 count is <350 cells/mm.[3,90] If CFS analysis is negative, three doses of

benzathine penicillin can be given. If it is positive and there are no other evident causes, treatment should be given for neurosyphilis. If a lumbar puncture cannot be done, many practitioners favor treatment as if neurosyphilis were proven to be present.

TREATMENT OF NEUROSYPHILIS, NO HIV INFECTION

The introduction of penicillin in the 1940s strikingly simplified the therapy and improved the outcome of neurosyphilis. At first, repeated intramuscular injections of aqueous penicillin were administered every 3–4 hours for a total dosage of 2–3 million units over a period of 8–16 days. By the early 1950s, it was apparent that the administration of 6–10 million units of penicillin (as either procaine penicillin G or procaine penicillin in oil with aluminum monostearate) over a period of 18–21 days produced a good therapeutic response in over 90% of cases. In the occasional patient who did not respond, another course of penicillin at a higher dose was usually successful in arresting the infection.

Among 765 patients treated with varying dosages of penicillin (2.4 to more than 9 million units) for asymptomatic neurosyphilis, only one subsequently went on to develop symptomatic disease and was considered an unequivocal treatment failure.[117] Similarly, the results of penicillin therapy of acute syphilitic meningitis have been very good, with clearing of the CSF changes and lack of progression to parenchymatous neurosyphilis. In one series of cases, spinal fluid findings indicated that the disease was arrested in each of 462 patients with various forms of neurosyphilis treated in this fashion.[118] Early reports of results of penicillin treatment of paresis indicated a relatively low rate (6% to less than 20%) of failure of response in the CSF, of clinical progression, or of late complications.[119] Among a group of 58 hospitalized patients with paresis treated with one or more courses of penicillin, 26 (45%) improved and were discharged from the hospital; this result indicates that this form of neurosyphilis is not hopeless, particularly when treatment is instituted as soon as clinical symptoms become evident, but response to therapy is by no means assured.[35,120] In a multicenter study involving treatment of over 1000 patients with paresis, a total penicillin dosage of 6 million units was judged to be adequate.[121]

The prognosis of tabes dorsalis is variable, and the disease can be compatible with long life. About 4–10% of untreated cases become spontaneously arrested at an early stage. In the prepenicillin era, treatment improved or arrested the clinical course in over 80% of cases. However, in view of the nature of the underlying pathology, disappearance of many of the clinical findings would not be expected. Similarly, many of the residual signs and symptoms may persist after penicillin therapy. The most satisfactory therapeutic results are achieved in early cases of tabes, in which the CSF findings are markedly abnormal.

As a result of this clinical experience, for several decades treatment with 7.2 million units of benzathine penicillin G (2.4 million units intramuscularly weekly for three doses) was regarded as adequate for all forms of neurosyphilis. Clinical failures were almost unheard of. The recommended dosages for the treatment of all forms of late syphilis were initially designed to maintain serum spirocheticidal levels of 0.031 unit or more per milliliter.[122] Studies in the late 1960s and early 1970s showed that 2.4 million units of benzathine penicillin produces serum levels $\leq$0.5 μg/mL. Because levels in CSF are probably no more than 2% of serum levels, spirochetacidal levels may not be achieved in the CSF of patients receiving this medication.[123] The principal reason for concern was the description of cases, in which treatment for early syphilis was followed by development of neurosyphilis.[124,125] In retrospect, these cases probably reflect early neurosyphilis (see above) in patients who were HIV infected; HIV infection had not yet been recognized at the time some of these cases were described.

As a result of these considerations, the Centers for Disease Control and Prevention 2006 Treatment Guidelines[112] no longer recommend benzathine penicillin to treat neurosyphilis, instead recommending use of intravenous aqueous penicillin G 18–24 million units daily for 10–14 days or intramuscular procaine penicillin G 2.4 million units plus probenecid 500 mg by mouth four times daily for 10–14 days. This dosage of procaine penicillin is very painful. Some authorities recommend that either treatment should be followed by benzathine penicillin weekly for 3 weeks because of the concept that duration of therapy may be as important as intensity. In Europe and the UK, recommendations are somewhat different, including in the UK primary use of intramuscular procaine penicillin plus oral probenecid, or as a first alternate, oral amoxicillin plus oral probenecid, with intravenous penicillin G as a second alternative.[126] Results appear to be equally good, but lack of suitable clinical trials limits conclusions that can be drawn. It should be emphasized that some authorities continue to recommend three doses of benzathine penicillin, 2.4 million units at weekly intervals to treat neurosyphilis in the absence of HIV infection.

In patients with penicillin allergy, options are limited. One may try to desensitize the patient in a hospital environment, with preparations for possible anaphylaxis.[112] Ceftriaxone penetrates the CSF and has good activity in early syphilis. A retrospective study observed patients for 6–24 months after treatment with 10–14 days of daily IV ceftriaxone, which appeared curative in six of seven with documented neurosyphilis.[72] The use of 1 versus 2 gm of ceftriaxone each day did not appear to have any impact on the outcome. Thus, in a penicillin-allergic patient, ceftriaxone might be considered, although there is still a 10% chance of cross reaction with ceftriaxone.

Follow-up

Clinical (including CSF) examination should be done 3 months after antibiotic treatment of patients with neurosyphilis and then at 6 month intervals, until the CSF findings return to normal.[112] Thereafter, reevaluation should be performed annually for several years. This is particularly important in patients who have been treated with alternative antibiotics, because limited data are available on the long-term efficacy of such therapeutic programs.

Normalization of CSF values may be taken as a reliable sign of antimicrobial efficacy of therapy. Failure of CSF cell count or VDRL to return to normal 1 year after completion of therapy may lead to retreatment, although there may be no further benefit. The recommendation by the CDC to seek advice from an expert sounds reassuring, but there is no consensus among experts as to what, if anything, should be done.

A true failure of therapy may rarely occur, in which an initial normalization of CSF findings is followed by relapse; in such cases, repeat therapy needs to be given. If relapse has not occurred during a period of 2 years after therapy, the patient can generally be regarded as cured.

TREATMENT OF NEUROSYPHILIS IN HIV-INFECTED PERSONS

The best regimens to treat neurosyphilis in HIV-infected persons are not certain. There are anecdotal reports of failure of benzathine penicillin to eradicate early neurosyphilis in HIV-infected patients treated for primary or secondary syphilis,[125] and there is consensus[112] that benzathine penicillin therapy is not indicated for neurosyphilis in HIV-infected patients, as discussed above. Intravenous penicillin is the standard of therapy, as in non-HIV-infected persons. Nonrandomized studies of patients treated with 18–24 million units of penicillin daily showed that some patients relapsed and several others had no apparent response during a relatively short time of follow-up.[127,128] Response to therapy, as measured by time to return of CSF VDRL to normal appears slower in HIV-infected persons.[129] Careful follow-up is required after therapy.

ROUTINE CSF EXAMINATION IN HIV-INFECTED PERSONS WHO HAVE SEROLOGIC EVIDENCE FOR SYPHILIS?

Should the CSF be examined in every patient who has early syphilis and concurrent HIV infection? In the past, CSF abnormalities including the presence of treponemes were found in up to 40% of patients with early syphilis, yet did not require an altered approach to penicillin therapy. In a study of "enhanced therapy" (oral amoxicillin plus probenecid, as compared to standard benzathine penicillin), response to therapy was essentially the same in HIV-infected and HIV-uninfected persons, even though treponemes were observed in CSF in 25% of patients before therapy.[18] This argues against routine lumbar puncture in early syphilis, regardless of HIV status, but many experienced clinicians in the United States and UK advocate lumbar puncture regardless. One must be aware that CSF abnormalities may be present owing to the HIV infection itself, although a CSF WBC count of over 20 cells/mm^3 supports the diagnosis of neurosyphilis.[90] Favoring the routine use of lumbar puncture in HIV-infected persons who have latent syphilis of any duration (e.g., defined by a reactive serum RPR $\geq$1:4 without clinical signs of syphilis) is the observation that a substantial proportion may be found to have evidence of active neurosyphilis.[71,72] Furthermore, repeated CSF analysis provides a means for following the results of treatment. However, repeated determinations of serum RPR may give equivalent insight into response or failure; lumbar puncture could then be reserved for those patients who have clinical or serological evidence for failure or for relapse.

Thus, there is not a clear answer to the question. A lumbar puncture certainly should be done in patients who have symptoms or signs consistent with neurosyphilis, and in any stage of infection when a patient does not show an appropriate serologic response to therapy.

Follow-up

Repeated, close evaluation is required for HIV-infected patients who have evidence of neurosyphilis. Recommendations[112] to do follow-up serum and CSF studies at 3-month intervals should be followed. There is enough questions about the efficacy of any recommended treatment and sufficient likelihood of a relapse, even if initial therapy appears to be effective that a substantial sense of insecurity should characterize the approach of the treating physician to his or her patient.

TREATMENT OF LATE SYPHILIS OF THE CARDIOVASCULAR SYSTEM AND LATE BENIGN SYPHILIS

There are no data in the modern era regarding the best antibiotic treatment of late syphilis of the cardiovascular system or of the other organs affected by "late benign" syphilis. In general, guidelines for late latent syphilis also pertain to late syphilis of the cardiovascular system and also late benign syphilis.

Late benign disease was approaching the vanishing point in the era before penicillin, and this trend was enhanced by the efficacy of penicillin therapy for early syphilis. There are no controlled studies of penicillin in any large series of patients. In 1948, Tucker reviewed the results of penicillin therapy in 50 patients, with either skin or bone disease at the Johns Hopkins Hospital clinics,[130,131] and concluded that satisfactory results were obtained in approximately

90% by the administration of a single course of penicillin. In a 1976 review of the literature on the treatment of late benign syphilis, St John[132] found no subsequent therapeutic trials and accepted Tucker's recommendation of treatment with "at least two million units of penicillin if not more."

TREATMENT OF THE PREGNANT PATIENT

A pregnant patient with primary or secondary syphilis should be treated with penicillin in the same dosages as in a nonpregnant patient. For any pregnant patient with primary or secondary syphilis who is allergic to penicillin, it seems reasonable to consider ceftriaxone, although series of cases showing efficacy have not been described. Moreover, there is a risk of cross-allergic reaction in the order of 10%, and a risk of fetal loss if there is an allergic reaction. The 2006 guidelines from the CDC do not endorse either ceftriaxone or azithromycin in pregnancy because of lack of data.[112] Pregnant women with penicillin allergy should be referred to a specialist for desensitization to penicillin. Erythromycin should not be used because it does not reliably cure an infected fetus.[133] Tetracyclines likewise should not be used in this case because of fetal toxicity. Special care in follow-up is mandatory for both mother and child after treatment during pregnancy, since failure to prevent congenital syphilis by treating pregnant women with penicillin is well documented.[134]

JARISCH–HERXHEIMER REACTIONS

After treatment for primary or secondary syphilis, about one-third or two-thirds of patients, respectively, have a reaction characterized by chills, fever, arthralgias, headache, and transiently increased prominence of lesions. This is called a Jarisch–Herxheimer reaction and is owing to the release of treponemal constituents. The onset is within 4–6 hours after treatment, and it subsides within 24 hours. The symptoms may be impressive in their severity; in one small group of 35 cases in which temperatures were monitored by rectal probe, two patients had peak temperatures ≥103°F.[135] The Jarisch–Herxheimer reaction is not dependent on type or dose of antibiotic used and should not be mistaken for a penicillin allergy. Jarisch–Herxheimer reactions are not an indication for discontinuance of treatment; most reactions can be managed by reassurance of the patient and aspirin or ibuprofen. Some authorities in Europe and the UK recommend concomitant short-term prednisone therapy in certain situations, particularly neurosyphilis, to avert inflammatory consequences of treatment, but this is not recommended in the U.S. guidelines.

FOLLOW-UP

Serologic tests should be repeated at 6-month intervals in non-HIV-infected persons to document the return to a negative RPR. Most patients with early syphilis will revert to VDRL or RPR negativity within 12 months, although a small proportion may remain positive at low titer ("serofast"). Therapy of latent or late syphilis may be followed by low titer seropositivity in a higher proportion of patients, and persisting low titer but stable VDRL or RPR in the face of normal clinical status does not indicate need for retreatment. It is important for the health provider to be aware of variability in testing kits and readers, such that a twofold difference is common in the absence of any change. This explains why repeated tests to document a trend are recommended.

In those situations in which cure is not so certain—patients receiving therapy other than penicillin, infants treated in utero, and HIV-infected persons—follow-up must be especially rigorous. Serologic responses and, where indicated, clinical observations should be checked every 3 months for 1 year and at 6-month intervals for at least another year.

38 Endemic Treponematoses

André Meheus and Francis J. Ndowa

Treponemal infections include venereal syphilis and the endemic (nonvenereal) treponematoses (i.e., yaws, endemic syphilis, and pinta). The similarities between the clinical manifestations of the various treponemal diseases are remarkable. They all have initial lesions followed by more extensive secondary manifestations, and they all exhibit the phenomenon of latency. In general, virtually any lesion produced by the three endemic treponematoses also may be produced by venereal syphilis.[1,2]

The immune-response pattern in syphilis and the nonvenereal treponematoses is similar. This complicates the interpretation of reactive serologic tests for syphilis (both nontreponemal, e.g., VDRL and treponemal tests, e.g., TPHA) in patients who have lived in areas where endemic treponematoses are still prevalent.

Small genetic differences have been identified between the causative organisms of venereal syphilis and the endemic treponematoses[3,4]; so far none of these variations can distinguish the subspecies, but breakthroughs in research are forthcoming which finally might resolve whether they are all the same or different organisms (Sheila Lukehart, Personal communication, 2005).

GLOBAL EPIDEMIOLOGY AND CONTROL

HISTORICAL CONTEXT

Since its creation in 1948, the WHO made the fight against the endemic treponematoses a major priority. In close collaboration with UNICEF, in the period 1952–1964, the global endemic treponematoses control program (TCP) was launched, and it became a real success story: More than 50 million patients were treated with long-acting penicillin in 46 countries, reducing the overall disease prevalence by more than 95%. The control strategy subsequently was changed from a vertical program to one that was integrated into basic health services, and it was felt that this approach would cope with the remaining "last cases" in the community until eradication was achieved. Global eradication did not occur, however, and a number of transmission foci remained. By the end of the 1970s, resurgence of endemic treponematoses had occurred in many areas, and the World Health Assembly of the WHO alerted the international community.[5]

In the early 1980s, renewed control efforts were implemented in a number of countries (such as seven West African countries: Benin, Côte d'Ivoire, Ghana, Mali, Burkina Faso, Niger, and Togo). But again, the final blow to the endemic treponematoses was not given.

BARRIERS TO CONTROL AND ERADICATION

Barriers to sustaining control efforts up to eradication are as follows[6]:

There is a perception by health decision makers that these diseases are already fully under control.

The economic impact is not evident; mainly children are affected.

The diseases are not fatal.

Foci of diseases are mainly in remote, rural, poor populations (often ethnic minority groups).

Health services in areas affected are inadequate or absent; political commitment has not been translated in implementation of primary health care (PHC).

Single disease programs are not "fashionable."

The infections are not a threat to industrialized countries and to the leading classes in urban areas of the developing world.

The main motive for dealing with these diseases and working toward eradication is humanitarian, to protect children and communities from the crippling, invalidating, and disfiguring sequelae and, through endemic treponematoses control, to develop effective health services for remote and poor communities.

A comprehensive overview of the global epidemiology of the endemic treponematoses goes back to the early nineties.[7] As reporting has become more and more incomplete, national and local statistics are increasingly unreliable.

Articles in the scientific literature have now become the major but very fragmented source of information.

ESTIMATION OF THE BURDEN OF DISEASE[8]

The population at risk is estimated at 34 million (mainly infants, children, and to a lesser extent, adolescents and young adults). They all live in the developing countries, with 21 million of them living in the so-called least developed countries (LDCs) (Fig. 38-1). The regions most affected are Africa and Southeast Asia, with some residual foci in Central and South America, the Middle East, and the Pacific Islands. The total number of cases (infectious, latent, and old cases) is estimated globally at 2.6 million, and infectious cases are estimated at 460,000, of which there are 400,000 cases in Africa. The prevalence of infectious cases is used for evaluating endemic treponematoses control programs. When infectious cases no longer appear in a geographic area, that area enters the consolidation phase of the control program. If serosurveillance indicates that transmission no longer occurs, then the disease can be considered eradicated. The number of disabled persons due to endemic treponematoses is estimated at 260,000 globally.

YAWS

Yaws, also known as framboesia, pian, or buba, is caused by *Treponema pallidum* subspecies *pertenue (T. pertenue)*. Although *T. pertenue* has not been grown on artificial culture media, it has been grown successfully in rabbits and hamsters.

EPIDEMIOLOGY

Transmission of yaws occurs through direct contact with an infectious yaws lesion. It is usually contracted in infancy or childhood. Indirect transmission by flies (*Hippelates pallipes*) has been suggested. Congenital transmission does not occur. In sparsely dressed populations, transmission is obviously facilitated by close bodily contact when children are playing or sleeping together.

Yaws occurs primarily in the warm, humid, tropical areas of Africa, South America, the Caribbean, Southeast Asia, and some Pacific Islands. Typically, yaws, like the other endemic treponematoses, is confined to populations with low standards of hygiene in remote areas with little or no health care; yaws is a disease found "at the end of the road."[9–13]

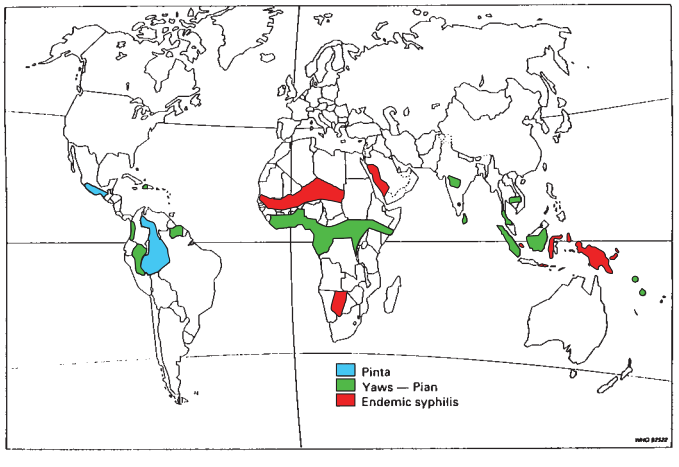

FIGURE 38-1 Geographic distribution of the endemic treponematoses since the early 1990s.

CLINICAL FEATURES

As in syphilis, the clinical manifestations of yaws are divided into early- (which includes primary and secondary lesions) and late-stage disease.[14]

Early-stage disease

Skin. An initial lesion develops at the point of entry of the treponeme (often the lower extremities) after an incubation period of 10–45 days or longer. Systemic spread of the treponemes probably occurs during the incubation period. The initial lesion assumes a variety of appearances but usually progresses over a period of several weeks from a small papule to a proliferative papilloma, which exudes serum that is rich in treponemes and therefore highly infectious. The lesion may persist for 3–6 months and may ulcerate as a result of bacterial superinfection. The initial lesion heals spontaneously, often leaving a scar.

A first crop of secondary lesions may develop before the initial lesion has healed but may not appear for 1–2 years.

Characteristic secondary lesions are the large, raised papillomas and papules from which exudation of highly infectious serum is a feature; in addition, a wide variety of lesions may appear on the skin and oral mucous membranes. Early lesions of the palms and soles include hyperkeratotic or squamous macular lesions, which may be combined with a papilloma. If such papillomas develop on the soles of the feet, walking becomes very painful, and the patient adopts a crablike gait (crab yaws). During the first 5 years of infection, there may be one or several relapses of early yaws lesions, separated by latent periods of variable duration. Each crop of secondary lesions may persist for more than 6 months; the lesions heal spontaneously and do not leave scars.

Change in climate may influence the number and distribution of early skin lesions. In the dry season, fewer lesions may be present, and they tend to be of the macular or papular type; papillomas tend to occur in the more humid body areas such as the axillae and anal folds.

Bone. Many patients with yaws experience bone pain, which becomes worse at night and may be accompanied by pathologic bone changes. Osteoperiostitis may involve the long bones and the bones of the hands and feet and presents as a polydactylitis of the fingers and goundou, a hypertrophic osteitis of the nasal process of the maxilla.[15] The etiology of goundou and saber tibia is still uncertain, but both conditions are commonly seen in yaws endemic areas.

Late-stage disease

Late active yaws lesions develop in about 10% of patients 5–10 years after the initial infection. Treponemes are microscopically scanty or absent in late lesions. Late lesions may involve the skin and subcutaneous tissues, including the skin of the palms and soles, the mucosae, and the bones and joints. In all these lesions, tissue destruction resulting in ulceration is common:

Gummas may involve the skin and the subcutaneous tissues or may be secondary to an underlying osteitis.

Hyperkeratosis of the soles and palms may result in atrophic skin and contractures of the fingers (ghoul hand). Gangosa (rhinopharyngitis mutilans) is a destructive ulceration of the palate and nasal septum leading to collapse of the nose.

Juxtaarticular nodules are lumps of fibrous tissue that develop in the subcutis in the vicinity of joints, with a strong predilection for the sacrum, elbows, greater trochanter, capitulum fibulae, and malleolus externus.

The skin tends to react to trauma with pigmentary changes (hypopigmentation).

It is generally accepted that neurologic and cardiovascular complications and sequelae do not occur in yaws.

ENDEMIC SYPHILIS (BEJEL, DICHUCHWA)

Endemic syphilis is caused by *T. pallidum* subspecies *endemicum (T. endemicum)*. Transmission occurs via infectious lesions on the skin and mucous membranes, often through the use of common feeding utensils. It is essentially a disease of hot, dry countries and used to be endemic in rural communities of the Middle East, Bosnia, Bulgaria, and Botswana, from where it is now practically eradicated. However, major foci still exist in the Sahelian region of Africa.[10]

■ CLINICAL FEATURES

Early-stage disease

Primary lesions are seldom seen. Patches on the mucous membranes, angular stomatitis, and papules and macules favoring the moist areas of the body are the most typical manifestations. Condylomata lata often occur and are comparable with those in yaws and venereal syphilis. Unlike venereal syphilis, however, the eruption may persist for many months or even years. In the early stage, a painful osteoperiostitis may occur, similar to the osteoperiostitis in yaws.[16]

Late-stage disease

Infections of skin, bones, and cartilage may lead to severe destruction, especially of the nose and palate (gangosa). On the skin, gummatous ulcers are characteristic. Periostitis with bone pain and gummas have been reported. Neurologic and cardiovascular involvement has not been reported, nor has congenital transmission.[16]

PINTA (CARATE, MAL DE PINTO)

Pinta is caused by *Treponema carateum*. It is the most benign of the endemic treponematoses; the skin is the only organ affected. Transmission most probably occurs through direct skin contact; the disease is mainly transmitted in childhood. Pinta is now confined to native populations living in the remote rural areas of Central and South America (e.g., the Amazon basin).[16,17]

■ CLINICAL FEATURES

Early-stage disease

After an incubation period of several weeks, initial lesions will appear in the form of an itchy erythematous papule, which may progress to an erythematosquamous plaque on the uncovered parts of the body accompanied by local lymphadenopathy. These lesions disappear spontaneously. In the secondary stage, widespread rashes or multiplication of papules develops. The lesions may persist for years and remain darkfield-positive for treponemes. Generalized lymphadenitis is common.

Late-stage disease

The late stage is characterized by pigmentary changes typical of pinta. At first, there are round, oval, or irregular patches of hyperpigmentation, ranging in color from reddish-purple to slate blue; later, achromic patches and skin atrophy develop. Pruritus is marked. These color changes are not necessarily synchronized, and patients may show the various stages simultaneously. A congenital form is not known.

ATTENUATED ENDEMIC TREPONEMATOSES

In areas of reduced transmission, the clinical manifestations of the endemic treponematoses can be much milder (few or even a single lesion of short duration) or most of the infected subjects can be fully asymptomatic.[2]

In the Gambia, 9.3% of pregnant women were syphilis serology positive; children up to 14 years old of these seropositive mothers showed no signs of congenital syphilis, and perinatal, infant, or child deaths were not higher than in children of seronegative mothers; no clinical signs of yaws or endemic syphilis were found, indicating the asymptomatic nature of the infection.[18,19] Similar observations were made in neighboring west African countries.[10,20]

TREATMENT OF THE ENDEMIC TREPONEMATOSES

The WHO recommends that patients and their contacts receive long-acting benzathine penicillin, 1.2 mU in a single intramuscular injection; children less than 10 years of age should be given half this dose.[1] Resistance to penicillin has not yet been proven, but reports from areas as far apart as Papua New Guinea and Ecuador suggest reduced effectiveness of penicillin in yaws patients.[11,21] Distinction between relapse, reinfection, or true resistance has not been possible, but nevertheless, some experts suggest doubling the recommended penicillin dosage.

Benzathine penicillin at the recommended dose will cure early lesions and prevent the development of destructive late lesions but often does not lead to seroreversal. Tetracycline, doxycycline, and erythromycin, at doses appropriate for venereal syphilis, are alternatives in patients allergic to penicillin. Tetracycline (including doxycycline) is not recommended for pregnant or breast-feeding women and children under 12 years old. About management of patients coinfected with HIV, as yet, no information is available.

MAJOR ISSUES FOR RENEWED ACTION

Control strategies for the endemic treponematoses are well established and remain largely unchanged. Major issues to stimulate renewed action are as follows[8]:

1. A single, cheap, and effective measure to stop transmission of these infections is available (single-dose injection of a long-acting penicillin); treponemes may not yet have developed resistance to penicillin, but this could occur.
2. These infections are resurging and reemerging in large areas of the developing world, particularly in the poorest countries.
3. Global elimination and ultimately eradication are feasible.
4. Characteristics of at-risk populations are often remote, end-of-the-road, ethnic minorities who are not covered at all or highly underserved by health services.
5. Endemic treponematoses control can be used to establish or strengthen PHC and to dramatically increase confidence in and the use of health services. A high degree of community participation in control activities is assured nearly everywhere.[22]

The new paradigm for the twenty-first century is poverty alleviation. Elimination of the endemic treponematoses in combination with other health initiatives and in a context of strengthening the health system would significantly contribute to this noble goal.

39 Chancroid and *Haemophilus ducreyi*

Stanley M. Spinola

Haemophilus ducreyi is a gram-negative coccobacillus that causes chancroid, which is characterized by painful genital ulcers and inguinal lymphadenitis. Chancroid is endemic in resource-poor countries and is a marker of poor public health infrastructure. Like other agents of genital ulcer disease (GUD), chancroid facilitates both acquisition and transmission of HIV-1.[1] Clinical data and mathematical models suggest that chancroid contributes substantially to the HIV-1 pandemic in sub-Saharan Africa and Asia.[1–4]

HISTORICAL CONTEXT

Chancroid, or soft chancre (ulcus molle), may have been present in human populations from the time of the ancient Greeks.[5] Several excellent review articles detail the history of the disease, the isolation of *H. ducreyi*, and controversy in its role in causing genital ulcers.[5–8] In brief, Leon Bassereau distinguished chancroid from syphilis, or hard chancre, in 1852. In the 1890s, Augusto Ducrey identified short, compact bacteria by weekly autoinoculation of pus from infected ulcers to the skin of the forearm in patients but was unable to grow the organism on artificial media. In 1900, the organism was isolated on blood agar plates by Benzacon and colleagues, who fulfilled Koch's postulates by experimental inoculation, infection, and reisolation of the organism from humans. Intradermal skin tests and animal and human models of infection were developed in the first half of the twentieth century.[6] However, there was no standard or selective media on which to grow the organism from clinical specimens. When the type strain (CIP 542) was established in 1975, three of four strains examined lacked outer membranes, indicating that several gram-positive organisms had been mistakenly classified as *H. ducreyi*.[9]

A major breakthrough in the study of *H. ducreyi* was the development of selective media using commercially available reagents by Hammond and colleagues in the late 1970s.[10,11] Isolation of *H. ducreyi* from clinical specimens fostered epidemiological studies that showed the link between chancroid and HIV-1 acquisition, which prompted studies on pathogenesis, host responses, diagnostics, therapy, and eradication.

TAXONOMY, GENOME, AND STRAIN CLASSIFICATION

H. ducreyi is a strict human pathogen and there is no known environmental or animal reservoir.[5] The organism is a fastidious, facultative anaerobe that was classified as a *Haemophilus* species because of its microscopic appearance, requirement for X factor, and biochemical properties.[5,7] However, by 16S rRNA sequence analysis, *H. ducreyi* is not found in the *Pasteurellacea* cluster that includes *Haemophilus* sensu stricto species such as *H. influenzae* and *H. aegyptius*.[12] *H. ducreyi* is grouped with the *Actinobacilli* in a distant cluster, which does not contain other organisms of high pathogenic potential for humans.[12]

The genome of *H. ducreyi* strain 35000HP (HP, human passaged),[13,14] was sequenced by Munson and colleagues (www.microbial-pathogenesis.org). The genome is composed of a single 1.7-Mb chromosome[15] and contains 1693 putative open reading frames (ORFs). The closest homologues of 66% of the ORFs were found in the sequenced genomes of *Haemophilus influenzae* or *Pasteurella multocida* as determined by BLAST analyses.[16,17] Substantial homology is observed for many genes, but there is little conservation of long-range gene order in the chromosome when *H. ducreyi* is compared to these species. The genes encoding several *H. ducreyi* toxins such as hemolysin and the cytolethal distending toxin (CDT) are absent from the *H. influenzae* and *P. multocida* genomes,[16,17] which is not surprising given that these organisms are somewhat distant taxonomically. Interestingly, the genome of *H. ducreyi* lacks the repetitive DNA motifs that promote slip-strand mispairing resulting in phase variation (on–off switch) of virulence genes, a mechanism that plays a critical role in the pathogenesis of *H. influenzae* and gonococcal infections.[18,19]

Clinical isolates of *H. ducreyi* form a homogeneous DNA hybridization group and share many of the same surface antigens, suggesting that there is limited diversity within the

species.[5,20] There appear to be at least two circulating classes of the organism, which express different immunotypes or variants of several outer membrane proteins[21] and different proteomes.[22] Compared to class I strains, represented by the prototype 35000HP, class II strains express a more truncated LOS, grow more slowly on agar plates, and may be underreported.[21] Clinical isolates can also be distinguished by restriction fragment length polymorphism of ribosomal DNA,[23] and multiple ribotypes may circulate in endemic areas or in outbreaks.[24,25]

EPIDEMIOLOGY

Chancroid is endemic in regions of Africa, Asia, and Latin America where syndromic management of GUD is emphasized, and where diagnostic tests for *H. ducreyi* are not routinely performed.[1] UNAIDS and WHO estimate that the annual global prevalence of chancroid is six million cases, based on the prevalence of syphilis and the relative percentage of syphilis and chancroid in GUD cases among STD clinic attendees in whom an etiology has been established.[26] Because the data are problematic, WHO does not include chancroid in their global estimates of prevalence of sexually transmitted infections (STIs). In industrialized nations, chancroid is now rare,[27,28] but sporadic outbreaks do occur.[1,29–31]

When selective media became available in the 1980s, several features of chancroid epidemiology became apparent. In endemic areas and in outbreaks in industrialized nations, infected men frequently reported intercourse with commercial sex workers (CSWs), who either had symptomatic GUD or internal ulcers that were painless, and who continued sex work without seeking treatment.[1,30,32] Lack of circumcision was associated with infection in men.[5] In outbreaks in the United States, additional risk factors for acquisition included exchange of drugs for sex, crack cocaine use, or sex with a partner who used cocaine.[25,29,30] In endemic areas, the male to female ratio of chancroid was 3:1, and in sporadic outbreaks the ratio was as high as 25:1.[5]

In the 1990s, Multiplex PCR (M-PCR) (Roche Diagnostic Systems, Branchburg, NJ), which simultaneously amplifies DNA targets from *H. ducreyi, T. pallidum*, and HSV-1 and HSV-2, replaced culture as the most sensitive method to detect *H. ducreyi*.[31,33–35] By M-PCR, the percent of chancroid in GUD cases among patients attending STD clinics in various countries is shown in Table 39-1,[27,29,31,33–43] which also includes studies that used investigator-designed reagents.[28,44,45] Most of the GUD cases were in men. The prevalence of chancroid in GUD cases was 0–5% in the United States, Peru, Europe, Thailand, and China[27,28,37,38,41] except in outbreak situations.[29,31] At the end of the 1990s, several studies suggested a trend toward lower chancroid and higher HSV prevalence in endemic areas, likely due to syndromic management for bacterial agents of GUD and reactivation HSV in patients coinfected with HIV-1.[35,36,43] These PCR-based studies showed that mixed infections with *H. ducreyi* and HSV, syphilis, or all three agents were common, occurring in 17.4% (95% confidence interval [CI], 13.1–21.5%) of the 1007 proven chancroid cases. Mixed infection likely accounts for the variable clinical presentation of chancroid described below and chancroid treatment failures. By M-PCR, the proportion of patients with no microbiologic diagnosis for GUD was initially as low as 6%.[33] Overall, no etiology was found in 25.8% (95% CI, 22.3–29.2%) of the 4461 GUD cases listed in Table 39-1, suggesting that PCR-based tests perform less well in field studies than in research settings or that agents other than those tested might be responsible for some cases of GUD.

CLINICAL MANIFESTATIONS

H. ducreyi is thought to enter the host through breaks in the epithelium that occur during intercourse.[5,6] *H. ducreyi* infects mucosal epithelium, keratinized stratified squamous epithelium, and regional lymph nodes.[5,11] Erythematous papules form at each entry site within several hours to days and evolve into pustules in 2–3 days. Papules and pustules are usually not painful, and only a small number of patients recall having these stages.[5] After a few days to 2 weeks, the pustules ulcerate and patients typically have 1–4 painful ulcers. Patients generally do not seek medical attention until they have had ulcers for 1–3 weeks, probably about 3–5 weeks after acquisition.[5,11,46]

Natural ulcers are classically described as very painful and nonindurated with ragged edges[5] (Fig. 39-1). The ulcer base may be covered by a yellow or gray necrotic purulent exudate, and the ulcer frequently bleeds when scraped. However, the classic presentation of chancroid occurs in a minority of patients,[47] and chancroidal ulcers may be indistinguishable

from syphilis and genital herpes. Lesions in men are usually localized to the external and/or internal surfaces of the foreskin, the frenulum, and the coronal sulcus or penile shaft (Fig. 39-1).[5] The majority of lesions in women are at the vaginal entrance (Fig. 39-2).[5] In women, asymptomatic carriage is rare.[48] However, infected women may have internal vaginal and cervical ulcers that are painless. Perianal lesions occur in women who report anal intercourse.[11] Lesions also occur in nearby areas such as the thighs and buttocks or at distant sites.[5,11] Extragenital skin lesions are thought to be due to autoinoculation.[5,11]

Ten to forty percent of patients with chancroid have suppurative inguinal lymphadenopathy or buboes[5] (Fig. 39-3). *H. ducreyi* can be recovered from buboes,[5,49] but how the organism traffics to lymph nodes is unclear. *H. ducreyi* does not cause bacteremia. In vitro, the organism dies at temperatures above 35°C, and temperature sensitivity likely precludes spread via the blood stream.[20]

In the preantibiotic era, chancroid could persist for 3–4 months and cause giant ulcers and erosion of the infected area until incision and drainage and topical therapies were given.[6] Chancroid also caused fibrosis of the foreskin, leading to phimosis or autoamputation.[5,6]

FIGURE 39-3. Left-sided inguinal bubo in a patient with a culture-proven chancroidal ulcer. (*Photograph provided by Professor David Lewis.*)

PATHOGENESIS AND HOST RESPONSES

NATURAL INFECTION

Information on pathogenesis and the host response to *H. ducreyi* is limited to a few cross-sectional studies on patients who present with ulcers. Chancroidal ulcers contain a superficial zone of polymorphonuclear leukocytes (PMNs) and necrotic tissue, and a perivascular and interstitial mononuclear cell infiltrate that consists of macrophages, T cells, and small clusters of B cells.[50–53] The T cells express the memory marker CD45RO, and similar numbers of CD4 and CD8 cells are present. A diffuse infiltrate of Langerhans cells is also present in the dermis. Thus, the histopathology of natural infection consists of two major components: a PMN infiltrate that coalesces at the ulcer base to form an abscess and a dermal infiltrate of T cells and macrophages that resembles a poorly formed granuloma. The combination of an abscess and a granuloma is an unusual histopathology for a bacterial pathogen. *H. ducreyi* is found at the ulcer base and associates with PMN and fibrin, consistent with results from human inoculation experiments.[54,55,55a]

Peripheral blood mononuclear cells (PBMCs) from HIV seronegatives with chancroid exhibit proliferative responses to several *H. ducreyi* antigen fractions, while PBMCs from HIV seropositives are less responsive.[56] Patients with chancroid have increased levels of soluble IL-2 receptors in urine and serum[57] and have significantly higher levels of antibody to *H. ducreyi* antigens than noninfected controls or patients with other STIs.[58–62] Antibody responses occur after 2–3 weeks of ulcerative symptoms, likely 4–5 weeks after inoculation.[46] Sera from chancroid patients are not bactericidal.[63]

Whether natural infection with *H. ducreyi* confers immunity to subsequent exposure has never been studied directly. In the weekly autoinoculation experiments performed by Ducrey, serial ulcers were maintained for up to 15 weeks.[5] In outbreaks of chancroid, thought to be due to one strain, patients have had up to three recurrences.[11,64] The data suggest that natural infection with *H. ducreyi* does not confer protective immunity to repeated exposures in those who form ulcers.

HUMAN INOCULATION EXPERIMENTS

Much of what is known about *H. ducreyi* pathogenesis in humans is derived from experiments in which bacteria are inoculated into nongenital skin of human volunteers.[26,65,66] Experiments done in the 1940s suggested that infection was safe.[67,68] Placement of 10^6 *H. ducreyi* onto intact upper arm skin does not cause disease.[65] A 1.9-mm puncture wound, which allows bacterial delivery into the epidermis and deep dermis, is sufficient to initiate papule formation. Whether a more shallow abrasion would be effective is unknown. The estimated infectious dose is between 1 and 100 CFU.[69,70] Papules develop within 24 hours of inoculation and either spontaneously resolve or evolve into pustules 2–5 days later. Pustules enlarge and generally become mildly pruritic and painful in 7–14 days of observation. The human volunteer model simulates the first 2 weeks of chancroid but does not provide information about later stages.

Within 24 hours of inoculation, micropustules are present in the epidermis.[55] By 48 hours, the bacteria are seen in the epidermal micropustules and in the dermis where they colocalize with PMNs, macrophages, collagen, and fibrin.[55] The relationships between *H. ducreyi* and host cells are maintained throughout the papular and pustular stages. The bacteria are predominantly extracellular, and the infiltrating PMNs and macrophages fail to ingest the organism. The bacteria do not colocalize with keratinocytes, fibroblasts, laminin, or fibronectin. Evasion of phagocytosis and phagocytic killing is a major mechanism of bacterial survival in the first 2 weeks of infection and likely extends to the ulcerative stage.[55a]

In addition to the intraepidermal pustules, a dermal infiltrate of mononuclear cells is recruited within 24 hours of infection.[71] The mononuclear cells consist primarily of macrophages and T cells that are predominantly CD4 memory cells.[72] The histopathology of experimental infection is nearly identical to that of natural infection except that CD4 and CD8 T cells are present in equal numbers in chancroidal ulcers.[26,50]

BACTERIAL EFFECTS ON OUTCOME

Putative virulence determinants of *H. ducreyi* include LOS structures that are similar to those found in *N. gonorrhoeae* and mimic human glycosphingolipids, secreted products or toxins, pili, iron-regulated proteins and receptors, and outer membrane proteins.[5,20,66] Isogenic mutants have been made in many genes encoding putative virulence determinants by allele exchange.[73,74] In mutant-parent comparison trials in human volunteers, many mutants were able to initiate papule formation. Mutants that do not make sialylated or paraglo-boside-like lipooligosaccharide (LOS), hemolysin, CDT, or both hemolysin and CDT, fine tangled pili, the major outer membrane protein, superoxide dismutase C, or the porin proteins (OmpP2A and OmpP2B) formed pustules at rates similar to the parent[66] (unpublished observations). Possible reasons as to why these mutants were virulent are discussed elsewhere.[66] Whether these gene products contribute to ulcer formation or lymphadenitis cannot be tested in humans, due to safety concerns.

Certain mutants were unable to form pustules. These included those that lack expression of the hemoglobin receptor (HgbA), the peptidoglycan-associated lipoprotein, an outer membrane protein that is the major known determinant of serum resistance (DsrA), an intact *flp* locus, two large supernatant proteins (LspA1 and LspA2), and an outer membrane protein involved in adherence to collagen (NcaA)[66,75,76] (unpublished). The exact cause for attenuation of these mutants in vivo is not known, but the DsrA mutant should have been killed by serum that transudates into the wound. The HgbA mutant may not have replicated due to its inability to acquire heme. The *pal* mutant has an unstable outer membrane, but is serum resistant and evades phagocytosis in vitro[77] (unpublished observations). The *flp* locus is required for microcolony formation and also resembles type IV secretion systems, which play an important role in the secretion of virulence factors in other species.[75] The LspA1 and LspA2 double mutant is unable to resist phagocytosis and to inhibit the uptake of secondary targets by phagocytic cell lines.[78] The LspA1 and LspA2 double mutant likely is unable to resist uptake and killing in vivo. The attenuation of the NcaA mutant likely underscores the significance of adherence to collagen in vivo.

HOST EFFECTS ON OUTCOME

No data directly address whether there are differences in host susceptibility to acquisition or to progression of disease in natural chancroid. However, in the preantibiotic era, a variant of chancroid called "chancre mou volant" was described in which spontaneous healing of the ulcer occurred in 5–6 days.[6] Spontaneous healing of ulcers was also reported in later outbreaks,[11] but its frequency and basis is unknown.

In the human infection model, the most significant predictors of outcome are gender and host. Men and women form papules (become infected) at similar rates, but the odds ratio of men developing pustules is 2.8-fold (95% CI, 1.6–5.0) that of women[70] (unpublished observations), consistent with the male to female ratio of ulcerative disease in endemic areas. The outcomes of multiple infected sites within a subject tend to be similar, suggesting that there is an overall host effect on the sites.[79] In reinfection experiments, some hosts repeatedly resolve all inoculated sites while others repeatedly form pustules, suggesting that some hosts are able to overcome the antiphagocytic properties of the organism.[79,80] Interestingly, there are no differences in the ability of isolated PMNs or macrophages from people who formed pustules on successive experimental infections and those who resolved on successive experimental infections to take up 35000HP in vitro.[79] These data suggest that the complex environment—dendritic cells, T cells, macrophages, and PMNs—at the site of infection within each subject modulates outcome.

OTHER PATHOGENESIS MODELS

H. ducreyi attaches to and invades human keratinocytes and fibroblasts in vitro,[81] but the relevance of these findings to human infection is unclear given the results of the human inoculation experiments.[55] *H. ducreyi* binds to type I and type III collagen, fibrinogen, fibronectin, and laminin in vitro[82] (unpublished observations) but only binds to collagen and fibrin in vivo.[55] *H. ducreyi* resists uptake and inhibits uptake of opsonized secondary targets by phagocytic cell lines,[78,83,84] consistent with the evasion of phagocytosis observed in humans.

Rabbit, swine, murine, and primate models for chancroid have been developed, and a detailed comparison of these models to the human model is presented elsewhere.[66] A major difference among the models is that the infectious dose in humans is between 10^1 and 10^2 CFU, while the infectious doses in the animals range from 10^4 to 10^7 CFU. *H. ducreyi* replicates to 10^4–10^6 CFU in human pustules[85] and is cleared in swine.[86,87] Lesions in mice develop in response to lipooligosaccharide (LOS), not replicating bacteria.[88,89] In contrast to the human model,[79,80] infection in animals evokes serum antibody responses and perhaps most importantly provides protection against repeat exposure.[87,90] Bactericidal activity develops in the serum of swine that are repeatedly infected, and passive transfer of swine immune serum protects against infection.[87]

DIAGNOSIS, CULTURE, AND DETECTION

Diagnostic tests for chancroid were reviewed recently by Lewis.[91] In brief, microscopy of exudates and antigen detection are neither sensitive nor specific enough to be clinically useful. Serology is only useful for prevalence studies.[46,62] Culture and PCR-based tests are the cornerstones of diagnostic testing.

The standard culture media for *H. ducreyi* consists of two plates, one containing gonococcal agar base, 2% bovine hemoglobin, and 5% fetal calf serum (GC-HgS), the other containing Mueller-Hinton agar base with 5% chocolated horse blood (MH-HB).[92] These media are supplemented with 1% CVA enrichment or 1% IsoVitaleX to provide L-glutamine and vancomycin (3 μg/mL) to prevent overgrowth of gram-positive organisms. GC-HgS, which contains fetal calf serum, is expensive. Gonococcal agar base supplemented with 5% Fildes extract and 5% horse blood (GC-FHB) is 82% as sensitive as the dual media and is a reasonable alternative for resource poor settings.[93] Transport and other media preparations are described elsewhere.[91,94,95]

Cultures are obtained by swabbing the base of the ulcer vigorously with a dry or moist cotton swab that becomes saturated with pus, which is immediately inoculated on the plates. Plates should be incubated for 48–72 hours in moist candle-extinction jars. The organism grows at 35°C, but optimal growth occurs at 33°C.[96] *H. ducreyi* is identified as a small yellow–grey colony that can be pushed intact across an agar surface. Gram stain shows pleomorphic gram-negative rods that are in short chains, pairs, or schools of fish. Colonial morphology and the characteristics of the Gram stain are likely due to tight intercellular adherence, whose basis is unknown (Fig. 39-4).[5] Biochemically, the organism requires X factor but not V factor for growth, is oxidase positive by the tetramethyl-*p*-phenelyenediamine method, but is otherwise inert.[5,92] V factor independence is plasmid mediated, and in some strains the plasmid is integrated into the chromosome.[97]

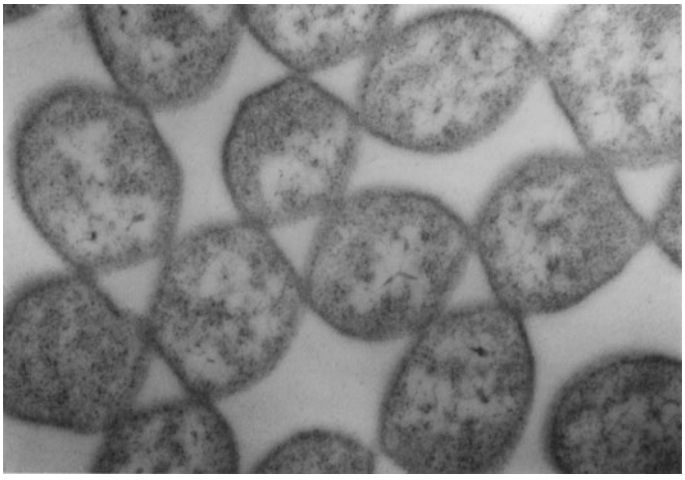

FIGURE 39-4. Transmission electron micrograph of a thin section of a colony of *H. ducreyi* stained with uranyl acetate. Note the areas of intercellular adhesin that result in the colonial characteristics described in text.

The Roche M-PCR assay has a resolved sensitivity of 95–98% and a specificity of 99.6% for *H. ducreyi*.[31,33] Compared to M-PCR, the clinical diagnosis of chancroid is neither sensitive (range, 52–75%) nor specific (range, 52–75%) and has poor positive predictive value even in endemic areas.[34,37,39,40] Compared to M-PCR, the resolved sensitivity for the dual culture system is approximately 75%.[31,33] Unfortunately, M-PCR is not commercially available and requires special training and equipment, and culture is the only reliable diagnostic test available for most clinical settings.

In nonendemic regions, most STD clinics do not routinely test GUD patients for chancroid.[29] In practice, the diagnosis of chancroid is typically made by exclusion of HSV and syphilis. If patients with GUD and inguinal lymphadenitis or treatment failures for primary syphilis appear in a community, public health authorities should be notified so that diagnostic testing can be initiated. Even in endemic regions, routine screening of GUD patients for chancroid may not be cost effective given the changing epidemiology of the disease. A reasonable approach may be to use culture or PCR-based tests to screen a limited number of GUD patients when chancroid is suspected and provide syndromic management if chancroid is found. PCR-based tests may also be used to develop syndromic treatment algorithms based on the local prevalence of HSV, syphilis, and chancroid.[43]

ANTIBIOTIC RESISTANCE AND THERAPY

Currently, little is known about the global prevalence of antibiotic resistant *H. ducreyi*, since few centers perform cultures and determine antimicrobial susceptibilities.[98] To complicate the issue further, there is no standard method for determining susceptibility.[20] Suggestions for using agar

dilution techniques are presented elsewhere,[20,99] and Etest may be an acceptable alternative.[100]

The history of antibiotic resistance in *H. ducreyi* parallels that of *N. gonorrhoeae*. Many *H. ducreyi* isolates have plasmid-mediated resistance to ampicillin, chloramphenicol, tetracyclines, and sulfonamides.[5,98,101] These plasmids are homologous to R factors found in *Neisseria and Haemophilus* species and gram-negative enteric organisms.[5] Some clinical isolates of *H. ducreyi* have a mobilizing plasmid that can transfer itself and antibiotic resistance plasmids to other species.[5] Strain 35000HP contains a 49-kb integrated conjugative resistance element (ICE) that is a member of a family of conserved genomic islands with a shared evolutionary origin found in some *H. influenzae* strains and strains of many diverse bacterial species.[102] ICE usually contains antibiotic, metal, and antiseptic resistance genes and other accessory genes.[102] These elements were likely responsible for the widespread emergence of ampicillin, chloramphenicol, and tetracycline resistance in many bacterial species in the 1970s. However, no antibiotic resistance gene is present in the 35000HP ICE. Trimethoprim resistance, whose mechanism is unknown, became widespread in the 1990s.[20,98] A few *H. ducreyi* isolates were also reported to be resistant to erythromycin; fortunately, these observations were not replicated.[20] Quinolone resistance does not appear to be widespread.[20,98,99]

Clinically, chancroid is successfully treated with macrolides, quinolones, and third-generation cephalosporins. Current treatment recommendations by the Centers for Disease Control and Prevention (CDC) include single dose azithromycin 1 g orally or ceftriaxone 250 mg intramuscularly, ciprofloxacin 500 mg orally twice a day for 3 days, or erythromycin base 500 mg orally three times a day for 7 days.[103] In general, most of these regimens have cure rates greater than 90%. In a small, randomized trial, a single-dose of ciprofloxacin (500 mg) and the 3-day regimen produced cure rates that were similar.[104] A larger double-blinded placebo-controlled clinical trial showed that single-dose ciprofloxacin was comparable to a 7-day course of erythromycin.[105] Thus, a single dose of ciprofloxacin seems to be a reasonable alternative to the 3-day regimen. Although single-dose ceftriaxone is highly effective in some settings,[106] one study in Kenya showed that bacteriologic failure occurred in approximately 30% of patients treated with this regimen.[107] Failures occurred in both HIV seropositive and seronegative patients.

The recommended azithromycin and erythromycin containing regimens are equally effective.[108] A low-dose erythromycin regimen (250 mg three times a day for 7 days) was as effective as the standard 500 mg regimen in one study.[109] The MIC of azithromycin for *H. ducreyi* is low (range, 0.0005–0.004 μg/mL), and azithromycin persists in tissues due to its long elimination half-life of 7.5 days.[110] In human inoculation experiments, a single 1 g dose of azithromycin prevents the development of disease for approximately 2 months in volunteers who are challenged weekly.[110] Thus, azithromycin may provide both therapeutic and prophylactic value.

In evaluating antibiotic regimens, one must distinguish between bacteriologic and clinical cure.[111] Even if *H. ducreyi* is eradicated, ulcers may persist if HSV or syphilis is present and not treated. Within 1 week of treatment, the ulcers should be less tender and there should be no purulence. Most ulcers heal in 2 weeks, but large ulcers may take up to 4 weeks to epithelialize.[111]

With the recent lack of antibiotic development, no comparative treatment trials have been published since 1999. Open label use of a single dose (5 g) thiamphenicol, a chloramphenicol derivative, in 1171 cases of chancroid resulted in a cure rate of 98.8%.[112] However, these cases were diagnosed by exclusion of syphilis and positive Gram stains of exudates, not by culture or PCR. Thiamphenicol and chloramphenicol are both substrates for chloramphenicol acetyl transferase,[113] and thiamaphenicol should not be effective in treating chloramphenicol-resistant *H. ducreyi*.

Buboes may be treated by incision and drainage or needle aspiration, which frequently needs to be repeated.[49] In a randomized study comparing these modalities, incision and drainage was preferable[49] and the time to healing was 1 week to 10 days.

INTERACTIONS BETWEEN *H. DUCREYI* AND HIV-1

ACQUISITION AND TRANSMISSION OF HIV-1

In case-control studies in areas endemic for chancroid and HIV, the relative risk of acquiring HIV infection for patients with GUD ranged from odds ratios of 3–18.2.[114–116] Per individual sexual act, GUD is estimated to enhance HIV acquisition by 4–23-fold; the exact magnitude of the cofactor effect is difficult to estimate due to confounding variables.[3,4,117] In serodiscordant couples, GUD in an HIV positive person enhances the relative risk of viral transmission per coital act twofold, after adjustment for viral load.[117,118] Simulation models estimate that GUD may have accounted for the acquisition of 40–80% of HIV infections in Africa in the 1990s.[3]

Disruption of epithelial barriers is likely a major mechanism underlying viral acquisition, as is the recruitment of T cells and macrophages expressing the CD4 receptor. In human inoculation experiments, lesional macrophages have significantly increased expression of CCR5 and CXCR4 and lesional CD4 T cells have significant upregulation of CCR5, compared to monocytes and CD4 T cells in peripheral blood.[119] However, upregulation of coreceptors has not been studied in natural infection. HIV-1 is shed from coinfected ulcers.[120] In coinfected persons, *H. ducreyi* may cause local

viral replication by recruitment and subsequent activation of CD4 CD45RO cells and macrophages that are latently infected with HIV-1, but this hypothesis has not been tested.

CLINICAL FEATURES OF COINFECTION

In the early 1990s, case reports indicated that patients who are HIV seropositive have atypical presentations of chancroid.[121,122] These reports were written when it was thought that *H. ducreyi* was intracellular and that cell-mediated immunity was a critical host defense mechanism, hypotheses that were not substantiated in the human challenge model. No further case reports have appeared in the literature. Interestingly, the histopathology of chancroidal ulcers in HIV seropositives and seronegatives is indistinguishable.[51,52]

Reports from Africa on persons coinfected with HIV and chancroid also indicated that coinfected individuals have a greater number of ulcers that persist for longer periods and do not heal as readily after antibiotic treatment as patients infected with *H. ducreyi* alone.[20,52] Antibiotic treatment failures were reported in HIV seropositives for what were suboptimal regimens even in HIV seronegatives.[107] Subsequent studies failed to show differences in antibiotic treatment efficacy in HIV seropositives and seronegatives for single-dose azithromycin or ciprofloxacin regimens.[105,123,124] Treatment failure of chancroid in HIV seropositives is likely due to coinfection with herpes simplex virus and does not represent failure to eradicate *H. ducreyi*.[105] Taken together, the data suggest that the effect of HIV on the histopathology, clinical course, and treatment of chancroid is minimal.

Immune activation may also cause systemic viral replication. HIV-infected female sex workers with clinically diagnosed GUD of undetermined etiology have statistically significant higher HIV viral loads than female sex workers who do not have GUD.[125] Men with urethritis and HIV plus GUD of undetermined etiology in a chancroid endemic country have lower CD4 counts and higher viral loads than HIV-infected men with urethritis without GUD.[126] These studies are difficult to interpret because they are not longitudinal and contain many confounding clinical variables.

TRANSMISSION DYNAMICS AND THE CASE FOR ERADICATION

As is discussed in Chapter 3, for an STI to remain endemic in a population, the reproductive rate ($R_0 = \beta cD$) must be ≥ 1. For *H. ducreyi*, the average duration of infectiousness (D) is estimated to be 4 weeks or 0.08 years based on the facts that *H. ducreyi* can be recovered from surface cultures of experimental papules and pustules, which represent the first 2 weeks of infection,[14] and that medical attention is sought for ulcers after 1–3 weeks.[11,46] The transmission rate per sex act (β) is unknown. In a small study, 70% of 28 women who were secondary contacts of men with chancroid had genital ulcers,[32] suggesting that the upper limit for β is 0.7. For $\beta = 0.7$, the calculated sex partner change rate (c) per year is 18; for $\beta = 0.35$, c = 36; and for $\beta = 0.18$, c = 72.[26] These estimates suggest that chancroid can be perpetuated only in highly sexually active populations such as CSWs, which is consistent with epidemiological data.

Elimination of chancroid from CSW should result in disappearance of the disease from the community.[1] In Thailand, widespread policies for 100% condom use and presumptive treatment of CSWs with quinolones led to a 95% decrease (from 30,000 cases to less than 2000 cases) in chancroid in the 1990s.[127] As a result of increased condom use and syndromic management, chancroid now accounts for less than 10% of GUD seen in clinics in Nairobi, Kenya.[1] In a South African mining community, monthly presumptive antibiotic treatment of CSWs with a 1 g dose of azithromycin, condom promotion, and education directed toward prevention resulted in a 78% decline in GUD prevalence over 9 months.[1,128]

Many countries with a high seroprevalence of HIV-1 are chancroid endemic areas.[1] Given the dynamics of *H. ducreyi* transmission and the association between chancroid and HIV-1, strong arguments have been made for public health programs to eradicate chancroid.[1,26]

40 Donovanosis

Nigel O'Farrell

HISTORY

Donovanosis is a chronic, progressive, and mildly contagious bacterial infection that usually involves the genital region. The causative organism was recognized as a gram-negative bacillus, *Calymmatobacterium granulomatis*, but a proposal that the organism be reclassified as *Klebsiella granulomatis comb nov* has been put forward.[1] The condition has been known under numerous terminologies, including serpiginous ulceration of the groin, lupoid form of groin ulceration, ulcerating granuloma of the pudenda, granuloma genitoinguinale, granuloma venereum genitoinguinale, infective granuloma, granuloma inguinale tropicum, chronic venereal sores, and ulcerating sclerosing granuloma, but is known more commonly as granuloma inguinale or granuloma venereum.[2] In the past, there has been considerable confusion between granuloma inguinale and lymphogranuloma venereum. Marmell and Santora[3] recognized this and recommended *donovanosis* as the most suitable name. Most authorities now accept this view.

The first description of donovanosis is attributed to McLeod, Professor of Surgery at the Medical College of Calcutta, India, in 1882.[4] He reported cases of serpiginous ulceration and formation of an imperfect cicatrix involving the scrotal and penile tissues in men and long-standing elephantiasis of the clitoris and labia in a woman. Subsequent cases were reported from British Guinea[5] and the UK.[6]

The causative organism was first described in 1905 by Donovan working in Madras, India.[7] He identified the characteristic Donovan bodies measuring 1.5 × 0.7 μm in macrophages and epithelial cells of the stratum malpighii. Difficulties in culturing the organism led to considerable debate about the causative agent. Aragao and Vianna[8] claimed to have cultured a pleomorphic bacterium from ulcer lesions and identified it as *C. granulomatis.*

Cornwall and Peck[9] cultured an organism that, when injected into rabbits, produced granulomatous lesions simulating donovanosis at the site of injection. Experimental transmission of the organism from one individual to another was reported by McIntosh in 1926.[10] DeMonbreun and Goodpasture[11] grew gram-negative bacilli of the *Aerogenes* group from ulcers and feces of patients with donovanosis in a filtrate of chick membrane in both the capsulated and noncapsulated forms. Greenblatt et al.[12] accomplished transmission of the disease into human volunteers by introducing material from a pseudobubo but were unable to grow the organism on the chorioallantois of chick embryos.[13]

Attempts at culture remained unconvincing until 1943 when Anderson[14] reported the isolation of the causative organism on the yolk sac of chick embryos and proposed a new genus, *Donovania*, and species, *granulomatis*.[15] Further efforts to develop an artificial medium for the culture of *D. granulomatis* met with only limited success. Some growth was achieved using beef heart infusion agar and normal chick embryo yolk sacs with subsequent transfer to tryptose beef heart infusion broth and modified Levinthal's stock broth.[16] Positive skin reactions were demonstrated in human subjects with donovanosis after injection of bacterial antigen prepared from infected yolk sacs.[17] It would now seem that some of the earlier claims of successful cultures may have been due to contamination.

A link between *C. granulomatis* and *Klebsiella* species was suggested on the evidence of antigenic cross-reactivity.[18] Goldberg[19] characterized the organism further and showed that two factors were necessary for growth: (1) a low oxidation-reduction potential, which could be satisfied by the use of a thioglycolate medium, and (2) a factor or factors in eggs, which could be substituted by the enzymatic digests of bovine albumin or soya meal.

Despite these developments, progress in donovanosis research was slow. After 1962,[20] there were no reports of successful culture until 1996–97 in Durban,[21,22] where the causative organism was shown to multiply in a monocyte co-culture system from biopsy specimens after pretreatment with amikacin. In Darwin, growth of the organism was achieved using a modified chlamydia culture system with human epithelial cell lines.[23] Polymerase chain reaction (PCR) tests were developed in Darwin and Durban and further

molecular characterization of the causative organism was undertaken.[1,24–26] DNA sequencing of the 16S rRNA and phoE genes demonstrated that *C. granulomatis* had a greater than 99% similarity with *Klebsiella. pneumoniae* and *K. rhinoscleromatis,* and Carter et al. proposed that the causative organism be reclassified as *K. granulomatis comb nov* and set out an amended description of the genus *Klebsiella* to include donovanosis.[1] However, Kharsany et al. performed a phylogenetic analysis of *C. granulomatis* based on 16S rRNA gene sequences and found that strains had similarities of only 95% and 94%, respectively, to the genera *Klebsiella* and *Enterobacter*.[26] They concluded that *C. granulomatis* was a unique species distinct from other related organisms belonging to the subclass of *Proteobacteria.* Differences in these results have not been explained, and resolution of the conflict regarding classification has not been achieved.

PATHOGENESIS AND BIOLOGY

The first manifestation of donovanosis is usually a small, firm nodule in the genital region in skin that has been subjected to a degree of trauma. Most established infections are associated with poor standards of personal genital hygiene. Goldzieher and Peck[27] were the first to identify Donovan bodies in histologic sections of tissue in 1926 and described a large, swollen mononuclear cell containing the specific organisms. Pund and Greenblatt,[28] using Delafield's hematoxylin and eosin and Dieterle silver-impregnation staining methods, also described a large mononuclear cell 25–90 μm in diameter with intracytoplasmic cysts filled with deeply stained bodies that they regarded as pathognomonic of donovanosis. These cysts eventually rupture and release the infective organisms. Sehgal et al.[29] described gram-negative intra- and extracellular Donovan bodies with different morphologic features—coccoid, coccobacillary, and bacillary.

Electron microscopic studies have shown organisms with typical gram-negative morphology and a large capsule but no flagella. Filiform or vesicular protrusions may be seen on a corrugated cell wall,[30,31] but other surface structures such as fimbriae and bacteriophages are not found.[32]

EPIDEMIOLOGY

In the preantibiotic era, donovanosis was prevalent in many diverse geographic locations. Rajam and Rangiah[2] stated that the disease was distributed in both hemispheres and endemic in southern China, the East Indies, northern Australia, some countries of Central, South, and North America and the West Indies. In the United States, Greenblatt[33] estimated a population prevalence of 5000–10,000 cases in 1947. Nowadays, significant numbers are found in only a few developing countries, although sporadic cases may occur in developed countries. A small epidemic of 20 cases was reported in 1984 in the United States.[34]

The main foci of donovanosis in recent times have been in Papua New Guinea,[35] southern Africa, particularly the Durban-KwaZulu-Natal region[36] but also eastern Transvaal[37] and Zimbabwe,[38] parts of India,[39] northeast Brazil,[40] French Guyana,[41] and aboriginal communities in Australia.[42] Papua New Guinea seems to be the worst affected region; in 1980, donovanosis accounted for 46% of genital ulcers in women.[43] In a study at five health centers in 1989–90, donovanosis was the second most common cause of genital ulceration after genital herpes[44] and the most common sexually transmitted infection (STI) amongst new STI attendees in Porgera Enga province in 1992–93.[45] However, a more recent WHO consensus report states that donovanosis has now become rare in Papua New Guinea.[46] The largest epidemic recorded was in Dutch South New Guinea between 1922 and 1952, when 10,000 cases were reported from a population of 15,000.[47]

In the main STI clinic in Durban, following a decrease after a peak in 1969–74,[36] the numbers of donovanosis cases recorded in the annual reports of the medical officer of health increased from 312 in 1988 to 3153 in 1997.[36,48] In a microbiologic study of genital ulcer disease among STI clinic attenders in Durban, donovanosis was diagnosed in 11% of men[49] and 16% of women in 1988.[50] Although genital ulcer diagnoses in Durban were recorded by syndrome without mention of likely specific etiologies after 1997, it would appear that donovanosis has now decreased significantly. Recent genital ulcer surveys in men identified donovanosis in 4% in 1999[51] with a further reduction to $\leq$1% in 2001[52] and 2004.[53] Before the 1980s, few cases were present in South Africa and it was suggested that donovanosis had all but disappeared.[54] A more likely explanation is that the condition attracted little interest and went unrecognized or was diagnosed as lymphogranuloma inguinale or lymphogranuloma venereum.[55] Elsewhere in Africa, sporadic cases of donovanosis have been reported in recent times from Botswana,[56] the Central African Republic,[57] Gabon,[58] and Zambia.[59]

In India, donovanosis accounted for 14% of genital ulcer cases at a southern STI clinic, 15% of whom were HIV positive between 1993 and 1997,[60] but in North India the numbers of cases dropped considerably in the 1990s.[61] In Jamaica, the prevalence of donovanosis diagnosed on clinical grounds decreased from 4.1% in 1982–83 to 2.3% in 1990–91.[62]

In Australia, a donovanosis elimination program was launched in 1998 amongst Aboriginals.[63,64] This involved designated clinical officers who coordinated clinical protocols, performed health promotion activities, validated epidemiological data, ensured laboratory control, and assisted in the follow-up of hard to reach cases. This program has achieved remarkable success and reduced the number of annual cases to a handful throughout Australia.[65]

It has been questioned as to whether donovanosis is a sexually transmitted disease (STD) because of the low incidence of the disease, the differences in the racial and sex

distributions, uncertainty about the incubation period, infrequency of cases of conjugal infection, and the occurrence of primary extragenital lesions.[66] The condition undoubtedly has several unusual epidemiologic features that warrant close scrutiny.

The majority of cases are in the 20- to 40-year age group, i.e., the most sexually active. Most case series have recorded a preponderance of males, although in some studies with limited numbers of cases, such as in Zambia,[59] western Australia,[67] and eastern Transvaal, South Africa,[68] more women than men have been reported. Rajam and Rangiah[2] recorded 1350 men and 562 women in their large series and similar male-to-female ratios have been reported in Zimbabwe[38] and southeast India.[69] Higher male-to-female ratios of more than 6:1 have been reported from Papua New Guinea[35] and India.[70] In Durban, HLA studies showed an association between donovanosis and HLA-B57 and a trend toward resistance to disease with HLA-A23.[71]

The incubation period is uncertain. Sehgal and Prasad[72] found the average incubation period to be 17 days, but a range of 1–360 days has been reported.[73] Experimental production of typical donovanosis lesions was induced in humans 50 days after inoculation.[12]

Among sexual partners of index cases, wide variations in the rates of infection have been reported. In Papua New Guinea[35] and the United States,[74] the coinfection rate was 1–2%, whereas in India rates of up to 50% were reported among marital partners examined.[69,75] A more recent study of 255 cases in India in which eight couples were examined found conjugal involvement in one pair only.[76] In many cases, the disease is mild, particularly in men,[2] and examination of all regular sexual partners is recommended.

Transmission via fecal contamination of abraded skin was suggested as a possible mode of transmission by Goldberg.[20] Although he isolated the causative organism from feces, there are no subsequent reports to support this hypothesis. Cases in children have been attributed to sitting on the laps of infected adults.[77] Disseminated donovanosis has been reported in a neonate born to a mother with a large granulomatous lesion of the vulva who incurred a third-degree tear during delivery.[78] Careful cleansing of neonates born to infected mothers is recommended.[79]

CLINICAL MANIFESTATIONS

The first sign of infection is usually a firm papule or subcutaneous nodule that later ulcerates. Four types of donovanosis are described classically: (1) ulcerogranulomatous—the most common variant—nontender, fleshy, exuberant, single or multiple, beefy-red ulcers that bleed readily when touched (Fig. 40-1), (2) hypertrophic or verrucous type, an ulcer or growth with a raised, irregular edge, sometimes completely dry with a walnut like appearance (Fig. 40-2), (3) necrotic, usually a deep, foul-smelling ulcer causing tissue destruction (Fig. 40-3), and (4) sclerotic or cicatricial, characterized by extensive formation of fibrous and scar tissue.

The genitals are affected in 90% of cases and the inguinal region (Fig. 40-4) in 10%. The usual sites of infection are, in men, the prepuce, coronal sulcus (Fig. 40-5), frenum, and glans penis and, in women, the labia minora and fourchette

FIGURE 40-1. Typical subpreputial ulcerogranulomatous donovanosis lesions.

FIGURE 40-2. Hypertrophic verruciform form of donovanosis in inguinal region.

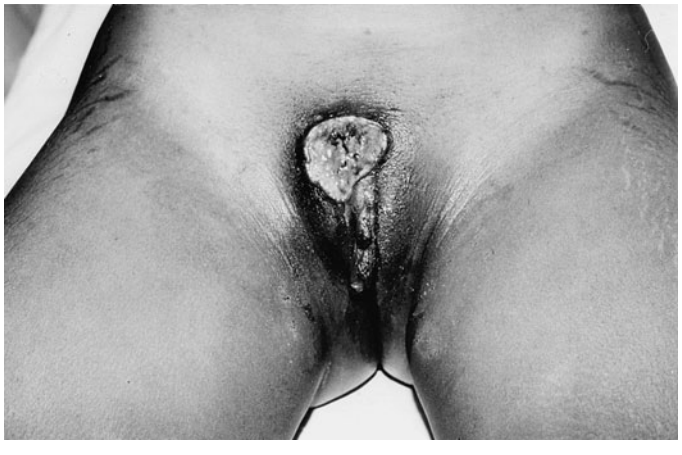

FIGURE 40-3. Deep necrotic donovanosis ulcer causing tissue destruction.

(Fig. 40-6). A preponderance of cases has long been recognized in uncircumcised men.[80] Lesions of the cervix may mimic cervical carcinoma. Extragenital lesions occur in 6% of cases but are often missed in nonendemic areas.[2,81,82] Sites of infection include the lip, gums, cheek, palate, pharynx, neck, nose, larynx, and chest. Extragenital lesions are usually associated with primary genital disease. On the rare occasions when primary extragenital lesions are diagnosed, the possibility of rhinoscleroma should be considered.

FIGURE 40-4. Inguinal lesions of donovanosis.

FIGURE 40-5. Multiple ulcerogranulomatous penile lesions of donovanosis.

FIGURE 40-6. Confluent donovanosis lesions at fourchette.

Lymphadenitis is an uncommon finding.[83] Disseminated donovanosis is rare; secondary spread to liver and bone may occur and is usually associated with pregnancy and cervical lesions. Donovanosis has a more aggressive course during pregnancy.[80,84,85] Polyarthritis and osteomyelitis are rare complications.[86] Neonatal cases often present with ear infections.[79,87]

DIAGNOSIS

Ulcerogranulomatous donovanosis lesions have a characteristic appearance and should be distinguished readily from the other classic STI causes of genital ulcer disease.[88] However, primary syphilitic chancres, secondary syphilis (condylomata lata), chancroid, and large herpetic ulcers can all be mistaken for donovanosis. Amebiasis and carcinoma of the penis should also be considered if tissue destruction or necrosis is present.

Tissue smears remain the mainstay method of diagnosis. Confirmatory specimens can usually be obtained as long as an adequate smear is prepared and antibiotic treatment has not been started. Most centers with experience with donovanosis have developed their own methods for maximizing the diagnostic yield from clinical specimens. Greenblatt and Barfield[89] advocated obtaining crush biopsy samples from the edges of lesions and stressed the importance of obtaining clean specimens for the preparation of tissue smears. Rajam and Rangiah[2] obtained material by means of a curette, forceps, the sharp end of a broken slide, or the edge of a safety razor blade and crushed the specimen between two slides and stained by the Leishman or Giemsa methods. Rapid results have been achieved using material obtained with a chalazion spoon.[90] Other stains used include Delafield's hematoxylin and eosin,[28] Wright's,[91] and pinocyanole.[92] A 100% success rate was claimed using a slow-Giemsa (overnight) technique.[93] A modified Giemsa's stain (RapiDiff) has yielded rapid results in a busy clinic environment[94] (Fig. 40-7). Donovan bodies also have been identified in Papanicolaou smears.[95] If multiple swabs are taken from ulcers and donovanosis is

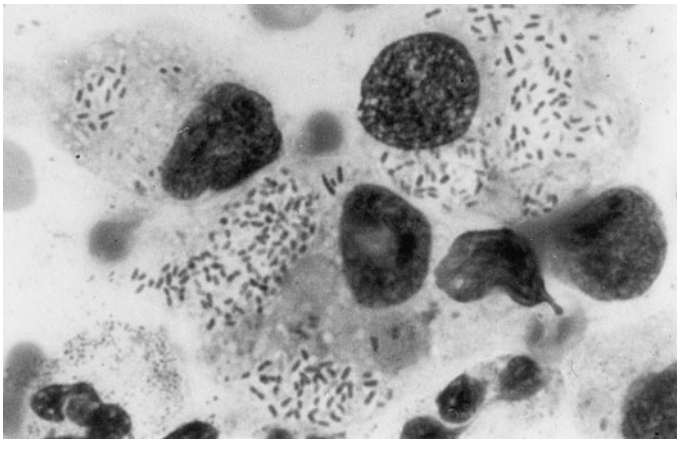

FIGURE 40-7. Tissue smear stained by rapid Giemsa (RapiDiff) technique showing numerous Donovan bodies in monocytes.

considered likely, the smear for Donovan bodies should be taken first so that an adequate amount of material can be obtained from the ulcer.

Biopsy and histologic examination may be required for lesions that are small, dry, sclerotic, or necrotic. Giemsa's or silver stains are the most effective methods for visualizing the organisms in tissue sections. The characteristic histologic picture shows chronic inflammation with infiltration of plasma cells and polymorphonuclear leukocytes[27]; the dermis shows a dense cellular infiltrate with large numbers of plasma cells. Ulceration and acanthosis with focal collections of polymorphonuclear leukocytes are found in the epidermis; elongation of rete ridges occurs in association with the hypertrophic variant.[29]

No serologic tests are currently in generalized use. Complement-fixation tests were developed and found to be quite sensitive.[16,17] An indirect immunofluorescent technique had a high sensitivity for established lesions but was not deemed suitable for early donovanosis ulcers. However, this test could be of use as an epidemiologic tool in population studies.[96]

The organism has been characterized further by the development of molecular-based tests and the similarity of the causative organism to *klebsiella* species confirmed. A diagnostic PCR was developed using the observation that two unique base changes in the phoE gene eliminate Hae111 restriction sites enabling clear differentiation from closely related *klebsiella* species.[25] This method has been refined further to a diagnostic colorimetric PCR test although further validation with samples from diverse geographic sites is awaited.[97] A genital ulcer disease multiplex PCR (GUMP) test has recently been developed in Australia using an in-house nucleic acid amplification technique that incorporates *C. granulomatis* primers.[98] This test will be useful in defining the prevalence of the various causes of genital ulcers in at-risk populations and also in assessing long-term efforts to eliminate donovanosis.

TREATMENT AND MANAGEMENT

Donovanosis is one of the few bacterial infections that could be treated in the preantibiotic era. Antimony compounds were used successfully for primary infections but had limited efficacy for recurrences or reinfections.

The first antibiotic shown to be effective for donovanosis was streptomycin in 1947.[99] Nowadays, various therapeutic treatments are used and probably reflect local availability of different drugs. Streptomycin has been used extensively in India and is effective for large lesions, although daily injections are required.[100] Chloramphenicol has been used in Papua New Guinea,[101] cotrimoxazole in India[102] and South Africa,[103] and thiamphenicol in Brazil.[104] Healing is usually achieved with tetracycline, although resistance is reported.[105] Norfloxacin,[106] ciprofloxacin,[107] and high-dose ceftriaxone[108] are also effective. Gentamicin 1 mg/kg 3 times daily intramuscularly or intravenously can be given if there is no response in the first few days with other regimens. Erythromycin is recommended during pregnancy. Encouraging results have been shown with azithromycin which has now become the drug of choice; a course of 500 mg daily for 1 week or 1 gram weekly for 4–6 weeks are both effective[109]; WHO recommends 1 gram followed by 500 mg daily[110] and the CDC recommends 1 gram weekly for at least 3 weeks until lesions are healed.[111] Children with donovanosis should receive a short course of azithromycin 20 mg/kg. Children born to mothers with untreated donovanosis should receive prophylaxis with a three-day course of azithromycin 20 mg/kg once daily.[79]

COMPLICATIONS

Rajam and Rangiah[2] found carcinoma, either as a complication of or a sequel to long-standing donovanosis, to be a rare occurrence seen in 0.25% of 2000 cases. Positive reactivity with *D. granulomatis* antigens was found in 9 of 62 cases of carcinoma of the penis in Jamaica, but this work was not developed further.[112]

Nowadays, the most frequent complication is pseudoelephantiasis (Fig. 40-8), which is more common in women and found in up to 5% of cases.[113] Surgical intervention may be indicated for advanced intractable lesions.[114] Stenosis of the urethra, vagina, or anus may occur in the sclerotic variant of donovanosis.[2]

The differential diagnosis between donovanosis and squamous cell carcinoma of the penis may be difficult. A therapeutic trial of antibiotic therapy should always be given, even if donovanosis is only a remote possibility.

FIGURE 40-8. Extensive vulval donovanosis with lymphedema and esthiomene.

Donovanosis ulcers may be coinfected with other STIs, particularly syphilis.[43,49] Such cases justify management by the syndromic approach with treatment for both conditions. However, it is important that these patients be followed, even when managed by primary health-care workers, until complete healing is achieved. The presence of donovanosis ulcers does not preclude sexual intercourse,[115] and the risks of reinfection should be stressed at the initial consultation.

DONOVANOSIS AND HIV INFECTION

The classic STIs, and genital ulcer diseases in particular, are significant risk factors for HIV in developing countries. In Durban, in a population where HIV infection had been introduced only recently, the proportion of men with donovanosis and HIV infection increased significantly as the duration of lesions increased, thereby suggesting that HIV was acquired via sexual intercourse in the presence of ulcers.[116]

The treatment of donovanosis may need to be modified in HIV-infected patients with significant immunosuppression. In Mumbai, India, the mean healing time in HIV-positive patients with donovanosis was 25.7 days compared to 16.8 days in HIV-negative subjects.[39] In Brazil, two AIDS patients with donovanosis failed to respond to conventional treatment with combinations of cotrimoxazole, tetracycline, and thiamphenicol.[117] Interestingly, two HIV-positive patients with oropharyngeal infections with *K. rhinoscleromatis* required prolonged courses of antibiotics before clinical cure.[118] However, among HIV-positive pregnant women without significant documented immunosuppression, the clinical presentation and response to treatment in donovanosis appeared to be unaltered by HIV.[119] Further clarification of the role of oral azithromycin in the management of donovanosis in HIV-positive patients is awaited.

PREVENTION AND CONTROL

Donovanosis is one of the most easily recognizable causes of genital ulcer disease clinically in endemic areas.[88] Because it is limited to a few specific geographic locations, local elimination and even global eradication are realistic objectives[65,120] that are justified if the high proportion of HIV transmissions attributable to genital ulcers is taken into consideration.[121] Such programs would need to appreciate the diverse nature of the communities affected and include careful appraisal of local customs and beliefs. Although communities in the donovanosis-endemic countries of Papua New Guinea, India, South Africa, Brazil, and Australia differ markedly, they all have similarities that may be relevant to donovanosis control. Most individuals with donovanosis in these communities are subject to social deprivation, low socioeconomic status, and poor standards of personal genital hygiene.

Donovanosis should remain high on the list of differential diagnoses of genital ulceration in female sex workers in donovanosis-endemic countries. In India,[2] the United States,[34] and Papua New Guinea,[35] prostitutes have been identified as source contacts of index cases and usually have clinically detectable lesions. In Papua New Guinea, local sexual practices and beliefs may play a significant role in the spread of donovanosis: It is not unknown for many men to have sexual intercourse with a single woman during festival occasions[122]; furthermore, some men believe that impurities in their blood cause donovanosis ulcers and resort to self-mutilation in an attempt to "release" the cause of the problem.[123] It should also be noted that Papua New Guinea now has the highest prevalence of HIV in the Oceania region.[124]

Since the overall prevalence of donovanosis in most endemic areas is low, mass surveys to identify cases or mass treatment campaigns are probably not justified. However, mass treatment of cases identified in house-to-house visits in Goilala, Papua New Guinea, was successful in controlling a localized epidemic in the 1950s.[77] This strategy merits further consideration as an HIV prevention measure in that country if donovanosis is found to be still prevalent there.

Poor understanding has in the past led patients with severe donovanosis to become shunned like lepers.[2] Many sufferers express profound feelings of shame, guilt, and embarrassment. Some have resorted to suicide. Greenblatt[33] has painted an emotive picture of the disease—"poorly understood and poorly handled, the disease becomes so loathsome that few clinics and fewer physicians are willing to treat those afflicted with it." Even now, extreme rejection is not unusual.[125]

In many developing countries, donovanosis patients are seen at STI clinics after attending primary health-care centers where various treatment approaches have failed. Patients with donovanosis may need prolonged courses of antibiotics and require careful explanation and reassurance about a condition that they may have had for a long time. Where possible, this is probably best given by staff who have chosen to work with STI patients and can give individual attention coupled with a sympathetic, nonjudgmental approach.[126] Clearly, there is a need for ongoing education of health-care workers about donovanosis in endemic areas and to raise community awareness of the importance of genital ulcer disease as a proven risk factor for HIV transmission.[127] Expanded access to azithromycin would be a major step forward and contribute significantly to limiting compliance problems with other therapies currently in use.

Globally, donovanosis has declined considerably over the last ten 10 years. The reasons for this are multifactorial but include syndromic management for genital ulcers at the primary health-care level and a more rational use of antibiotics. However, there is still a need for clinicians to be vigilant for outbreaks in the same way that recent epidemics of syphilis and lymphogranuloma venereum have been identified.

41 Genital Mycoplasmas

Patricia A. Totten, David Taylor-Robinson, and Jørgen Skov Jensen

INTRODUCTION

Research in the past decade has led to many exciting discoveries of the disease associations and pathogenic mechanisms of the genital mycoplasmas. The recognition of *Mycoplasma genitalium* as a cause of idiopathic urethritis in men and a possible cause of cervicitis and upper tract disease in women suggests that this organism may have a significance rivaling that of *Chlamydia trachomatis.* Recognition that *Ureaplasma urealyticum* organisms, previously called T-strain mycoplasmas, represent two distinct species, designated *U. urealyticum* (formerly biovar 2) and *U. parvum* (formerly biovar 1), has led to research evaluating their possible differential disease associations in both men and women. These studies have only recently become possible due to the development of specific PCR assays to identify and easily differentiate these fastidious species. In the following chapter, we focus on the most common genital mycoplasmas—*M. genitalium,* the ureaplasmas (*U. urealyticum and U. parvum*), and *Mycoplasma hominis*—their detection, prevalence in various populations, role in human disease, pathogenesis, and treatment, when appropriate.

The genital mycoplasmas, as with other bacteria in the class *Mollicutes* ("soft skin"), are thought to have devolved from ancestral anaerobic bacteria (clostridia) by gene deletion. Indeed, one species, *Mycoplasma genitalium,* holds the distinction of having the smallest genome of any known cellular organism that can be cultured axenically, and thus has been used as a model for the minimal requirements for cellular life.[1,2] Of the eight genera within the class, five, namely, *Mycoplasma, Ureaplasma, Acholeplasma, Anaeroplasma,* and *Asteroleplasma,* comprise more than 120 species, most of which belong to the genus *Mycoplasma.* The term "mollicutes" is sometimes used trivially to describe any of the organisms in the class, irrespective of genus or species, as is the term "mycoplasmas," which is used in this chapter. However, the term "ureaplasmas" is often used to refer to organisms that hydrolyze urea and are therefore classified within the genus *Ureaplasma.* Of the approximately 20 mycoplasmas that have been detected in the human species, four are commonly detected in the genitourinary tract, which is their primary site of colonization. Characteristics of these mycoplasmas and their disease associations in comparison with the human respiratory pathogen, *M. pneumoniae,* are listed in Table 41-1. Due to orogenital contact, some of these genital species are found occasionally in the oropharynx and, conversely, some of those mycoplasmas that have the oropharynx as their primary site of colonization are found in the genital tract.

EPIDEMIOLOGY

COLONIZATION OF INFANTS AND CHILDREN

Infants may become colonized with genital mycoplasmas during passage through the birth canal; infants who are delivered by cesarean section are colonized less often than those delivered vaginally.[7,8] Ureaplasmas have been isolated from the genitalia of up to one-third of infant girls, and *M. hominis* from a smaller proportion.[7,9,10] These genital mycoplasmas are isolated even less frequently from the genitourinary tract of infant boys.[10] Mycoplasmas, mainly ureaplasmas, have also been isolated from the nose and throat of infants of both sexes.[7] Infant colonization figures for these genital mycoplasmas vary from one population and from one study to another, depending upon the proportion of pregnant women who are colonized. Since *M. genitalium* is frequently detected in the cervix, vagina, and endometrium, the potential for neonatal infection exists, yet neonatal infections with this organism have rarely been reported to date.[10a]

Neonatal colonization with *M. hominis* and the ureaplasmas tends not to persist, particularly in boys, and the proportion of infants who are colonized decreases quite rapidly as they get older. Thus, these genital mycoplasmas are seldom recovered from urine or genital-tract specimens from prepubertal boys, but 5–22% of prepubertal girls are colonized with ureaplasmas and 8–17% with *M. hominis.*[11–15]

Table 41-1. Distinguishing Features and Disease Associations of the Most Prevalent Human Mycoplasmas with Possible Pathogenic Significance

Species	Energy Source	Genome Size (kb)[a]	Disease Associations[b]					
			Urethritis (Men)	Cervicitis	Bacterial Vaginosis	Endometritis and/or PID	Preterm Birth	Infertility (Women)
M. hominis	Arginine	ND[c]	–	–	++++	+/–	–	–
M. genitalium	Glucose	580	++++	+++	–	++	+/–	+
M. pneumoniae	Glucose	816	–	–	–	–	–	–
Ureaplasma spp.[d]	Urea	NA	+/–	?	+++	?	+/–	?
U. urealyticum[d]	Urea	840–1140	+	?	?	?	?	?
U. parvum[d]	Urea	750–760	–	?	?	?	?	?

The primary site of colonization for all species listed is the reproductive tract except for *M. pneumoniae* for which the respiratory tract is its primary colonization site.

[a]Genome size was determined by whole genome sequencing *(M. genitalium and M. pneumoniae)*[2,3] or RFLP analysis *(U. urealyticum and U. parvum)*[4]; whole genome sequencing confirmed the genome size of *U. parvum* as 752 kb.[5] These genomes are approximaly 10-fold smaller than most Firmicutes, for example, *Escherichia coli.*

[b]++++, strong association, +, weak association; +/–, association in some, but not other studies; -, no association or negative (inverse) association.

[c]ND, not determined; NA, not applicable.

[d]*U. urealyticum* and *U. parvum*, formerly designated as T960 and Parvo biovars within the sole species *U. urealyticum* (designated as the ureaplasmas or *Ureaplasma* spp. herein) are now considered two different species.[6] *U. urealyticum* (T960 or biovar 2) consists of serovars 2, 4, 5, and 7–13. *U. parvum* (parvo or biovar 1) consists of serovars 1, 3, 6, and 14.

In sexually abused children, figures of as much as 48% and 34%, respectively, have been recorded.[13]

COLONIZATION OF ADULTS

After puberty, colonization with *M. hominis, M. genitalium,* and the ureaplasmas occurs primarily as a result of sexual contact.[11,16–20] Sexually mature individuals without a history of sexual contact are colonized infrequently with these genital mycoplasmas and colonization increases proportional to the number of different sexual partners. Recently, the prevalence of *M. genitalium* in two general population-based studies was reported as 2.3% and 1.1% in 21–23-year-old women and men in Denmark[20] and 1.4% and 1.1% in 18–27-year-old women and men in the United States.[19] In the latter study, the prevalence of this organism in this largely asymptomatic population was similar to that of *Neisseria gonorrhoeae* (0.4) and *C. trachomatis* (4.2). In both studies, detection of *M. genitalium* was associated with a history of sexual intercourse. Sexual transmission of this organism is also supported by the concordance of *M. genitalium* detection[21] and identity of strain types[22] among sexual partners.

CLINICAL MANIFESTATIONS AND SEQUELAE

ROLE OF GENITAL MYCOPLASMAS IN DISEASES OF THE GENITOURINARY TRACT OF MEN

Nongonococcal urethritis

In the past 10 years, *M. genitalium* has become increasingly recognized as a possible cause of urethritis with a prevalence similar to that of *N. gonorrhoeae and C. trachomatis.* This bacterium was originally isolated from urethral specimens from 2 of 13 men with nongonococcal urethritis (NGU),[23] yet the difficulty of culturing this fastidious organism in subsequent studies precluded assessment of its association with reproductive tract disease in men and women. Initially several investigators developed DNA probes to detect this organism in patient specimens,[24,25] but this approach was superceded by the superior sensitivity of PCR assays developed for this organism.[26,27] The availability of these assays provided the first opportunity to show that *M. genitalium* is associated with NGU.[28,29]

To date, more than 10 PCR assays have been used in more than 20 studies showing the association of *M. genitalium*

with NGU.[30–32] From the earliest studies,[28,29] *M. genitalium* has been detected more frequently in the urethra of men with NGU than in men without this condition (OR_{unadj} 4.7[3.5–6.3]), particularly among men with nonchlamydial NGU (OR_{unadj} 7.0 [4.6–10.8] see Fig. 41-1). Studies using multivariate analysis to assess possible confounders confirmed the association of *M. genitalium* with NGU with reported odds ratios of similar magnitudes and statistical significance.[33,34] Among STD clinic populations, 85–90% of *M. genitalium* infected men have microscopic evidence of urethritis, defined in different studies as ≥4, ≥5, or ≥10 PMNs/HPF or urethral "threads" containing ≥10 PMNs/HPF,[21,29,33,35,36] and the majority of *M. genitalium* infected men (65–77%) reported symptoms.[21,35] The development of quantitative PCR assays for *M. genitalium* allowed the demonstration of a dose/response relationship between signs and symptoms of urethritis and *M. genitalium*-DNA load in urethral and urine specimens,[37–39] further supporting the causal relationship of *M. genitalium* with urethritis. Finally, animal experiments demonstrated that intraurethral inoculation of male chimpanzees with *M. genitalium* resulted in the development of urethritis in the majority, shedding of the organism for up to 18 weeks after inoculation, and a humoral antibody response, thus fulfilling Koch's postulates of causation.[40,41]

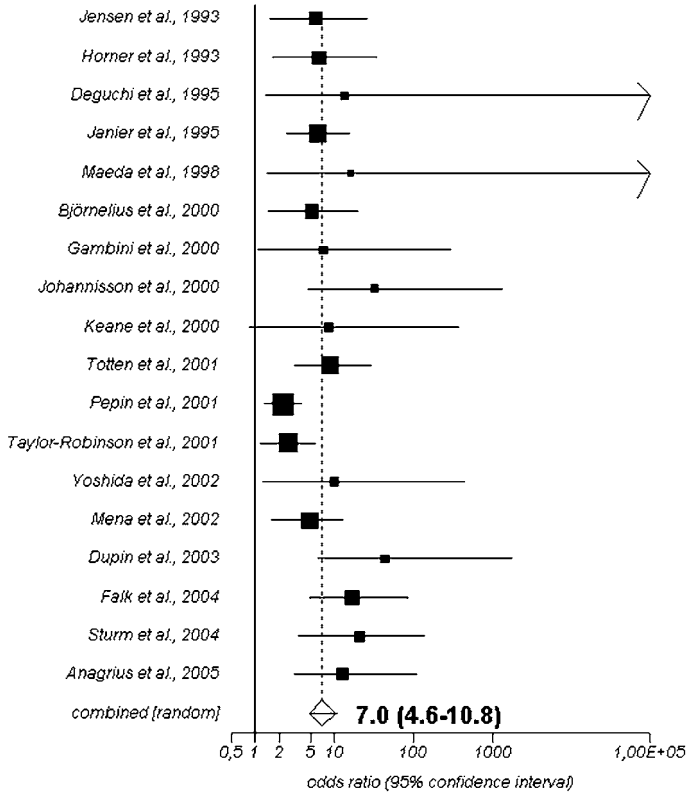

FIGURE 41-1. Forest plot showing the association between *M. genitalium* infection and nonchlamydial NGU expressed as odd ratios with 95% CI as calculated from published studies.

Several studies have shown a strong correlation of *M. genitalium* with persistent and recurrent NGU, perhaps due in part to the association between microbiologic treatment failure and persistence of urethritis.[42–48] In settings where tetracyclines or quinolones are the drugs of choice, *M. genitalium* has been found in a high proportion of patients with recurrent or persistent urethritis. For example, in a follow-up study of 86 men with acute NGU, Horner et al.[46] found that 7 (13%) of 56 men with chronic NGU were *M. genitalium* positive and all *M. genitalium*-positive men identified during follow-up had chronic NGU. Similarly, Taylor-Robinson et al. reported that 11 (21%) of 52 men with persistent or recurrent NGU were *M. genitalium* positive.[45] In a study of 78 men who had received standard treatment for urethritis with doxycycline, and who reattended the clinic because of persisting or recurring symptoms, Wikström and Jensen[47] found that 32 (41%) were *M. genitalium* positive, demonstrating both the lack of efficacy of doxycycline and the strong correlation with symptomatic urethritis. More recently, azithromycin treatment failure was reported among men with *M. genitalium*-positive NGU (28% treatment failure, CI_{95} 15–45%) and was correlated with a reduced susceptibility of *M. genitalium* to this antibiotic.[48] Clearly, randomized, controlled, treatment trials are needed to establish the optimal treatment regimen for this emerging pathogen.

In contrast to the consistency of studies linking *M. genitalium* with NGU, the association of ureaplasmas with this syndrome has been controversial. In several studies conducted in the 1970s and 1980s,[49–53] these bacteria were isolated significantly more often, and in higher quantities, from men with chlamydia-negative NGU, than from men with chlamydia-positive NGU, controls, or both. In contrast, other studies did not reveal this association.[33,54–56] In one study, this organism was associated with chronic, but not acute, NGU.[46] Notably, the strongest association of ureaplasmas with NGU (and high quantities [$\geq 10^3$ ccu/mL] of ureaplasmas with NGU)) was conducted among Caucasian men with first episode nonchlamydial NGU,[49] a population that has not been typically analyzed in subsequent studies of STD clinic populations. Finally, a role for ureaplasmas in urethritis is supported by a study in which two investigators from the UK inoculated themselves intraurethrally with a ureaplasma strain previously isolated from patients who had NGU; both subjects developed urethritis and a specific antibody response to this organism.[57]

The association of the ureaplasmas with NGU may be partially resolved by assessing the correlation of the newly recognized species, *U. parvum* and *U. urealyticum*, with disease. These two species, initially recognized as biovar 1 and 2 within the genus *Ureaplasma* based on serotype groupings and manganese susceptibility, now can be differentiated by genome size, whole cell DNA homology, protein antigenicity and polymorphisms, and sequence divergence within selected genes.[6,58]

The designation of the two *Ureaplasma* species as *U. urealyticum* and *U. parvum* is a little confusing considering that formerly all urea-hydrolyzing human *Mycoplasma* spp. were also designated as *U. urealyticum.* Thus, in this chapter, we will use the terms "the ureaplasmas" or "*Ureaplasma* spp." in studies in which the two species were not differentiated.

Three studies to date assessing the association of the newly defined *Ureaplasma* spp. with NGU have yielded conflicting results.[59–61] In all three studies, *U. parvum* was detected more often in controls, consistent with its role as a commensal at this site. In contrast, the association of *U. urealyticum* with NGU differed among the three studies. In their study of 235 men with, and 205 without, NGU, Povlsen et al.[59] detected *U. urealyticum* in 18% of cases and 9% of controls ($p = 0.01$, our calculations) in contrast to *U. parvum* which was detected in 14% of cases and 21% of controls. The association of *U. urealyticum* with NGU was further supported in a study by Deguchi et al.[60] in which 16% of 329 men with NGU and 8% of 141 men without NGU were infected with this organism ($p = 0.025$). However, the results of both the studies were contradicted by the study by Bradshaw et al.[61] in which *U. urealyticum* was not associated with NGU (*U. urealyticum* was detected in 43 [13%] of 329 cases and 54 [18%] of 307 controls), even after controlling for possible confounders by multivariate analysis. Clearly, the association of *U. urealyticum* with NGU requires further study. Differences in the association of *U. urealyticum* with NGU may reflect differences in the population studied, selection of cases and controls, PCR method used, prevalence of more pathogenic strains in different geographic locations, and/or previous infection with, and possible partial immunity to, *Ureaplasma* spp. Further studies, including those in which race, age, number of sexual partners, and past history of NGU are assessed for their effect on this association, are needed to resolve this controversy. In addition, the impending whole genome sequencing of all 14 ureaplasma serovars (John Glass and Ken Waites, personal communication) might reveal the presence of potential virulence factors that could be exploited to assess the differential association of *Ureaplasma* spp., serotypes, or strains with disease.

Treatment trials assessing clinical cure and clearance of *U. urealyticum, U. parvum,* and other pathogens may increase our understanding of the role of ureaplasmas in NGU. In one study, men were treated with aminocyclitols, which are active against ureaplasmas but not against chlamydiae, or with sulfisoxazole, which is active against chlamydiae but not against ureaplasmas.[62] The clinical results suggested that both chlamydiae and ureaplasmas could cause urethritis. In another study, men who had NGU were treated with rifampicin, which is active against chlamydiae but not against ureaplasmas.[63] The proportion of patients cured clinically was much smaller than that of another group who were given minocycline, which is active against both kinds of microorganism. Of course, the extent to which the existence of *M. genitalium* in some of the patients in these studies, not appreciated at the time they were undertaken, may have affected the results and jeopardized the conclusions is unknown. In clinical trials assessing the responses of *Ureaplasma* spp. to the tetracyclines and azithromycin, microbiologic and clinical treatment failures of 22–55% have been reported,[64–69] consistent with the occurrence of tetracycline resistance mediated by *tet*M among a subpopulation of ureaplasma strains[70] and the moderate baseline susceptibility of ureaplasmas to macrolides.[71]

Studies using either PCR or culture to detect *M. hominis* do not indicate that this organism is a cause of NGU.[33,50,72]

Prostatitis

Thirty years ago, Mårdh and Colleen[73] recovered *M. hominis* from urethral specimens of 8 (10%) of 79 patients with chronic prostatitis (now presumably classified as category III in the current NIH classification of prostatitis, the chronic prostatitis/chronic pelvic pain syndrome) and from none of 20 normal age-matched controls, a difference certainly insufficient to suggest an association with the disease. Likewise, Peeters and associates[74] isolated this mycoplasma from 10 (12%) of 85 men who had prostatitis of unknown origin and from two (4%) of 51 healthy men ($p = 0.26$) and *Ureaplasma* spp. were isolated from 40 (47%) of the patients and from 13 (26%) of the healthy men ($p = 0.02$). Hofstetter et al.[75] studied men with what was described as urethroprostatitis and found that mycoplasmas, mainly ureaplasmas, were also isolated significantly more often and in greater numbers from patients with disease than from normal men who served as controls. Later, Brunner and colleagues[76] associated ureaplasmas with prostatitis in 82 (13%) of 597 patients who had the disease, and Weidner and coworkers[77] implicated these organisms in 46 (11%) of 412 men who had urethroprostatitis, a claim also made by Ohkawa et al.[78,79] a decade later, in chronic prostatitis on the basis of isolation and antibiotic investigations. In contrast to these studies in which isolation was successful, this was not always so; Meares[80] and Vinje et al.[81] failed to recover ureaplasmas from men with chronic nonbacterial prostatitis. On reflection, three important issues are raised by these various studies. First, the accuracy of the diagnosis. It clearly appears that chronic prostatitis has not always been truly chronic but sometimes "acute on chronic prostatitis" or "acute urethritis on chronic prostatitis." Second, patients with chronic disease have often been subjected to multiple courses of antibiotics before microbiological investigations have been undertaken, diminishing the chance of recovering an etiological agent. Third, whether the organisms that were detected had been derived entirely from the prostate or are "contaminants" that had come partly, or totally, from the urethra as a consequence of the detection procedure is unclear. With the first and third points particularly in mind, biopsies taken under transrectal

ultrasound control from the prostates of 50 men with chronic prostatitis, defined by the Stamey technique, were found to contain chronic inflammatory cells but no microorganisms.[82] Most recently, *M. genitalium* was detected by specific PCR assays in 5 (4%) of 125 prostatic biopsies from men with chronic idiopathic prostatitis.[83] Thus, the available evidence suggests that a causative role for the genital mycoplasmas in the truly chronic condition is at best questionable and can be no more than minimal.

Epididymitis

Most cases of acute epididymitis in heterosexual men less than 35 years of age are due to *N. gonorrhoeae or C. trachomatis,* whereas among older men and homosexuals, gram-negative bacilli are usually responsible.[84–86] The recovery of *M. hominis* from an epididymal aspirate has been recorded once.[87] Furthermore, although ureaplasmas may be recovered from urethral specimens from some men who have epididymitis, recovery from percutaneous aspirates of the inflamed epididymis has also been recorded only once, in this instance in association with a greater than fourfold serologic antibody response.[88,89] Thus, the role of genital mycoplasmas seems to be meager, but the influence of ureaplasmal biodiversity has not been assessed and thus the ureaplasmas should not be discounted completely as a cause. In addition, the association of *M. genitalium* with epididymitis has not been assessed, but clinical experience suggests that it may play a role in some patients.

ROLE OF GENITAL MYCOPLASMAS IN DISEASES OF THE GENITAL TRACT OF WOMEN

Cervicitis

In most, but not all studies, *M. genitalium* has been associated with cervicitis (Table 41-2), an important finding, given the increased risk of upper tract infection associated with other organisms causing this disease. After the initial report of an association of *M. genitalium* with cervicitis in 1997,[90] in which *M. genitalium* was detected among 5 (7.8%) of 64 cases and none of 80 pregnant controls ($p < 0.05$), several studies have assessed and expanded upon this association. In a cross-sectional study, Manhart et al.[92] showed that *M. genitalium* was detected in 24 (11%) of 215 women with, and in 26 (5%) of 504 women without mucopurulent cervicitis and that this organism was independently associated with cervical mucopus ($p < 0.01$), cervical PMNs ($p < 0.01$), and easily induced cervical bleeding ($p = 0.06$). Further, after controlling for age, phase of the menstrual cycle, and other known cervical pathogens, the strength of this association (3.3 [CI_{95} 1.7–6.4]) was similar to that for *N. gonorrhoeae* (3.0 [CI_{95} 1.8–5.2]) and *C. trachomatis* (4.7 [CI_{95} 2.7–8.2]). Subsequently, in a study of 826 West African women, Pépin et al.[93] demonstrated by multivariate analysis that four signs of cervicitis (cervical discharge, cervical pus, easily induced bleeding, and inflammatory cervix) were associated with *M. genitalium* ($p \leq 0.05$ for each sign) with adjusted OR (between 1.6–1.8 for the four signs) very similar to that for *C. trachomatis* (1.3–4.1). A similar association of *M. genitalium* with signs of cervicitis was detected by Anagrius et al.,[21] Falk et al.,[94] and Gaydos et al.[95] Interestingly, in these latter two studies, *M. genitalium* was also associated with urethritis in women, a not unexpected finding given its strong association with this disease in men. In contrast to the above studies, no association between *M. genitalium* and cervicitis was detected by Casin et al.[91] in a study that differed from those above in its high prevalence of women with mucopurulent cervicitis (85%) and vaginal discharge (100%), analysis of multiple specimen types in some women, and definition of cervicitis as ≥10 PMNs/HPF. An etiologic role of *M. genitalium* in cervicitis is consistent with the results of chimpanzee experiments in which increased vaginal PMNs were detected, an antibody response was induced, and *M. genitalium* was persistently cultured (up to 11–14 weeks after inoculation) from the vagina in all four chimpanzees inoculated with this organism.[41]

The association of *M. hominis* and the ureaplasmas with cervicitis has been studied infrequently. In the study by Paavonen et al.,[101] it was found that mucopurulent cervicitis was associated with isolation of ureaplasmas ($p = 0.02$), although the relative prevalence of *U. urealyticum* and *U. parvum* and the role of *M. genitalium* and bacterial vaginosis as confounders in these analyses were not assessed.

Bartholin's gland abscess

Genital mycoplasmas have been isolated from Bartholin's gland abscesses, but often they had ruptured or been opened surgically before specimen collection; hence it is not clear to what extent the results represent "contamination" of the abscesses by mycoplasmas present in the vagina.[72] This problem was overcome by Lee et al.[102] who obtained percutaneous aspirates from 34 intact Bartholin's gland abscesses; *M. hominis* was isolated from only one, together with other vaginal organisms, and ureaplasmas from none of the aspirates. Thus, it would appear that genital mycoplasmas are not an important cause of Bartholin's gland abscesses. Whether they might have any role in less severe disease (Bartholinitis) and whether *M. genitalium* is associated with this disease has not been determined.

Bacterial vaginosis

Vaginal specimens from women who have bacterial vaginosis are positive for *M. hominis* more often, and contain larger numbers of the organisms, than specimens from women who do not have this syndrome.[100,103–107] Although mycoplasmas are resistant in vitro to metronidazole, this drug is often effective in treating bacterial vaginosis and at

Cervicitis defined by

[a]Purulent or mucopurulent cervical discharge or ≥ 20 PMNs/HPF[90]

[b]≥10 PMNs/HPF[91]

[c]Mucopurulent cervicitis (visible mucupus or > 30 PMNs/HPF in cervical mucus[92]

[d]Many indicators of cervicitis measured; shown is the association of mucopurulent discharge (yellow cervical exudates ("swab test")[93]

[e]More PMNs than epithelial cells in wet smear of lateral fornix and lateral vaginal wall[94]

[f]≥30 PMNs/HPF[21]

[g]Cervical discharge or friability[95]

[h]NS, non significant

[i]Note that this is an inverse association

the same time eliminating *M. hominis* from many of the subjects,[108] suggesting that *M. hominis* proliferates in the milieu created by the other microorganisms and when the latter are eliminated, so too is *M. hominis*. Thus, although *M. hominis* could conceivably play a role in bacterial vaginosis as a primary pathogen, it is more likely to behave symbiotically with the other bacteria that are an integral part of this condition. The ureaplasmas have also been associated with bacterial vaginosis in most, but not all studies.[100,105,107,109,110] The relative association of *U. urealyticum* and *U. parvum* with

bacterial vaginosis has not yet been assessed. Preliminary studies indicate that, unlike the ureaplasmas and *M. hominis, M. genitalium* is not associated with bacterial vaginosis[100] and may even be inversely associated with this condition[92] (Table 41-2).

Pelvic inflammatory disease

Pelvic inflammatory disease (PID) is caused by an ascending infection in which organisms present in the vagina and cervix invade the endometrium, fallopian tubes, and surrounding structures. *C. trachomatis* and *N. gonorrhoeae* are the organisms that are most frequently associated with PID. In addition, a mixture of aerobic and anaerobic bacteria, many associated with bacterial vaginosis, has been implicated as a cause of this condition by some investigators[111–114] and it is against this background that the role of the genital mycoplasmas is considered.

M. hominis has been recovered more frequently from vaginal and cervical specimens from women with PID than from normal women.[112,115–117] However, this organism is often recovered from the lower genital tract of women who have bacterial vaginosis (see the preceding) and, as the aforementioned studies linking *M. hominis* to PID did not include an assessment of bacterial vaginosis, the data are difficult to interpret. Relating the microbial flora of the lower tract to changes in the upper tract is difficult and studies based on laparoscopy are much more relevant. Mårdh and Westrom[118] first drew attention to the possibility that genital mycoplasmas might have a role in PID, by showing that *M. hominis* was isolated from the fallopian tubes of four (8%) of 50 women with salpingitis, but not from those women without salpingitis. More recently, in a study in which laparoscopy and endometrial biopsy were undertaken on 36 women with suspected PID, *C. trachomatis* or *N. gonorrhoeae* was identified in 11 of 14 women with both salpingitis and endometritis, in two of nine with salpingitis or endometritis, and in none of 13 patients who had neither condition ($p < 0.0001$), but *M. hominis* organisms were not isolated from any of the patients.[113] On the other hand, in another laparoscopy study, *M. hominis* was isolated directly from the fallopian tubes of 1 (5%) of 21 women with salpingitis and from the endometrium of 7 (33%) of these women.[119] However, since it is rare to dissociate *M. hominis* from bacterial vaginosis, one should be cautious before accepting *M. hominis* as an unequivocal cause of PID.

In several studies, antibody to *M. hominis* and fourfold rises in antibody titer to *M. hominis* were found more often among women who had PID than among controls.[112,116,120] In several such studies, the antibody titer rises were associated with the isolation of *M. hominis* from the lower genital tract or from the inflamed fallopian tubes.[119,121,122] In one study, an increased level of IgM antibody was found in 34% of patients with acute salpingitis and was associated with the isolation of *M. hominis* and with the presence of indirect hemagglutinating antibody to the mycoplasma.[123] High coinfection rates with other microorganisms[124] suggest that epithelial damage caused by these organisms allows contact between *M. hominis* and the immune system and thus an immune response.[125] Damage to fallopian tube epithelium has also been studied in organ cultures. *N. gonorrhoeae* produced profound damage to the epithelium.[126] In contrast, *M. hominis* multiplied and persisted but did not cause damage.[127] However, scanning electron microscope examination showed that the organisms induced pathologic changes in the form of ciliary swelling,[128] possibly due to the effect of ammonia produced by mycoplasmal metabolism. Studies in intact animals may be more relevant than studies in organ cultures. Female grivet monkeys infected with *M. hominis* developed a self-limited acute salpingitis and parametritis.[129] Further studies in grivet monkeys have shown that ascending *M. hominis* infection of the genital tract must be preceded by mechanical injury to the epithelial barrier and that subsequent spread occurs via blood and lymph vessels rather than by the canalicular route.[130]

Ureaplasmas have also been isolated directly from the fallopian tubes of patients with PID, as well as from pelvic fluid obtained by culdocentesis from such patients,[118,131–134] yet their occurrence at both sites is rare and usually in association with other known pathogens. Since most serological tests and inoculation studies in subhuman primates and in fallopian tube organ cultures have proved negative, ureaplasmas probably do not play a role in salpingitis.[127,135] In the cluster analysis of bacterial vaginosis-associated bacteria conducted by Ness et al.,[136] PID was associated with the absence of hydrogen peroxide-producing lactobacilli and the presence of *Gardnerella vaginalis*, *M. hominis,* anaerobic gram-negative rods, and ureaplasmas (p for trend = 0.008), but the role of individual organisms in this disease could not be assessed.

M. genitalium may play a casual role in upper tract infection, including endometritis and PID. In one study, 12 (39%) of 31 women with PID who had not been infected with *N. gonorrhoeae* and had no antibody to *C. trachomatis* or *M. hominis* had a fourfold or greater rise in the titer of antibody to *M. genitalium* as measured by microimmunofluorescence,[137] although another study failed to confirm these data.[138] In a case-control study of PID, *M. genitalium* was detected by PCR in cervical specimens in 6 (13%) of 45 women with the disease, but in none of 37 controls (p <0.01), and only one was coinfected with *C. trachomatis* and none with *N. gonorrhoeae.*[97] *M. genitalium* has also been associated with endometritis. Using PCR to detect this organism in both cervical and endometrial specimens, Cohen et al.[96] found an association of *M. genitalium* with endometritis (9 [16%] of 48 with histologically confirmed endometritis were positive vs. 1 [2%] of 57 women without this condition [p–0.02]). *M. genitalium* was detected by PCR in 1 of 123[139] and 1 of 23 (D. Taylor-Robinson and J. Jensen, unpublished data) laparoscopically obtained fallopian tube specimens

from women with salpingitis and has been shown to cause lower genital tract inflammation as well as salpingitis in marmosets, grivet monkeys, and baboons.[140] In addition, this organism is able to attach to spermatozoa, perhaps enhancing its ascension into the upper genital tract.[141]

In summary, there is some evidence that *M. hominis* may be a cause of PID, but very little evidence that ureaplasmas have a similar role. The possibility that these organisms play a role only within the context of bacterial vaginosis needs to be addressed. *M. genitalium* is not associated with bacterial vaginosis, but evidence is mounting that it may play a causal role in cervicitis and possibly endometritis and PID.

ROLE OF GENITAL MYCOPLASMAS IN DISORDERS OF THE URINARY TRACT

Urinary calculi

Infection (struvite) stones, composed of ammonium magnesium phosphate, are thought to be caused by urea-hydrolyzing bacteria including *Proteus* and *Ureaplasma* spp. In several studies, ureaplasmas have been detected in 12–27% of infection stones, often in pure culture,[142–145] and are more frequently detected in the urine and stones of patients with infection, compared to those with metabolic stones.[146]

Several groups have demonstrated the development of struvite stones in rats following inoculation with ureaplasmas (either *U. urealyticum* or *U. parvum,* depending upon the study),[147–150] and inhibiting the growth of ureaplasmas, either with doxycycline or with the urease inhibitor flurofamide, prevented stone formation.[150] In one study,[147] magnesium ammonium phosphate calculi developed in the bladders of male, but not female, rats after ureaplasmas were inoculated directly into the bladder or renal pelvis. Ureaplasmas have also been shown to induce crystallization of struvite and calcium phosphate in urine in vitro.[146,151] However, in a recent study, Reyes et al.[149] showed that susceptibility to infection with ureaplasmas and subsequent struvite stone formation was associated with a robust immune response in rats, a response that differentiated rat strains that developed stones from those that did not. Although these findings suggest that ureaplasmas have a role in the development of infection stones and that the inflammatory response plays a key role in stone development, ureaplasmas are less often detected and implicated in stone formation than other urease-positive bacteria.

Pyelonephritis and urinary tract infection

M. hominis does not appear to play a role in acute cystitis, similar isolation rates having been recorded for symptomatic women and controls, and the organism was not found in suprapubic aspirates.[152] In contrast, ureaplasmas have been associated with chronic urinary symptoms and the acute urethral syndrome (defined by dysuria and frequency in women whose urine contains $<10^5$ /mL of known uropathogens[153,154]). Stamm et al.[153] isolated ureaplasmas from 4 (27%) of 15 suprapubic aspirates taken from women with an acute urethral syndrome of unknown etiology and showed an association of relatively larger numbers of ureaplasmas ($\geq 10^3$ ccu/mL) with pyuria. Similarly, in a study by McDonald et al.,[155] ureaplasmas were recovered from suprapubic urine aspirates of one-fifth of patients with urinary tract infections; in one-third of these as the sole isolate. Potts et al.[156] assessed urinary tract infections in women referred to their clinic for chronic voiding symptoms and possible interstitial cystitis and found that 22 (46%) and 1 (2%) of 48 subjects had ureaplasmas and *M. hominis,* respectively, the majority of whom were clinically improved and had negative cultures following treatment. Together, the results of these studies suggest a role for ureaplasmas, but not *M. hominis,* in lower urinary tract infections, but confirmatory studies are needed, such as those controlling for possible vaginal contamination among women with bacterial vaginosis and those in which *U. urealyticum* and *U. parvum* are differentiated.

The association of ureaplasmas and *M. hominis* with pyelonephritis has also been assessed. Thomsen[157] isolated *M. hominis* from the upper urinary tract of 3 (14%) and ureaplasmas from the renal pelvis of 2 (9.5%) of 21 women with chronic pyelonephritis in contrast to none of 40 patients with noninfectious urinary tract diseases. In this study, only one of the three patients who harbored *M. hominis* had an associated bacteriuria, but all three patients had an acute exacerbation of pyelonephritis, two of whom developed antibody to *M. hominis.* In another study of patients with acute pyelonephritis,[158] ureaplasmas and *M. hominis* were isolated from the upper urinary tract of 5 (7%) and 7 (10%) of 67 such patients, respectively, in contrast to none of 50 control women with noninfectious diseases of the urinary tract. Antibodies to *M. hominis,* measured by indirect hemagglutination, were found in serum and in urine from some of these patients.[159] In dogs, ureaplasmas have multiplied and survived for at least 3 weeks after being introduced into experimentally obstructed upper urinary tracts, causing severe interstitial nephritis accompanied by an antibody response.[160] However, there is no evidence that ureaplasmas cause this disease in humans and there is insufficient evidence to indicate that they cause acute pyelonephritis. We conclude that to date, there is no clear evidence that either *M. hominis* or ureaplasmas is a significant cause of pyelonephritis, a concern highlighted by the lack of confirmatory clinical studies in the almost 30 years from the original observations.

ROLE OF GENITAL MYCOPLASMAS IN DISORDERS OF REPRODUCTION

Involuntary infertility

Ureaplasmas and *M. hominis* have been isolated more often from genital specimens from infertile than from fertile couples by some investigators but not by others.[161–165] Similarly, antibodies to these organisms have been linked to infertility in some, but not all, studies.[166–169] In several studies, ureaplasmas were recovered more often from endometrial specimens from infertile women than from fertile women.[170–172] However, the role of other organisms has rarely been considered, nor the possibility that ureaplasmas might be involved in only one of the several clinical categories of infertility. In this regard, Cassell and colleagues found ureaplasmas twice as commonly in a subpopulation of women whose infertility was associated with a "male factor" than in other women.[173]

Treating infertile couples with antibiotics is clearly one way of defining the role of microorganisms in infertility. However, the results have been contradictory. As reviewed elsewhere,[72] conception rates ranging from 23% to 84% have been recorded among ureaplasma-colonized infertile couples who were treated with tetracyclines. Busolo et al.[174] reported that conception had occurred in 5 (26%) of 19 doxycycline-treated patients in whom ureaplasmas were eradicated; there were no conceptions among 29 couples in whom ureaplasmas persisted after treatment with doxycycline. In another study, ureaplasmas were eradicated from 129 infertile couples; the 3-year conception rate was 60% compared to only 5% for 32 infertile couples in whom ureaplasmas could not be eliminated ($p < 0.001$).[175] In contrast, although others were able to eradicate ureaplasmas from 91% of infertile couples, the subsequent pregnancy rates were the same whether or not eradication had occurred.[161] Furthermore, in another study, after 1 year the conception rate among untreated ureaplasma-positive infertile women was 28%, similar to that among untreated ureaplasma-negative women (27%).[162] It is obvious that double-blind, placebo-controlled, antibiotic studies of couples with unexplained infertility are likely to provide the best information. In this regard, Harrison et al.[176] gave couples who had primary infertility of unknown cause either doxycycline or a placebo. Although a 28-day course of the antibiotic eradicated *M. hominis* and ureaplasmas, the rate of conception (17%) was no greater in those given the antibiotic than in those given the placebo. The results of three other studies also failed to show an association between administration of tetracycline to ureaplasma-colonized couples and conception.[171,177,178] However, these results may be confounded by antibiotic resistance of ureaplasmas and *M. hominis*.[70,179] We conclude that to date, there is no convincing evidence to implicate *M. hominis* or ureaplasmas as important causes of infertility.

The role of *M. genitalium* in involuntary infertility has also been examined. In a seroepidemiologic investigation of 308 infertile women, Clausen et al.[98] found that 22% (29/132) of women with tubal factor infertility had antibodies to a recombinant antigen specific for *M. genitalium* compared to 6.3% (11/176) of women with normal fallopian tubes ($p = 0.005$). In a subsequent study, this group[99] determined that antibodies to *M. genitalium* were detected in 17% (5/30) of women with tubal factor infertility compared to 4% (7/164) of women with normal tubes (OR of 4.5 [CI_{95} 1.2–15.6]) after adjusting for *C. trachomatis* infection and age]. Surprisingly, *C. trachomatis* was not associated with tubal factor infertility, a finding attributed to the recent effective programs for diagnosis and treatment of this pathogen. Others have shown that approximately one-quarter of infertile women have antibody to *M. genitalium*, although there is no correlation with abnormal hysterosalpingograms as there is when antibody to *C. trachomatis* is associated with infertility.[180] A role of possible tubal damage leading to tubal scarring and occlusion was demonstrated by Baczynska et al.,[181] who showed that *M. genitalium,* but not *M. hominis,* damaged ciliated cells in a human fallopian tube organ model, although the effect was moderate compared to that of *C. trachomatis.* Clearly, future studies are needed to clarify the role of *M. genitalium* in this important sequela to upper tract infection in women.

Habitual spontaneous abortion, stillbirth, and preterm birth

Ureaplasmas *and M. hominis* have been associated with adverse outcomes of pregnancies in some, but not all, studies. In one study, ureaplasmas were found more often in endocervical specimens from women with a history of spontaneous abortion, especially recurrent spontaneous abortion, than from a control group of women ($p < 0.05$).[182] However, most investigators have not been able to relate lower genital tract colonization with ureaplasmas to fetal loss, although the possibility that a smaller subgroup was at higher risk could not be excluded.[72,183–186] Ureaplasmas have also been isolated more frequently from spontaneously aborted fetuses, stillborns, or premature infants than from induced abortions or normal full-term infants and isolation was not entirely due to superficial contamination, since the organisms were isolated from the lungs and from the brain, heart, and viscera.[72,187–191] Others found a significant association between chorioamnionitis and mycoplasmal infection, even when the duration of the rupture of the membranes was taken into account in the analyses.[189,192–198] Such membrane inflammation might be important in bringing about the poor outcome of pregnancy. Furthermore, there are serologic data to support the concept that ureaplasmal infections occur more commonly in women who have poor pregnancy outcomes than in those who have normal

pregnancies.[199] Unfortunately, none of these observations answers the major question of whether abortion of the fetus occurs because mycoplasmas invade it and cause its death, or whether they invade after the fetus dies for some other reason. Furthermore, the question of an etiological association is difficult to resolve, since possible roles of other microorganisms were ignored in most studies. This is of critical importance because ureaplasmas often are part of the complex bacterial flora of bacterial vaginosis, and bacterial vaginosis has been associated with preterm labor and stillbirth.[200] However, in one study in which bacterial vaginosis was excluded and women were analyzed who were infected apparently only with ureaplasmas, the T960 biovar (now designated *U. urealyticum*) was dominant in patients who had had a miscarriage and in those who delivered preterm.[201] Nevertheless, the role of ureaplasmas is difficult to interpret because it is necessary to assume that infection with a single microorganism occurred and the outcome of pregnancy in those without ureaplasmas was not revealed. In another study, Donders et al.[202] determined that bacterial vaginosis, or isolation of *G. vaginalis, M. hominis,* or ureaplasmas was associated with a six- to sevenfold increased risk of spontaneous abortion ($p < 0.01$).

There are reports of successful pregnancies occurring after antibiotic treatment of women who were colonized by ureaplasmas and who had had frequent abortions previously.[170,190,203] However, to postulate on the basis of this that mycoplasmal infection is a cause of reproductive failure seems inadvisable as specimens were not examined for other microorganisms and the treatment trials were largely uncontrolled or the numbers of persons studied were too few.

An observation in the early 1960s indicated that rates of low-birth-weight deliveries were unexpectedly low in pregnant women who had received tetracycline.[204] This notion was supported by finding that the rates of isolation of genital mycoplasmas from the nose and throat of newborn infants were roughly inversely proportional to birth weight[7] and occurrence of *M. hominis* and ureaplasmas in cervical specimens taken from women at their first antenatal visit was related to the low birth weight of their infants.[9] Other workers[189,195,197] agreed and the results of serological[205] and therapeutic[206] studies also supported the association of ureaplasmas with low birth weight. In the latter study,[206] women given erythromycin for 6 weeks during the third trimester had babies of a significantly greater mean birth weight (3331 g) than did those given a placebo (3187 g) ($p < 0.05$). However, not all investigators have been able to associate ureaplasmas with low birth weight.[10,207,208] Indeed, the true association may be confounded by the fact that ureaplasmas and *M. hominis* are only two of the flora associated with bacterial vaginosis and this syndrome itself is associated with low birth weight.[209–211]

In more recent studies, the association of preterm birth with *U. urealyticum, U. parvum,* and also *M. genitalium* has been assessed. Kataoka et al.[212] found an association of vaginal *U. parvum* (3.0, CI_{95} 1.1, 8.5), but neither *U. urealyticum, M. hominis,* nor *M. genitalium* with preterm birth. In contrast, Edwards et al.[213] analyzed vaginal fluid specimens from a prospective cohort of 134 women of 23–32 weeks gestation, of which 22% delivered preterm (31–36 weeks gestation), and determined that *U. urealyticum,* but not *U. parvum,* was associated with preterm birth (prevalence 38%, OR 2.27 [1.01–5.08]). In this same study, *M. genitalium,* detected in 20% of the women, was associated with preterm delivery (OR 3.48; CI_{95} 1.41, 8.57) independently of demographic factors, other mycoplasmas, other genital pathogens, anaerobic bacteria, or bacterial vaginosis-associated bacteria. This finding was consistent with another study in which *M. genitalium* was associated with preterm birth (4% vs. 2%, OR 2.5, CI_{95} 1.2–4.9),[214] but not with others.[212,215]

Perhaps the most convincing data associating adverse outcomes of pregnancy with mycoplasmas were obtained from prospective studies in which the adverse outcome occurred subsequent to detection of ureaplasmas in amniotic fluid, sampled by amniocentesis prior to rupture of membranes.[198,216–218] Gray et al.[216] cultured for ureaplasmas from the amniotic fluid obtained from 94 women undergoing second-trimester genetic amniocentesis and determined that all of the 8 ureaplasma-positive women subsequently delivered prematurely or had spontaneous abortions, compared to 9 (10.5%) of 86 ureaplasma-negative women ($p < 0.001$). Similar results were obtained by Horowitz et al,[217] who determined that adverse pregnancy outcomes were associated with 3 (50%) of 6 and 15 (12%) of 123 women with ureaplasma-positive and -negative amniotic fluid cultures, respectively, ($p = 0.035$)]. *M. hominis* was not detected in these studies. In possibly the most comprehensive study of aerobic and anaerobic bacteria detected in amniotic fluid obtained by amniocentesis of women in preterm labor with intact membranes, Watts et al.[219] reported that ureaplasmas, detected in 7 (35%) of 20 women in preterm labor, were one of the three most common bacteria isolated in this study. These organisms were detected in 5 (8%) of 61 women at 31–35 weeks of gestation, compared to 2 (4.5%) of 44 women at 23–30 weeks of gestation and were detected as the sole isolate in 4 (57%) of the 7 ureaplasma-positive cases. *M. hominis* was detected in only one specimen, which also contained ureaplasmas. These results were expanded by Hitti et al.[220] who used a broad range 16S PCR to detect occult amniotic fluid infections and subsequently identified previously uncultured ureaplasmas in 1 (20%) of the 5 analyzed.[218] Additional studies of the role of the ureaplasmas and *M. genitalium* in preterm birth are eagerly awaited.

Postpartum and postabortal fever

Endometritis is the most common cause of postpartum fever, whether in the first 24–48 hours, or later. It occurs more often after cesarean section than after vaginal delivery, infections developing after vaginal delivery also tending to be less severe and often remitting spontaneously.

A relation between genital mycoplasmas and fever is least likely to be determined if it is based on vaginal colonization, unless the number of subjects studied is very large. In a study of over 300 women who were delivered consecutively, no association was seen between detection of genital *M. hominis* and postpartum fever.[221] However, Harrison et al.[185] evaluated 1365 pregnant women and reported that *M. hominis*, but not the ureaplasmas, was associated with fever and/or endometritis after vaginal delivery (relative risk 7.3). Furthermore, Berman et al.[222] studied more than 1200 Navajo women and found that those undergoing cesarean section had a higher rate of postpartum endometritis if *M. hominis* was present on predelivery endocervical culture. The association between vaginal colonization and postpartum fever is likely to be seen best when there is prolonged labor and prolonged rupture of the membranes.[223]

Employing protected transcervical catheters, Eschenbach et al.[224] found that *G. vaginalis* was the most common endometrial isolate in early febrile postpartum women, but that nearly 20% had ureaplasmas as a sole isolate. From 3 of 18 such patients, ureaplasmas were also isolated from the blood. Jones and Tobin[225] avoided the vagina and cervix by examining the amniotic surface of placentas obtained at cesarean section; they found that patients whose placental cultures were positive for *M. hominis* or ureaplasmas were more likely to be febrile after delivery than those who had negative cultures. Williams and associates[226] studied intraoperative transabdominal specimens from women undergoing cesarean sections and found that ureaplasmas were isolated from the amniotic fluid and lower intestinal segment of 5 (25%) of 20 and 6 (42%) of 15 febrile women, respectively, compared to none of 49 and 4 (10%) of 40 afebrile women cultured at these sites. There was a high degree of coisolation of virulent bacteria with the ureaplasmas, suggesting that the latter might play a symbiotic role in the pathogenesis of endometritis following cesarean section or could possibly just be a marker of the disease or of other organisms associated with bacterial vaginosis.

Finding genital mycoplasmas in the blood is perhaps the best way of establishing a relationship between the organisms and fever; however, many commercially available blood culture systems do not support mycoplasma growth due to the addition of sodium polyanetholesulphonate (SPS). Genital mycoplasmas as well as other vaginal microorganisms can be found transiently in the bloodstream following vaginal delivery, but this transient invasion has not been associated with postpartum fever.[227] As detailed elsewhere, there have been many reports describing individual patients with postpartum fever, from whom *M. hominis* or the ureaplasmas were isolated a day or more after delivery.[72,228] An antibody response was seen in nearly all cases with *M. hominis* infection.[221,229] In one study,[230] *M. hominis* was isolated from the blood of 9 (7%) of 125 febrile postpartum women, compared to none of 60 afebrile postpartum subjects ($p < 0.005$). Very rarely, *M. hominis* spreads, even in an immunocompetent postpartum woman, to an extragenital site such as the brain and causes a major problem.[231] In addition, the association of *M. hominis* with febrile abortions is undoubted. Thus, in one study,[232] *M. hominis* was isolated from the blood of 4 (8%) of 51 women who had febrile abortions but from none of 53 women who had afebrile abortions. Antibody responses to *M. hominis* were detected in 50% of the women who had febrile abortions but in only two (14%) of 14 women who had afebrile abortions. The role of *M. genitalium*, if any, in postpartum and postabortal fever has not been assessed.

From the above studies, we conclude that *M. hominis* is capable of causing postpartum and postabortal fever, and there is some but less evidence for ureaplasmas being involved. This assumes that these organisms have been recovered from the blood and other sites in pure culture, at least in a proportion of cases. Otherwise, it is possible that genital mycoplasmas, particularly *M. hominis,* might be no more than a marker for bacterial vaginosis and not have a role in their own right.

OTHER DISEASE ASSOCIATIONS IN MEN AND WOMEN

Sexually acquired reactive arthritis

Sexually acquired reactive arthritis (SARA) or the less common Reiter's disease, in which conjunctivitis also develops, occurs in men who have or have recently had NGU, and less often in women. The disease is seen most often in those who are genetically predisposed, that is, who have the HLA-B27 histocompatibility antigen. When exposed to infectious and, possibly, other stimuli, these individuals develop the disease. There is considerable evidence that *C. trachomatis* is capable of initiating this pathophysiologic process, based principally on the detection of chlamydial elementary bodies and chlamydial DNA in joint material from some patients with SARA.[233,234] HLA-B27-positive men who have chlamydia-negative NGU are just as likely to develop arthritis as men who are chlamydia positive.[235] This suggests that agents other than *C. trachomatis* associated with NGU may play a role in SARA and Reiter's disease, but the role, if any, of the ureaplasmas or *M. genitalium* in SARA or Reiter's disease is unclear. Serologic studies have been of limited utility,[236] and evidence for the involvement of ureaplasmas, not entirely convincing, is based on a specific response of synovial

mononuclear cells to ureaplasmal antigens.[237,238] Attempts to isolate mycoplasmas by cultural procedures from diseased joints have not been fruitful. However, using a PCR assay, *M. genitalium* was detected in the joints of 2 of 13 patients with arthritis, one with Reiter's disease and one with rheumatoid arthritis,[239] and the results of further attempts to detect this mycoplasma and to seeking ureaplasmas by such technology are awaited.

Association of mycoplasmas with immunodeficiency states and HIV

Patients with primary antibody deficiency disorders, agamma- and hypogammaglobulinemia, are particularly susceptible to extragenital *M. hominis* and ureaplasmal infections, and there are reports of several different species being involved in sinusitis, pneumonia, cystitis, cellulitis, osteomyelitis, suppurative arthritis, and subcutaneous abscesses.[240–242] In some patients, the arthritis responds to antibiotic therapy, whereas in others, the disease persists and so do the organisms in the joints for many months, despite antibiotic and antiinflammatory treatment, and γ-globulin replacement.[243] *M. hominis* and the ureaplasmas have also been implicated in infections of the vascular system, sternal wounds, the central nervous system, joints, and the respiratory tract, particularly after immunosuppressive therapy and after organ transplantation.[244,245] Thus, suppressed cell-mediated immunity or antibody deficiency, or both, promote mycoplasmal infections at extragenital sites. Given the immunologic defects among subjects with AIDS, it is not surprising that genital mycoplasmas would be more often detected among HIV-infected versus noninfected individuals. Indeed, Cohen et al.[246] reported that HIV infection was associated with an increased risk of *M. genitalium* infection (adjusted HR = 2.2, CI_{95} 1.2–3.5) among a cohort of sex workers in Nairobi, Kenya. *M. genitalium* has also been detected more often in endometrial biopsies from HIV-infected than HIV-uninfected women (19.1% versus 4.6%).[246]

In the late 1980s, investigators in the United States raised the possibility that a novel *Mycoplasma* spp., originally called *M. incognitus* and subsequently found to be *M. fermentans,* was an important cofactor in the pathogenesis of AIDS.[247–252] This organism was detected in a significant number of tissues and organs in patients with AIDS in some,[251] but not other,[253] studies. Supporting the contribution of an antibiotic susceptible agent in AIDS progression was the observation that tetracyclines or a fluoroquinolone inhibited the cytopathic effect induced by HIV-1 or 2 in lymphoblastoid leukemic cells without suppressing virus growth,[254,255] a finding consistent with the observation that various mycoplasmas in cell cultures enhance HIV replication and are able to bring about cell death.[256–259] Thus, several investigators postulated that *M. fermentens* (and other mycoplasmas) could enhance the proliferation of HIV in vivo by stimulating immune activation, lymphocyte proliferation, cytokine production, and HIV-LTR-dependent gene expression.[260–268] However, the hypothesis that *M. fermentans* is an important cofactor in AIDS pathogenesis was muted by the finding that this mycoplasma was detected in only a small subpopulation of HIV-positive patients,[269,270] its prevalence was similar in HIV-positive and HIV-negative subjects,[271] there was no significant association between the occurrence of *M. fermentans* and disease severity in the HIV-positive subjects, and there was no association between the presence of this mycoplasma and viral load.[271] Currently, there is no consistent evidence implicating the role of *M. fermentans* nor *M. penetrans*, another species originally detected in HIV-infected individuals,[272] in the development or progression of AIDS. Although the results of in vitro studies indicate the ways in which *M. fermentans* and other mycoplasmas could hasten the onset and progression of AIDS, as yet there are few indications from studies in vivo that this is a reality. We conclude that these organisms may in fact be opportunists that are able to proliferate among subjects suffering from immunosuppression mediated by HIV.

Other Mycoplasma spp. identified in the human urogenital tract

In addition to *M. fermentans* and *M. penetrans,* other *Mycoplasma* spp. have been detected in genital tract specimens. Some, such as *M. primatum* and *Acholeplasma oculi*, are detected very infrequently and are not known to be associated with disease.[273] *M. pirum,* which was isolated originally only from cell cultures and then from cells that had been cocultivated with peripheral blood lymphocytes of AIDS patients,[274] has been detected subsequently using PCR technology, in the rectum of homosexual men,[275] but its role in disease, if any, is unknown. Similarly, *M. pneumoniae*[276,277] and *M. spermatophilum*[278] have been detected in human genital tract specimens, but have yet to be associated with disease at these sites. *M. amphoriforme,*[279] the most recently isolated mycoplasma of human origin, has been isolated from the respiratory tract, but its recovery from the urogenital tract has not so far been reported.

DETECTION AND CULTURE OF GENITAL MYCOPLASMAS

Collection of Specimens

The collection of specimens for culture of *M. hominis* and ureaplasmas in the male genitourinary tract can be successfully accomplished using a urethral swab specimen and/or a first-void urine specimen.[280] Vaginal and endocervical swab

specimens are likely to be more satisfactory than urine specimens for recovering these organisms from women,[280] and avoiding antiseptics, analgesics, or lubicants is important.[281] Swabs should be expressed immediately in mycoplasma broth or another suitable transport medium such as 2SP medium without antibiotics. In temperate climates, mycoplasmas survive well for at least 24 hours at room temperature if transported in 2SP or mycoplasma broth. However, because of the rapid growth of ureaplasmas, specimens for quantitative cultures should be transported at 4°C.[280] If room temperature transportation is chosen, overgrowth of other bacteria could be a problem, but addition of polymyxin B (50 μg/mL) and penicillin G (100 U/mL) to the transport medium may suppress most of the contaminating flora. Urines should preferably be transported directly to the laboratory or transported at 4°C within 24 hours. Culture of *M. genitalium* is considerably more difficult than culture of the ureaplasmas or *M. hominis*, but can be accomplished from male urethral or urine specimens as outlined below.

For specimens to be examined in nucleic acid amplification tests (NAATs, ex. PCR), viability is not important, and thus these specimens can be transported in phosphate-buffered saline (pH 7.2), 2SP, SP4, or other media found to be compatible with the subsequent detection assay. If transport medium is not available, or if vaginal specimens are analyzed, the swab may be transported "dry" to the laboratory, preferably within 24 hours, then frozen dry or in transport medium until analysis. The relative performance of different specimen types (ex. urethra vs. urine for men and cervix, vagina, or urine for women) for detection of *M. genitalium* by NAATs has been assessed (see below), but may depend upon the sample preparation procedure as well as the NAAT assay used.

Culture

The isolation of mycoplasmas has traditionally depended on a medium comprising beef-heart infusion broth, available commercially as PPLO broth, which supplies amino acids, supplemented with fresh yeast extract supplying nucleic acid precursors, horse serum providing the essential cholesterol, and phenol red as a pH indicator to monitor growth.[280] This medium is supplemented either with arginine or urea for the growth of *M. hominis* or ureaplasmas, respectively. Other sera, such as fetal calf serum, may improve growth, and media of quite different formulations have been used satisfactorily for the isolation of both mycoplasmas and ureaplasmas.[283] In particular, SP4 medium, developed originally to cultivate spiroplasmas, has improved the isolation of not only the more fastidious mycoplasmas,[284] but also those more easily isolated, such as *M. hominis.*[285] Alternatively, H broth, a simple medium composed of soy peptone, yeast extract, and horse serum, has been used successfully by other researchers.[286] It is important to note, however, that the mere fulfillment of a particular medium formulation is unlikely to be successful without systematic work on improvement of the quality; different manufacturers and even lot numbers of undefined components may drastically influence the ability to culture these organisms. Therefore, pretesting of medium components for their ability to support growth and maintaining rigorous quality control, using a fastidious isolate, are important features of successful isolation.

Inoculation of specimens into liquid medium, which is diluted serially, followed by subculture to liquid or agar media, provides the most sensitive method for isolation of ureaplasmas.[287] Thus, the specimen is inoculated in liquid medium to make a 10-fold dilution, further serial 10-fold dilutions are made to at least 10^3, and the vials are incubated at 37°C. As ureaplasmas possess a urease that hydrolyzes urea to CO_2 and ammonia, their growth results in a color change in the medium, set initially at pH 6.0, from yellow to pink. We have recently used a soy peptone-based broth for this purpose,[33] the formula for which is described in detail elsewhere.[54]

To detect *M. hominis* in broth, the specimen is diluted in broth similar to that used for ureaplasmas except containing arginine, rather than urea. *M. hominis* metabolizes arginine with the resulting release of ammonia, also resulting in an increase in pH, initially set at 7.0, and a color change from yellow to pink. Ureaplasmas usually produce a change within 24–48 hours or less and rarely thereafter, *M. hominis* less rapidly, but usually well within a week. Serial dilution of specimens is valuable for various reasons, most notably for diluting antibiotics and other inhibitors of growth in the original specimen, for reducing the number of contaminating bacteria, and for providing an estimate of the number of organisms in the original specimen; thus, the highest dilution at which a color change is seen may be regarded as containing one color-changing unit (ccu).[287] As an example, a change up to the10^5 dilution suggests that the original specimen that was inoculated contained 10^5 ccu (or 10^5 organisms).

To confirm the identity of the cultured mycoplasma, aliquots (0.1 or 0.2 mL), taken from liquid cultures that are just changing color, are introduced into fresh broth medium and onto agar medium. On the latter, colonies of the genital mycoplasmas may develop in ambient air, in CO_2 or in N_2 plus 5% CO_2. Those of *M. hominis* have the classical "fried egg" appearance and are up to 200–400 μm in diameter (Fig. 41-2). Ureaplasmas produce much smaller colonies, 10–30 μm in diameter, which usually do not have a "fried egg" morphology because they lack the peripheral surface growth. On agar medium containing urea, HEPES buffer, and a sensitive indicator of ammonia, that is manganous sulphate or better still calcium chloride, ureaplasmas produce colonies that are slightly larger and dark brown so that they are easier to detect (Fig. 41-2).[288,289] However, because these colonies are so tiny, scanning the agar medium with a dissecting

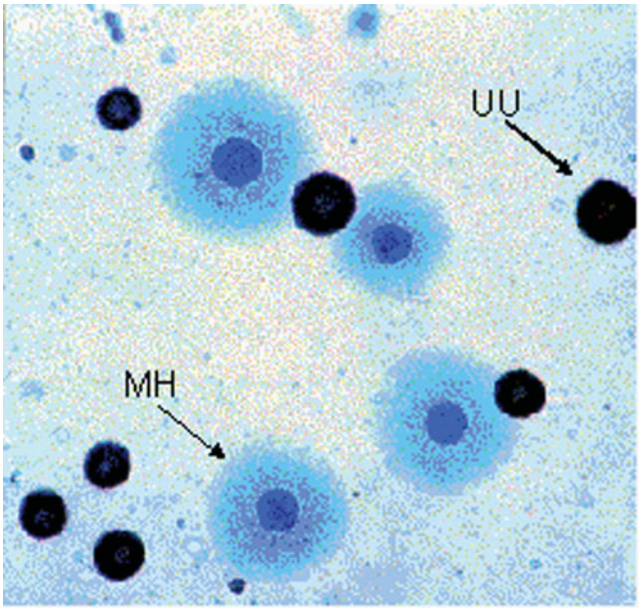

FIGURE 41-2. Differentiation of colonies of *Ureaplasma* spp from those of *M. hominis* resulting from inoculation of a clinical specimen from a patient with NGU. The colonies have developed on A7 agar medium (containing urea, ampicillin, and manganous sulfate). The brown/black colonies of the ureaplasmas can be easily distinguished from those of *M. hominis*, which have a typical mycoplasmal "fried egg" appearance and appear blue after the addition of Dienes strain. *(Figure courtesy of Trends in Microbiology and JD Pollack.[407])*

microscope is required for detection, a labor-intensive exercise. We recommend A8B plates for growth of ureaplasmas and *M. hominis* as we have described previously.[33] On these plates, which contain 1.0 mM rather than 1.5 mM calcium chloride as an indicator, dark brown ureaplasma colonies can be detected more easily.

Commercial kits designed for the isolation, quantitation, identification, and antimicrobial susceptibility testing of *M. hominis* and ureaplasmas are available in several European countries and sold, for example, by bioMérieux, Marcy l'Etoile, France, but are unavailable in the United States. Specialist laboratories are likely to have media of superior quality, but successful use of the kits has been reported and they may be of particular value where the need to detect these microorganisms arises infrequently.[290,291] No commercially available kits or media are available for the growth of *M. genitalium*.

Cultured organisms require specific identification, and certain nonspecific features that are determined routinely during the course of isolation may give a lead. Thus, a specimen from the genitourinary tract that produces an alkaline color change without turbidity in medium containing arginine is most likely to contain *M. hominis,* and one that produces a similar change in medium containing urea is almost certain to contain ureaplasmas. Such clues narrow the range of specific antisera required to make a definitive identification. Incorporation of such antisera in filter-paper discs on agar to inhibit colony development (agar growth inhibition)[292] is widely used, but more than one antiserum to a species may be required to identify various strains of that species. Epiimmunofluorescence or immunoperoxidase techniques used to stain colonies are advantageous in enabling different ureaplasmal serovars or, indeed, mycoplasmal species to be distinguished in mixtures.[293] Alternatively, and perhaps more easily, depending upon the laboratory, PCR assays for *M. hominis*, *U. urealyticum*, and *U. parvum* can be used to identify the cultured mycoplasmas.

Contrary to the experience with *Ureaplasma* spp. and *M. hominis*, culture of *M. genitalium* by primary inoculation of conventional mycoplasma media has rarely been successful. A method of inoculating the clinical specimens into Vero cell cultures[294] and monitoring the growth by PCR allowed the successful isolation of more than 20 *M. genitalium* strains shown to be genotypically distinct.[22,37,294] The method has been optimized by the use of quantitative PCR[37] which allows a closer monitoring of the growth. In brief, the swab or freshly obtained urine specimen is washed by resuspending the cell pellet in mycoplasma broth after centrifugation and in cell culture medium after a subsequent centrifugation step. The washed specimen is inoculated into Vero cells grown in Eagle's MEM with 2% Ultroser G and incubated at 37°C with daily inspection for bacterial contamination. When, after 2–3 weeks, approximately 50% of the cells detach from the surface, the remaining cells are scraped off, and 1 mL of the cell suspension is added to 2 mL of fresh cells and the incubation is repeated. When the *M. genitalium* titer, determined by quantitative PCR, is >100,000 copies/mL, Friis' broth medium without antibiotics[294] is inoculated with the cell culture to provide a 10-fold dilution of the latter. When good growth in broth medium is observed, passage onto solid medium may be attempted, but usually, several passages in broth are needed before colonies will form on agar. It is not recommended to use the G37 strain as a positive control during the isolation attempts, since this strain is very fast growing and may contaminate the new isolates.[28] DNA typing of the new isolate in comparison to the DNA type in the inoculum is highly advisable in order to document the absence of cross-contamination between strains. There have been reports of the isolation of *M. genitalium* directly in SP4 medium, notably from the respiratory tract, from a joint fluid in a mixed culture with *M. pneumoniae*, and from vaginal and cervical specimens.[295–297] However, based on the ability of these strains to grow after only 14–20 days incubation and their genotypic similarity to G37, concerns have been raised about the validity of these presumptive novel isolates.[37,298,299] For validation we recommend the system developed by Jensen et al.[37] because it is easily performed by sequencing the amplicons generated by the standard PCR assay used to detect this organism and is conserved between sexual partners and between specimens obtained months apart from the same patient.[22] A detailed description of

methods to isolate clinical strains of *M. genitalium* has been published recently.[300]

Noncultural methods of detection

Noncultural procedures have enhanced the appreciation of the disease associations of genital mycoplasmas, particularly by those, such as *M. genitalium*, that are almost impossible to culture directly from patient specimens. While such tests are sometimes essential for detection of these fastidious organisms, culture still remains a worthy goal since it allows the assessment of antibiotic sensitivity or other biological features of the infecting strain. NAATs are the most widely used and will be described below.

Use of the two PCR tests for *M. genitalium* developed in 1991[26,27] resulted in the association of this organism with NGU.[28,29,301] Subsequently, many different PCR tests have been developed to detect this emerging pathogen.[31] Most target the MgPa adhesin gene,[26,27,34,36,302,303] undoubtedly because it was the first to be sequenced, or the rDNA gene,[304] of which there is only one copy in the limited *M. genitalium* genome. Several of these PCR assays[302,304] contain internal controls to assess PCR inhibition. More recently, a research-only transcription-mediated amplification assay specific for *M. genitalium* has been developed by Gen-Probe, Inc.,[305,306] but this test is not yet commercially available. Finally, quantitative PCR assays, targeting the *gap* gene in the glycolysis pathway,[38] the MgPa adhesin gene,[307] or the 16S rDNA gene[37] have been developed and have been used to assess growth in vitro as well as the organism load in patient specimens relative to treatment efficacy and to signs and symptoms of disease.

The relative performance of the different NAATs depends not only on the sample preparation method, the target sequences, and the detection methods, but also on the sample type used for analysis. Among men, urine was more sensitive than urethral specimens for detection of *M. genitalium* in one study,[308] but these specimen types were comparable to each other in another (Totten, unpublished). A comparison of vaginal, cervical, and urine specimens from women, all analyzed by both PCR and TMA, served to validate both assays and establish that self-obtained vaginal specimens were the most sensitive specimen type for detection of this organism in this study,[306] a finding that would facilitate specimen collection in nonclinic settings. Indeed, self-obtained vaginal swabs are well accepted by women and have been successfully used for home-based self-collection, with subsequent testing for. *C. trachomatis* after the swab was placed in the provided container and mailed to a reference laboratory.[309] Undoubtedly, a similar strategy could be used to enhance detection of *M. genitalium* in future studies.

PCR methods for *Ureaplasma* spp. and *M. hominis* have not been as extensively developed, probably because these organisms are much easier to detect in patient specimens by culture. Importantly, PCR assays targeting the urease or 16S rDNA genes of the ureaplasmas are able to distinguish the newly designated species, *U. urealyticum* and *U. parvum*, in patient specimens and have allowed the assessment of the association of these two species with NGU in men.[310–312] Yoshida et al.[310,312] developed a PCR assay designed to amplify a broad range of mollicute species within patient specimens, but its sensitivity relative to species-specific PCR assays has not been assessed.

Serology

Detection of antibodies to individual mycoplasmal species is useful when assessing the prevalence of these organisms within a subpopulation or geographic site, when genital tract specimens are not available for analysis, and when assessing the association of these organisms with sequelae of infection. However, detection of mycoplasma-specific antibodies in a single serum specimen is of less diagnostic value than demonstrating a rise in titer of antibodies associated with symptoms, and cross-reactions with other mycoplasmas need to be ruled out. Many serological tests have been used to measure antibodies to mycoplasmas and differ in the antigen and technique used to detect reactivity, sensitivity, and specificity. The complement fixation, indirect hemagglutination, indirect immunofluorescence, and metabolism-inhibition tests have all been used to detect antibodies to mycoplasmas in human sera but are not currently widely employed, either due to the complexity of the test, specific expertise required, or the lack of sensitivity or specificity.[72] However, these tests have been used to detect antibodies to ureaplasmas in two-thirds of patients with NGU,[313] to *M. hominis* among women with acute salpingitis,[121] and to *M. genitalium* in women with salpingitis.[287,314] Devising *M. genitalium*-specific serologic tests is particularly challenging, given the cross reactivity between *M. genitalium* and *M pneumoniae* antibodies.[98,315–317] Fairly recently, an enzyme immunoassay, based on lipid-associated membrane proteins (LAMPs) to measure antibody to *M. genitalium*, was developed and showed a high sensitivity (15 positive/15 specimens from *M. genitalium*-positive subjects) and specificity (64 negative/64 blood donors tested) relative to genital infections detected by PCR.[318] Clausen et al.[98] used a cloned portion of the MgPa adhesin gene of *M. genitalium* and an immunoblot assay to demonstrate a lack of cross-reactivity with *M. pneumoniae* antibodies, and then showed that seropositivity was associated with tubal-factor infertility. This test was further refined by incorporating other *M. genitalium*-specific recombinant peptides, then assessed relative to a LAMP-based ELISA test among *M. genitalium* infected and uninfected men (detected by PCR) with and without urethritis.[319] This test was 59% sensitive and 81% specific relative to *M. genitalium* infection in men and should prove useful for assessing the association of *M. genitalium* with sequelae of infection. No serological

tests for urogenital mycoplasmas have been standardized and made commercially available.

Strain typing and serotyping

Several methods have been developed to differentiate between strains of *M. genitalium*. This was performed initially by amplified fragment length polymorphisms applied to whole cell DNA from cultured *M. genitalium* strains.[298] However, the need for culture was eliminated by detection of sequence polymorphisms within PCR products specific for *M. genitalium* derived directly from PCR amplification of patient specimens.[37,299] These sequence-based typing systems, one based on polymorphisms within the MgPa adhesin gene (also designated MG*p*B and MG191), the other based on the number of tandem repeats in the lipoprotein gene MG309, are stable over time in persistently infected individuals, allowing the demonstration of concordance among sexual partners, consistent with sexual transmission of *M. genitalium*.[22] A fourth typing system based on polymorphisms within the variable region of MG192,[320] should be used with caution because the portion of this gene analyzed has been shown to be highly variable within isolated strains.[321]

The ureaplasmas have been traditionally differentiated into 14 serotypes based on reactivity with polyclonal antibodies, with serotypes 1, 3, 6, and 14 now classified as *U. parvum* (formerly biovar 1) and types 2, 4, 5, and 7–13 classified as *U. urealyticum* (formerly biovar 2). This differentiation has allowed the assessment of the disease associations and relative pathogenicity of the cultured serotypes, which remains controversial.[322–324] Possible variability in different preparations of polyclonal antibodies may be resolved by using serotype-specific monoclonal antibodies,[325,326] although this has not been extensively analyzed. Hopefully, future studies based on DNA typing,[327] serotyping, or expression of specific virulence factors in different isolates may clarify differences in pathogenicity among ureaplasma strains.

PATHOGENESIS

The ability of mycoplasmas to colonize and elicit pathological changes in the human host depends upon a complex set of interactions between the organisms and host. For example, the organisms must be able to adhere to host tissues, to attenuate or escape the innate and adaptive immune response of the host, and, as a special adaptation to the reproductive tract, adjust to changes in host tissue occurring as the result of the cyclical effect of hormones. Although much needs to be learned about bacterial/host interactions, some of the strategies used by *M. genitalium*, *M. hominis*, and the ureaplasmas to survive in this unique anatomical niche will be discussed below.

M. genitalium

The ability of *M. genitalium* to elicit pathological changes and persist in infected subjects is remarkable given its small genome size (580 kb) and limited predicted coding capacity (approx 500 predicted proteins). Even more astonishing is this organism's ability to encode a complex attachment organelle composed of an ordered array of at least seven proteins, required both for adherence to host cells and for cellular locomotion. Although the biogenesis and function of many of the proteins comprising this organelle are not fully understood, two, MgPa (aka MG191 and P140) and P110 (aka MG192), have been the most studied, primarily by Baseman et al.[328–333] Both MgPa and P110 are highly immunogenic and are required for adherence to host cells. MgPa is the primary adhesin of *M. genitalium* for host cells and is exposed on the bacterial cell surface,[329,334–337] but the specific function of P110 is currently unknown. However, as demonstrated by using defined mutants in these genes, expression of both MgPa and P110 is required for the typical structure and function of the attachment organelle (Fig. 41-3).[338] Furthermore, the "gliding motility" of *M. genitalium* is also mediated by the structural components of the attachment organelle as well as at least two proteins specific for motility.[338]

The attachment organelle of *M. genitalium* is similar to a homologous appendage of *M. pneumoniae* in which the structure and function of its component proteins have been best characterized, including host cell adherence and motility.[339–344] Presumably, due to the homology of the attachment organelle genes between *M. pneumoniae* and *M. genitalium*,[345] a similar mechanism for motility exists in the latter. How motility relates to virulence in *M. genitalium* has not been described, although presumably it contributes to expanded surface colonization and perhaps translocation through cervical or vaginal mucus to the underlying tissue.

Despite the surface exposure and antibody accessibility of MgPa (and possibly P110), single strains of *M. genitalium* are able to persist for months, if not years, in infected individuals.[22,246] However, the finding that both MG*p*B and MG*p*C vary within single strains of this organism cultured in vitro or detected in vivo[321,346,347] suggests a mechanism for immune evasion and persistence. A mechanism for this variation was first evident in the study by Dallo and Baseman,[328] who determined that specific sections of MG*p* B were homologous to sequences present at other sites on the *M. genitalium* chromosome. Subsequent studies[2,321,346,347] revealed that full-length copies of MG*p*B and MG*p*C are present at only one site, yet nine incomplete copies, designated MgPar sites that are homologous but not identical to these genes, are distributed throughout the chromosome (Fig. 41-4A). These MgPar sites contain sequences that are homologous, but not identical to sequences within three regions (designated B, EF, and G) of MG*p*B (see Fig. 41-4B)[346,347] and to the 5′ region of

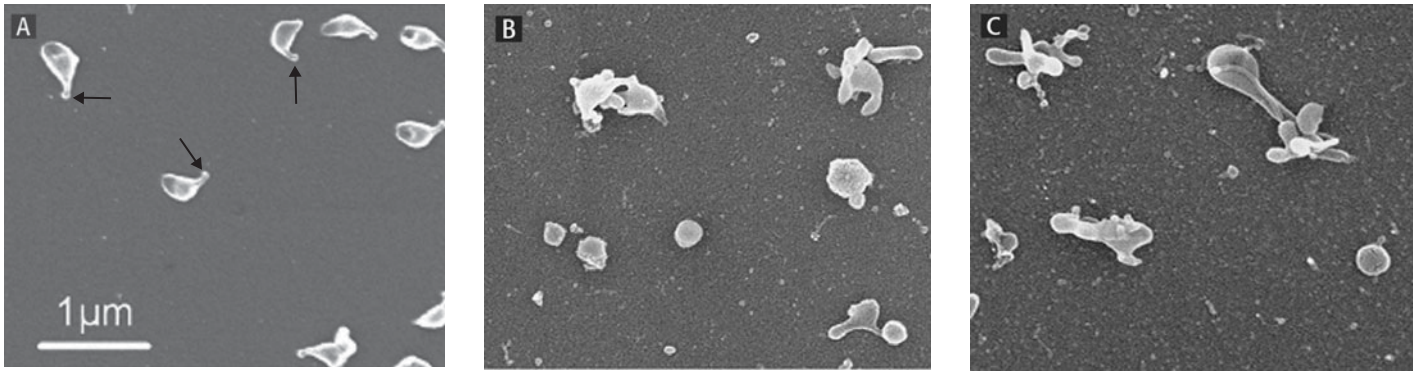

FIGURE 41-3. Scanning electron micrographs of *M. genitalium* type strain G-37 and its derivatives: **A.,** G37; **B.,** a *mgp*B deletion mutant; and **C.,** a *mgp*C deletion mutant, showing that expression of the characteristic structure of the terminal attachment organelle is dependent upon expression of *mgp*B and *mgp*C. Unlike the wild type G-37 strain, the *mgp*B and *mgp*C mutants have a rounded, pleomorphic morphology lacking the typical attachment organelle structure, are deficient in adherence to red blood cells, and have decreased levels of both MgPa (designated as P140 in this study) and P110.[335] Arrows point to the attachment organelle in the wildtype G-37 strain. *(Figure courtsey of J. Piñol, and further described in the study by Burgos et al.[335])*

MG*p*C[321] and mediate sequence variation within *mgp*B/*mgp*C by reciprocal recombination[321] possibly contributing to the heterogeneity of these genes, antigenic variation of the resulting proteins, and persistence in vivo.

In addition to the ability of *M. genitalium* to attach to epithelial cells, exhibit gliding motility, and perhaps express antigenic variants, other virulence-associated phenotypes have been characterized. *M. genitalium* is able to attach to mucin,[348] and reside intracellularly within epithelial cells.[329,349–351] An antioxidant repair enzyme, methionine sulfoxide reductase,[352] and a surface-localized glyceraldehydes-3-phosphate dehydrogenase[348] have been identified, the former enhancing survival in the hamster model and the latter mediating binding to mucin.

Ureaplasma spp.

The requirement for urea as an energy source makes *Ureaplasma* spp. uniquely suited to the urinary tract where this compound is abundant. Although ureaplasmas lack the complex attachment organelle of *M. genitalium*, several cell-surface proteins have been identified and adherence to eukaryotic cells has been demonstrated. However, the specific adhesins that enable these organisms to attach to eukaryotic cells,[353,354] and presumably withstand the clearing action of urination, have been elusive. The multiple-banded antigens (MBA) are surface-exposed immunodominant proteins that differ in size and sequence among different serovars and are thought to provide the serotype specificity both among and between *U. urealyticum* and *U. parvum* strains.[327,355–359] Remarkably, the 3′ two-thirds of this gene contains 18-nucleotide tandem repeats that are identical in sequence, but variable in repeat number within a single strain,[355] suggesting a possible role in differential antigenicity, phase variation, or function. Several potential virulence factors have been identified in the fully sequenced strain of *U. parvum*,[5] but their phenotypic expression, role, and presence in different strains and serotypes of both *U. parvum* and *U. urealyticum* have not been determined. Perhaps the imminent whole genome sequencing of all 14 ureaplasma serovars, including the first whole genome sequence of *U. urealyticum* (John Glass and Ken Waites, personal communication), might reveal species and serotype differences between these, and other as yet unidentified, potential virulence factors that might enhance knowledge of the pathogenesis of this group or organisms.

The pathogenic effect of ureaplasmas on tissue cultures and in animal models has also been studied. Ureaplasmas of bovine origin were reported to cause a loss of ciliary activity in bovine oviduct organ cultures, an effect suggested to be due to a putative toxin-like product.[360,361] However, such a change was not seen with ureaplasmas in fallopian tube organ cultures.[127] Nevertheless, several ureaplasmal metabolites and extracellular enzymes may have the capacity to damage eukaryotic cells. Several groups have identified a proteolytic activity that is specific for human IgA1, but not human IgA2, nor IgA from mice, pigs, or dogs,[362–365] presumably enhancing survival by immune evasion in mucosal secretions. However, the possible role of this enzyme in virulence or persistence or in cleaving targets other than IgA (such has been demonstrated for the gonococcal IgA protease[366]) has not been examined. In addition, the production of ammonium ions and the local changes in pH as a result of urea hydrolysis may have a role in pathogenicity.[367,368] The enhanced colonization of ureaplasmas mediated by estrogen treatment in the mouse model,[369] possible serotype-specific differences between colonization between strains,[370] and the ability of ureaplasmas to recruit inflammatory cells and induce a local cytokine response need further study. Clearly, much needs to be learned about the pathogenicity and apparent differential virulence of ureaplasma species, serotypes, and strains.

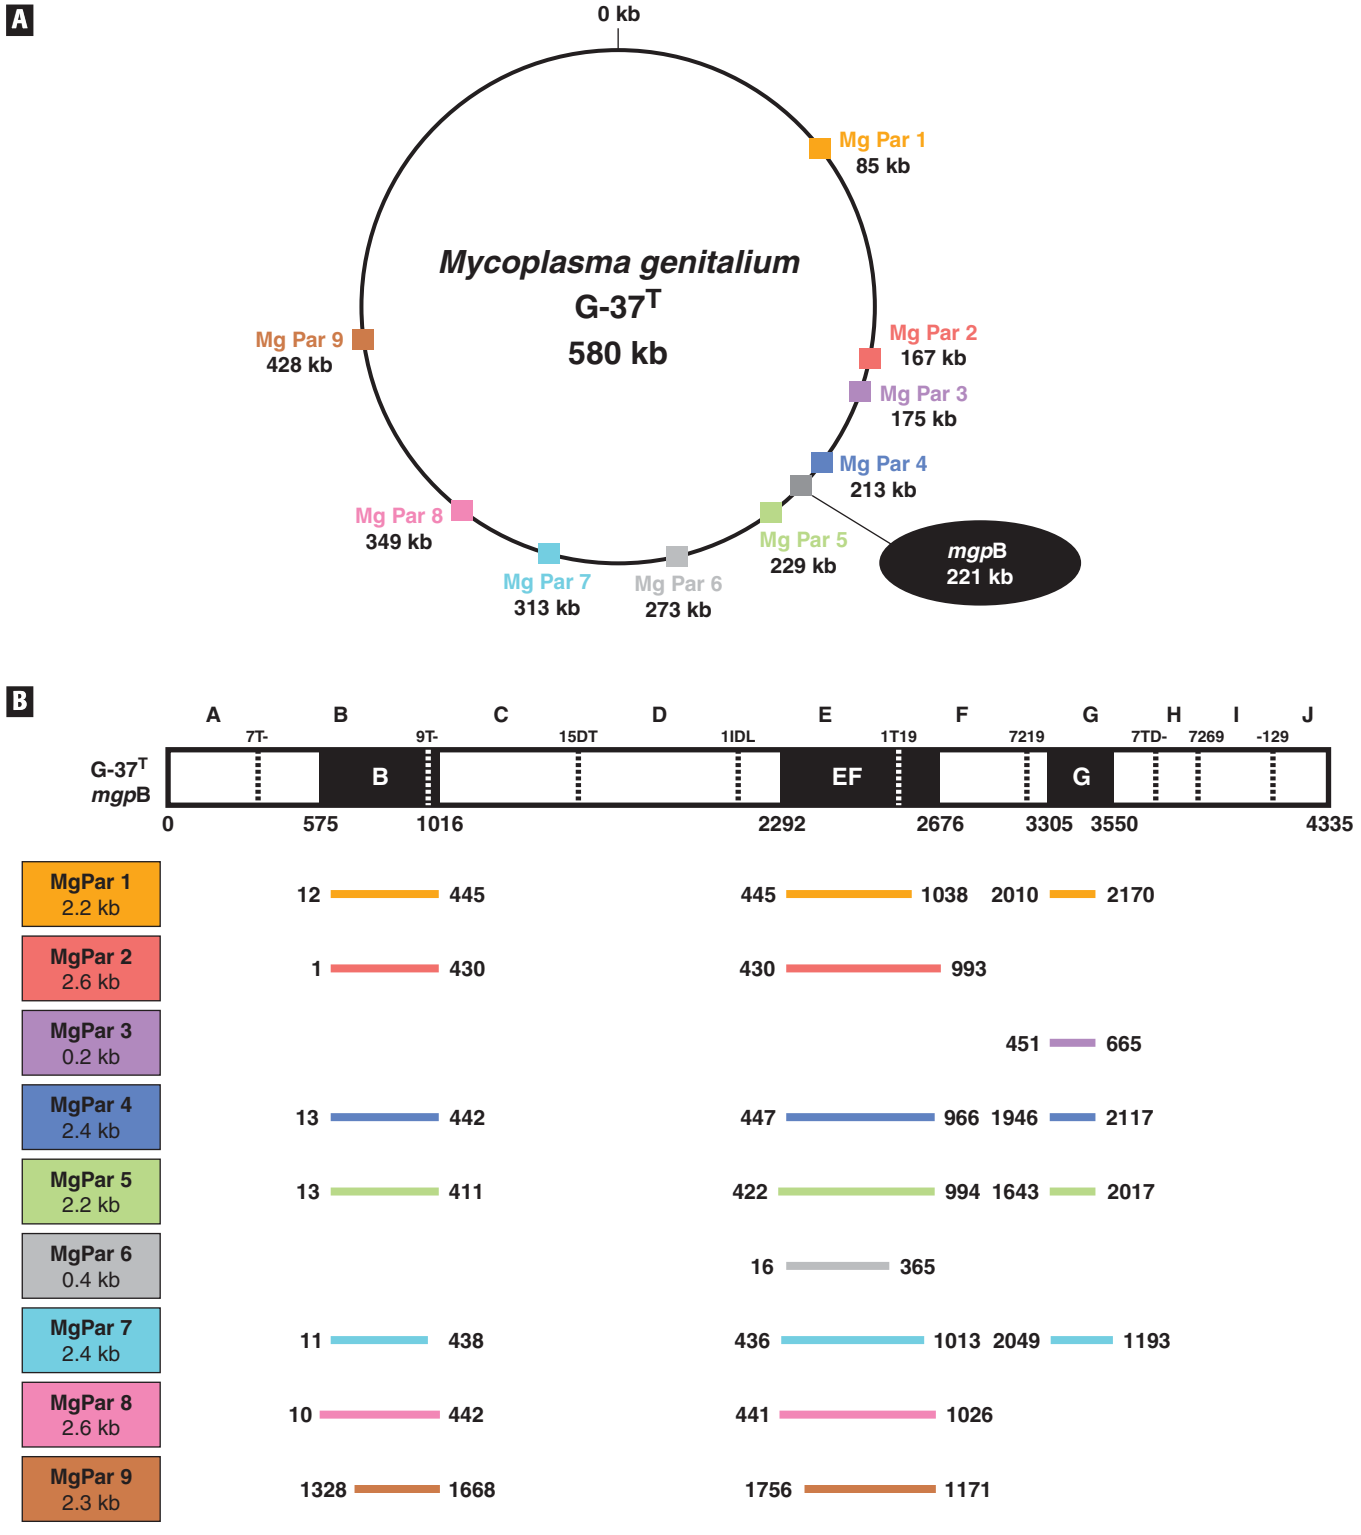

FIGURE 41-4. Schematic drawing of the *mgp*B and the MgPar sites, showing their architecture and the location of these sites on the *M. genitalium* genome. **A.** Location of the nine MgPar sites and the *mgp*B expression site in the completely sequenced G-37^T genome. **B.** Schematic of *mgp*B and the nine MgPar sequences showing that only portions of *mgp*B (regions B, EF, and G, designated in black boxes) are homologous to the MgPar sites, while the remainder of *mgp*B is unique to the expression site. Below the schematic of *mgp*B, each of the nine MgPar sites is listed with their corresponding sizes. Sequences within each MgPar site containing homology to *mgp*B are shown diagrammatically by a colored line, placed relative to the location of the homology with *mgp*B. Note, by the numbering indicating the consecutive order of the sequences within each MgPar site, that these sites contain incomplete copies of *mgp*B and regions homologous to B, EF, and/or G, but not the intervening sequences of *mgp*B.
