PREFACE

WITH due regard to the law *humanum errare est*, this work aims at giving a complete description of all the compounds known in Inorganic Chemistry, and, where possible, these are discussed in the light of the so-called Physical Chemistry. The separation of Organic from Inorganic Chemistry is nothing more than a conventional convenience; it is probable that the sharper the line of demarcation, the greater the loss which each of these divisions of chemistry will suffer. In the analysis of inorganic compounds, for example, some extraordinarily sensitive tests are available, and some extraordinarily clean separations can be effected by utilizing the properties of certain organic compounds of the metals.

In the past, several complete records have been made. Starting from W. Nicholson's *A Dictionary of Chemistry* (London, 1795–1808), there have appeared in **England**: A. Ure's *A Dictionary of Chemistry* (London, 1821–35), and H. Watts' *A Dictionary of Chemistry* (London, 1866–68), which was later edited by H. F. Morley and M. M. P. Muir. There is also Sir Edward Thorpe's *A Dictionary of Applied Chemistry* (London, 1890–92), a new and revised edition of which is now in the press (1921). The English translation of L. Gmelin's *Handbook of Chemistry* (London) appeared in nineteen volumes between 1848 and 1872. This work covered both organic and inorganic chemistry. The sixth German edition appeared as the *Handbuch der anorganischen Chemie* (Heidelberg) in 1871–86, while the seventh edition, commenced in 1905, is not yet complete. A number of other related books have appeared in **Germany**. The more important of these are A. Ladenburg's *Handwörterbuch der Chemie* (Breslau, 1882–89); H. von Fehling's *Neues Handwörterbuch der Chemie* (Braunschweig), which commenced in 1874 and is not yet completed. It was founded on J. von Liebig, J. C. Poggendorff, and F. Wöhler's *Handwörterbuch der reinen und angewandten Chemie* (Braunschweig, 1837–64). There is O. Dammer's *Handbuch der anorganischen Chemie* (Stuttgart, 1892–1903), and his *Handbuch der chemischen Technologie* (Stuttgart, 1895–98). R. Abegg's *Handbuch der anorganischen Chemie* (Leipzig), commenced in 1905, is not yet completed. In **France** there are E. Frémy's *Encyclopédie chimique* (Paris, 1882–1905); C. A. Wurtz's *Dictionnaire de chimie* (Paris, 1868–1908); and H. Moissan's *Traite de chimie minérale* (Paris, 1904–6). In **Italy**, L. Guareschi's *Nuovo enciclopedia di chimica* (Torino), commenced in 1900, is still in progress. I have been more or less indebted for hints and ideas to all the above-named works, as well as to H. Kopp's *Geschichte der Chemie* (Braunschweig, 1843–47).

Much of the material of this work was compiled in card-index form long before my *Modern Inorganic Chemistry* appeared; and that work was really an abridgement of this one. The references which were not included in the scheme of that work will be found here. It was not originally intended to make the larger work assume the exhaustive character which this book has now acquired. Rightly or wrongly, I came to the conclusion that it is a mistake to load up a student with facts as if he were going to be a specialist in all branches of inorganic chemistry. In addition to the general principles, the salient features of certain type-compounds should be taught, and anything further should be left for works of reference, where full information may be obtained—to be absorbed or forgotten as may be expedient. Consequently, in the ideal case, a work of reference should not only give the authorities for statements of fact, but it should also indicate what knowledge has been gleaned on the particular subject in question. To do this in a practicable manner, attention must be directed to the original publications on the subject. This naturally makes the work of compilation extremely laborious ; in some cases, indeed, it happens that scores of independent references are involved in the statement of one particular fact. Fortunately I have rather a unique collection of dissertations and theses ; in a few cases, these have not appeared in the regular channels of publications. Where the original references are not in the libraries of this country, I have had to depend on an assistant in Berlin, who has generally been successful in tracking them where our libraries have failed. This has made some references very costly. A large proportion of the references will be found in the Abstracts of the London and American Chemical Societies, and of the Society of Chemical Industry.

In the references, the usual abbreviation for the title of a periodical is given, then follow in clarendon type the volume number, the page or pages, and, last of all, the year of publication. In cases where a volume is made up from a number of bulletins with independent pagination, the number of the bulletin is employed instead of the page. In the cross-references, the first number in clarendon type refers to the volume, the second to the chapter, and the third to the § (section). It will be observed that the diagrams of the chapters have an independent numeration.

In former times little more than a mere qualitative knowledge of the so-called physical and mechanical properties of elements and compounds was considered ample, but with the tremendous ramifications of the various industries increasing demands for precise data have been made from the workers in pure science. In reviewing the data I have been impressed with the prevailing lack of perspective in the measurements of physical properties, for, in some cases, these have been carefully measured with elaborate apparatus involving an experimental error hundreds of times smaller than the magnitude of the disturbing effects produced by impurities. It is not always enough to say that the materials were Herren X.Y.Z.'schen " chemically pure " preparations. For instance, in pre-war days I have had to make very serious complaints about the quantities of glass contained in their highest grade " chemically pure " potassium pyrosulphate. This would not have been suspected had its use not been attended by an epidemic of bad analyses. Of course, the best representative values of the physical constants of pure elements and compounds are very important, but in commercial work, materials of an extremely high degree of purity are regarded more as chemical curiosities, and larger errors may be introduced by using data—atomic weights, etc.—derived from pure materials, than by using data obtained with material of " commercial " purity.

I think it was P. J. Macquer who apologized for the alphabetic form of the subject-matter of his *Dictionnaire de chymie* (Paris, 1766), by stating that chemistry was little more than a collection of facts scarcely entitled to the name of science, or capable either of synthetic or analytic explanation ; and hence he concluded that the dictionary form was the best mode of arranging the facts. The dictionary thus belongs to a primitive stage in the development of a science in that it is but a collection of facts to be employed in building up the science.

We now flatter ourselves that the periodic law has given inorganic chemistry a scheme of classification which enables the facts to be arranged and grouped in a scientific manner. The appearance of order imparted by that guide is superficial and illusory. Allowing for certain lacunæ in the knowledge of the scarcer elements prior to the appearance of that law, the arrangements employed by the earlier chemists were just as satisfactory, and in some cases, indeed, more satisfactory than those based on the periodic law.

The arrangement of the subject-matter of inorganic chemistry according to the periodic scheme is justified solely by expediency and convention. It has a tendency to make teachers over-emphasize unimportant and remote analogies, and to underestimate important and crucial differences. I imagine that when we have found a truer basis of classification, such differences as are displayed between, say, *ferrosum* and *ferricum* compounds will be exhibited as if two different elements are involved, and that iron alone appears as the stable form when separated from these compounds. Similar remarks apply to other multi-valent elements. The difference between the higher and lower valent forms of an element with a given acid are often greater than between the compounds of two totally different elements with the same acid.

The first volume of this work is mainly introductory, and in it the atom is considered to be the chemist's unit, or the unit of chemical exchange. The newer work on the structure of atoms, and the so-called elements with variable atomic weights will be introduced in the third volume, as a sequel to the radio-active elements. The collection in the first volume of most of the generalizations required for application to special cases in subsequent volumes has simplified many explanations. This applies, for example, to thermal diagrams, equilibrium diagrams for ternary systems, etc. The general historical sketches in this volume facilitate the reviews of the histories of the elements and their compounds which appear in subsequent volumes.

Hydrogen and oxygen, and the compounds of these two elements, have been worked in with the introductory volume. The second volume includes the halogens and the alkali metals. The ammonium compounds are included with the compounds of the alkalies. The other elements will appear mainly in the order of the periodic law. The metal hydrides, oxides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are included with the metals; the other compounds are described with the acids, or the acidic elements. With the complex salts and intermetallic compounds of an element are included analogous compounds of ammonium, hydrazine, and hydroxylamine, as well as of all those elements which have been previously discussed. It should therefore be possible to locate a desired compound from an inspection of the backs of the volumes, which are lettered to show what elements are discussed inside. The indexes and cross-references are also available.

In the 1778 edition of his *Dictionnaire*, P. J. Macquer referred to *la nomenclature très complète* which was available. We are not so well provided to-day. Our nomenclature is inadequate and insufficient; nor has it sufficient elasticity to adapt itself to increasing knowledge. Unfortunately, we have grown so accustomed to the system inaugurated near the beginning of the last century that we are afraid to make a drastic change.

The systematic names of many compounds naturally depend on what view is taken of their constitution. Many names are thus determined by the prevailing fashion as to the nature of the compounds. For example, the mercury ammonia-compounds; the complex salts involving two metals and an acid radicle—sodium sulphato-aluminate, or sodium aluminium sulphate, etc.; the character of the contained-water as water of crystallization or aquo-water: ammonia of crystallization or ammino-ammonia; hydrogen-peroxide of crystallization, or hydrated peroxide, etc.

The application of the methods of physical chemistry is rendering it necessary to revise the list of compounds of a given element; as a result, descriptive chemistry is in state of flux. There is no doubt that many compounds of the older chemists are not chemical individuals, but rather mixtures. The laws of constant composition and multiple proportions have proved inadequate; analysis alone is not a test of chemical individuality. It is, however, necessary to use care because compounds may be prematurely rejected when they do not appear on, say, a thermal diagram, and yet they may be quite stable under another set of conditions. Similar remarks apply to the application of the phase rule to binary or ternary systems at a given temperature. Compounds may be rejected because they do not appear on an equilibrium diagram, and yet they may be quite stable at other temperatures; or in the presence of some other compounds—stabilizers.

There are a couple of minor difficulties in connection with the spelling of names in Slavonic countries with alphabets different from those of the Romance languages. The spelling of the name may appear different according as the paper has been published in England, France, or Germany. The result is that work may seem to have been done by a totally different savant. Thus, Менделѣевъ becomes Mendeléeff, Mendelejeff, Mendelejew, etc.; Жемчужнао may be rendered Zemczuzny, Schemtschuschny, or some other way. I have then taken the liberty of trying to keep to one uniform interpretation. In some cases, therefore, where a Slavonic name appears misspelt, it is probable that one of a number of possible spellings has been selected. Where possible I have included most of the initials with each name. This elaboration might appear redundant; but there are cases where four different workers on the same subject have the same surname. The initials do not always appear with the original publications. Some have been found in J. C. Poggendorff's *Biographisch-literarisches Handwörterbuch zur Geschichte der exakten Wissenschaften* (Leipzig, 1863–1904) or elsewhere. It will be observed that by collecting the references at the end of each section, instead of placing them as footnotes, the appearance of the page is considerably improved, and space economized.

I desire to thank many helpers. My colleagues, Dr. A. Scott and Mr. H. V. Thompson, M.A., have kindly read the proofs and made good suggestions; Messrs. A. T. Green and A. Rigby have given valuable help in proof-reading; Mr. F. Clifford, Librarian of the Chemical Society, has kindly helped in locating many awkward references; and Mr. P. Roche has checked innumerable references. The typewriting and indexing have been in charge of Miss M. Lycett. Many specific obligations are indicated in the references.

J. W. MELLOR.

CHAPTER I

THE EVOLUTION AND METHODOLOGY OF CHEMISTRY

§ 1. The Evolution of Chemical Science

> The progress of science is as orderly and determinate as the movement of the planets, the solar systems, and the celestial firmaments. It is regulated by laws as exact and irresistible as those of astronomy, optics, and chemistry.—S. Brown (1843).

As a result of fiery controversies waged about the philosophy of Aristotle, we are told that the citizens of Geneva, towards the end of the sixteenth century, decreed: "For once and for ever, in no branch of learning shall anyone stray from the philosophy of Aristotle." The modern student cannot obey this dictum in blind faith. Knowledge grows. There is a universal law of progressive development whereby error gradually diminishes and truth expands. Consequently, the opinions of Aristotle were founded upon a less developed and a cruder knowledge of facts and phenomena than is the case with the present generation, which has a wonderful heritage of accumulated experience and ideas which have been stored, selected, and sifted by centuries of toil and labour.

There is no evidence that "all knowledge was revealed to the primitive races of mankind, and subsequently obscured by civilization," although this belief is said to be deep-rooted in many religions; for example, in the ancient Indian doctrine of Crishna, we are told:

> Truth was originally implanted in mankind, but having been suffered gradually to slumber, it was finally forgotten. Since that period, knowledge returns to us as a recollection.

In 1554, in his *Cena di cenere*, G. Bruno combatted the saying that "in antiquity there is wisdom," for he showed that what is called the ancient or golden age really represents an early or youthful stage of growth in contrast with recent or modern times which must, in turn, represent older and more mature knowledge. Hence, also, Francis Bacon could wittily say that "we are more ancient than those who went before us."

Auguste Comte's celebrated *Cours de philosophie positive* (Paris, 1839)[1] teaches that it is characteristic of the progressing human mind to employ three different methods of explaining natural phenomena, and that man's opinions *de rerum natura* can usually be traced through three epochs which he called—*l'état théologique ou fictif; l'état métaphysique ou abstrait; l'état scientifique ou positif*—the theological or fictitious, the metaphysical or abstract, and the positive or scientific stages. Otherwise expressed, in the first stages of his learning, man attempted to explain natural phenomena by supernatural agencies; in the second, by metaphysical abstractions; and in the third stage, by ascertaining the laws of succession and similitude by a study of accurately observed facts. This famous hypothesis, first announced by A. Comte in 1822, is sometimes called **la loi des trois états,** and it appears to have been derived from A. R. J. Turgot (1750), or possibly T. Bergmann, who, in his essay *De primordiis chemiæ* (Upsala, 1779), said: "The history of chemistry is properly divided into the mythological, the obscure, and the certain." True, the three epochs may overlap and blend with one another so that no sharp boundaries can be made with respect to time or place, and, owing to special circumstances, there may be a retrograde movement by the advent of an age of intellectual darkness; yet, in the main, these three periods characterize the growth of science as surely as the child, the boy, and the man characterize the development of an individual's mind. Chemistry is a particularly happy illustration of Comte's idea.

I. The first, the mythological, anthropomorphical, or superstitious stage.—This represents the childhood of chemistry, for, as man emerged from the mists of prehistoric antiquity, everything must have appeared to be full of wonder and mystery. He was overawed by the wind and the rain; by the lightning and the thunder; by the eclipse and the comet; and by the rainbow and the clouds. The student of nature lived in a bewildering dreamland of mixed magic and myth which led him to ascribe supernatural explanations to inaccurately known facts, and consequently, he seemed to be surrounded on all sides by *un monde invisible des esprits et des démons*. Just as man's own actions seemed to be the result of his own efforts and volitions, so did natural phenomena appear to be the work of benignant or malignant spirits in air, earth, or sea; and man accordingly made oblations to their residing deities to secure their kindly offices. Chemical phenomena were produced by spirits—the salamander or the sylph, the naiad or the nymph, the undine or the gnome—indwelling in different bodies, whose aid was invoked by incantation or charm to produce successful experiments.

Accordingly, men who studied nature in those days were often suspected of tampering with the spirits of evil, and chemistry came to be known as one of the seven devilish arts. So too arose a childish fear and hatred of science, and the belief—widespread in the Middle Ages—that science is dangerous, and its votaries ought to be suppressed. In illustration, in 1287, the Order of Dominicans proposed to suppress chemical studies as had been attempted with physics in 1243; again, the *Accademia dei Segreti*—Academy of Nature's Secrets—founded by J. B. Porta in 1602 for the discussion of scientific subjects, was dissolved by Pius III, after *une existence courte mais glorieuse*, apparently because it was believed that magic and the black arts were practised at its meetings. In the thirteenth century, Roger Bacon was arraigned at Oxford on an indictment for practising sorcery and magic; and in order to disprove these accusations, he wrote his celebrated *Epistola de secretis operibus artis et naturæ et de nullitate magiæ* to show that phenomena and appearances, then attributed to supernatural agencies, were simply due to the operation of natural laws. Again, in his *Magiæ naturalis* (Naples, 1558), J. B. Porta tried to show that the magic of nature is quite as wonderful as that of wizards and witches.

T. Thomson opens his work, *The History of Chemistry* (London, 1830), by pointing out that chemistry sprang originally from delusion and superstition, and was at its commencement exactly on a level with magic and astrology. Superstition can flourish only where knowledge is imperfect and fragmentary. Day, adds C. J. Keyser (1914), is just as mysterious as night, and the mystery of knowledge and understanding is more wonderful and awesome than the darkness of the unknown. Mysterious phenomena, explained in one generation as the vagarious work of invisible demons or deities, appear to succeeding generations as the ordered workings of natural laws. The mists of superstition are always dissipated as positive knowledge extends into wider and wider fields.

The cuneiform inscriptions and the records of antiquity which have been transmitted to us, show that the early chemists were dominated by the gratuitous assumption that "the interior agencies which keep the world in motion were personal forces essentially out of and above nature." The magician and the sorcerer, the necromancer and the wizard were the founders and keepers of the first rudimentary knowledge of nature. Accordingly, knowledge and superstition were interwoven with wondrous ingenuity and subtilty. The alchemists, following the mysticism introduced by the Alexandrian and Arabian schools, had virtually reverted to this stage of development when they spoke of red bridegrooms (gold) and lily brides (silver); of green dragons (mercury) and red lions (gold); of black crows (lead), and yellow scorpions (sulphur); and of flying eagles, fugitive stags, and inflated toads. One of the older chemists described the result of triturating mercuric chloride with mercury, resulting in the formation of mercurous chloride, in these pompous words :

> The fierce serpent is tamed and the dragon so reduced to subjection as to oblige him to devour his own tail.

The anonymous work, *Artis auriferæ quam chemiam vocant* (Basil, 1572), represents the dissolution of gold in aqua regia by a lion devouring the sun, as depicted in Fig. 1. This language persisted even as late as the eighteenth century. In W. Clarke's *The Natural History of Nitre* (London, 1670), for example, the red vapours formed when nitre is heated in a retort are called " the flying dragon."

The seven metals—gold, silver, an alloy, copper, tin, iron and lead—known to the early Chaldeans, were also designated by the names and symbols of the seven greater heavenly bodies—the Sun, Moon, Mercury, Venus, Jupiter, Mars, and Saturn. A close relation was supposed to subsist between the metals and their respective planets so that nothing could happen to the one which was not shared by the other ; and it was further supposed that experiments with any particular metal were more likely to succeed when the governing planet was in the ascendant, and near its zenith. Thus, in Paracelsus' directions for preparing an amalgam of lead and mercury, the two fluid metals are to be mixed " at the very moment of the conjunction of Saturn and Mercury." In some cases it is possible to see a fanciful reason why a particular metal was assigned to a particular heavenly body, but in other cases the connection is too remote to hazard even a guess. *En passant,* it may be pointed out that an ingenious hypothesis to explain how the metals are affected by the planets was in circulation long after the original fancies had been forgotten. As N. Lemery expressed it in his *Cours de chimie* (Paris, 1675) :

FIG. 1.—Copied from an old Symbol representing the Dissolution of Gold in Aqua Regia.

> An infinite number of minute corpuscles pass to and from the metals and the planets, these corpuscles can easily pass through the pores of the metals and the planets they represent, but they cannot pass into other bodies whose pores are not figured properly to receive them, or if they do get into other bodies, they cannot stay there to contribute any nourishment. The metals are thus perfected and nourished by the influence which comes from the planets and conversely.

II. The second or philosophical stage.—At last man roused himself from his stupor of helpless wonder and childish guessing. He dimly realized some method in nature's inscrutable complexity. Unfortunately, his vision was soon bedimmed and his mind intoxicated. Accordingly, we now find him arrogantly proclaiming the supremacy and omnipotence of the human reason. The majority of educated people of that age believed it to be undignified for a self-respecting man to make experiments, and they did not consider knowledge obtained by observing nature to be a serious subject worthy of mental occupation. Indeed, men were so proud of their intellectual supremacy that they persuaded themselves that their fancies about nature were finer, nobler, and more worthy of belief than nature herself ; and Plato apparently considered that the secret laws of nature could be invented by abstract thinking ; for, in his *Republic,* he said that " real knowledge is obtained by a simple process of reasoning independently of all information furnished by the senses." In his *Phædo,* Plato expresses his delight with Anaxagoras' saying that "the mind is the cause and orderer of all things." The numerous absurdities obtained by the application of this principle are well exemplified in the pages of Plato's *Timæus*, where there are many illustrations of the vanity of the attempt to explain incomprehensible facts by nebulous words; for example, Plato there states:

> The universe is a unique, perfect, and spherical production, because the sphere is the most perfect of figures; and it is animated and endowed with reason, because that which is animated and endowed with reason is better than that which is not.

Even Aristotle, the father of logic, reasoned that a vessel containing ashes would hold as much water as when the vessel contained no ashes. The conclusion is not true, showing that Aristotle did not always recognize the need for the discipline of the imagination by relentlessly checking reason against inexorable fact.

Thus, man did not always see with Cicero that nature is a better teacher than the most ingenious philosopher. Prompted by a sublime imagination, R. Descartes, in his *Principia philosophiæ* (Amsterdam, 1644), built a hypothetical universe which had no substance, and is now regarded as little more than an idle dream. Well might T. Bergmann's essay *De indagando vero* (1779) claim:

> The philosophical method, by pretending to unlock the secrets of nature with ease and expedition, soothes a natural impulse to explain all things; and by assuming everything to be accessible to the human intelligence, administers pleasing flattery to vanity and arrogance.

The methods of thinking, the much vaunted philosophy of Plato and Socrates, in its attempt to proclaim the laws of nature from the throne of human reason, actually obscured the path of progress for many centuries, for it became the fashion to look with lofty scorn on knowledge gleaned by observing nature. Accordingly, the leading philosophers worshipped what Francis Bacon might have called *idola cogitationis*—idols of the imagination; they devoted themselves to fantastic and chimerical hypotheses about material things; and made no earnest attempt to discriminate between the unreal and the real. As a result, their minds became so prejudiced that the facts were either denied, or else explained by extravagant ideas and fancies uncontrolled by truth and reality as we understand these terms to-day.

III. The third, the scientific, or the positive era.—The marvellous Greeks gave promise of inaugurating this era before the advent of Christianity, but the feeble light kindled by Aristotle flickered and almost expired in the atmosphere of mysticism which prevailed in the Middle Ages. During this period, man almost reverted to the pandemonium of miracle and magic of his childhood days. The light re-appeared about the thirteenth century, and gained brilliancy during the succeeding centuries; man then learned to see that nature is as she is, and is not subjected to the capricious will of deity or demon; man recognized that nature is always conformable with herself without contradictions and without inconsistencies.

The growth of chemistry as a science was nourished in the seventeenth century by the establishment of academies and societies for the cultivation of science. The famous *Society of Rosicrucians*,[2] which flourished mightily towards the end of the sixteenth or beginning of the seventeenth century, was perhaps an exception, for, judging from the many books which were poured from its presses between 1600 and 1630, it rather fostered mysticism and obscurity, and was not favourable to the true scientific spirit. Long before the advent of the scientific societies, there were associations which fostered human knowledge, for example, the priests of Egypt had their temple laboratories; and the same spirit led to the formation of the various schools of philosophy in Greece; but the special feature of the later associations was their energetic protest against the worship of antiquity, where the authority of an ancient master was placed above experience.

The *Accademia del Cimento*, founded at Florence, in 1657, under the presidency of Prince Leopold de Medici, was the first scientific society of any importance ; its main object was " the repudiation of any favourite system or sect of philosophy, and the obligation to investigate nature by the pure light of experiment." Although it lived but ten years, it enriched the world by leaving a volume of important records of experiments, chiefly in pneumatics—*Saggi di naturali esperienze fatti nell' Accademia del Cimento* (Firenz, 1666). This work has been reprinted a number of times in several languages. *The Royal Society* of London was founded in 1660 ; *l'Académie des Sciences* of Paris in 1666 ; the *Academia naturæ curiosorum* of Germany in 1652 ; and many others were founded in the eighteenth century. In some exceptional cases, these associations degenerated into " fastnesses from which prejudice and error were latest in being expelled ; and they joined in persecuting the reformers of science." The attitude of the University of Paris towards Galilei, and of the University of Oxford towards Roger Bacon have been cited as examples. In general, however, the policy of these associations was to encourage the investigation of nature by observation and experiment ; *Arrière les théories, vivent les faits !* was their watchword ; and, instead of clothing their results in the enigmatical and allegorical language of the Rosicrucians, they sought to give a candid and straightforward account of their investigations and thoughts. In this way, the obscure mysticism of the Middle Ages was gradually dispelled. Man thus rediscovered that he does not bring any knowledge into the world with him ; that " the subtilties of nature far transcend the subtilties of the human reason " (F. Bacon) ; and that " knowledge cannot be invented, it must be discovered." Progress was then assured, and the manifold achievements of the observational and positive sciences during the past century are in striking contrast with the paucity of the results of philosophical thinking applied in vain for thousands of years.

§ 2. The Observation and Record of Facts. Collecting Data

The mind is like a blank tablet upon which experience writes that which is perceived by the senses.—ARISTOTLE (B.C. 320).

To what can we refer for knowledge ? What can be a more certain criterion than the senses themselves ? If we cannot trust the senses, how is it possible to distinguish what is true from what is false ?—LUCRETIUS (B.C. 60).

I know only that truth is in the things and not in my mind which judges them, and that the less I put my mind in my judgments about them, the more sure am I to come near to the truth.—J. J. ROUSSEAU (1770).

H. Poincaré, in his *La science et l'hypothèse* (Paris, 1904), emphasized in a very telling manner that true knowledge about material things can be acquired only through the senses—*experientia docet* ; there is no other way. Experience is the well-spring of true knowledge ; experience alone can teach something new ; it alone is irrefutable ; it alone can give certainty. The same idea was suggested by Aristotle and the peripatetical philosophers : *nihil est in intellectu, quod non prius in sensu*—nothing is in the intellect which was not first in the senses ; and by Roger Bacon in his *Opus majus* about 1266, when he said : *Sine experientia nihil sufficienter sciri potest*. Experience comprises all the impressions we observe and perceive through the various organs of sense. These impressions are recorded in our notebooks, dictionaries of chemistry, etc., as empirical realities or facts. Although knowledge cannot transcend the human faculties, much of the data of science is not *directly* furnished by the senses, for the senses are quite unable to discriminate the subtilties of nature. For instance, the speed of light and the size of atoms are magnitudes either too great or too small to be accessible to sense perceptions. Yet much data derived indirectly from the insensible physical world are assumed to be realities or facts, when actually they are known only by inference from data furnished by the senses. Without facts, science can do nothing; they are the foundation and building stones of the whole superstructure. The edifice can be stable only in so far as it is founded upon the immutability of facts. The facts must be accurate, or the edifice will be unstable.

Not very many years ago, an apt quotation from one of the classical writers—say Aristotle—was considered ample proof of the truth of any statement, and this in spite of repeated warnings; even in the thirteenth century, Albertus Magnus could say:

> I pored over the books of all the sages from Morienus, Aristotle, and Plato downward, but yet I went wrong, until, by trial and mistakes, I at length discovered the truth.

Science does not accept P. Bonus' dictum, in his *Margarita novella* (Basil, 1572): "The mere fact that a great body of learned men believe a statement supersedes the necessity for proof." To-day, science looks askance on records of mere opinions, and focuses its attention on records of facts. It is not always easy to record facts faithfully without unconscious distortion or bias. What we wish, said Demosthenes, that we believe; what we expect, said Aristotle, that we find.[1] Things are not always what they seem. Seeing is not always believing. It is often difficult to distinguish appearances from realities for we are easily deceived by the mockery of sensations. The senses cannot be divorced from the mind; neither is always to be trusted alone. The sun appears to rise and set; in reality it does neither. So, although experience is the source of truth, it may also be a source of error. Superficial appearances may obscure hidden realities. Plato of old was unduly oppressed with the illusions and deceptions of sensory impressions, and he was accordingly led to deny the validity of knowledge derived from the sensations; but Aristotle rightly showed that difficulties arise only when the mind wrongly interprets the testimony of the senses.

In 1689, John Locke[2] emphasized the view that the senses are the tentacula of the mind because the mind primarily derives its knowledge of the external world through the senses. All our knowledge, said he, consists of a stock of ideas which were primarily produced in the mind by sensation, and which have remained after the sensation had ended. Our knowledge of chemistry, physics, etc., depends on the ability of the senses (i) to receive accurate impressions of the external world; and (ii) to convey these impressions to the mind or brain. When the mind receives a sensation, it immediately begins to interpret the meaning, and it usually *infers* the existence of something outside itself which gave rise to the sensation. It may seem as if the mind directly perceives the external object which gives rise to the sensations; but this is an illusion. The mind apprehends the sensation alone; and it *assumes* that there exists a cause of the sensation external to itself. There is no doubt about the sensation, but there is less certainty about the inference; the sensation must be accepted as a fact, but the inferential knowledge will be true or false according as the interpretation of the external cause of the sensation was correct or otherwise. The sensation does not err, it is the mind which fails when it misinterprets the material furnished by the senses. Hence, Plato could say that we do not see with the eyes but with our reason; J. W. Goethe, that we see only what we know; and E. Mach (1883), that the adaptation of thoughts to facts is the aim of all scientific research.

It is therefore sometimes necessary to receive with caution the testimony of evidence derived from sensations. The mind interprets a sensation by comparing it with some former sensation, the source of which has been previously determined. Consequently, the faithfulness of the interpretation is dependent upon the memory of past sensations, or upon the sensitiveness of the mind to detect resemblances and differences. Otherwise expressed, the accuracy of an inference as to the nature of the *objective* source of a *subjective* sensation varies from a mere guess to virtual certainty.[3] The idea has been aptly illustrated this wise : just as a number of bits of glass irregularly arranged always form symmetrical patterns when viewed through the kaleidoscope, so does the understanding of each man impose a pattern of its own upon the various sensations which it perceives. Consequently, as Robert Hooke [4] once said : It is necessary to be on guard against deep-rooted errors which may have been grafted upon science by the slipperiness of the memory, the narrowness of the senses, and the rashness of the understanding. The greatest caution must be exercised in accepting, on secondhand evidence, facts which cannot be verified. No reliance can be placed on vague impressions. Evidence must be clear and precise.

Few persons can estimate and register facts impartially and fairly. As W. S. Jevons [5] puts it: "Among uncultured observers, the tendency to remark favourable, and forget unfavourable events is so great that no reliance can be placed on their supposed observations." T. Bergmann long ago drew attention to this very trait. He said :

> One observer will relate an event with the most extravagant encomiums ; another will detract from its real merit ; a third, by some oblique insinuation, will cast suspicion on the motive ; and a fourth will represent it as a crime of the blackest dye. These different descriptions represent the character of the respective observers.

Untutored minds are very prone to mistake inferences for observations, and prepossessions for facts ; their observations and their judgments are alike vitiated by dogma and prejudice ; they do not seek to investigate, they seek to prove. The old proverb is inverted, believing is seeing. The student of science must pledge himself to do his best to eliminate prepossession and dogma from his judgments, and he must spare no pains to acquire the habit of recording phenomena as they are observed ; and to distinguish sharply between what is or has been actually seen, and what is mentally supplied. It requires a mind disciplined like a soldier to avoid the natural inclination to look away from unwelcome facts.

The purity of truth is almost certain to be corrupted when the observer is ruled by preconceived opinions, for, as O. W. Holmes puts it : When we have found one fact, we are very apt to supply the next out of the imagination ; or as T. Bergmann said in his essay *De indagando vero* (1779) :

> An observer swayed by preconceived opinions, may be considered as one who views objects through coloured glasses, so that each object assumes a tinge similar to that of the glasses employed. He who seeks the truth must learn to observe with equal candour those facts which controvert his opinions, and those which favour them.

It is only in a pseudo-science, said O. W. Holmes, that positive evidence, or such as tells in favour of its doctrines, is admitted ; and all negative evidence, or such as tells against it, is excluded. C. Darwin, in his *Autobiography* (London, 1887), states that one of his golden rules was to make a memorandum of any fact or thought which he found to oppose his general results, because he noticed by experience that such facts or thoughts were far more apt to escape the memory than favourable ones. Above all, said Robert Hooke (1665), a good observer needs a sincere hand and a faithful eye, to examine and record things themselves as they really appear. "The mind and the reason of the trustworthy observer must be trained to rebel against all desire, and to disobey all inclinations."

The belief that bodies contained a definite quantity of heat substance or caloric prevented Black's successors from regarding the fact, known to every savage, that heat is produced by friction ; the theory of phlogiston prevented some of the early chemists from recognizing the increase in weight which occurs when metals are calcined—*oculos habent et non videbunt* (Psalm **115.** 5) ; the assumption that air is absorbed when lead is roasted prevented Stephen Hales recognizing oxygen as the gas evolved when red lead is heated ; and, as E. Mach (1892) has pointed out in his *Populäre Vorlesungen* (Leipzig, 1903), the undulatory theory of light prevented C. Huygens marking the fact of polarization which Isaac Newton, undisturbed by theories, perceived at once.

§ 3. The Collating, Sifting, and Clarifying of Observations. Classifying Data

> History teaches that the commencement of every branch of science is nothing more than a series of observations and experiments which had no obvious connection with one another.—J. VON LIEBIG (1846).
>
> In order that the facts obtained by observation and experiment may be capable of being used in furtherance of our exact and solid knowledge, they must be apprehended and analysed according to some conceptions which, applied for this purpose, give distinct and definite results, such as can be steadily taken hold of, and reasoned from.—W. WHEWELL.

The record of facts obtained by observation and experiment, *per se*, is empirical knowledge. *Empirical* is derived from the Greek word ἐμπειρικος, meaning experienced. It has just been emphasized that all knowledge is derived from experience, and hence empiricism would appear to be the right method of acquiring knowledge. The term, however, has slightly changed in meaning, for it is now usually applied to chance experiences which occur irregularly without any orderly plan of investigation.

All true science, said T. Huxley, must begin with empirical knowledge. Nature, however, presents to our senses a panorama of phenomena co-mingled in endless variety so that we are sometimes overwhelmed and dazed by the apparent complexity of empirical knowledge. It is work for the intellect to educe the elements of sameness amidst apparent diversity, and to see differences amidst apparent identity. It is work for the judgment to reject accidental and transient attributes, and to consolidate essential and abiding qualities. Consequently, while the primary aim of science is to collect facts, the higher purpose of science is to show that, amidst wild and terrible disorder, order and law reign supreme. The man of science seeks a refuge from this bewildering complexity in unifying principles by which the facts can be grouped and classified into systems. As he gazes into nature, the man of science must be quick to discern hidden resemblances amidst a thousand differences; he must be quick to disentangle natural relations from a medley of detail; and quick to detect dissemblances amidst alluring similarities.

Empirical knowledge describes facts; science begins by comparing facts. Empirical facts, in consequence, can form a science only when they have been arranged, rearranged, grouped, or classified so as to emphasize the elements of similarity and identity in different phenomena. Accordingly Thomas Hobbes expressed the opinion that the main purpose of science is the tying of facts into bundles. This bundle-tying, indeed, forms no small or insignificant part in the development of science; otherwise expressed, a significant advance has been made in the development of a science when the observed facts have been codified into a system so that a medley of empirical facts is systematically summarized under a small number of heads. This means that the facts must be arranged in a methodical and systematic manner until finally all the relevant facts taken together may form one system. The process of classification and correlation is one of the methods of scientific investigation. Knowledge so systematized is scientific knowledge. T. Bergmann (1779) illustrated the idea in his essay previously cited:

> A vast number of observations without order or regularity is not unlike a confused heap of stones, lime, beams, and rafters requisite for constructing an edifice, but which being combined with no skill fail in producing the proposed effect.

The material framework of the world appears in a myriad different guises and combinations, but the chemist can resolve each combination into a few definite elementary forms of matter; similarly, a multitude of forces can be resolved into comparatively a few primitive forms of energy. About 150 A.D., the Egyptian astronomer Claudius Ptolemy measured the angles of incidence and refraction of a beam of light passing from air into water, but more than fourteen hundred years elapsed before W. Snell (1621) detected the law of refraction hidden in Ptolemy's data. By tabulating his measurements of the volumes of air confined under different pressures, Robert Boyle discovered the law known by his name. Each of these laws summarizes in one simple rule myriads of possible measurements.

Scientific knowledge is not necessarily more accurate than empirical knowledge. Empirical uncoordinated facts are no less true, definite, and real than scientific facts, for all facts are equally true *per se*. A collection of empirical facts always requires some theory to serve as framework in order that the facts may be arranged, grouped, and pigeon-holed. According to F. Hoefer (1843):

> Il n'y a rien de plus stupide qu'un fait, quand il ne se rattache à aucune cause connue, à aucune loi dominante. Il faut donc concilier l'individualisation des faits avec leur généralisation. C'est là que réside le vrai critérium, l'avenir de la science.

If a group of facts—scientific facts—has been organized on an erroneous system, the facts are no less true though the system be false. Chemistry presents a curious mixture of empirical facts with isolated fragments of scientific knowledge.

§ 4. The Generalization of Observations

> Facts are the body of science, and the idea of those facts is its spirit.—S. BROWN.
>
> It is the intuition of unity amid diversity which impels the mind to form science.—F. S. HOFFMAN.

The correlation of empirical facts requires qualities of the mind different from those employed in observation and experiment. Both qualities are not always located in the same individual. Some excel in the one, not in the other. J. Priestley, C. W. Scheele, and H. Davy, for instance, were admirable observers, but they were not brilliant in the work of correlation; J. Dalton and A. L. Lavoisier were not particularly distinguished as experimenters, but they excelled in correlating observed data. W. Hamilton[1] did not rate the fact-collecting faculty very highly. He said:

> In physical science the discovery of new facts is open to every blockhead with patience, manual dexterity, and acute senses; it is less effectively promoted by genius than by co-operation, and more frequently the result of accident than of design.

J. Priestley (1783) recognized his own limitations when he said: "I have a tolerably good habit of circumspection with respect to facts, but as to conclusions from them, I am not apt to be very confident." Skill in the critical analysis of observational data, and in collating, sifting, and clarifying records, is not a sufficient recommendation to the adytum—the *sanctorum sanctissimum*—of science. There is still a higher type of work for but a few seekers after knowledge. It is

> To search thro' all
> And reach the law within the law.—TENNYSON.

It is the sprite imagination which usually reveals the deeper meaning of facts which have been diligently garnered, and laboriously sifted.

It cannot be doubted that science in its higher work, requires a supple and well-developed imagination [2] which T. Gomperz says is the instrument of genius, no less for scientific discovery than for artistic creation. The secret charm of scientific discovery is not in the facts *per se*, but rather in the extrication of natural relations among the facts one with another. Particular groups of facts must be unified or generalized into a system—the so-called **law.** Science begins with facts and ends with laws. Law is the essence of facts. As pointed out elsewhere, Newton's celebrated law epitomizes in one simple statement how bodies have always been observed to fall in the past. Immortal Newton did not discover the cause or the why of the falling of the apple, but he did show that it was due to the operation of the same forces which hold the earth, the planets, and their satellites in their appropriate orbits. Newton's simple and comprehensive law epitomizes in one single principle the many and varied phenomena associated with falling bodies, planetary motions, etc., and generally, the scientific generalization explains the operations of nature by showing the elements of sameness in what at first sight appears to be a confused jumble of phenomena. Generalization is the golden thread which binds many facts into one simple description. That peculiar type of genius, that rare quality of mind required for the work of generalization, is found only in a Newton or a Darwin. Plato said that if ever he found a man who could detect the *one in many* he would follow him as a god.

Unification is the supreme goal of modern science, or, as Heracleitus (*c.* 450 B.C.) proclaimed, the highest goal of knowledge is the one law regulating all events. However, with A. Comte,[3] the majority will have *la profonde conviction personelle*, that the attempt to explain all phenomena by *une loi unique* is chimerical. Several natural phenomena belong to different categories, and are irreducible one to another. At best, man has to apply a very weak intellect to a very complicated world ; and the resources of the human intellect are too narrow, and the universe is too complex to leave any hope that it will ever be within man's power to carry scientific perfection to Tennyson's last degree of simplicity :

> . . . one law, one element.

§ 5. The Aim of Science in General, and of Chemistry in Particular

> Let us remember, please, that the search for the constitution of the world is one of the greatest and noblest problems presented by nature.—G. GALILEI.
>
> The ordered beauty of the world of nature suggests an infinite intelligence with powers of action such as no man possesses.—BENJAMIN MOORE.

Science embraces the sum-total of human knowledge, and it ranges over the whole realm of nature. Science is not a mass of empirical knowledge gained by observation and experiment, but it is an organized body of facts which have been co-ordinated and generalized into a system. Science tacitly assumes that nature is a harmonious unity, and that rational order pervades the universe. Science seeks a complete knowledge of the multitude of inter-related parts of the universe which act and react on one another producing endless variety. In fine, science aims at omniscience. The target, however, appears to recede with increasing knowledge. As man grows in wisdom and knowledge, he begins dimly to realize that the unknown multiplies into boundless proportions.

The sciences are too complex and too vast to be comprehended by one man's mind.

> One science only will one genius fit,
> So vast is art, so narrow human wit.—POPE.

Our feeble wit has rendered it necessary to rear a tree of scientific knowledge with many branches: astronomy, physics, chemistry, mineralogy, geology, biology, sociology, etc. "The divisions of the sciences," said Francis Bacon, "are like the branches of a tree that join in one trunk," and they are therefore more or less closely related with one another. The astronomer, the physicist, the chemist, each usually keeps to his own particular branch. This separation of the sciences is mere convention. Even in the middle of the thirteenth century Roger Bacon saw that there are no real lines of demarcation between the different sciences, for he pointed out in his *Opus tertium* (1267):

> All the sciences are connected; they lend each other material aid as parts of one great whole. Each does its own work, not for itself alone, but for the other parts. . . . No part can attain its proper result separately; since all are parts of one and the same complete wisdom.

The science of chemistry is man's attempt to classify his knowledge of all the different kinds of matter in the universe; of the ultimate constitution of matter; and of the phenomena which occur when the different kinds of matter react one with another. The science of chemistry is itself so vast, that many branchlets are necessary for useful work, and thus we have: inorganic chemistry, organic chemistry, physical chemistry, mineralogical chemistry, bio-chemistry, agricultural chemistry, pharmaceutical chemistry, etc. The chemist also frequently aims at applying his knowledge to useful purposes in the arts and industries; and thus arises applied, industrial, or technical chemistry.

Applied chemistry.—About the middle of the thirteenth century, Roger Bacon distinguished between knowledge sought for the sake of truth, and knowledge utilized in the practice of the various arts; or, as I. R. Averroës expressed it a century earlier: In pure science, *scimus ut sciamus*; and in applied science, *scimus ut operemur*. The distinction, however, was recognized in the fourth century B.C., for it was explicitly expounded in Aristotle's *Metaphysics*, and it was also intimated still earlier in Plato's *Republic*.[1] The purpose of pure science is to observe phenomena and to trace their laws; the purpose of art is to produce, modify, or destroy. Strictly speaking there is no such thing as applied science, for, the moment the attempt is made to apply, science passes into the realm of art. It has been well said that "science is indebted to art for the means of experimenting, but she instructs art concerning the properties and laws of the materials upon which the latter operates." In an essay on *The usefulness of experimental philosophy*, Robert Boyle (1663) emphasized the mutual benefits which would obtain when science, or, as he called it, when natural philosophy is applied to the various arts and crafts; and he claimed that it is prejudice, no less pernicious than general, which has kept science so long a stranger in the industries. Boyle's ideas have been still further emphasized by Lord Kelvin (W. Thomson), who said in 1883:

> There cannot be a greater mistake than looking superciliously upon practical applications of science. The life and soul of science is its practical application, and just as the great advances in mathematics have been made through the desire of discovering the solutions of problems which were of a highly practical kind in mathematical science, so in physical science many of the greatest advances that have been made from the beginning of the world to the present time have been in the earnest desire to turn the knowledge of the properties of matter to some purpose useful to mankind.

The so-called applications of science to the industrial arts—say, applied chemistry—may be (i) An attempt to extend the methods of scientific investigation to the industrial arts; or (ii) To adapt known operations and laws to useful purposes. When the chemist is occupied in the systematic observation of phenomena, and in tracing their laws, he is engaged in scientific investigation, no matter if the work be conducted in academy, in counting house, or in factory.

§ 6. Experiment

Experiment is the interpreter of nature. Experiments never deceive. It is our judgment which sometimes deceives itself because it expects results which experiment refuses. We must consult experiment, varying the circumstances, until we have deduced general rules, for experiment alone can furnish reliable rules.—LEONARDO DA VINCI.

Nature speaks to us in a peculiar language, the language of phenomena. She answers all the questions we ask her, and these questions are our experiments.—J. VON LIEBIG.

Chemistry is largely an experimental science. Experiment is really a method of observation, which is employed when the facts are so masked by other conditions that they cannot be accurately observed unless the obscuring conditions are suppressed. The chemist would not make much progress if it were only possible to observe phenomena just as they occur in nature, and not possible to make observations under determinate conditions. By experiment, it is possible to make combinations of different forces, and different forms of matter which are not known to occur in nature; to eliminate complex disturbing conditions; and to observe phenomena under simplified conditions. An experiment has been well defined as *une observation provoquée*. Experiment, said G. A. Reid, is useful only when there are conditions which obscure direct observations. The most successful experiment does no more than make a fact which was previously obscure as patent as one that was open to direct observation from the first. Chemical phenomena, *per se*, are usually too complex for our minds to grapple, and they must be simplified by simple experiments. Consequently, chemistry is an experimental science because its facts can rarely be observed in any other way. If data could be obtained by direct observation, there would be no need for experiment.

It requires much acumen to determine the precise conditions under which an experiment shall give a successful result. Every experiment has the character of a specific question. The skilled questioner—the experimenter—knows what he is asking, and he tries his best to interpret nature's reply, be it affirmative, negative, or evasive. If the answer be negative or evasive, the question has not been properly asked, and it must be plied again and again until

A sharphooked question baited with such skill
It needs must catch the answer.

Paradoxically enough, the investigator can usually say with "Dr. Moreau": "I asked a question, devised some method of getting an answer, and got—a fresh question." Some such ideas were in Robert Hooke's mind when he said:

> The footsteps of nature are to be traced, not only in her ordinary course, but when she seems to be put to her shifts, to make doublings, and turnings, and to use some kind of art in endeavouring to avoid our discovery.

The more intricate the experiment, the greater the probability of an obscure and ambiguous result. As A. L. Lavoisier has pointed out, "it is a necessary principle in experimental work to eliminate every complication, and to make experiments as simple as possible." The *quality* of an experiment, not the *quantity*, is best adapted to throw light upon a phenomenon. Experiments carelessly performed may be sources of error and obscurity. Many of the results obtained by the alchemists in the Middle Ages show how ineffective or abortive are the results of experiments in incompetent hands—here, the experiments wandered into eccentric by-paths, and furnished preposterous conclusions. Experiment is an art, said G. A. Lewes (1864) and demands an artist.

Joseph Priestley believed in making a large number of haphazard experiments, and said that he discovered oxygen by trying the effect of heat on many substances, apparently selected at random by John Warltire of Birmingham. Thomas A. Edison, also, appears to have discovered the phosphorescence of calcium tungstate when exposed to Röntgen's rays by deliberately trying the effects of these rays on a large collection of different substances. This old prosaic method of experimenting by trying everything is necessary in some cases, and, though usually dubbed empirical or rule-of-thumb, the process is fundamentally scientific, but it is not generally economical in time and labour. Discoveries are then due, as J. Priestley once argued, more to "chance than to any proper design or preconceived theory." More frequently, the track of the experimenter is blazed by means of working hypotheses.

§ 7. Hypothesis, Theory, and Law

We are gifted with the power of imagination, and by this power we can enlighten the darkness which surrounds the world of senses. Bounded and conditioned by co-operant reason, imagination becomes the mightiest instrument of the physical discoverer.—J. TYNDALL.

The nearer to the practical men keep, the mightier their power. The theorist who dreams a rainbow dream, and calls his hypothesis true science, at best is but a paper financier who palms his specious promises for gold.—T. L. HARRIS.

Hypotheses are cradle songs by which the teacher lulls his pupils to sleep.—L. W. GOETHE.

It is a popular belief that the aim of science is to explain things ; as a matter of fact, the so-called explanations of science do not usually get much beyond describing the observed facts in the simplest possible terms so as to make their relations with one another clear and intelligible.[1] The description may emphasize the history of a phenomenon, or the conditions under which the phenomenon occurs : In other words, science may explain a phenomenon by describing how one event is determined by an antecedent action—sometimes called a **cause;** and how one particular set of conditions—the cause—can give rise to another set of conditions—the **effect.** Science explains a phenomenon (the effect) by showing that it is a necessary or rather a probable consequence of another phenomenon (the cause).

Classical scholars tell us that Aristotle has forty-eight, and Plato sixty-four meanings for the word cause. The later metaphysicians have also played a game of shuttle-cock with the term. The word cause is usually applied to an event, action, or process which "produces" an effect ; or, with R. Shute, cause may be regarded as that which the mind selects as a sign of the coming of that other phenomenon which it calls the effect ; or conversely, an effect is regarded as something which the mind selects as a sign of the past existence of a cause. There can therefore be no cause without an effect, and no effect without a cause. The one presupposes and completes the other. Hence, as P. Carus has observed, the law of causation describes a transformation in which form alone is changed ; and consequently, the law of causation is nothing more nor less than another aspect of the famous law of the conservation of matter and energy. The search for the cause of an event is a search for the determining factors which would produce that event. When the cause of an event has been discovered, the event is said to be explained by the cause.

There are certain circumstances or conditions which may exercise, directly or indirectly, a determinative influence on the effect produced by the activity of a cause ; and very often certain *conditions* must obtain before an event can occur, thus the temperature of hydrogen must be raised above its ignition point before combustion can ensue. The effect obtained by burning hydrogen is more vigorous if the flame be in oxygen gas than if it be in air. Hence, an atmosphere of oxygen gas is a favourable condition for the combustion of hydrogen ; a reduced pressure is a retarding condition because it hinders the speed of combustion and reduces the vigour of the flame. The term cause is frequently employed when *reason* is intended. The difference is marked in different countries by the use of different terms—Greek : *αἰτία* (cause), *αἐχή* (principle, reason) ; Latin : causa, ratio ; French : cause, raison d'être ; German : Ursache, Grund ; Italian : causa, ragióne ; etc. Gravitation is said to be the cause of the falling of a vase from the mantelpiece, whereas the cause of the fall may have really been a push from the elbow. In the former case, the reason why the vase fell downwards is the very same reason why all masses gravitate, and a push was the real cause of the catastrophe. Here the reason of the fall is referred to an inherent quality of bodies, just as the reason why bodies react chemically is explained by investing matter with an inherent quality or *vis occulta*—chemical affinity. If these distinctions be borne in mind, there is no need for confusing cause, reason, and condition, even if one term be used for all three concepts.

The **law of continuity**—emphasized by G. W. von Leibniz (1687)—assumes that no interruption between cause and event is possible, and that there is a connected chain in the order of natural phenomena so that when several of the links are known, the intermediate links can be inferred. Consequently, men of science assume that each phenomenon is an effect of a previous event, and is itself the cause of a succeeding effect, and that under like conditions, the same causes produce the same effects. Apart altogether from the question whether or not nature can do precisely the same thing again under precisely similar circumstances as she has done before, the principle of continuity or uniformity assumes that any phenomenon will be repeated if all the preceding phenomena be precisely repeated; otherwise expressed: the same antecedents are invariably accompanied by the same consequents. Hence, it has been said that science does not now seek for the reason or the why of events, but rather for invariable relations between phenomena. The law of causation is taken to *describe* a sequence of changes starting with the cause and ending with the effect. G. Kirchhoff introduced the term *description* as a synonym for *cause* at the very beginning of his *Vorlesungen über mathematische Physik* (Berlin, 1876), where he said: " The object of mechanics is to give a complete *description* in the simplest possible manner of such motions as occur in nature."

Although every effect may be traced to a previous event as its cause, in the physical world, phenomena follow one another as links in an unbroken chain of cause and effect. It is soon recognized that the cause of a phenomenon is an effect which itself needs explaining by some ulterior cause, so that causes can be traced backwards in a never-ending chain of events. Owing to the limited range of man's understanding in a world of infinite complexity, we are far, very far, from comprehending the true conditions, the true causes, or the true reasons for natural phenomena.

The mind cannot receive a long series of details without encircling and connecting them by a common bond which is a kind of *mental nexus*; similarly, in the attempt to find the causes of many phenomena, man is compelled to build an imaginary model showing how a given set of conditions—the hypothesis or theory—is always followed by particular effects. A phenomenon is then explained by showing that it is bound to occur by the operation of the set of conditions postulated by the hypothesis. Consequently, hypotheses are essentially guesses at truth. The rational observer does not trust to random guesses, but he is guided by a more or less vague intuitive conjecture (hypothesis) as to the meaning of the phenomena under investigation, and experiments are devised accordingly, for

Man's work must ever end in failure,
Unless it bear the stamp of mind.
The head must plan with care and thought,
Before the hand can execute.—SCHILLER.

The Spanish philosopher J. L. Balmés emphasized this same idea in his *Filosofia fondamental* (Barcelona, 1846), when he said:

> Although one accepts as a *real* truth the most uncontested and the most certain fact, it remains sterile if ideal truths do not fecundate it. . . . To acquire scientific value, the facts must become objective, or, being submitted to reflection, must be impregnated by the mind with the light it lends to necessary truths.

Hypotheses precede observation and prompt experiments, for they indicate the conditions under which the search for new facts is likely to be successful. Hence, when Leonardo da Vinci (*c.* 1500)[2] said that "hypothesis is the general, and experiments are the soldiers," he probably meant that hypotheses direct or indicate what experiments should be made. Accordingly, hypotheses are indispensable aids in the systematic quest after the secret meaning in nature's deeds. Those who refuse to go beyond fact, said T. H. Huxley (1887), rarely get as far as fact. It is difficult to believe that so astute an investigator as Joseph Priestley really overlooked this mode of investigation, as might be supposed from some preceding remarks—nor did he. On the contrary, he said:

> It is by no means necessary to have just views, and a true hypothesis, *a priori*, in order to make real discoveries. Very lame and imperfect theories are sufficient to suggest useful experiments which serve to connect those theories, and give birth to others more perfect. These then occasion further experiments, which bring us still nearer to the truth, and in this method of approximation, we must be content to proceed, and we ought to think ourselves happy if, in this slow method, we make any real progress.

The many gaps in our knowledge are temporarily bridged by the assumptions called hypotheses. Hypotheses thus help to render intelligible the interrelations between different facts, and they are employed by men of science to extend and deepen their experience by predicting and disclosing new facts; to correct and purify their knowledge of natural phenomena by eliminating errors and contradictions; and to systematize their description of facts so as to obtain the greatest control over them with the least possible effort.

An hypothesis contains a speculative term, an assumption which goes beyond the observed facts; while a law is a generalization which does not extend beyond the observed facts. A law is thus limited by the facts it describes. When an hypothesis has been so extended that it has a wide and comprehensive scope, the hypothesis becomes a theory. Like the hypothesis, a theory usually contains an unproved assumption—*e.g.* the kinetic theory, the electron theory, etc. Some writers—*e.g.* W. Ostwald—apply the term theory to a generalization which does not extend beyond the observed facts, and in that case, theory becomes law when the generalization has a wide and comprehensive scope. There are several other uses of the term theory. For historical reasons the term may appear to be confused because the passage from hypothesis to theory, or from theory to law, has not always been attended by a change in the corresponding terms—*e.g.* Avogadro's hypothesis, by the definitions here given, might be called a theory.

The verification of hypotheses. An hypothesis may seem to be the logical consequence of known facts, or it may be a random flash of the imagination. However probable an hypothesis might appear, both the hypothesis and the logical consequences of the hypothesis must be tested by comparison with facts. Aristotle (*c.* 320 B.C.) certainly recognized the need for basing reasoning on observed facts, but, as G. H. Lewes (1864) has emphasized, Aristotle did not realize the very vital importance of verifying his logic by comparing its conclusions with facts, nor did he recognize that the true purpose of experiment is to verify the accuracy of data and of theoretical conclusions. We are indebted to Roger Bacon (*c.* 1280), perhaps more than to any other, for first insisting on verification as the essential pre-requisite for every trustworthy conclusion. He said:

> Experimental science is the mistress of speculative science. She tests and verifies the conclusions of other sciences. . . . In reasoning we commonly distinguish a sophism from a demonstration by verifying the conclusion through experiment.

Experiments have a way of giving results which differ from those which rigorous logic concluded must occur; and when the prediction fails, it is necessary to find what has been overlooked. This does not mean that constant verification is needed to establish the validity of the *process* of reasoning, for that may be irreproachable and yet the conclusion may be false because the facts or premises upon which the reasoning was founded may have been interpreted to mean something very different from what actually obtains in nature, or because some unrecognized or undiscovered factor was involved. It is not wise to dogmatize when direct trial is possible: "Do not think," said J. Hunter, "try."

It has been aptly said that the remarkable discoveries of modern science have been made by invariably sifting the truth through a fine mesh of logical experiment. One of C. Darwin's favourite methods of applying this method was to reason : " If my hypothesis be true, then certain consequences must also be true. Now let us find if they are true ; " and H. St. C. Deville used to say that there is no need to argue if an experiment can be made. In fine, it is necessary to submit all conjectures to the incorruptible test of fact in order to avoid being seduced by immaterial creations of the imagination. Faith without facts availeth nothing. The *ad experimentum* test must be made with unremitting diligence, rigorously and impartially, without conscious bias. Trial by a combat of wits in disputations has no attraction for the seeker after truth ; to him, the appeal to experiment is the last and only test of the merit of an opinion, conjecture, or hypothesis.

If one hypothesis does not fit the facts, it is discarded, and a modification of the old, or totally new hypothesis is tried. Thus, J. Kepler, in his *De motibus stellæ martis* (1608), is said to have made nineteen hypotheses respecting the form of planetary orbits, and to have rejected them one by one until he arrived at that which assumed their orbits to be elliptical. " To try wrong guesses," said W. Whewell, " is apparently the only way to hit the right ones." This method of trial and failure is continued until the golden guess crowns the investigation ; but one single real conflict between fact and hypothesis will destroy the most plausible hypothesis. Of fifty hypotheses, only one may prove fruitful ; the unsatisfactory ones are weeded out, until that particular one remains which has established its right to live by proving itself useful or by satisfying some need. Quoting M. Faraday :

> The world little knows how many of the thoughts and theories which have passed through the mind of a scientific investigator have been crushed in silence and secrecy by his own severe criticism and adverse examination ; that in the most successful instances not a tenth of the suggestions, the hopes, the wishes, and the preliminary conclusions have been realized.

This quotation may give a wrong impression,[3] for Michael Faraday displayed consummate skill, not only in framing hypotheses *per se*, but in deducing hypotheses that were worth testing. Without hypotheses, the experimental method may degenerate into empiricism ; without experiments, hypotheses may degenerate into speculation.

The promulgation of immature or premature hypotheses without a substantial basis of fact is discouraged by most scientific societies. The celebrated nebular hypothesis was ushered in by P. S. de Laplace (1796) with those misgivings and doubts which must of necessity becripple all hypotheses which are not based upon observation or calculation. An hypothesis may be invaluable when it can be verified or refuted by a definite appeal to observation. If this check be not possible, the imagination riots in the wildest speculations. If the evidence of an alleged phenomenon cannot be tested by verification, it is outside the range of science. A. W. Hofmann is reported to have said that he would readily listen to any suggested hypothesis, but on one condition—that he be also shown a method by which it might be tested. Accordingly, scientific inquiry is limited to such objects and phenomena as admit of direct or indirect observational or experimental verification. On the other hand, science cannot enter into the dark territory beyond the scope of man's faculties, and where verification, direct or indirect, is not possible. A vivid imagination can people this region with phantasms and be deluded with the hallucination that these creatures of the imagination are real, substantial, objective facts. It is now generally recognized that imagination, uncontrolled by facts, has produced all the palsying superstitions which have blinded and cursed the human race—past and present.

Rival hypotheses.—Two or more contradictory hypotheses may be consistent with the facts ; both cannot be right. There is then need for an *experimentum crucis,* an experiment which will decide in favour of the one and exclude the other. An hypothesis is supposed to be established when it, and it alone, is in harmony with known facts. The hypothesis then ranks as a theory or law. In the majority of cases, the so-called laws of nature can be regarded as prophecies which, because they have always been fulfilled in the past, are expected to be also fulfilled in innumerable cases in the future. Laws, theories, and hypotheses are all on probation. However successful a theory or law may have been in the past, directly it fails to interpret new discoveries its work is finished, and it must be discarded or modified. However plausible the hypothesis, it must be ever ready for sacrifice on the altar of observation. On account of the unproved assumption embodied in all hypotheses, they are of necessity transient, fleeting, and less stable than theories ; and theories, in turn, are less stable than laws. A theory believed to-day may be abandoned to-morrow. New facts need new laws. An hypothesis is invalid when it fails to unite and coordinate facts. All our hypotheses and theories are to be superscribed "subject to revision," for they are continually changing. "Science in making is a battlefield of competing theories," the path of progress is strewn with dying and dead hypotheses. For example, W. Ostwald (1893) claims that the theory of chemical combination is a strange and contradictory conglomerate of the fossil constituents of earlier hypotheses. Science is not a *state*, but is rather a *stage* of progress. Even Isaac Newton's law of gravitation is included in this category ; and the astronomer R. Ball[4] could say :

> When the law of gravitation is spoken of as being universal, we are using language infinitely more general than the facts warrant. At the present moment we know only that gravitation exists to a very small extent in a certain indefinitely small portion of space.

Ever since T. Bergmann's time (1779), science has been compared with a building in the course of erection, and scientific hypotheses have been compared with the scaffolds and ladders required by the builder in order to place the stones of experience where they belong. The scaffolding must be rejected when it hinders further developments, and when the purpose for which it was erected has been fulfilled. Accordingly, an hypothesis is not the end, but rather the means of attaining that end. To think otherwise would be to suppose that the builder erects a mansion for the sake of showing off the ladders and scaffolds used in its construction. The imperfect notions and hypotheses of men of science must not be mistaken for descriptions of observed facts. In the *chemica docens* of our schools, the term science usually includes both the growing building and the auxiliary scaffolding ; otherwise expressed, the term includes the immutable facts, the ephemeral hypotheses, the transient theories. and the more or less incomplete generalizations from observations. The facts alone are certain to endure throughout all time. When S. Brown (1849) inquired : Is it necessary to the nature of a science that it be all true, and that it contains no admixture of error ? and answered : By no means ! Otherwise chemistry was no science during the reign of phlogiston, and the Lavoisierian chemistry no science so long as oxygen was taken for the principle of acidity—he included in the term science those transient theories which are necessarily employed in the erection of the temple of truth.

Deductive and inductive induction.—The term *induction* is applied by the logician to the quest of science for generalizations, that is, for the *canones* or *universales regulæ* of Roger Bacon. In *deduction*, the attempt is made to widen the bounds of knowledge without stepping outside known facts—the Euclidean method is a good illustration ; in *induction*, a leap is taken from the known into the illimitable beyond. Two important methods of induction will be recognized—one may be called the deductive method, the other the inductive method. The former was favoured by Francis Bacon, the latter by Isaac Newton.

1. *Bacon's deductive method*, by what he called the *interpretatio naturæ*. Here the facts are exhaustively classified until the generalization becomes clear. a is either M or N, or O, or P, or . . . ; but a is not N, nor O, nor P, nor . . . ; and consequently, a is M. Thus, in the 105th aphorism of his *Novum Organum* (London, 1620), F. Bacon said :

> The induction which is to be available for discovery and demonstration . . . must analyse nature by proper rejections and exclusions; and then, after a sufficient number of negatives, come to a conclusion on the affirmative instances.

The method appears to proceed from known facts to general conclusions, *a particulari ad universale*. It is based on facts already known, and has therefore been called *a priori* reasoning. The method by which Boyle's and Charles' laws were discovered might be cited in illustration of one form of the method of deductive induction.

2. *Newton's inductive method*, by what F. Bacon called the *anticipatio naturæ*. Here the attempt is made to infer the hidden generalization from the consequences of the assumption (hypothesis) what that generalization is. The process is sometimes called *a posteriori* reasoning. This method of investigation was extensively employed with glorious results by Isaac Newton, although it had been advocated by Aristotle two thousand years earlier. Francis Bacon, indeed, before Newton's time, protested against anticipating nature by hypotheses, but the greatest triumphs of modern science have been won by the application of the Newtonian method while the Baconian method has been singularly unfruitful. Francis Bacon's failure in the practice of his own method was complete.

The particular form which the Newtonian method takes in science is to devise provisional generalizations called hypotheses or *working hypotheses* to explain facts and phenomena. The appeal is then made to observation and experiment in order to test the validity of the proposed generalization. Examples: The cause of the increase in the weight of metals calcined in air; A. L. Lavoisier's theory of combustion, and his experiments on the transformation of water into earth; J. Mayow's work on combustion; etc. The application of this method of inquiry involves (*a*) The accumulation of facts by observation and experiment; (*b*) The employment of the imagination in framing hypotheses to explain the facts; and (*c*) The appeal to facts to prove or disprove the hypotheses. By this procedure, said W. Whewell, the hypothesis becomes the guide of its former teacher—observation. There is a kind of cycle from facts to hypothesis, and from hypothesis to facts.

Induction, said Aristotle, does not prove. I. Newton's phrase: *Hypotheses non fingo*—I do not frame hypotheses—is often quoted to show that he discountenanced the inductive method of scientific investigation. This is based upon a misunderstanding, for Newton here referred to hypotheses not suggested by observation. On the contrary, Newton's own procedure was to use hypotheses deduced from phenomena similar to the way science uses them to-day. Accordingly he asserted that "no great discovery was ever made without a bold guess," and his immortal *Philosophiæ naturalis principia mathematica* (London, 1687) is a wonderful record of discoveries made possible only by the exercise of the greatest freedom in the elaboration of hypotheses. Indeed, from the first of his communications on light to the Royal Society to the last revision of his *Principia*, Isaac Newton seems to have been steadily and persistently guessing.

The method of investigation employed in scientific, positive, or modern chemistry thus involves four operations: (i) observation and experiment; (ii) classification and comparison; (iii) deduction, or speculation and hypothesis; (iv) testing and verification. Francis Bacon did not grasp the prime importance of testing his induction by comparison with facts. A. de Morgan (1872)[5] puts this rather cleverly: According to Francis Bacon, facts are used to make theories *from*, and according to Isaac Newton, to try ready-made theories *by*. Chemistry could progress as a science only when this method of investigation was discovered, so that, as S. Brown stated in 1843, before discovering chemistry it was necessary to discover the art of discovering chemistry.

§ 8. The History of Chemistry in China, India, and Chaldea

> It is vain and ridiculous to attempt to trace the origin of chemistry to the first men who worked in the metals, cut and polished stones, fluxed sand, or dissolved and crystallized the salts. This would be analogous to an attempt to trace the elements of geometry in the efforts of the savage to trim irregular fragments of rock to a more regular form in order to adapt them to his first needs.—A. F. DE FOURCROY (1782).

There can be no doubt that the chemical arts had their origin in the darkness before the dawn of history; the very etymology of the word chemistry is lost in obscurity. Many have been the attempts to fix a date at which chemistry began, and as often have these attempts proved abortive. The names of mythological, classical, and scriptural writers have been enrolled among the adepts, and as often have these names been expunged from the list. What L. Blanc (1847) said of the beginning of the French Revolution applies also to chemistry. Its history begins and ends nowhere. The origins are so confused and the many facts known to the ancients are so obscurely connected that there is no event which can be regarded with certainty as a first cause.

The historians and antiquarians in chemistry now recognize how futile must be the attempt to fix time or place for the birth of chemistry. They see that inquiries can be profitably directed only in the attempt to find what particular form chemistry took, or what particular ideas concerning chemical phenomena prevailed during any given epoch. Thus, in his work *Les origines de l'alchimie* (Paris, 1885), M. Berthelot[1] says:

> Chemistry is not a primitive science like geometry or astronomy, because it is constructed from the *débris* of a previous scientific formation which, half chimerical and half positive, is itself founded on the treasure slowly accumulated by practical discoveries in metallurgy, medicine, industry, and domestic economy.

Evidence of an old prehistoric civilization, long prior to that indicated at the beginning of the biblical record, has been laid bare during excavations in Egypt and elsewhere. The antiquities which have been unearthed are arranged by archæologists in three successive periods—the stone age, the bronze age, and the iron age. It is assumed that stone would be used by a rude savage people before metal, and that copper, being oftenest found native, and readily hammered into shape, would come into use before iron. This view was taken by Lucretius in his *De rerum natura* (**5**. 1282) written about 60 B.C. He said:

> The first weapons used by man were the hands, the nails, and teeth, also stones and the branches of trees; and then was discovered the power of iron and copper. The use of copper was known earlier than that of iron, since copper is more abundant and easier to work than iron.

Long before Lucretius, Hesiod (*c.* 700 B.C.) stated that the earth was first tilled with copper instruments because iron had not been discovered.

The three periods do not altogether represent divisions of time, but rather stages of human culture, and they were not uniform in all parts of the world; rather did they merge more or less one into the other so that stone weapons were used throughout the age of bronze, while bronze and iron were known in the stone age; and similarly, stone and bronze were used in the iron age. Hence, this classification is not altogether reliable historically, but it is so convenient that it has been adopted by the leading museums in the world for the classification of antiquities or ancient relics.

The Aryans.—Comparative philologists [2] who have studied the languages of the different countries of Europe and Asia, have brought forward evidence in favour of the theory that most of the European languages were derived from a family of people speaking one language—now called the *Aryan language*—and that this primitive language is also the source of much of the Indian, Iranian, and Armenian languages. The common parentage is suggested by striking similarities in the roots of many words in the languages of these different peoples. The evidence further indicates that the primitive Aryan tongue was spoken by nomad herdsmen wandering over the plains of Europe during the neolithic age, that is, when man had learned to polish his flint weapons—very roughly about 6000 B.C. There is no satisfactory evidence to prove that the Aryans were a civilized people which invaded Europe from the East—as was once supposed. In time, the geographical continuity of the primitive Aryans was disturbed and local variations in speech—dialects—began to arise which ultimately were fractionally crystallized, producing the different languages which now separate the different families derived from the original Aryans.

Owing to the absence of any common root for words connected with the smith's craft, we are told that the arts of extracting and working the metals were developed after the linguistic separation; and for similar reasons, the philologists suppose that the Aryans were not acquainted generally with iron, tin, or gold. Their common knowledge of copper is supposed to be shown by the relation of the different words—Sanscrit, *ayas ;* Gothic, *aiz ;* Latin, *æs ;* German, *erz ;* English, *ore*—for the metal or its ore. The probability is increased by the fact that copper occurs native in the metallic state. Some of the oldest metal implements, imitating the older stone implements, found in old tombs and in the remains of pile-dwellings in various parts of Europe, are of copper, not bronze. The knowledge of the metals seems to have spread in Europe from the Mediterranean northwards, and is supposed to have been introduced by Phœnician traders. The different stages of development of the people, after the differentiation of the language, were not synchronous, since, when one nation was in the stone age, another was in the bronze age, and a third in the iron age.

Chaldea.—In Chaldea the remains of ancient cities and temples have been ransacked, and the existence of another civilization before that of Egypt has been revealed. The early Chaldeans must have been skilful workers in the metals over sixty centuries ago—4000 B.C.—and, since there were no mines and very little fuel in the country, it is thought that the Chaldeans must have got some of their knowledge from another people more favoured in this respect. There is no written record of early Chaldean chemistry, nor of any historical names in connection with their chemical arts. Zoroaster (*c.* 1500 B.C.) is reputed to have been the founder of the philosophy of the early Chaldeans and Persians. This subject, however, is very obscure. Zoroaster is said to have made a very special study of the movements of the planets. The cuneiform inscriptions show that the Chaldean wise men or priests were practised in the arts of astrology, incantation, divination, and conjuring. The number 7 appears to have been considered very important in their philosophy and religion ; and the Chaldeans recognized this number of gods, devils, planets, colours, metals, etc. The Babylonians established the divisions of time which are employed to-day ; the seven days in a week thus originated from religious and astrological considerations before 2300 B.C. The same number is sacred in the Zarathustrian faith, the Mithras religion, and among the Buddhists, Jews, and early Christians. A. Origen in his *Contra Celsum* (*c.* 22), says that the Persians represented the revolutions of the heavenly bodies by seven stairs which led to the same number of gates each of a different metal—lead, tin, copper, iron, a mixed metal, silver, gold. He added :

> The leaden gate had the slow tedious motion of Saturn ; the tin gate the lustre and gentleness of Venus ; the third gate of copper was dedicated to Jupiter ; the fourth, iron,

was dedicated to Mercury on account of its strength and fitness for trade; the fifth, mixed metal, to Mars; the sixth, silver, to the moon; and the last, gold, to the sun.

The astrological nomination of the metals has thus been traced to the Chaldeans, and it appears to have been used by the Hindus, for F. Philostratus said in his *Vita Apollonii* (**3.** 41), that the Brahmin Iarchas gave Apollonius seven rings named after the seven planets; one ring to be worn daily—each one on the day of the week which bore its name.

The characters employed by the early writers to represent the planets were also used for the corresponding metal,[3] but they were not agreed in the dedication of particular metals to particular planets, and the characters themselves were subjected to certain changes of form. Thus, G. F. Rodwell says that in a manuscript written by Antonio Neri before 1613, mercury is designated by no less than thirty-five different names and twenty-two symbols; lead by sixteen names and fourteen symbols; and sulphur by two names, and sixteen symbols. The mythological symbols used largely by the alchemists of the Middle Ages were:

☉	♀	♂	♃	♄	☾	☿
Gold	Copper	Iron	Tin	Lead	Silver	Mercury
Sun	Venus	Mars	Jupiter	Saturn	Moon	Mercury

J. Beckmann has suggested that these symbols are the remains of Egyptian hieroglyphics, or else corrupted forms of the initial letters of the names of the deities which were supposed to reside in particular planets; and he claims that the symbol for copper ♀, said to symbolize the looking-glass of Venus, may really be a distorted form of the initial letter of the Greek term Φωσφόρος for that goddess; the so-called scythe of Saturn, a corruption of the first two letters of his Greek name Κρόνος; the imaginary caduceus of Mercury, a modified form of the initial letter of his Greek name Στίβωι which in the oldest manuscript was written C or ◡ with the next letter added below; the lance and shield of Mars, an abbreviation of the Greek name of the deity Θοῦρος, obtained by placing the last letter above the first; and the symbol for the thunderbolts of Jupiter was similarly derived from the initial letter of the Greek equivalent Ζεῦς for Jupiter with the last letter added below, as is actually done in some of the older writings. The circle, the symbol for the sun, was also the symbols of divinity and perfection. The semicircle for the moon is appropriate since it is the only one of the heavenly bodies which appears in that form to the naked eye. The following excerpt from K. Digby's *Chemical Secrets* (London, 1683) illustrates the way the alchemists employed the symbols:

> Take good mineral ♀, mortifie it with radicated vinegar; then separate its quintessence with pure S.V.; with that quintessence, dissolve ☿ duplicatum of ♀, that both become an oyl, which unite with a subtle calx of ☉, and bring them to an incombustible oyl, which will transmute ☿ into ☉.

Hence, astrology, and the emphasis which the alchemists later sometimes laid on the number 7, are relics of Chaldean thought. The Chaldeans supposed that the planets influenced the properties of the metals, the organs of the body, and the destiny of man.

The Chaldeans seem to have had some knowledge of metallurgy, dyeing, weaving, the manufacture of colours, glass, and the imitation of gem stones. The chemical arts practised by the early Chaldeans were probably adaptations of chance observations to useful purposes; these arts gradually drifted to the early Egyptians. For instance, it is related that Abraham came from Ur in Chaldea (*Gen.*, **11.** 31),[4] and he probably brought a higher civilization into Canaan, and also to Egypt. The Egyptians developed and improved the Chaldean arts in the laboratories and workshops attached to their temples. When the Babylonian empire ceased to exist, the Chaldean nation was dispersed, and the priests were scattered over the neighbouring lands, so that the term *Chaldean* became a by-word synonymous with "a wise man from the East." The scholars also tell us that the Assyrian *rab-mag* or the Semitic *mag*—meaning a priest—has furnished the Latin and European language with the terms *magus*, *magic*, and *magician*.

India.—India played no direct part in the development of Western science. It is a tradition that Hermes the Egyptian predicted that naught of the history of Egypt, but the letters engraved on stone, would survive. Whether this be true or not, scholars are now mainly dependent upon the inscriptions on tombs and monuments for their knowledge of the early Chaldeans and Egyptians. On the other hand, what remains of Indian thought is recorded in their books—the *Vedas*, the *Charaka*, and the *Susruta*—for the Indians were a literary people. According to Max Müller, there are many points in common between the early Greek and Indian philosophers, and there is a historical possibility that the Greeks were influenced by Indian thought travelling through Persia. From this point of view, it was only when commerce had opened up the country that it became possible to recognize the debt which European science owes to India, and to find that a great deal formerly attributed to the Arabians was of Indian origin. The learning of Greece, Persia, and India is said to have been taxed to help the sterility of the Arabian mind.

In his *History of Hindu Chemistry* (London, 1902), P. C. Rây has shown that Indian chemistry developed largely on independent lines—medicine, not the metals, was mainly emphasized. The contact between the Hindus and Persians is thought to have given the latter a bias towards medicine which later showed itself in the polypharmacy of the Arabians. Very fair accounts of the philosophical views of the Hindus are available. H. T. Colebrooke,[5] for instance, has shown that an early philosopher Kanaka developed an atomic theory rivalling that of Lucretius (60 B.C.). The Hindus also developed a five-element theory of the constitution of the world, but the elements of the Hindus were not the same as the quintet—air, earth, fire, wood, metal—of the early Chinese. The Hindu quintet embodied: *Water*, the first thing created; the sacred *fire;* the unbounded *æther*; the foster-mother *earth;* and the *air* which animates all living beings. The idea that water is the most primitive element of all is found in many of the classical books of India.

The Vedic hymns, over 1000 B.C., personify the elements and natural phenomena—for instance, they raise the active principles of plants to the dignity of gods. The medical work *Charaka*, and the more recent *Susruta*, seem to be repositories of information—chemical and therapeutical—which had accumulated between the Vedic period and approximately the eighth century. Gold, silver, copper, iron, tin, lead, as well as some varieties of brass were known. The writers also mention a number of salts of the metals—*e.g.* alum, copperas, sodium and potassium carbonates, and a few products of the mineral kingdom. The Hindus developed some alchemical notions, but they directed their attention mainly to medicine. According to P. C. Rây, the practice of chemistry between the twelfth and thirteenth centuries was distinctly in advance of that of the same period in Europe. The Hindus learned about zinc and mercury; but, as L. Hoefer has pointed out, real progress in chemistry in India and China was not possible so long as the preparation of the mineral acids was unknown. These acids are incidentally described in works dating from the sixteenth century.

The arts and sciences were largely cultivated by the higher classes, but, according to P. C. Rây, when the caste system was established, the opinion that industrial work tends to lower the standard of thought, which at one time threatened Europe, seems to have likewise developed in India with disastrous results. The arts and sciences were relegated to the lower castes, the spirit of inquiry gradually died, and the artisan classes, guided solely by their mother wit and common sense, alone kept up the old traditions. The withdrawal of the intellectual community from active participation in the arts rendered India "unfit for the birth of a Boyle, a Descartes, or a Newton, and her very name was all but expunged from the map of the scientific world."

China.—So far as we can gather, the Chinese were civilized, and cultivated the arts and crafts at a time when the European nations were barbarians. Some scholars claim that there is strong evidence of a Western origin of Chinese civilization, and that the first Chinese settlers came from a country in the far West which was closely connected with the founders of Babylonian culture. The earliest documentary evidence of man's attempts to answer the question: From what are all things made ? occurs in the Chinese work *Shoo King*, which is said [6] to contain a document called *The Great Plan* purporting to have been given by heaven to Yü the Great, about 2200 B.C., and which is considered by the scholars to be older than Solomon's writings. Here reference is made to five elements—water, fire, metal, wood, earth. The Chinese element wood was never recognized as an element in the West. The early Chinese philosophers supposed that two elementary principles—*yang* (male or active) and *yin* (female or passive)—were derived from *t'ai kih*—the Great Origin of the Grand Cause. The two principles *yang* and *yin* gave rise to the five elements. Fire and wood belong to the *yang* element; water and metal to *yin ;* and earth is neutral. The union of the five elements produces *yang* and *yin ;* and the union of these two principles produces the grand cause which is itself without cause. The Chinese Buddhists symbolized the five elements by the square (earth), circle (water), triangle (fire), crescent (air), and the gem (æther)—as indicated in Fig. 2. In the mediæval European symbolism, the two latter figures are treated as one, and serve as the common symbol of air. It is said that all over those parts of Asia dominated by Chinese civilization, *stupas* or monuments built in the general shape of the symbols of the five elements are to be found—*e.g.* the gateway to the Buddhist monastery of Pekin, etc.

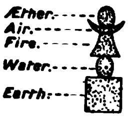

FIG. 2.—Stupa form of the Chinese Symbol for the Five Elements.

The philosopher Lao-tze, founder of the Taou religion in the sixth century B.C., believed that a fine essence or spirit arising from matter may become planets and stars; and these speculations led to the search after the sublimated essence of things. The Taouists sought some flux which would purge man from the dross of animalism and leave the higher part of man's nature to be crystallized out and sublimed into some stable and eternal form. They had no success in finding an elixir of life, or philosopher's stone; but they obtained a number of fairly pure mercurial preparations. According to J. Adkins (1855), the earliest Chinese work on alchemy now extant is the second-century treatise *Chen tung chi*, by Wei Peh Yang; and two centuries later, P'au P'on Tsze wrote many works on alchemy and kindred subjects. Later still, a disciple of Lao-tze—Wei Poh Yang—wrote a book *The Uniting Bond* in which reference is made to a *red elixir* which was probably mercuric sulphide or vermilion, prepared from galena or lead ore—symbolized by a white tiger—and mercury—symbolized by a blue dragon. The red elixir was regarded as an elixir of life even though Wei Poh Yang appears to have been poisoned when he attempted to practise his own philosophy. There seems to have been some contact between eastern and western Asia during the seventh-century invasions of the Mahomedans, and the teachings of the Taouistic alchemists penetrated Arabia, and appear there as the philosopher's stone and the elixir of life.

W. A. P. Martin,[7] in a chapter on *Alchemy in China* (1901), considers that the alchemy of China is not an exotic but a genuine product of the soil of that country; alchemy is indigenous to China, and coeval with the dawn of letters. He understands the words alchemy and chemistry to represent different stages in the progress of the same science, and says that the skill of the Chinese in the chemical arts and their knowledge of many chemical compounds give evidence of lives passed among the fumes of the alembic. Whatever be the true facts, there can be little doubt that the early Chinese practised the chemical arts somewhat extensively, and they knew quite a long list of chemical preparations—nitre, borax, alum, corrosive sublimate, arsenic, mortars, cements, oils, paper, sugar, etc. They appear to have invented printing, the manufacture of paper, and gunpowder—or rather a kind of Greek fire which was placed in vessels, ignited, and projected from a throwing machine. They were acquainted with various precious stones; some of their pottery has never been surpassed. Chinese porcelain seems to have originated about the time of the Han dynasty—206 B.C. to 220 A.D.—and it attained its highest development under the Ming dynasty—1368–1644. Glass was made in China in the Wu Ti dynasty—422–455—and was probably derived by contact with Western nations. They knew about gold, silver, mercury, lead, copper, iron, zinc, nickel, and various alloys. The method for making zinc was probably derived from India. They seem to have had ideas about the transmutation of the base metals into gold; and they are credited with a knowledge of oxygen and the composition of water as early as the eighth century. All this, however, exerted no direct influence on the development of European chemistry, although there is much evidence to show that indirect communication between Europe and China was possible—*e.g.* the Arabian alchemist Avicenna is said to have been born at Bokhara on the borders of the Chinese empire. From the time of Confucius, the Chinese made little progress in the arts and sciences, while Europe rapidly grew in knowledge.

§ 9. The History of Chemistry in Egypt

> Let us confess at once, without going round the subject, that practical chemistry took its rise in the workshops of the smith, the potter, or the glass-blower, and in the shops of the perfumer; and let us agree that the first elements of scientific chemistry date no further back than yesterday.—J. B. DUMAS.

According to Diodorus Siculus' report[1] of his visit to Egypt—*Bibliotheca historica* (*c.* 30 B.C.)—during the reign of Julius Cæsar, the Egyptians regarded **Hermes Trismegistus** as a man[2] to be esteemed above all others for his penetrating genius in discovering everything that could be useful in life; and it was the favourite opinion of the Arabian and European alchemists in the Middle Ages, that this Hermes laid the foundations of chemistry about the time of Moses. Hermes was accordingly called the father of philosophy and of alchemy by the alchemists of the Middle Ages—*e.g.* by Albertus Magnus (*c.* 1250), Roger Bacon (*c.* 1250), etc. It was also said that before the time of Hermes, the transmission of knowledge from one generation to another depended upon oral tradition, but Hermes invented a system of recording events upon stone pillars in the same way that modern writers employ parchment or paper; consequently, engraved pillars were the standard literature of the day. Some of those who now appear to be the more credulous writers of early history, state that Hermes inscribed upon an emerald the most essential secrets of alchemy, and presented this jewel to Sarah the wife of Abraham; and that after many subsequent adventures the stone was lost; they also state that a copy of the inscription survives. From the translations which have been made of the supposed inscription it appears that even if the inscription itself be not lost, its meaning has gone. The alchemists honoured Hermes when they spoke of the *hermetic* sealing of a vessel.

Attempts have been made to identify Hermes Trismegistus with the Egyptian king Siphoas or Memnon, who had the surname Hermes, and also with various biblical celebrities—Adam, Cain, Enoch, Joseph, Moses, and Abraham. Some writers maintain that Hermes Trismegistus is a fabulous personage, and it is generally supposed that this Hermes was identical with the Egyptian god *Thoth*—literally a pillar. Thoth is represented by the Egyptians as an ibis-headed god with a pen in his hand, the tutelary deity of wisdom and letters, Fig. 3. It is further said that the supposed writings of Hermes really cover three successive epochs—the first Hermes dealt with the period down to the deluge; the second Hermes was concerned with early traditions; and the third Hermes embodied the full-grown science of Egypt. The whole system of Thoths or pillared literature was personified as Hermes Trismegistus—τρις, thrice; μέγιστος, greatest—meaning literally thrice great interpreter. It is therefore easy to understand how Hermes might have been credited with being an extraordinarily prolific author. Thus, in his *De mysteriis Ægypt* (*c.* 360 A.D.), Iamblichus says that Hermes was the author of 36,525 books—T. Bergmann (1779) laconically observes that, if so, the books must have been very concise after the manner of those times, and that each book could have contained but a few sentences. Indeed, in his *Stromata* (*c.* 200), Clement of Alexandria describes imposing celebrations in which the books of Hermes were borne in processions.

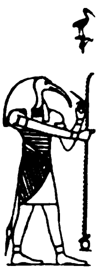

FIG. 3.—The Egyptian God Thoth.

Most of the writings attributed to Hermes appear to have been lost at the destruction of the Alexandrian library; a few passages are quoted from them by Zosimus (*c.* 400); and copies of some dealing with burial rites and the future life have been found buried with the mummies of kings and priests; these have been embodied in what is now called *The Book of the Dead*. In general, it has been said that Egyptian thought was heavily hampered and severely restrained by a powerful priestcraft; that the people were haunted by dread and dismal shadows from the underworld; that they fostered an elaborate cult of the dead; that their houses were temporary abiding places; while their tombs were their eternal homes.

Herodotus (*c.* 440 B.C.) believed that the early Egyptians were the wisest of men. He said that they had three communities of priests—at Heliopolis, Memphis, and Thebes. The priests were responsible for the preservation of such knowledge as was considered worthy of being retained; this knowledge was kept secret and not divulged except to the elect. The sacerdotal secrets were in part described by hieroglyphics on stone pillars, and on manuscript papyri, but the allegorical nature of the symbols prevented them being read or understood by the uninitiated. According to Iamblichus (*c.* 360), every discovery which was approved by the priests was engraved, without the author's name, on stone pillars in the temples. Clement of Alexandria, Plutarch, and others say that the priests possessed still more secret writings. No original record of the early writers is available, and our knowledge of the practice of the Egyptian arts is gleaned from fragments in the writings of Pliny (*c.* 23), Plutarch (*c.* 100), C. Galen (*c.* 190), etc.

About 332 B.C., while Egypt was under Greek rule through conquest by Alexander the Great, the Greeks were received in the Academy of Alexandria; and some of the Egyptian manuscripts were translated into Greek, and later on distributed over Europe—Paris, for instance, among others, has one by Zosimus; the St. Mark manuscript is preserved at Venice; and a number are reported to be at the Vatican in Rome, the Sultan's museum in Constantinople, etc.[3]

The *Rhind mathematical papyrus* in the British Museum is the main source of our knowledge of the early Egyptian mathematics. It is considered to be a copy made about 1600 B.C., by an Egyptian priest, from a document seven hundred years older. Researches near Memphis have given indications of Egyptian medical practices 4500 B.C., and pictures of surgical operations of a date not later than 2500 B.C. have been found. The celebrated *Georg Ebers' papyrus*[4] was found in the winter of 1872–3, near Memphis, in a terra-cotta vessel between the legs of a mummy which was buried about 10 ft. deep. The papyrus is supposed to be a copy of one of the six medical papyri of Hermes (*c.* 1550 B.C.) about the time of Moses, and the text refers back to kings who reigned 3700 B.C. The papyrus is a kind of materia medica and medical treatise; it gives some directions to the medical attendant of a sick person, and describes the necessary incantations and invocations for the co-option of the help of the gods. The papyrus also contains references to a number of metals and some compounds.

A portion of one of the earliest Egyptian manuscripts is preserved in the museum at Leyden, and is known as the *Leyden papyrus*. It was found enclosed in the wrappings of a mummy at Thebes, and is considered to have been written about the third century. It was presented to the Netherlands by I. d'Anastasi, the Swedish consul at Alexandria in 1828. The work contains over a hundred magic formulæ, and recipes for the preparation of alloys used in making various objects of the goldsmith's art. It also has drawings of some chemical apparatus. It has been investigated by C. J. C. Reuvens, M. Berthelot, etc.[5] The grammatical errors and spelling have led to the opinion that the papyrus must have been the memorandum book of an uneducated artisan engaged in attempts to imitate gold and silver for fraudulent purposes—*e.g.* the preparation of *asem*, an alloy of copper and tin, occupies a prominent place among the recipes for imitating gold. The Royal Swedish Academy of Stockholm also acquired a papyrus about the same time and from the same source as the Leyden papyrus; but the existence of the *Stockholm papyrus* seems to have been overlooked until about 1906. It was translated by C. O. Lagercrantz in 1913.[6] It deals with tho diplosis of silver, the imitation of precious stones, and dyes.

These papyri are supposed to represent the class of books on the chemistry of gold and silver which, according to Suidas' *Lexicon* (*c.* 1000), were burned by the order of the Roman emperor, Diocletian, about 290 A.D., as a supposed punishment for an attempted rebellion, and to prevent the Egyptians making gold, and so acquiring wealth sufficient to enable them to oppose the authority of the Romans. These incendiary forays on the books of a prohibited and feared art—alchemy—were not infrequent in the early Christian era—witness *The Acts of the Apostles* (**19.** 19). This helps to explain the paucity of the early records of Egyptian science; yet, in spite of various conquests of Egypt by the Persians, Babylonians, Greeks, and Romans, the arts were cherished by the priests with more or less vigour until the Saracen invasion of the seventh century, when every abode of learning, and every monument of science was destroyed with a ruthless hand. In 642 A.D., the famous Alexandrian Library, with its 700,000 books, was condemned to destruction by Kaliph Omar, who, in refusing a petition to spare at least a part of the library, is reported to have said: "If the books agree with the Koran, they are useless; and if they differ from it they are dangerous." A mania for pillage and destruction with the idea of terrorizing the stricken inhabitants of a conquered territory, has long been characteristic of the temper of invading barbarians in ancient and modern times—witness the invasion of Europe by the Goths, the Vandals, and the Huns early in the Christian era, and the more recent rape of Belgium and North France by Teutonic hordes maddened with the lust of a world's conquest. Egypt never recovered from the severe blows she received, and what was presumably the greatest treasury of knowledge garnered by the ancient world, was used for kindling the fires of the baths of the invaders. Probably a few volumes were surreptitiously preserved; others, said to have been saved from the plunderers, are probably forgeries.

The Egyptians appear to have been acquainted with some six or seven metals and with some alloys.[7] Various metallurgical processes for extracting or melting metals have been depicted in their tombs, etc.—Fig. 4, for instance. The Egyptians were well versed in the arts of glass-making, potting and the manufacturing of precious stones and enamels; they were familiar with the arts of dyeing, painting, tanning, brewing, and baking; they were acquainted with many poisons and their antidotes, and with expressed and distilled oils. They were highly skilled in the use of antiseptics—particularly in the embalming of the dead. Among the operations employed in the arts and crafts of the Egyptians were: calcination, digestion, decoction, distillation. expression, evaporation, fusion, fermentation, levigation, and sublimation. So far as the available records go, there is nothing to show that any results were obtained by experiments directed as deliberate questions to nature. To know that liquids boil and evaporate, or that metals fuse and form calces, may indicate an unconscious sagacity in observation, but it is not scientific observation; the early arts, said W. Whewell,[8] were the parent, not the progeny of science.

So far as we can learn, the disjointed knowledge of technical processes, so jealously guarded by the Egyptian priests, was purely empirical, and it required centuries of effort before man learned to view these processes in a comprehensive rational way. Evidences of the practice of these chemical processes are found in ancient monuments and tombs of high antiquity—see, for example, R. Lepsius' *Die Metalle in den ägyptischen Inschriften* (Berlin, 1872)—and Fig. 4 represents the washing, fusion, and weighing of gold as is reported to have been depicted on an old Egyptian tomb. The records are too imperfect to form a clear idea of Egyptian science, if they really had one such. There is some fragmentary evidence, more or less confused by fictions, and disguised by personifications, that the Hermetic writings assumed that all substances are produced from two elements: *fire*, the spirit of the world; and *mortuum malum*, the inert matter of the earth—that is, energy and matter; although, according to Seneca's *Quæstiones naturales* (**3**. 14, *c.* 63 A.D.), the Egyptians adopted an extended form of the four-element theory in which each element had an active (male) or passive (female) form—*e.g.* active air was the *wind*, and passive air the *atmosphere; flame* was active fire, and *light*, passive fire. According to Diodorus the Sicilian (*c.* 30 B.C.), the Egyptians taught that by some internal changes, all bodies sprang from their seeds or *atoms*, and were changed, perfected, and then destroyed.

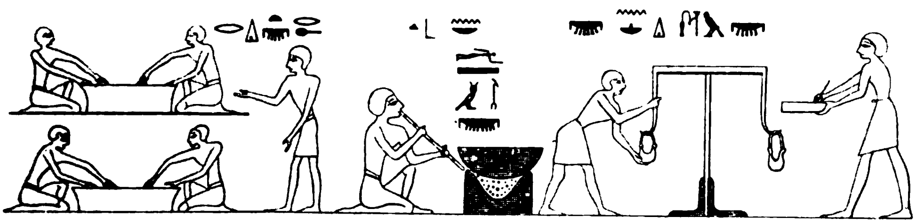

FIG. 4.—Gold Washing, and the Fusion and Weighing of the Metal as depicted in an early Egyptian Tomb.

Consequently, the impression that Egyptian chemistry was mainly practical recipe and unverified speculation, is well founded on pertinent evidence; but others claim that too little inside knowledge is available to justify speaking with any confidence. In any case, it will be clear that before the Christian era, Egypt must have been a kind of focus or centre which collected, assimilated, extended, and developed knowledge derived from various Eastern sources; otherwise expressed, the rise of chemistry in Egypt can be compared with a river which drains a large tract of territory, there is not one source, but many sources, each feeding a tributary of the river.

Phœnicia.—It is fairly clear that the indefatigable merchant Phœnicians had acquired some knowledge of the so-called chemical arts during their contact with the Egyptians. The Phœnicians were famous for the manufacture of a purple dye —*Tyrian purple*—the special boast of Tyre ; for the manufacture of glass—*Sidonian glass*—particularly at Sidon ; for the weaving of fabrics of various kinds ; for working in metals; and for the engraving of gems (*II Chronicles*, **2**. 14). The Phœnicians were great navigators, and it is supposed that they circumnavigated Africa. Strabo says that they made a special study of astronomy and arithmetic. Posidonius, a Greek writer of the first or second century B.C., made a special study of Phœnician mining, and gathered his data from the remains of the Phœnician mines in Spain.[9]

The biblical record.—The biblical records of the unfortunate Israelites show evidence of the chemical arts and crafts employed by their Egyptian masters. The Israelites must have carried much of this knowledge into Asia during their exodus from Egypt under the leadership of Moses. Even from the beginning of *Genesis*, we are told that Tubalcain (3870 B.C.), the eighth man from Adam, was a worker in metals (*Gen.*, **4**. 22) ; good gold is said to have been obtained at Havilah (*Gen.*, **2**. 11), and silver coins were in use at the time of Abraham (*Gen.*, **23**. 16) ; in all, about six metals—gold, silver, copper, iron, lead, and tin—were known to the Israelites (*Numb.*, **31**. 22) ; Noah made wine from grapes (*Gen.*, **9**. 21) ; and vinegar was in use (*Numb.*, **6**. 3) ; bricks were burned for the building of the tower of Babel (*Gen.*, **11**. 3) ; weaving and dyeing were known (*Exod.*, **26**. 1) ; and oils, perfumes (*Exod.*, **30**. 23), and butter (*Gen.*, **18**. 8) were manufactured.

The mechanical performance of operations essentially chemical in their nature is not chemistry, otherwise the first man to light a fire, boil a rabbit, or roast a pig was the father of chemistry. It is difficult to see why the mere practice of these arts should be taken to prove that the early artisans were chemists in all but name, unless there is some collateral evidence of scientific procedure in the development of the empirical crafts—roasting and boiling, baking and brewing, or potting and dyeing. Moses' demonstration[10] of the solubility of Aaron's golden calf (*Exod.*, **32**. 20) has been taken to show the profundity of the chemical knowledge he must have acquired during his tuition by the Egyptian priests ; but, before the indignant prophet can be credited with any profound knowledge of chemistry, more details are required. Well might Francis Bacon, in his *Novum Organum* (London, 1620), protest against the vanity of the attempt to found science upon the scriptures.

In *Exodus* (**31**. 3) we are told that Bezaleel, the son of Uri, was endowed with the spirit of the Lord, and with skill to work in metals and precious stones. These hints of the early arts have been expanded by surmise and guess, and deformed by fiction and fable. For instance, it has been said that man received his first knowledge of the arts and sciences by divine or diabolic revelation. In his *Chronicorum canonum* (*c*. 300), P. Eusebius tells us that the apocryphal Enoch was taught by the angels, and transmitted his divine revelations orally, through Methuselah (*c*. 3300 B.C.) and his descendants down to Abraham. From the writings of Zosimus (*c*. 400), it would appear as if there was once a race of amorous genii prone to fall in love with women, for he says that the secrets of nature were revealed by such genii to the daughters of men in return for love. The dowry was called *παρδώσιν θείαν*—the divine tradition ; the first account of these revelations was called *χήμα* (chema) ; and the art itself, *χήμια* (chemia). Chema is thus an early tradition respecting the operations of nature taught to mankind by angels, who appear to have been *damnati a Deo* for their ill-timed loquacity. The credulous and imaginative O. Borrichius, in his *De ortu et progressu chemiæ dissertatio* (Hafniæ, 1668), said that the angels or demons here mentioned were the offspring of Seth and of Tubalcain, who had been instructed by their progenitors in the mysteries of nature, and who profaned their trust by communicating heavenly secrets to the daughters of Cain by whose charms they were seduced (*Gen.*, **6.** 2–4). The gynecial myth of the origin of chemistry recalls the Jewish story of the fall of man, and also the Grecian legend of the Sibyl who demanded both length of years and a knowledge of the divine *arcana* as the price of her favours to Apollo the sun-god. Somewhat similar myths are reported to have been current among the Phœnicians, the Persians, and the Egyptians. They illustrate the extreme credulity of man in the first of Comte's *les trois états*, when everything that is not understood is believed to have a supernatural origin.

§ 10. The History of Chemistry in Greece and Rome

They had visions. Oh! They were as grand
As ever floated out of fancy land.

From the testimony of Diodorus the Sicilian (*c.* 30 B.C.), Clement of Alexandria (*c.* 200 A.D.), and Iamblichus (*c.* 350 A.D.), it would appear that the Greeks learned the practice of the chemical arts and crafts largely from the Egyptians.[1] Diodorus says in his *Bibliotheca historica* (*c.* 30 B.C.):

> Orpheus, Musæus, Melampus, Dædalus, Homer, Lycurgus, Solon, Plato, Pythagoras, Eudoxus, and Democritus the Abderite all went into Egypt, and they doubtless learned there all those things which rendered them afterwards famous among the Greeks. For thirteen years Plato and Eudoxus associated with those priests in Egypt who most excelled in the knowledge of celestial things. They kept their knowledge in the greatest secrecy for a long period and would not deign to impart it to any one. At length, subdued by time and humble entreaty, they revealed some few things, but the greater part they concealed entirely from the vulgar.

In the opinion of E. Zeller[2] there is little trustworthy evidence to support the assumption that the philosophy of the Greeks was derived from Oriental or Egyptian influences, although it is highly probable that it received some impulses from the East; but whatever the Greeks borrowed from foreign sources was clarified and refined by the fire of their own genius. For example, it has been said that the Phœnicians taught the Greeks the art of writing, but that it was the Greeks who wrote.

The knowledge of the secret arts, and the prevailing opinions of the Egyptian priests, as Herodotus (*c.* 440 B.C.) relates, must have been communicated in part to many vagabond Greeks during their sojourn in Egypt from about 660 B.C. The unrivalled Grecian artists surpassed their teachers in the beauty and elegance of their æsthetic productions, and also in works dependent upon imagination and fancy; but artisans and craftsmen made much slower progress with the philosophical Greeks than with the more practical Egyptians. An Alexandrian Society is reported to have been formed among the Greeks in Alexandria about the third century, but, so far as we can gather, the knowledge which they are supposed to have acquired mainly from the Egyptians, was confused with metaphysical fancies; and its expression was obscured by ambiguous allegories and cabalistic symbols—possibly aping the hieroglyphics of Hermes—so that their writings now appear to us as if the authors tried to conceal their own ignorance in a cloud of words and symbols.

The Greeks did not contribute much to the chemical arts, but they furnished chemistry with a science of method applicable to all the sciences. The Egyptians accumulated facts and invented useful arts; the Greeks discovered the laws of investigation, the principles of discovery, and the laws of thought. The most important result of centuries of Grecian effort was consummated in the mighty *Organon* of Aristotle (*c.* 320 B.C.). This organon of deductive and inductive methodology should have inaugurated the third of Comte's *les trois états*, but it did not. The facts had not been determined with sufficient accuracy. Isaac Newton could not have discovered the gravitational law if accurate data had not been prepared for him by J. Kepler and G. Galilei. Aristotle's organon came too early. In any case, the method of investigation so gloriously established by Aristotle was unproductive; it was degraded, misunderstood, and perverted by his disciples, who, instead of applying the great principles of the organon, worshipped their master's opinions on a host of special subjects as if they were oracles divine. Thus, I. R. Averroës, about the middle of the twelfth century, went so far as to say, "The doctrine of Aristotle is the perfection of truth, for his understanding attained the utmost limit of human ability."

The method of Aristotle was rediscovered and restated by Francis Bacon in his *Novum organum* (London, 1620). The two methodologies are substantially the same. To some, Bacon's organon appears to have inaugurated a kind of Lutherian reformation in science; rather did the Baconian organon grow tardily from seeds planted by Aristotle and his predecessors in the unproductive soil of metaphysical speculation. According to G. H. Lewes' *Aristotle* (London, 1864), the main cause of the sterility of the method of Aristotle and Francis Bacon was their failure to appreciate the need for unremitting verification, so well emphasized by Roger Bacon (*c.* 1280)[8]—Bacon the First—in order to vindicate the principles deduced from the available facts. The same idea was emphasized by Albertus Magnus, about the same time as Roger Bacon:

> A principle which does not agree with *experimentali cognitione* (experimental knowledge acquired by the senses) is no principle, but rather the opposite.

Aristotle himself frequently emphasized the danger of relying on mere guesses as if they were observed facts, but he so often departed from his own precepts that he was frequently inveigled by the perils of his own speculations. The illustrious Francis Bacon likewise completely failed in vigilance when he attempted to apply his own method because he did not practise the very principles he had expounded so well. Bacon the Second even went so far as to say that if his methods were adopted, little would depend upon the acuteness of the intellect, for the varied talents of all men would be reduced to one common level. He said:

> Our method of discovering the sciences is one which leaves not much to the acumen and strength of wit, but nearly levels all wits and intellects.

Although the principles of Francis Bacon's organon have been available for nearly three hundred years, they have proved quite inadequate, and there are no signs of this socialistic levelling, for the interval between mediocrity and talent is as great as ever it was. Francis Bacon himself can scarcely be considered to have been a scientific man, or even to have possessed the scientific instinct. Science may have been *about* him but it certainly was not *in* him.

The Greeks seem to have generally emphasized subtilty in speculation and debate rather than accuracy in observation and experiment. In theoretical work, they had an overweening tendency to extreme abstraction, and they were careless and credulous in observation; otherwise expressed, they founded arguments too confidently on unproved statements. and seem to have regarded logical consistency of greater weight than accuracy in the statement of facts. This characteristic was well summed up by the saying which Plato, in his *Timævs*, ascribes to the Egyptian priest of Sais: "Ye Greeks will be always children . . . for though wisdom falls from your lips, your actions are weak and puerile;" or as S. Brown expressed it: "In the art of experiment, the Greek was as feeble as a child; but in the sphere of ideas and vast conceptions it is not a paradox to say that he was sometimes stronger than a man."

The Ionian doctrine of one primal element.—The *Theogony* of **Hesiod** (*c.* 700 B.C.) assumed that "the **earth** is the unmovable basis of the cosmos," but the poem is rather a record of mythic cosmology, and anthropomorphism, characteristic of the first of Comte's *les trois états*, and it had no influence on the development of philosophical opinions.[4] Similar remarks apply to **Pherecydes** (*c.* 600 B.C.), who followed Hesiod with an improved mythology. Pherecydes made a definite attempt to distinguish between the material constituents of the universe—*e.g.* between the earth and its atmosphere, and also between matter and force. He regarded force as a mysterious power exerted by the god Zeus.

The Ionian philosophers—Thales, Anaximander, and Anaximenes—still further substituted impersonal causes, acting uniformly and continuously, for personal causes acting capriciously and arbitrarily. At this time, therefore, the Greeks were in a transitional stage between the first and second of Comte's *les trois états*. Thus, the early philosophers of Greece soon recognized that a belief in superhuman gods was not sufficient to explain the complex phenomena in the physical world. They then promulgated hypothesis after hypothesis to explain how the universe grew from some simple principle—earth, water, air, fire. The new explanations proved just as unmanageable as those which regarded natural phenomena as the work of supernatural agencies. These early speculations of the Greeks do certainly testify to the vigour and activity of their questioning spirit,[5] but their ardour and confidence were untamed by labour or reverses. It required centuries of chastening discipline for man to learn that "he must acquire, slowly and patiently letter by letter, the alphabet in which nature writes the answers to such inquiries."

The first of the seven wise men of Greece, **Thales** of Miletus (*c.* 600 B.C.)—a contemporary of Solon—made one of the earliest protests against the personification of nature by assuming natural phenomena to be produced by capricious designing agencies—diabolic or divine. Three centuries later, Epicurus likewise protested emphatically against referring natural phenomena to the deliberate interventions of gods. Thales believed that natural phenomena are due to the operation of invariable laws to be discovered by a proper application of the human intellect. According to Thales, all the various forms of matter are different manifestations of one underlying essence or *prima materia*. The universe, to him, was made from **water**, which he regarded as the primal element. The same idea occurs in many of the sacred books of the Hindus—*e.g. The Institutes of Manu*—about the ninth century B.C. There is really nothing to show how Thales was led to make the assumption. It has, however, been noted that it is typical of systematic thinkers to reduce to one general proposition that characteristic which is possessed in common by a number of simple facts; and it is therefore hinted by Aristotle that Thales, meditating on the constitution of the universe, saw that water or moisture is omnipresent; that Thales was impressed by the marvellous transformations of water in the form of rain and dew, snow and hail, river and sea; and that the earth appeared to be floating in an ocean of water. All things also seemed to be nourished by water, and he accordingly assumed that water is the sole primal element which is convertible into all the manifold varieties of matter—mineral, vegetal, and animal—found in the world. W. Whewell, however, emphasizes his belief that the opinions of the philosophers of this period are based on vague suggestions and casual analogies, rather than on reasons which will bear examination. It is very remarkable, said A. Comte (1839), that the most inaccessible problems, such as the origin and cause of phenomena, should be the very ones which first occurred to students of nature, while those which were within their reach were considered to be unworthy of *méditations sérieuses*.

Another Miletian, **Anaximenes** (*c.* 500 B.C.), is considered to have been the pupil of Anaximander, who, in turn, was the disciple of Thales. Anaximenes sought for the first principle of things in the omnipresent yet invisible **air**, which he regarded as the equivalent of life because all living beings were nourished by air. Air embraces the whole world, said Anaximenes, and he regarded air as the one eternal essence, more primitive than Thales' water. He called air τὸ ἄπειρν—the infinite—and considered it to be devoid of any material differentiation. Even as late as the eighteenth century, some chemists accepted Anaximenes' air as the primordial element. Thus S. Hales, in his *Vegetable Staticks* (London, 1727), supposed that atmospheric air deprived of its elasticity entered in a solid form into the composition of most substances, and that air is the universal bond in nature. G. E. Stahl also wrote to the same effect in his *Experimenta, observationes, animadversiones CCC numero chymicæ et physicæ* (Berlin, 1731). We have no record how the Ionians—Thales and Anaximenes—accounted for the formation of the different forms of matter from their primitive elements, since matter by itself can only be matter.

The Ephesian **Heracleitus** (*c.* 450 B.C.) expressed himself in such enigmatical terms that he has been called the Obscure Philosopher.[6] A few fragments of his writings have survived. Heracleitus appears to have maintained that all ideas are derived from sensations, and he was the author of the celebrated doctrine that all things are perpetually in a state of motion or flux, and that there is no rest or quietude. Strife between opposite tendencies is the parent of all things. All life is change, and change is strife. The living and moving element in nature seemed to him to be an ætherial exhalation, or **fire**. All things in nature are formed of the principle of fire, which, in turn, is composed of small indivisible parts, ψιγμάτα or atoms, which are in perpetual motion. If all things are conceived to be in perpetual motion or change, then all things are fire. Never-resting fire rules all. Everything has arisen from fire by condensation or rarefaction, and all things resolve themselves back into fire. This idea is but a modification of the water and air elementals of the Ionian philosophers. Obviously, Heracleitus' elemental fire was not ordinary fire; he probably understood fire to mean that which by constant transmutation causes all the varied changes seen in the universe, and which itself remains unchangeable. This idea of a *primum mobile* comes as near to the modern doctrine of *energy* as was possible with the facts then available.

The Grecian **Hippocrates** (*c.* 400 B.C.) was not exactly a follower of Heracleitus, although there is a strong resemblance between the views of both. Hippocrates specialized in medicine, and he has been called the oracle of medicine; he expressly rejected the use of hypothetical philosophy in medicine; he did not altogether rely on empirical experience, but attempted to formulate general rules and principles derived from experience and knowledge. From the chemist's point of view, a small treatise, *On airs, waters, and sites*, is considered to be the most interesting of the works attributed to him. As might have been anticipated it contains many errors and inexactitudes.

The Ionian doctrine of one primitive element was abandoned by **Anaxagoras** in a work *On nature* (*c.* 450 B.C.).[7] He assumed that every difference in the sensible qualities of bodies is fundamental, original, and inalienable; and that there are so many elements as there are simple substances; no means were known at that time for breaking down the majority of substances, and they were accordingly assumed to be simple or elemental. The number of elements was therefore supposed to be very large, or infinite. By repeated subdivision, Anaxagoras argued that all natural things could be resolved into ultimate particles which were later on termed *homœomeriæ*—ὅμοιος, like; μέρος, a part. The homœomeriæ were supposed to be eternal, unchangeable, infinitely divisible, and capable of continuous extension. Like homœomeriæ act on like, and so form matter. If the qualities of the homœomeriæ are assumed to be developed only when the particles are in combination with others, Anaxagoras' homœomeriæ are not very different from the atoms of Leucippus, Democritus, and Lucretius. Anaxagoras' atoms are the same in kind as the substance itself; Leucippus' or Democritus' atoms are indivisible particles of one kind of matter. Anaxagoras also introduced the idea of a motive principle, which he called νοῦς, as the cause of all changes. Democritus called this principle ἀναγκη; Heracleitus, ἀναθυμιασις or *fire*; and Aristotle, αἰθὴρ, æther.

The four and five element theories.—The four and five element theories are among the oldest attempts to classify the protean and multitudinous forms of matter which make up the world. The five-element theory seems to have been favoured by the Chinese and Hindu philosophers. The Greeks reduced the number of elements to four. Diogenes Laertes (*c.* 250) tells us that the five-element theory was first promulgated by the Pythagoreans, and that **Empedocles** (*c.* 500 B.C.) first advocated the four-element theory as a consistent doctrine. Empedocles cited the burning of wood in favour of his hypothesis. When wood burns, *smoke or air* rises upwards, and this is followed by *flame or fire*; *moisture or water* is deposited upon any cold surface in the vicinity; and *ash or earth* remains behind. Empedocles' simple statement seems to be the first record of a chemical analysis. Wood is resolved into its supposed elementary constituents—fire, earth, water, air. True enough, modern methods can probe much deeper, but Empedocles' analysis is excellent for its time. The doctrine of the four elements thus appears as a methodical deduction from facts observed during the analysis of wood, by burning it in air. This analysis has been claimed as "the starting-point of chemistry in history."

Empedocles also formulated the germinating conception of chemical affinity, for he said that the cause of the various combinations and separations of these four elements is love (φίλια) and hate (νεῖκος), which are exerted as active forces producing the union or decomposition of substances. The four elements of Empedocles soon lost their *material* character, and grew into *abstract principles*. It was then fancied that the whole world was compounded of four distinct principles or entities—the *earth* typified all solids; *water*, liquids; *air*, the winds, clouds, and the breath; and lastly, *fire*, which was symbolized by the sun, and worshipped by many as a god. Hence, in the writing of the alchemists of the Middle Ages, there is usually a chapter devoted to this quartet—earth, water, air, and fire. In J. Lacinius' alchemical treatise *Pretiosa margarita novella de thesauro* (Venice, 1546), fire is symbolized by an angel, air by a bird, water by a dragon, and earth by a bull. Aristotle added a fifth element, αἰθὴρ, æther, more divine than the others, and which pervaded all things, and was in perpetual motion. Later, Aristotle's æther became the *quinta essentia*—a kind of primal matter, a divine subtle extract, the quintessence of the other four. The ancient Hindu philosophers also had a fifth element, which, in their system, was wrongly supposed to be a medium for propagating sound, etc., and which, in consequence, had something in common with the modern concept of an æther pervading all space. The *Institutes of Manu* regarded the subtle æther as being first created; and from this, by transmutation, sprang air, which changed into light or fire, and thence into water, and finally earth.

Aristotle assumed that the one primitive quintessence of matter can act as a vehicle or carrier for four primitive qualities: hot or cold, wet or dry. If these four qualities or elements are united with inert passive matter in pairs, the four primary forms of matter—air, earth, water, fire—are produced; for instance, *fire* has hot and dry; *water*, cold and wet; *air*, hot and wet; and *earth*, cold and dry. The different varieties of matter arise when different degrees of these four elemental qualities are impressed on matter. Aristotle denied that the four elements of

Empedocles are really elements because they are mutually convertible one into another. Empedocles' elements, however, may represent the four primary forms of matter perceived by the senses, and into which the four qualities appear to be resolvable :

> For hot, cold, moist, and dry, four champions fierce,
> Strive here for mast'ry, and to battle bring
> Their embryon atoms.—J. MILTON.

The alchemists of the Middle Ages supposed that the elements were formed when the primal essence was clothed with **three principles**—*tria prima*—which they called respectively salt, sulphur, and mercury. In the quaint words of Paracelsus :

> Eisen, stahel, bley, smaragd, sappir, kieszling, nichts anders seind denn schwefel, salz, und mercurius.

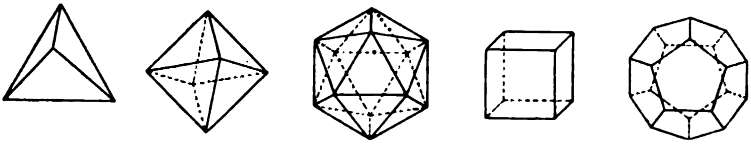
Salt represented the earth or *the principle of fixity and solidity ;* **mercury** represented air and water, or *the principle of liquidity and gaseity ;* and **sulphur** typified fire or *the principle of combustion.* Thus, said Paracelsus, " whatever fumes and evaporates in the fire is *mercury ;* whatever flames and is burnt is sulphur ; and all ash is *salt.*" Albertus Magnus typified the three principles by arsenic, sulphur, and mercury, for he supposed the metals were compounded of these elements.

The three principles of the alchemists were not substances or *corpora*, but rather *principia* or qualities ; they were representative types of qualities or classes. Sometimes the *tria prima* were confused with the four elements of the Greeks, and it is difficult to understand clearly what was gained by the invention of the three principles. The mystic alchemists went even further and imagined that all material things were composed of a trinity : " A body and a soul held together by a spirit which is the cause and the law." They believed the soul of matter to be the transforming principle which they tried to extract in a pure form, and which they expected would enable them to transform the baser forms of matter into the purer forms, of which gold was the best type.

The four-element theory was demolished when water, air, and the earths were decomposed into still simpler bodies ; and when fire was shown to be a manifestation of energy. The term " element " was obviously not intended to be used in the same sense as it is to-day. The four and five elements of the ancients were not considered to have an independent natural existence, but to be derivatives of one another ; the earlier notion of an element rather referred to the genesis of matter than to its ultimate analysis, for the distinction between simple and compound substances does not seem to have entered their minds. Whatever the idea involved in the three, four, or five element theories, it was believed by many different races in different parts of the globe ; it has pervaded the philosophy of all thinking races ; it has been sung by the poets of every land ; and it has had a longer life than any succeeding philosophy. The theory was living three centuries ago ; it is now dead.

The Greek philosophers.—Three gigantic spirits have dominated Grecian thought —Pythagoras, Plato, and Aristotle. Each one in his turn exerted a profound influence on his contemporaries, and on subsequent thinkers. Thomas Carlyle has well said that all history revolves around certain famous personages. The records of **Pythagoras** (*c.* 500 B.C.) and of his school are overgrown with myths and fictions ; and, as with the records of other influential men of old, the older the records, the greater the tendency to associate miraculous and extraordinary events with the men's lives.[8] The Pythagoreans formed primarily a moral, religious, and political association, although the sect early gave a definite trend to philosophical thought. The scholars are now mainly dependent upon more or less untrustworthy reports for their knowledge of the physical tenets of the Pythagoreans. It is generally agreed, however, that the Pythagoreans believed that *number* is the essence of all things. It is difficult to gather what was meant by this high-sounding phrase, for number appears to be merely a relation, or the expression of certain facts. One section of the Pythagoreans—*e.g.* Iamblichus—held number to be the substantial element of corporeal things; otherwise expressed, like Plato's ideas, numbers are the eternal archetypes of things; another section—*e.g.* Hippasus—held that all things are formed, not out of number, but after the pattern of numbers—otherwise expressed, number is the pattern or model from which things are copied, meaning that all things bear the same fixed relation that a series of whole numbers bears to unity; or again, as expressed by Philo, or whoever wrote the *Book of Wisdom*, "God ordained all things in measure, number, and weight." According to E. Zeller's account of the Pythagoreans, the idea must have arisen as man dimly realized the definite and mathematical order in natural phenomena.

From the more or less legendary accounts of the Pythagoreans, it appears that they reduced all things ultimately to one incorporeal *monad*, and assumed that all things are compounded of monads with dissimilar and opposite natures, the uniting bond being harmony. Later writers—*e.g.* Ecphantus—appear to be in error when they state that Pythagoras' monads were corporeal. The Pythagoreans attached special importance to the number 4, the quarternion, which was said to be the source and root of eternal nature; and the later Pythagoreans—*e.g.* Philolaus—were fond of arranging things in series of four. Philolaus considered that the elementary nature of bodies depended upon their form, and it was assumed that the smallest constituent parts of the *earth* had the form of a cube; *air*, an octahedron; *fire*, a tetrahedron; *water*, an icosahedron; and the fifth dodecahedral element represented the *universe*, and embraced all the others. The diagrams, Fig. 5, explain the idea. The historical evidence has not enabled the scholars to decide whether Empodocles adopted four from Pythagoras' five elements, or whether Pythagoras added a fifth element to Empedocles' four. It is thought that the Pythagoreans probably derived the five-element theory from the Hindus. According to Max Müller, the coincidences between the teachings of Pythagoras and Hindu learning are so numerous as to make it highly probable that Pythagoras obtained his leading tenets by contact with the Indians in Persia.



Tetrahedron (Fire)
Octahedron (Air)
Icosahedron (Water)
Cube (Earth)
Dodecahedron (Universe)

FIG. 5.—Primitive Particles of Pythagoras' Elements.

The celebrated Athenian pupil of Socrates, **Plato,** expounded his views on natural phenomena in his *Timæus* (*c.* 360 B.C.). He assumed that all things and all phenomena are transitory and unreal, but the abstract idea of them is alone eternal and real. Hence, the aim of philosophy is to discover the ideas or abiding principles of which the phenomena of the material world are but the image. I. Kant (1790) described Plato's hypothesis by the celebrated metaphor: Just as a flying dove, feeling the resistance of the air, might wrongly suppose it would be able to fly faster in airless space, so did Plato, feeling the limits which the sensuous world opposed to his understanding, assume that by abandoning the sensuous world, he would be more successful in the void space of pure intellect. Plato asserted as an *a priori* truth that the principle of matter was infinite, eternal, and deprived of all qualities; that matter is converted into bodies by being impressed with some occult moving power; and that matter may possess particular qualities—hotness, dryness, coldness, and wetness. He considered that there are four elements—air, water, fire, earth—and assumed that these elements can never be destroyed. The elements can be divided into infinitely small particles incapable of further subdivision; the ultimate particles of the elements have definite forms analogous to those suggested by Philolaus, Fig. 5.

The differences between the various kinds of the same elements are due to differences in the bounding planes of the constituent particles. Fire, air, and water can be transformed into one another by the coalescence of the primitive particles into forms peculiar to these substances. Earth cannot be converted into any of the other three elements because its cubical particles have no mathematical relation with the forms of the other three.[9]

The influence of Plato's pupil, **Aristotle,** on the world of thought has been rivalled only by the founders of the great religions. Aristotle lived between 384 and 322 B.C. Excluding his *Organon,* to which reference has already been made, Aristotle's most interesting contribution to natural science is entitled *Meteorology,* and it deals with astronomical, chemical, and geological subjects ; his views on the constitution of matter are expounded in his *Generation and Corruption.* There is a work on *Physics* containing unfruitful disquisitions on abstract space, motion, infinity, etc., and also a kind of sequence to this work entitled *The Heavens.* Aristotle also wrote some biological works. There has been some discussion as to whether a work on *Mechanical Problems* attributed to him is really the one to which he sometimes refers.[10]

Greek was not a familiar language to the philosophers of the Middle Ages, and Aristotle's writings in the original Greek do not appear to have been known in Western Europe prior to the thirteenth century. Aristotle's works were translated into Syriac, thence into Arabic, and carried to Spain by the Moors. About the fourteenth century Latin translations, made direct from the Greek manuscripts, were read in Europe, and soon got a remarkable hold on European thought. In a general way, it has been said that although Aristotle professed to rely on experience and induction as the sources of true knowledge, he often went astray ; his treatment of natural philosophy displays a capable mind, hampered by unsuspected superstitious prejudices, wrestling with problems beyond its strength. Aristotle rejected Plato's idea-hypothesis and Pythagoras' number-hypothesis. He supposed matter to be capable of infinite division, and he objected to Democritus' idea of atoms, although he admitted that matter may be made up of particles which are actually though not potentially indivisible. Aristotle did not agree with Pythagoras' and Plato's hypotheses that the elemental monads have definite geometrical forms. He said that the attempt to bestow an intrinsic figure on the elements—Fig. 5—is absurd, an element cannot have one. Elementary matter must be formless and amorphous, ready to take on any form according to circumstances, but itself possessing no particular form.

A famous disciple of Aristotle, **Theophrastus** (*c.* 372–287 B.C.) of Lesbos, succeeded his master at the Lyceum.[11] Theophrastus wrote two works on botany which were standard even throughout the Middle Ages ; a history of physics, a work on natural science, and several other fragments—some writings ascribed to him are no doubt spurious. Theophrastus followed the philosophy of Aristotle rather closely in his *Treatise on Fire* (*c.* 315 B.C.)—περὶ πυρός. Theophrastus removed fire from the list of elements ; and he recognized that air plays an important part in the maintenance of a flame, and in the development of plants. In a fragment *On Odours,* he adds that the odour of a substance is due to its volatility. The more important parts of Theophrastus' writings, from the chemists' point of view, dealt with minerals—περὶ λίθων. Here he mentions coal, cinnabar, orpiment and sandarach (arsenic sulphides) for the first time, and he also describes the preparation of white lead, red lead, verdigris, colcothar, chrysocolla, etc.

A number of writings and fragments of **Archimedes** of Syracuse (287–212 B.C.) has been preserved.[12] They deal with some mechanical and hydrostatical problems. The discovery of the celebrated *principle of Archimedes*—if a solid be weighed in air, and then immersed in water, the apparent loss of weight is equal to the weight of a volume of water equal to the volume of the solid—is described in M. P. Vitruvius' *De architectura,* published near the beginning of the Christian era. Al-Khazini's account in the twelfth century lacks the piquancy and interest of that of Vitruvius.

It has been remarked that although Archimedes had fairly entered upon the right path of his department of experimental science, no further advance was made for nearly two thousand years, when Galilei and Stevinus took up the work. The celebrated **Hero** flourished about 117 B.C. In his work on *Pneumatics*, he described the principal physical properties of air known to the ancients, and indicated some ingenious mechanical contrivances operated by means of rarefied or compressed air; he also wrote a treatise on the properties of reflected light; and two treatises on the mechanical powers.[13]

The main contributions of the Greeks to chemical science are the *prima materia* hypothesis; the four-element theory; the atomic theory; the idea of the transmutation of matter from one form to another by some agent or principle; and more or less vague notions of an active principle causing combination or change. There is also Aristotle's work on methodology.[14] The Greeks were not generally guided by observation and experiment either in founding or in verifying their hypotheses. Consequently, their great conceptions were wondrous feats of the imagination; but Lord Macaulay would have none of it, for, in his essay on *Lord Bacon* (London, 1837), he claimed that the Greeks aimed at the stars, and through no want of skill the shot was thrown away. The arrow was indeed followed by a track of dazzling radiance, but it struck nothing. Their philosophy began in words and ended in words.

Rome.—The Romans acquired some knowledge of the chemical arts after they had conquered the Egyptians and the Greeks. The Romans had no philosophy of their own, but they borrowed ideas and learned lessons at the feet of conquered Greece.[15] War was the strength of the Romans, and they favoured the arts and crafts which made good soldiers. The works of art which the Romans acquired as loot from conquered nations attracted much attention, and stimulated some of their artisans to imitate these productions. The Romans, however, displayed but little inventive genius, and it is probable that what successes they obtained were largely due to the work of imported craftsmen. The early Romans developed a code of civil law which has been a pattern for succeeding nations. The doctrine of the supremacy of law inculcated by the Romans probably exerted some influence on man's subsequent attitude towards external nature, and some confusion has resulted from the assumption that a law of nature represents an obligation on the part of natural phenomena analogous to the obligations of a people to its civil law. The modern view of a law of nature is very different from this.

The poem of **Lucretius** (95–52 B.C.), *De rerum natura*, is much admired, and is intimately associated with the history of the atomic theory. It has been considered curious that, with the exception of a few fragments and letters, the works of the three founders of the Grecian atomic theory—Leucippus, Democritus, and Epicurus—should have been lost, and that we have to rely upon the Roman's eloquent poem for a clear and concise account of Epicurus' doctrine. There is nothing to show if Lucretius added anything new to what he found in Epicurus' two works—*Concerning nature*, and *On atoms and voids*—which have been lost.

The principal writings dealing with the physical arts and crafts of the Romans are the works of Vitruvius, Galen, Dioscorides, Varro, Seneca, and Pliny. **M. P. Vitruvius** was an engineer and architect in the service of the Roman state at the time of Augustus—near the beginning of the Christian era. He wrote the cultured work, *De architectura*,[16] in which he gives many indications of the learning of his time, viewed more particularly from the point of view of the practical application of theoretical knowledge. Another celebrity—**Dioscorides**—was born in Asia Minor and flourished in Rome about 75 A.D.[17] contemporaneously with Pliny. His *De materia medica* was a standard work for many years. In this book, Dioscorides describes the art of distillation for the first time, although Aristotle (*c.* 320 B.C.)[18] seems to have had this operation in his mind when he wrote in his *Meteorology* (2. 2):

> Sea water is rendered potable by evaporation; wine and other liquids can be submitted to the same process, for, after having been converted into vapours, they can be condensed back into liquids.

Dioscorides also describes other chemical operations—*e.g.*, the extraction of mercury from cinnabar, by heating a mixture of the latter with carbon. He also mentions lime-water, zinc oxide, blue vitriol, white lead, etc.

Another Greek, **C. Galen** (131–201 A.D.), regarded himself as a disciple of Hippocrates. He practised medicine in Rome about 160 A.D. He was an experimental physiologist, and wrote on human anatomy, physiology, and botany. **M. T. Varro** (116 B.C.–28 A.D.) wrote on agriculture, law, mensuration, etc. **A. Seneca** wrote a work, *Quæstiones naturales* (*c.* 63 A.D.), which appears to have been largely drawn from Aristotle's *Meteorology*.[19] It deals mainly with astronomy, meteorology, and physical geography; and it was the authority on science in the Middle Ages up to the fourteenth century, when it was largely supplanted by Aristotle's works, which then became accessible in Europe through the Latin translations of the Greek texts. *Caius Plinius Secundus*, or **Pliny the Elder**,[20] wrote the *Historia naturalis* about 77 A.D. It deals with an enormous variety of subjects and is a congested and uncritical compilation from credible and incredible authorities and popular beliefs. E. Gibbon, in his *Decline and Fall of the Roman Empire* (London, 1789), called it "an immense register of the discoveries, arts, and errors of mankind." The works of but a few of the authorities quoted by Pliny are known.

The prosperity of the Roman Empire—which included England, France, Spain, and all the countries about the littoral of the Mediterranean Sea—was on the wane about 180 A.D. The Romans, satiated with conquest, became indolent and corrupt, and their intellectual activity slackened. Their empire was invaded by the uncivilized northern races—Goths, Vandals, and Huns. The destructive impulses of the invaders led to the complete disintegration of the empire; and about the fifth century, culture and civilization in Rome were crushed in a few dark years. Many of the records of science, literature, and art were deposited in monasteries, where they were preserved as sacred trusts until civilization again revived in Western Europe. Fortunately, however, Constantine transferred the Roman capital to Byzantium (Constantinople) in the fifth century, and the New Rome maintained a continuity of government and of civilization until the raid of the fourth crusaders in 1204. It is considered that more destruction and damage to ancient records were wrought in the sack of Constantinople by these Crusaders than by the Mahomedan conquest in 1453.[21]

§ 11. The History of Chemistry in Syria, Persia, and Arabia

Very little advance in culture could be made even by the greatest man of genius if he were dependent for what knowledge he might acquire merely on his own personal observations. Indeed it might be said that exceptional mental ability involves a power to absorb the ideas of others, and even that the most original people are those who are able to borrow the most freely.—W. Libby (1917).

About the third, fourth, and fifth centuries, the Neo-platonic schools at Alexandria and at Athens included Ammonius Saccas, Plotinus, Porphyry, Iamblichus, Proclus, etc. These schools cultivated mysticism and magic. As with the Pythagoreans, they taught that the air is full of spirits and demons which control health and disease, and natural phenomena in general. It was said:

> God rules the world. He has demons under his control, some of which govern animals, some vegetables, and others minerals. . . . One demon governs the liver and another the heart.

When animals or vegetables were destroyed by fire, the gases which escaped were supposed to be subtle spirits returning to the air. With beliefs like these, natural phenomena could be investigated only by contact with the supreme divinity, and this could be attained only by certain mysterious ceremonies involving the use of secret symbols, incantations, and prayers. A knowledge of these ceremonies was regarded as a divine gift particularly reserved for the priests and the initiated. Somewhat similar ideas were later incorporated in the mystical forms of alchemy of the Middle Ages.

In the period between the first and fifth centuries, alchemy attracted the attention of many learned men, and authentic writings on alchemy began to appear. The first, **Zosimos** of Panopolia, lived in the third century, and most of his writings seem to have been lost. Some fragments attributed to him have been collected from Greek papyri, and he is often quoted by later alchemists. Zosimos described various forms of apparatus and furnaces, minerals, and alloys, and he frequently refers in more or less obscure language to the transmutation of the metals. Fragments of the writings of Zosimos, Africanus, Synesius, Olympiodorus, (pseudo) Theophrastus, (pseudo) Democritus, and several other Greek alchemists [1]—about

150 in all—were preserved in European museums—Venice, Rome, Paris, Munich, etc.—whither they drifted after the conquest of the Turks in 1453. The essays reproduced in M. Berthelot's *Collection des alchimistes grecs* are all composed in an enigmatical style with obscure chemical terms used in many different ways; they discuss magical and astrological formulæ; and give citations from mythical authors. The writers were acquainted with many ores, minerals, earths, salts, and animal and vegetable substances; there is no evidence of a scientific classification; and the writers were in ignorance of the mineral acids and their important derivatives. They were chiefly concerned with the operations of solution, distillation, and heating.

The conquests of Rome brought the Orient and the Occident, the East and the West, into close communication. At the beginning of the Christian era, Alexandria was the asylum of Eastern traditions, the centre of medical, alchemical, and philosophical culture; and the sanctuary of the world's learning. The Roman depredations in the fourth century led to a rapid decline; and as a result of the Mahomedan conquest of Egypt in the sixth and the seventh centuries, the Alexandrian philosophers and teachers were scattered, and some refugee Byzantine alchemists travelled to Constantinople; others settled in Persia and Syria, where they introduced the Greek and Egyptian philosophies. Some of the writings of the Greek philosophers were translated into Syrian.

In the seventh century, the Arabians overran Syria and Persia; and the Syrian schools languished and died. The Arabians then began to cultivate those very arts which they had done so much to destroy. Syrian scholars were employed by the rulers for positions demanding wisdom, knowledge, and judgment. Copies of two Syrian manuscripts are preserved in the British Museum; one is translated in M. Berthelot's *La chimie au moyen âge* (Paris, 1893). It contains various technical recipes, discussions on magic and mystic doctrines, the elixir of life, the adulteration of gold, and descriptions of some chemical apparatus. An Academy was founded at Bagdad about 800 A.D., and the Arabians began to collect and translate books from various countries—East and West. The works of Aristotle were translated from the Greek into Syrian, and re-translated from Syrian into Arabian. Consequently the alchemists of Arabia derived their ideas and knowledge from those of Syria; the Syrians in turn were largely dependent on the Greek works of the pseudo-Democritus, Zosimos the Panopolite, the pseudo-Cleopatra, and others who flourished at Byzantium. Historians generally consider that the Greek writers of this period, in turn, derived their ideas from the Egyptians.[2] In any case, the Arabians, like the Greek writers of the Alexandrian school, imparted mysticism into their versions of Hellenistic philosophy, so that there was a partial reversion to the first of Comte's three states. Instead of regarding natural phenomena as the workings of natural law, they were inclined to consider them to be subject to the capricious wills of superior intelligences, and creatures of an imagined demonology. As a result, physical science reverted to magic, astronomy to astrology, and philosophy to theosophy. The alchemical operations were described in mystic language. Hence too arose the philosopher's stone, the elixir of life, etc. The Arabians had a bias in favour of medicine and pharmacy rather than metallurgy, and they appear to have interpreted the alchemical writings from the Egyptians, in terms of medicine and pharmacy—a bias possibly derived from the Hindus. Consequently, the philosopher's stone of the Alexandrian school became the Arabian elixir of life.

The reputation of one **Geber,** an Arabian writer of the eighth century, loomed mightily in the alchemical world about the later half of the Middle Ages. He is credited with having been the first to give chemical knowledge a systematic form by publishing the first extant system of chemistry. It is very true that the ideas expressed in these writings are the earliest to stand in historical continuity with those of the present day. This fact has invested the writings of Geber with a special interest, and this interest is only quickened by a knowledge of their contents and style. The fragmentary information which is available respecting Geber is most disappointing; there is no agreement among the historians concerning his birth-place, his parents, his social or political relations, his rank, the events of his life or his death.[3] There are, however, quite a number of Latin treatises alleged to be translations of Arabic texts of Geber's writings. For example, up to recent years, the *Summa perfectionis magisterii* was credited to Geber, and it was said to have been the first work exclusively devoted to chemistry. The book is an attempt to summarize what was then known or believed with respect to chemical operations and processes. It is, however, disfigured by unintelligible matter which has wrongly led some to the idea that the term " gibberish " for unintelligible words, is a tribute to Geber's style of writing.

The Latin Geber was acquainted with alum, copperas, saltpetre, sal ammoniac, aqua fortis, oil of vitriol, aqua regia, etc.; he described the action of mercury on gold, and of sulphur on red-hot iron; and he supposed that there are three elementals —mercury, sulphur, and arsenic. The metals, said the Latin Geber, are compound bodies which are extracted from their earthy ores when the latter are mixed with carbonaceous materials and heated in a furnace in the absence of air. It seemed to him as if the calx got something from the furnace and so became a metal. According to the Latin Geber, the metals are compounds of the same substances—mercury and sulphur—united in different proportions. Geber also accepted as dogmas of his faith, the transmutation of the metals, and the influence of the planets on the metals—although he said:

> It is as impossible to transform the metals into one another as it is to turn a bull into a she-goat; for it has taken nature thousands of years to make the metals, and we cannot hope to effect the transformation when we rarely live a hundred years.

Many grave doubts have arisen as to the genuineness of the Latin writings which have been attributed to the eighth-century Geber. M. Berthelot has compared the texts of the Latin works, and translated the known Arabic texts preserved in the Museums at Paris and Leyden. He has also compared these works with those of contemporary writers. The style and standards of the Latin and Arabian works are altogether different; and, as a result, Berthelot concludes that *the Latin works attributed to Geber were the composition of one or more writers about the thirteenth century*, who forged the name of the Arabian Geber to crown the book with veneration and respect. The Latin version of Geber is not to be regarded as a translation from Arabic texts. The Latin versions, on which Geber's reputation rests, are sometimes called the thirteenth-century works of the **pseudo-Geber** to distinguish them from some Arabic texts which were probably the work of an unimportant Geber, or of some writer between the eighth and eleventh centuries. The Arabian Djaber (Geber) is reputed to have been the pupil of a Khâled ben Yezid ibn Moaouia, the first Mahomedan writer on alchemy. M. Berthelot's translation of the works of the Arabian Geber show that Geber used the hydrostatic balance; attempted to classify minerals; discussed the changes in volume which occur when substances are heated; and stated that he had seen many persons ignorantly attempting to manufacture gold and silver by wrong methods, and added: " I perceived these workers were divided into two categories, the dupers and the duped. I had pity for both of them."

A debate among the Arabians as to the possibility of alchemy is described in the writings of the Arabian **E. S. Avicenna** (980–1037). The doctrine was defended by **A. M. Rhases** (840–940), or *Rhazes*, whose writings are often quoted by mediæval alchemists. The Arabic physician Avicenna wrote on chemistry and medicine, and he also wrote commentaries on the works of Aristotle. Judging from the reports of his *Porta elementorum* and his *Dictiones*, his philosophical ideas closely followed those of Aristotle; his medical work, *The Canon*, was mainly a compilation of Hippocrates and Galen; and his general knowledge was but little in advance of the Greeks. Notwithstanding this, Avicenna's medical works were long revered as a code of science; but they sank into almost complete oblivion about the end of the seventeenth century. Similar remarks apply to the commentaries of

I. R. Averroes (1126–1198) upon the works of Aristotle; in fact, it was mainly through the commentaries of Averroës that Aristotle's scientific work became known in Europe in the Middle Ages.

There is a very important treatise, *The book of the balance of wisdom,* written in the twelfth century by the Arabian optician and physiologist **Al-Khazini,** or *Alhazan.*[4] It contains a memoir on the use of the balance for the determination of specific gravities, and is supposed to have been based upon a work by **Abu-r-Raihan** written about 1000. Al-Khazini said:

> The water-weight of a body visibly changes according to the difference between the waters of different regions in respect to variety and density, together with incidental difference due to variety of seasons and uses. . . . In winter one must operate with tepid, not very cold, water on account of the inspissation and opposition to gravity of the latter, in consequence of which, the water-weight of the body comes out less than it is found to be in summer. . . .

The temperature was apparently estimated by the distance a kind of hydrometer sank in water. The specific-gravity bottle was described, and an improvement on the floating hydrometer of Pappus (*c.* 400 B.C.) indicated. Gravitation seems to have been regarded as a force directed to the centre of the earth, and which diminished proportionally with the distance; it remained for Newton to show that it diminishes as the square of the distance. Both Abu-r-Raihan and Al-Khazini compiled tables of the specific gravities of various solids and liquids with which they were acquainted; and the numbers agree closely with those adopted to-day.

During the period of the intellectual darkness which prevailed in Europe after the decline and fall of the Roman Empire, the torch of learning was borne by the Arabians, but there is little to show that the Arabian alchemists—Avicenna, Anvenzoar, Averroës, etc.—who flourished between the eleventh and thirteenth centuries —did much to extend the chemical knowledge which they derived mainly from their contact with the Egyptians, Greeks, and Hindus. The Arabians borrowed freely; but they showed little genius for independent thought. In his posthumous *A History of Chemistry* (London, 1913), J. C. Brown sums up by saying: "far from crediting the Arabians with being the originators and improvers of chemistry, as stated by E. Gibbon (1789),[5] much of their knowledge was not understood, and they involved it in mystical confusion which hindered the progress of science for centuries;" and W. Whewell, by saying:

> The Arabians cannot claim in science or philosophy, any really great names, they produced no men and no discoveries which have materially influenced the course and destinies of human knowledge, they have tamely adopted the intellectual servitude of the nation which they conquered by their armies; they joined themselves at once to the string of slaves who were dragging the car of Aristotle and Plotinus.

About the eighth century, the Arabians amalgamated with the European settlers in Egypt, and under the name Moors, crossed into Spain, where they founded Academies at Cordova and Granada. These Moorish universities flourished between the eighth and eleventh centuries, and furnished the schools of Europe with many learned teachers. The power of the Moors in Spain was destroyed with the conquest of Granada by the Christians under Ferdinand and Isabella in 1492. The Arabian centre of learning at Bagdad was captured in the eleventh century by the Turks, a tribe which separated from the Mongols in the sixth century, and settled in Asia Minor. The Turks gradually extended their power westwards, and formed the Ottoman or Turkish Empire under the leadership of Othman (born 1258). The Turks crossed into Europe in 1356, and about a century later, 1453, captured Constantinople. The learned men congregated in that city then slowly drifted westwards with their manuscripts and learning.

The authors of the earlier Arabian alchemical books were directly or indirectly associated with the famous schools of Alexandria, the last resting-place of the secrets of the Egyptian priests. There can be no doubt that the chemical arts were well developed in old Egypt. The Egyptian origin of the term chemistry would harmonize with the prefixing of the article *al* (the) to the word *Khem* (Egypt) when the Arabians overran Egypt, and thus learned many of the secrets of the temple laboratories of the Egyptian priests. No doubt also the contact of the Arabians with Persia made them acquainted with some chemical knowledge derived by the Persians from India. The Arabians also learned from the Grecian philosophers through the Syriac translations. The learning derived by the Arabians from East and West was probably distorted, modified, and adapted to suit their own particular dogmas, and carried to Europe partly by the currents of returning crusaders, and partly by the Moors *viâ* North Africa and Spain.

The origin of the term chemistry.—Chemistry had no special name prior to the sixth century, before which it was variously known as the *art of Hermes*, the *Hermetic art*, the *Sacred art*, the *Occult art*, or the *Black art*. Many have tried to trace the origin of the name chemistry, and the quest has led etymologists to suggest several different hypotheses; accordingly, the student has the choice of a number of plausible guesses at his disposal.[6]

(1) The various attempts which have been made to make the root a Greek word have not been very successful. H. Barbarus, in his *Compendium scientiæ naturalis* (1547), and A. Libavius, in his *Alchymia* (Francofurti, 1606), consider it possible that the term is derived from *χύμος*—a juice or menstruum—in reference to the use of various solvents by the early alchemists; or from *χέω*—to fuse or melt; and J. A. Quercetanus, in his *De priscorum medicina* (c. 1600), uses the term *halchymiam* for a fused salt—*ἅλς*, salt; and Alexander the Aphrodisian (c. 200 A.D.) speaks of the use of *χυικὰ ὄργανα*—a kind of crucible for melting substances. While this derivation of the word was in fashion, alchemy was spelt *alchymy*, and chemistry, *chymistry;* but this spelling was dropped when it was recognized that the Greeks had neither the name *chemia* nor the science; it was only near the beginning of the Christian era that the new science began to attract attention in Europe. The scholars tell us that the word alchemy does not occur in Greek writings earlier than the third or fourth century, when J. F. Maternus mentioned the *scientia alchemiæ* in an astrological work entitled *Mathesis*, written about 337 A.D. He says, in the jargon of astrology: "If man be born in the house of Mercury, he will devote himself to astronomy; if in Venus, he will be fond of singing and pleasure: if in Mars, he will apply himself to arms; if in Jupiter, he will follow religion and law; if in Saturn, he will devote himself to alchemical knowledge. . . ." Zosimos of Panopolis (Egypt), a writer possibly contemporaneous with, or possibly earlier than, Maternus, refers to *χημία*, *chemia*—or *χημεῖα*, *chemeia*—as the art of making gold and silver. We are also told that the term was seldom or never used by subsequent writers before the ninth century, but thereafter somewhat frequently.

(2) It has been argued that the word is derived from the Hebrew word *Chaman* or *haman*, meaning a mystery or secret, in which case, chemistry would mean the *secret art;* and Zosimos (c. 400) considers that chemistry should be treasured as a religious secret to be known and jealously guarded by the priestcraft. S. Bochart (c. 1660) favours a derivation with a similar connotation, for he refers the word to the Coptic *kema* or *kemo*, obscure or hidden, or the Arabic *chema*, to hide. Hence the old designation the *occult science*, and the Arabic book of secrets called *Kemi*.

(3) It has been suggested by S. Bochart, in his *Geographiæ sacræ* (Cadomi, 1646), that the word may be derived from Noah's son *Cham*, whom he thinks was identical with Zoroaster the founder of the Magi. According to Diodorus Siculus' *Bibliotheca historica* (c. 30 B.C.), the word chemistry is derived from the name of an Egyptian king named *Chemnis* or *Chembes;* and, according to H. Goring's *De hermetica medicina* (Helmestadii, 1648), the god Chemnis was worshipped in the city of Thebes, which was famous for its metal and colour industries.

(4) Plutarch, in his *De Iside et Osiride* (c. 100 A.D.) implies that the word comes from the Egyptian *Kham* or *Khem* (Psalms, **105**. 27)—meaning black or dark—because the same word was applied to the country of Egypt. The term thus refers to the art of the black country, or the Egyptian art. The trend of opinion seems to favour this suggestion.

§ 12. The History of Chemistry during the Middle Ages. Alchemy and Medico- or Iatro-chemistry

> The applications of chemistry to various kinds of industries are all buried in the tombs of many generations of artists who have left no other traces of their existence than a few of their productions.—P. LACROIX (1869).

The Middle Ages are sometimes taken to extend from about the seventh to the seventeenth centuries. During the fourth century Western Europe was ravaged by Teutonic barbarians—the Goths and the Vandals. The Roman Empire transferred its capital to Byzantium (Constantinople), on the banks of the Bosphorus, where Greek metaphysics mingled with Oriental mysticism; and intellectual Europe there managed to exist until the Turkish conquest of Constantinople in the fifteenth century. The traditions of the Greek philosophers were preserved in the schools of Alexandria and Byzantium,[1] and there was a succession of real though feeble students of philosophy, physical and natural science, mathematics, and medicine. Byzantium thus kept alive the thought and knowledge of the ancient world during a period when Western Europe was submerged in turmoil and strife.

During the fifth century, the Huns, under Attila, devastated the fairest provinces in the West about the time the Anglo-Saxons were conquering England. Natural science could make no progress under these turbulent conditions; and ignorance and superstition prevailed in the West. There was a gradual infiltration of ideas, knowledge, and art from Byzantium, the Greco-Roman Empire, into Western Europe between the fifth and the fifteenth centuries. The fall of Byzantium (Constantinople) in 1453 led to the westward migration of the scholars of the Eastern Empire. Europe also gained some hints of the chemical lore of the Arabians from the returning crusaders; and after the Moors had carried Arabian literature into Western Europe *viâ* Spain in the tenth century, some progress was made. The works of the Grecian and Egyptian writers were not directly known in the West until after the thirteenth century, although Latinized versions of Arabian translations, preserved in the Mahomedan libraries in Spain, were available. This gave rise to the erroneous impression that chemistry originated in Arabia.

Some Latin translations of the Arabic writings were collected and printed in the seventeenth century—for instance, the *Theatrum chemicum* (Argentorati, 1613–22) and J. J. Manget's *Bibliotheca chemica curiosa* (Genevæ, 1712). M. Berthelot found in these works whole passages taken from the older Greek alchemists. The meaning of the original writings seems to have been distorted and perverted during the many translations and re-translations; as a result, the mediæval chemists or alchemists started their work with mutilated and incoherent descriptions of the technical and philosophical works of the Greeks and the Egyptians; and the literary productions of the alchemists of this period are characterized by much obscurity, either in unconscious mimicry, because their mutilated models were similarly tainted, or else to hide their real meaning from a hostile community, or from the vulgar. It was said: "A profound secret should not be revealed in the vulgar tongue, the true adept can sufficiently comprehend the mystical language, and it would not be right that it should be understood by the people."

Historians tell us that the tardy growth of science in the early Middle Ages was largely due to the constitution of society. The chief elements of feudal society were the barons and the priests. The barons were perpetually at war, and the study of natural science and philosophy was eminently distasteful to them. The priests were often men of great learning, but they devoted their energies mainly to theology. They possessed great power over society, for on them devolved both the spiritual and the temporal teaching of the people. Except in rare cases, the priests did not devote special attention to the physical and chemical sciences. Aristotle's works were considered sufficient for all purposes, and speculations in reference to natural phenomena were discountenanced, and in some cases forbidden. Ignorance appeared to be a sacred duty. It was generally thought impious to attempt to draw aside the veil enshrouding nature's mysteries, and man shrank from all inquiry into the perplexed ways of the universe. What a reversion from the intellectual fearlessness with which the Greek unwearyingly interrogated nature, and wrestled with her secrets ! What a contrast with Euripedes' hymn (*c.* 450 B.C.) :

> Happy is the man who has learned to search into the reasons of things, and to discern the deathless and ageless order of nature—whence it arose, how, and why.

The alchemical school.—The most celebrated alchemists during the twelfth and the thirteenth centuries were Albertus Magnus, Thomas Aquinas, Roger Bacon, Arnold Villanovanus, and Raymond Lully. Their works serve as milestones indicating the state of alchemy at that period. Very few important additions to chemical knowledge were made, since the general tendency of the age was towards magic, sorcery, and the transmutation of the base metals into gold. Albertus Magnus and Thomas Aquinas were Dominican friars ; Roger Bacon was a Franciscan monk ; and Arnold Villanovanus was a university professor at Barcelona. Some of the works attributed to these men are no doubt spurious.

Some religious orders sought to spread a knowledge of the arts and sciences, but they unfortunately also attempted to control the progress of science in predetermined channels ; and the promulgation of hypotheses, or the discovery of facts which did not harmonize with accredited authorities, or orthodox beliefs, was regarded as a serious offence against the State or Church. The students of alchemy were believed to be magicians, and were supposed to be in communication with beneficent or malignant spirits ; and, although Albertus Magnus denied this assumption when he declared that "all those stories of demons prowling in the regions of the air, and from whom secrets of futurity may be ascertained, are absurdities which can never be admitted by sober reason," yet, the fear and dread of magic took complete possession of the popular mind ; even "the church service books gave agonizing petitions for averting these dire influences, and prescribed impressive exorcisms for thwarting the occult powers."[2] The first step to be taken by a student of nature was thought to be to league himself with Satan by bartering his soul for knowledge and occult power, and whenever a mediæval thinker appeared to be inspired by a love of knowledge and freedom of thought, the disease was ascribed to diabolic agency.

One of the oddest and oldest tricks of the human mind, in ancient and modern times, is to invoke spirits, in time of need, to explain ill-understood phenomena. In accord with the beliefs and customs of the times both Roger Bacon and Arnold Villanovanus were prosecuted for being in league with demons, and in 1317, the inquisition of Tarragona condemned the writings of Arnold to be burned on account of their heretical sentiments. Both Albertus Magnus and Thomas Aquinas were astute enough to escape the severe persecution which befell many of their brother monks who studied the alchemical arts.

It must be confessed that the authorities probably had some justification for their attitude against the "unholy quest of alchemy," just as to-day it is necessary to limit the activity of fortune-tellers, etc., by legislation. In the fifteenth century severe interdicts against the practice of alchemy were issued in the Roman provinces, in England, and elsewhere; indeed, Duke Frederick I of Württemberg is said to have kept a special gallows for hanging the alchemists [3]—but the alchemists still continued their labours.

The views of the eminent German alchemist, *Albert of Bollstädt*, or **Albertus Magnus** (1193–1280),[4] were mainly derived from those of Aristotle. The alchemical writings attributed to Albertus Magnus have been shown by the scholars to be in the main compilations from Arabian sources, although he introduced several novelties. Albertus Magnus specially studied the union of sulphur and the metals; and, like the Arabian Rhases, he considered the metals themselves to be compounds of different proportions of the three principles or elementals: arsenic, mercury, and sulphur. Sulphur, said he, "blackens silver and burns the metals on account of the *affinity* which it has for these substances." The term affinity was thus used for the first time to designate the unknown cause of chemical action. Silver was supposed to be the metal most closely allied to gold, so that he considered the transmutation of silver into gold would be the easiest to realize. Albertus Magnus knew how to separate the noble from the base metals by fire, and how to separate gold from silver by *aqua regia*. Some suppose that the treatise on alchemy ascribed to Albertus Magnus is spurious. The canonized scholar, **Thomas Aquinas** (1225–1274),[5] was a pupil of Albertus Magnus. It has been said that while the master was a student of nature and philosophy, the pupil was a student of man and society. Both are considered to have excelled as exponents of theology rather than as students of natural science. From the little knowledge which is available concerning the alchemical labours of Thomas Aquinas, he would appear to have been particularly attracted by the action of mercury on the metals—lead, tin, etc.—and he applied the term *amalgam* to the liquid or paste which is formed when these metals are opened up with mercury.

Among the foremost in substantial knowledge in the thirteenth century stood **Roger Bacon** (1214–1294). He saw far beyond his age; and his reputation among his contemporaries was so great that he was styled *Doctor Mirabilis*. His knowledge was thought to be uncanny; his insight was mistaken for wizardry. Roger Bacon's knowledge of physical science was probably derived from Arabian and Greek sources,[6] for no new principle has been traced to Bacon himself. S. Vogl has pointed out that, during a great part of his life, Roger Bacon was practically without the means of prosecuting experimental research; and he was thwarted in his aspirations at every turn by his superiors. It is therefore not surprising that he failed to enrich science by any striking original discoveries. Nevertheless, his critical examination of the science of his time was conceived in a broad philosophical spirit which showed that he had made a great advance in the methodology of science. Bacon was not exactly an admirer of Aristotle, for he said:

> If I had all the books of Aristotle in my power, I would cause every one of them to be burnt, because studying them is only a loss of time, and a cause of error, and a multiplication of ignorance, beyond what can be explained.

In his *Opus majus*, R. Bacon emphasized very clearly the importance of *scientia experimentalis*, which, in his opinion, is the mistress of all the sciences—*domina est omnium scientiarum*. Indeed, he actually claimed an equal rank for observation and experiment. True enough, towards the end of the Grecian epoch, there dawned an era of experiment, for C. Galen experimentally investigated the nerve system, and C. Ptolemy, the refraction of light; consequently the experimental method was not a new thing. R. Bacon's merit lies in having explicitly indicated the importance and bearing of experiment as a universal instrument of research. The more important scientific works of Roger Bacon are: the *Opus majus* written in 1266, and the supplementary *Opus minor*, with its introductory *Opus tertium*, completed within a year of the publication of the *Opus majus*. The last-named work contains very little about alchemy, but much more occurs in the two subsidiary works.

Alchemy, said R. Bacon, falls into two divisions—speculative and operative. Operative alchemy includes the practical and industrial processes pursued, with more or less wisdom, by men who have a definite purpose in view. *Alkimia speculativa* treats of the transformations of matter from its simplest to its most complicated form, and in this sense the problem of R. Bacon's speculative alchemy approaches that of modern chemistry. Roger Bacon was necessarily ignorant of the fundamental truths of chemical science, and he could do little more than compile a number of empirical facts. He believed that air is the food of flame, for if a lighted lamp be placed in a closed vessel, the flame is extinguished. Like Albertus Magnus, he supposed the best and basest of metals to differ only in the relative proportions of their constituent parts—mercury and sulphur—and their degree of purity. He also devoted special attention to the properties of saltpetre and gunpowder. **Arnold Villanovanus** (1234–1312)[7] specially studied distillations, and he prepared many essential oils—turpentine, rosemary, etc. The fanatical **Raymond Lully** (1235–1315) enjoyed an ephemeral reputation; he led a turbulent restless life, and although an enormous number of books have been attributed to him, it is certain most are spurious.[8] There is also the probability that there are two different Raymond Lullys—one the fanatic, one the alchemist. Lully is reputed to have made spirit of wine which he called *aqua vita ardens*, and he seems to have rectified it by distillation from potassium carbonate.

This quintet may be taken to represent characteristic types of alchemists during the twelfth century. Arnold Villanovanus ascribed any successes which he obtained in his experimental work to the favourable position of the planets and stars, and to suitable prayers; these conditions seemed to him to be more important than a mastery of the controllable conditions under which the operations were performed. This was rather unsatisfactory because no science is possible if the phenomena under consideration are subject to the capricious wills of beneficent or malignant spirits, for science postulates that natural phenomena are but links in an endless chain of cause and effect, and that in experimenting "the same antecedents are invariably followed by the same consequents." The intellect of man now began to assert its claim for independent thought; and a general yearning for progress was apparent. Learning revived in Italy, the land whence it had been almost blotted out of existence a thousand years before. A few literary societies appeared during the fifteenth century, and in the sixteenth century these societies became quite numerous. Their chief work was the study of the philosophy of Plato, and the development of the Italian language. Scientific societies were also founded.

The invention of printing, about the middle of the fifteenth century, gave an impetus to the pursuit of literature. There was also a spirit of social unrest. The voyage of Columbus opened up the New World for those who sought new fields of discovery, fortune, or adventure. Martin Luther's revolt was inaugurated in 1517 by the posting of his thesis upon the church door at Wittemburg. That versatile genius **Leonardo da Vinci** (1452–1519), whose compendious manuscripts were so long thought to be written in secret script because written backwards, has been but recently appreciated, and his notes in part transcribed and edited. He was a pioneer of the modern spirit of investigation and practised the inductive method a century before Francis Bacon. The foundations of astronomy, mechanics, and physics were laid about this time; **Nicolas Copernicus** had published his *De revolutionibus orbium cœlestium* in 1543. During the next fifty years fuller and more accurate data were compiled by **Tycho Brahe** (1546–1601). About 1608, the astronomical Don Quixote, **Johann Kepler** (1571–1630), published voluminous works[9] which have been styled "a most singular medley of sound thoughts and unmitigated nonsense." Kepler, however, did submit his ridiculous conceptions to the test of observation, and rejected those which did not stand the trial. Among the wildest of guesses on the motions of the planets and their satellites, he discovered those truths which have long been known as Kepler's laws. **Galileo Galilei** made important experiments on the laws of motion, towards the end of the sixteenth century; and a century later, **Isaac Newton** demonstrated the all-embracing law of gravitation in his epoch-making *Philosophia naturalis principia mathematica* (London, 1686).

A Latin compilation on technological chemistry, entitled: *Compositiones ad tingenda*, was published towards the end of the eighth century, and about the tenth century one entitled: *Mappæ clavicula*. These works contain recipes for industrial processes closely resembling those of the ancient Greek papyri. The term *vitriol* for impure ferrous sulphate was used for the first time in the eighth-century work. Reference is made to the use of the hydrostatic balance in the analysis of alloys of gold, and this has been taken to show that the knowledge of this instrument did not pass through Arabian channels to Western Europe, but came direct from the writings of Archimedes of Syracuse (287–212 B.C.), which were carried west by the fugitives from Constantinople after its capture by the Turks in 1453.

A large number of alchemists—P. Bonus, N. Flamel, Isaac of Holland, G. Ripley, T. Norton, T. Charnock, E. Kelley, John Dee, M. Sendibogius, M. Maier, J. Boehme, T. Vaughan—who wrote under the *nom de plume*, Eupenius Philathes—and another —who wrote under the pseudonym, Erenaeus Philathes—laboured with some skill, between the fourteenth and seventeenth centuries, although the alchemical school was perhaps at its zenith in the fifteenth century. About this time there were three different types of alchemist. The first or *bookish type* spent his time commenting upon, elucidating, or unconsciously obscuring the views of the earlier writers; this type might also include the mystical chemists who hinted at a secret doctrine of a spiritual order. The second or *mercenary type* hoped to find unlimited riches when he had succeeded in converting the base metals into gold; and the third or *investigating type* sought to discover the properties and combinations of the metals, and the best means of extracting them from their ores. The last formed the prototype of the modern chemist, although representatives of all three types still survive. The majority of the alchemists were diligent experimenters, and although they worked in a stupendous chaos of phenomena, their indefatigable zeal will long be remembered for the multitude of primary facts which they discovered, even though the names of the discoverers are forgotten. The alchemists crystallized and calcined, digested and distilled, filtered and fused, just as chemists do to-day.

Auguste Comte [10] has said that it is difficult to understand how the early investigators could have had the energy and perseverance to discover the chief chemical phenomena had they not been constantly incited by unbounded hopes arising from their chimerical notions of the constitution of matter. The alchemists were indeed stimulated and guided in their work by a logical system of hypotheses. For instance, they accepted the older *prima materia hypothesis* of the ultimate constitution of matter. The changes which were observed in the different forms of matter appeared as the outer clothes of an unchangeable all-pervading essence. The qualities of the elements, not their essences, are changeable; some of these qualities are more easily removed than others, thus the four elements were regarded as firmly clinging coverings, while heat and cold, moistness and dryness, were more easily removed. The different varieties of matter were the different vestments or wrappings of the one universal entity, the quintessence of things. The universal essence was regarded as the perfect thing—*The One Thing*. This one thing was given many different names—*e.g.* the stone of wisdom or the philosopher's stone,[11] a term which, according to M. Berthelot, appeared in alchemical writings about the seventh century, although the central idea is much older.

The property of matter which enabled it to withstand the action of fire was attributed to its possessing the quality of fixidity later symbolized by salt; if it possessed the principle of volatility—later symbolized by mercury—the substance would volatilize; if it possessed the principle of combustibility—later symbolized by sulphur—the substance would burn; the principle of redness gives matter a red colour; and so on. To the Romans, lead and tin were differently coloured varieties of the same metal, and called dark and light lead respectively. Thus, the variations in the different forms of matter were supposed to depend on the qualities or principles with which it was endowed. The chemical properties of matter were but dimly recognized even in the Middle Ages; and the differences between bodies were considered to depend essentially on their physical qualities. Hence, it was assumed that the properties of a body could be modified by the abstraction or addition of qualities and forms. It was argued that just as the hardness, colour, fusibility, and other properties of certain metals can be altered, so must it be possible to change all the properties of one metal into those of another, and thus produce a veritable transmutation. Consequently, the alchemists believed in **the transmutation of the metals.**

The idea of transmutation occurs in the pre-Christian Greek writings, but the idea of transforming the base metals into gold developed near the beginning of the Christian era when the Egyptian goldsmiths seem to have carefully studied the diplosis—διπλώσις—or doubling of gold; in other words, the art of increasing the weight and bulk of gold by adulteration with cheaper metals. In M. Berthelot's *Collection des anciens alchimistes grecs* (Paris, 1887–8) quite a number of works on this subject are cited—one by Moses (not the law-giver of Israel, though possibly by one who adopted this name as a *nom de plume*) is entitled περι διπλώσεως χρύσον, or *The diplosis of gold*, is preserved in the collection of alchemical writings at Venice; another by Cleopatra (not the celebrated queen), entitled κλεοπάτρας χρυσοποίια (*c.* 50 B.C.) or *The chrysopoeia of Cleopatra*, is in the collection at Leyden; etc. The last-named manuscript deals with the preservation of beauty; with weights and measures; and with the making of gold. In the *Collection des anciens alchimistes grecs* there are drawings of digesters, aludels, alembics, and a variety of apparatus for distillations, and of water baths [12] for heating in the laboratory. It may be added that the water bath was in use, 500 B.C., in Egypt, and was called the *bath of Isis*: the name was later altered to the *bath of Mary*—or the *bain marie*, as it is still called in France—after an Egyptian Jewess, Mary, a writer on alchemical subjects.

In the opinion of M. Berthelot [13] the idea of alchemy, as a method for transmuting the base metals into gold, was a development from the fraudulent practices of the goldsmiths in Egypt as an accidental accretion to chemistry, either from a misreading or misunderstanding of ancient manuscripts. As a result, the working recipes for adulterating gold were regarded as directions for the transmutation of the metals. This is shown by the fact that some of the Egyptian papyri—*e.g.* the Leyden papyrus—contain elaborate prescriptions for the falsification of the precious metals, and these recipes reappear later obviously copied as formulæ for the transmutation of the base metals into gold. Hence H. Kopp could say: *Die Geschichte der Alchemie ist die Geschichte eines Irrtums.*

According to the transmutation hypothesis, the baser metals were diseased and imperfect; gold was the most perfect of the metals. The process of transmutation consisted in healing and ennobling the diseased metals. It was postulated that a stone of wisdom, or philosopher's stone, could be found which would heal the diseased metals, for, said W. Salmon, in his *Bibliothéque des philosophes chimiques* (Paris, 1672–8), the philosopher's stone is "the universal medicine for all imperfect metals, it fixes that which is volatile, purifies that which is impure, and gives colour and lustre more brilliant than nature herself." This hypothesis is quite legitimate, but the questions which the alchemists asked from nature appear to have been too profound; they could not understand her responses. The idea of a *universal medicine* for diseased metals was extended and the philosopher's stone was invested with all kinds of mystic properties by extravagant visionaries. The Arabian pharmaceutists supposed it to have the power of elevating man's diseased and sickly body into a state of golden health, and thus arose the idea of an *elixir of life* [14] or *elixir vitæ*—or universal medicine capable of curing all curable diseases, and which later developed into an elixir of immortality. Still later, in the old age or dotage of alchemy, the alchemists sought a philosopher's stone which would preserve health, raise the dead, rejuvenate the old, make cowards brave, etc. The enthusiastic visionaries gave still further play to their fancies, and Paracelsus imagined an **alkahest** or universal irresistible solvent which would dissolve every substance with which it came into contact; there was also the *perpetual lamp* which would burn for ever;[15] *perpetual motion;* etc. The series of facts which nature revealed to the first experimenters in chemistry were so unlike anything already known that the ordinary principles of belief were shaken or subverted; and their mind became so exceedingly credulous that J. Playfair, in an essay *On the progress of mathematical and physical science* (Edinburgh, 1853), could say that one who professed to be in search of truth ever wandered over the regions of fancy in paths more devious and eccentric.

The medico-chemical or iatro-chemical school.—In the sixteenth century, alchemy received an impetus in another direction—medicine. Philip Hoehener, who, on commencing his professional career, styled himself **Philippus Aureolus Theophrastus Paracelsus Bombastus,** was born at Zurich in 1493,[16] and he seems to have developed the amazing arrogance, insolent presumption, and swelling vanity now implied by the term "bombast." It has been pointed out that it is not generally the calm, cautious, common-sense men who do the new and great things of the world, for it seems to require vigorous impulses and certain extravagances of character to institute drastic reforms. W. Ostwald, in his *Grosse Männer* (Leipzig, 371, 1909), attempted to arrange men of genius in two classes which he called respectively *romanticists* and *classicists*. The classification is based on mental reaction velocity—or mental temperature, so to speak. The romanticist has a high and the classicist a low mental reaction velocity. The latter is inclined to be phlegmatic and melancholic, and the former sanguine and choleric. The romanticist with his agile mind reads everything, he is interested in everything and everybody, and, as a result of his enormous consumption of facts, he writes a great deal. On the other hand, the classicist works more silently and more alone, and he writes comparatively little. W. Ostwald would undoubtedly have classed the wayward erring Paracelsus among the romanticists. Paracelsus seems to have combined in himself the personality of two men: there is the daring reformer and incessant observer, and there is also the mystic hypnotized by conceit who claimed that he was privileged above all others, and received knowledge direct from God or by inspiration from the Divine.

The works of Paracelsus embrace many subjects—chemistry, botany, philosophy, physics, astrology, theosophy, magic, and most important of all, medicine. His style is generally clear, and characterized by energy and vigour, but suffused with mysticism. Paracelsus maintained that each disease has its own specific symptoms and cause, and must be combated by specific remedies—every disease, said Paracelsus, must have a remedy. The development of this idea led to his being called the Luther of medicine since, previously, all diseases were considered to result from an excess of phlegm, bile, or blood. Paracelsus introduced many new remedies, and he directed the attention of medical men to the importance of chemical preparations and medicines; he taught that the direct object of chemistry is not to make gold, but to cure disease; and he gave a bias to the quest for the essences or quintessences of things—*e.g.* he investigated the active principles of plants which he used medicinally in the form of tinctures, extracts, essences, etc.— and thus he prepared tincture of opium or laudanum.

There is little evidence to show that Paracelsus contributed any important discovery to chemical science. There are, however, references in his writings to zinc and bismuth which he characterized as bastard metals because, though resembling the metals in general appearance, they lacked the characteristic ductility and malleability of the seven metals known from ancient times. Paracelsus prepared arsenic acid by the action of nitre on arsenious oxide; he discriminated between the alums and vitriols by showing that the former had an earth and the latter a metal as base; he prepared copper amalgam by the action of mercury on copper precipitated from its sulphate by iron; he noted the development of a gas during the action of oil of vitriol on iron; he used an infusion of nut-galls for detecting iron in mineral waters; he mentioned the bleaching action of the fumes from burning sulphur on red roses; and he described the separation of hydrochloric from nitric acid by means of silver. Paracelsus promulgated some astounding, even childish hypotheses on the slenderest of evidence, so that the wildest vagaries were promulgated by the followers of the mystic Paracelsus during the succeeding century. The great merit of Paracelsus lies in his having undermined faith in the traditions which had previously corrupted and demoralized the thought and works of most of the earlier alchemists.

Soon after Paracelsus' degraded death in 1541, the alchemists seem to have parted ways. The **palæo-alchemical school**—παλαίος, ancient—still pursued the transcendental and ever-vanishing images of alchemy which could not be brought into harmony with the inflexible world of fact. It is characteristic of a science in its early stages, said S. Brown (1843) and A. N. Whitehead (1916),[17] to be both ambitiously lofty in its aims, and trivial in its handling of details. This statement is very true of the mediæval alchemists, and "their successors still tried to scale to heavenly heights; but their vitality was gone and they degenerated into fanatical inanities of no historical significance; and their compilations are usually mystical anonymities fathered on to the potentates of old." The **neo-alchemical school**—νέοφς, new—soon renounced the unattainable sublimities of the earlier alchemists, they dropped the Arabian *al*, and sagaciously pursued the sober and attainable aims of a truer chemistry. They sought knowledge, not gold; they confined their attention to phenomena and reactions which could be realized experimentally; and they assiduously devoted themselves to the discovery of primary facts, without dissipating much energy on attempts at transmutation. In fine, they were undoubtedly the working chemists of their day, and they laid the foundations of experimental chemistry.

Masses of information were rapidly accumulated by **George Agricola** (1491–1555)—the father of metallurgy, and author of the painstaking *De re metallica* (Basil, 1556),[18] on mining and metallurgy; by **Andreas Libavius** (1540–1616),[19] the discoverer of tin tetrachloride or *liquor fumans Libavii;* and by **Angelo Sala** (1575–1640),[20] who severely criticized the old mystic hypotheses, and who would have chemists cease from trifling with sublimities. To the alchemists who professed to extract from antimony a mercury which would effect the great transmutation, A. Sala said: "Show me only one drop of your wonderful mercury and I will believe you; but meanwhile I am deaf to your nonsensical claims." A. Libavius proved that the acid obtained by distilling alum and green vitriol (ferrous sulphate) is the same as that obtained by burning sulphur with saltpetre; he studied the action of nitric acid on sulphur; and prepared artificial gems by tinting glass with metal oxides. A. Sala specially studied ammonia; and he synthesized ammonium chloride by treating ammonium carbonate with muriatic acid. A. Sala recognized that iron is not changed to copper when dipped in a solution of blue vitriol, for he saw that the copper comes from the blue vitriol. Paracelsus had given a bias to alchemy which led its followers to study diligently the preparation of medicines rather than pursue an emasculated alchemy in the quest for the unattainable. The new school of medico-chemists and pharmaceutists made a mistake in attempting to explain the changes and processes which occur in the human organism by fanciful hypotheses founded upon their ignorance of the facts. Paracelsus himself seems to have made the childish assumption that a demon named Archæus resided in the stomach, and changed bread into blood, etc.

The talented **J. B. van Helmont** (1577–1644) of Brussels, began his career an enthusiastic alchemist, and ended a worthy chemist; he also specialized in medicine, and helped to carry on the medical reform inaugurated by Paracelsus. Consequently, his posthumous collected works [21]—*Ortus medicinæ* (Amsterdam, 1648)—appear to be both alchemical and chemical. J. B. van Helmont is particularly noted for distinguishing clearly between *air* and *gases;* for his work on carbon dioxide which he did not distinguish sharply from sulphur dioxide, ammonia, and nitrogen peroxide; for wholeheartedly advocating Thales' doctrine that water is the *prima materia* out of which all things are made—although Paracelsus had something to say in the same direction; and for his denying the elemental nature of fire which he considered was not a material substance at all. J. B. van Helmont is also noted for first using melting ice and boiling water as fixed points in thermometry; for his use of the term *saturation* to signify the combination of an acid with a base; for emphasizing the imperative claims of the balance for a premier place in the chemical laboratory; and for showing that although a metal can enter into many combinations, yet it does not lose its own peculiar nature since it can always be again separated unchanged—no metal can be obtained from a salt if it is not already present therein. The clear recognition of this fact was a necessary condition for progress in chemistry. It was previously supposed that a change in the appearance of a metal constituted a veritable transmutation. It was not until the chemical properties had been studied that it became possible to realize that the differences between the various kinds of matter depend on differences in their chemical composition, and are not produced solely by the addition or abstraction of certain qualities or principles.

The famous **J. R. Glauber** (1604–1668) was a laborious and diligent chemist who studied the preparation and properties of several salts—*e.g.* he prepared blue vitriol by the action of sulphuric acid on verdigris; various acetates by the action of wood vinegar on alkalies, earths, or metals; ammonium sulphate, or as he called it *secret sal ammoniac*, by the action of sulphuric acid on sal ammoniac; ammonium nitrate which he called *nitrum flammaris;* etc. J. R. Glauber prepared nitric acid by distilling a mixture of nitre and alum or sulphuric acid; and hydrochloric acid by distilling common salt with sulphuric acid. The term *muriatic acid* for this acid was also coined by him. The residue in the last-named operation is known to this day as *Glauber's salt*, or sodium sulphate, which J. R. Glauber regarded as a most wonderful salt—*sal mirabile*—for he ascribed to it extraordinary curative properties when used as a medicine. He said:

> This salt is the beginning and end of all things, and it increases and exalts their powers and virtues; it is the true universal medicine; not that I would have any man persuade himself, that in these words I would assert immortality, for my purpose tendeth not thither, seeing that I am not ignorant there is no medicine against death.

J. R. Glauber[22] also studied the products of the distillation of bones, and of wood. He described the preparation of *pyroligneous spirit* or *wood vinegar—acetum lignorum*—by the destructive distillation of wood, and stated that it could be made as virtuous as wine vinegar—*acetum vini*—by re-distillation. He also noted the preservative action of wood tar. J. R. Glauber recognized the law of chemical exchange—double decomposition—in the action of sulphuric acid on common salt, and of potassium silicate on gold chloride. He said that the potash of the silicate neutralizes the acid of the gold salt, so that the silica and gold are both deprived of their solvents, and are precipitated.

F. Sylvius de la Boé (1614–1672), C. Glaser (1615–1673), O. Tachen (1620–1690), Robert Boyle (1627–1691), J. Kunckel (1630–1715), N. Lemery (1645–1715), J. K. Dippel (1673–1734), and many other interesting chemists flourished during this period. Their work will be discussed more specifically later on. Most of these men believed in the alkahest, the philosopher's stone, and in the transmutation of the metals. Their faith may have been largely founded upon J. B. van Helmont's assurance that he had verily witnessed the transformation of mercury into gold.[23] Fortunately, these men were indefatigable workers, and did not fritter away much time on fantastic fictions. Said S. Brown (1851): It is never the originators of a great but useful scientific error, nor yet its true believers, but it is the indolent perpetuators, who will not move to the music of a new fact and the new time, that are ridiculous, shifty, ambiguous, and not respectable.

Some important works, written under the *nom de plume* **Basil Valentine,** probably in the sixteenth or seventeenth century, were for a long time wrongly supposed to have been the work of a fifteenth-century Benedictine monk, before Paracelsus. On account of the many parallel statements in the writings of Basil Valentine and Paracelsus, J. B. van Helmont and others assumed that the latter was indebted to the former for many of his ideas and facts. The truth is more probably the direct converse of this, and the imposition of Basil Valentine as a pre-Paracelsian writer has been called " a seventeenth-century hoax." Anachronisms in the supposed writings of Basil Valentine show that these could not have been written so early as the fifteenth century. In common with the later views of H. Kopp, J. Ferguson, K. Sudhoff, M. Berthelot, F. Strunz, C. W. G. Kastner, etc., W. Hommel says that all the evidence indicates that the name was a pseudonym for Johann Thölde who, in 1603–1604, first published the works of Basil Valentine, and pretended that he had translated them from an old Latin manuscript which he had discovered.[24] The writings are characterized by some clearness, particularly when describing the results of experiments. The masterpiece, *Triumph-Wagen des Antimonii*, published at Leipzig, in 1624, seems to include almost all that was known about antimony up to the seventeenth century. Basil Valentine precipitated gold from its solution by the addition of mercury ; copper from its solution by means of iron ; and iron from its solution by potash ; he obtained metallic mercury by the distillation of corrosive sublimate with chalk ; and he is sometimes regarded as one of the founders of analytical chemistry. A number of other works are attributed to the same writer.

Special attention should be directed to **Robert Boyle,** who, more than any previous worker, emphasized the importance of the science or, as he called it, the philosophy of chemistry.[25] He has accordingly been called "the father of chemistry," although the same cognomen has been applied to several others. R. Boyle claimed that those who had previously studied chemistry regarded it as a means of preparing medicines or improving the metals, while he considered the art neither as a physician nor as an alchemist, but rather as a philosopher. Chemistry, he claimed, had been too often practised by illiterate arrogant impostors who wrote in a language which could scarcely be understood by a philosopher.

> Without seeking the grand elixir, chemistry may greatly promote our knowledge of the works of nature. It is certain that some meliorations of metalline and mineral bodies may be made, useful medicines prepared, and various productions serviceable in particular trades may be obtained by means of chemistry, and therefore this subject may be studied to advantage.

R. Boyle further claimed that he had a larger view in cultivating the science—no less a purpose, indeed, than the general advancement of natural philosophy.

> Chemistry is eminently conducive to extend the empire of mankind by enlarging our views, and giving us a command of nature. Just as the Bologna stone would never become luminous unless it were chemically prepared, so many natural bodies would never afford light to philosophy unless it be struck to them by chemical operations.

In his remarkable *Sceptical Chymist* (Oxford, 1661), Robert Boyle introduced the modern conception of an element, and dropped the four principles or elements of the peripatetic school, and the *prima tria* of the alchemists. In 1660, Boyle designed a new air pump based upon that of O. von Guericke. Between 1660 and 1672, R. Boyle tried the effect of a reduced pressure upon the properties of many substances, and he made many experiments on the elasticity of gases. He demonstrated what is now known as Boyle's law ; he showed that air expanded by heat (1662) ; he studied the action of alkalies on vegetable tinctures (1663) ; and attempted a classification of substances into acids, bases, and salts (1680). He also studied the calcination of metals in sealed vessels (1673), and assumed that during the calcination " a subtle fluid is able to pierce into the compact and solid bodies of metals " imparting to them " no despicable weight." Robert Boyle had a clear conception of the ponderable character of air, for he several times attempted to determine its weight, and showed that the weight of a bladder of air appears to be greater in vacuo than in air.

§ 13. The Evolution of Ideas regarding the Nature of Calcination

> Let all the greatest minds in the world be fused into one mind and let this great mind strain nerve beyond its power; let it seek diligently on the earth and in the heavens; let it search every nook and cranny of nature; it will only find the cause of the increased weight of the calcined metal in the air.—JEAN REY (1630).

The principle operations of the earlier chemists were performed by fire, and one of the many names applied to chemistry in its early days was *Pyrotechnia*—πῦρ, fire; τέχνη, art. Calcination has always been one of the most important operations in the chemical laboratory. Paul de Canotanto,[1] about the middle of the fifteenth century, defined this operation as involving "the incineration of the metals, or the destruction of the igneous principle."

The term **calx** (calcis) is the Latin word for lime, but the meaning was extended by the alchemists to anything produced in the same way as quicklime—namely, by roasting to a powder or friable substance. The operation of heating or roasting was called **calcination**. Consequently, as the Latin Geber expressed it in his *De alchemia*, calcination is the pulverization of a thing by fire by the deprivation of the humidity consolidating its parts—in illustration, the ash of wood, the oxide of a metal, and the ignited residue of a substance dissolved in acid were all calces. The alchemists regarded the calx as the purest and most refined residuum of a substance which remained after the coarser parts had been dispelled by heat.

It was probably known very early that limestone loses weight during its conversion into a calx, and it came as an incredible surprise to find that an increase in weight occurs when the metals are converted into calces. Near the end of the fifteenth century—November, 1489—P. Eck de Sultzbach [2] was probably the first to demonstrate experimentally that when a metal is calcined in air, the resulting calx—or *cineris fixi*, as he called it—is heavier than the original metal. He also showed that an amalgam of silver and mercury increased in weight 50 per cent. when heated for eight hours in air. The increase in weight, which many later observers also noticed, seems to have puzzled the earlier chemists. P. Eck de Sultzbach attributed the increase to the union of a spirit (gas) with the metal; and, as will soon appear, he was nearly right. No notice seems to have been taken of P. Eck de Sultzbach's surmise, and many probable and improbable explanations of the increase in weight, and of the change in the appearance of the metal, were made during the sixteenth and seventeenth centuries. Two sets of hypotheses now struggled for existence.

One set of hypotheses assumed that the metals are naturally compounded of a substance lighter than air which buoys up the metals, so to speak, against gravitation; during calcination this component is driven from the metal and the calx remains. Thus, H. Cardan, in his book *De subtilitate* (Basil, 1553), stated:

> The metal during calcination dies, for the celestial heat—*calor cœlestis*—which gave it life and rendered it light, is dissipated, and the metal consequently becomes heavier during calcination.

Paracelsus expressed a similar idea a short time previously: Calcination, said he, separates watery moisture, fat, natural heat, odour, and whatever else is combustible. Accordingly, terms like *terra damnata* and *caput mortuum* were applied to the residues left after the spirit had been driven from the metals by calcination, and the *residua* were often symbolized pictorially by a skull and cross-bones.

In another set of hypotheses, it was assumed that something ponderable is absorbed by the metal. R. Boyle attributed the increase in weight to "the arresting of *igneous corpuscles*," and N. Lemery,[3] to the assimilation of *corpuscles de feu* by the metal. In R. Boyle's essay, *Fire and flame weighed in the balance* (London, 1672), a number of experiments are described showing the actual gain in weight which occurs when metals are calcined in air; thus, an ounce of copper filings gained 49 grains in two hours, and an ounce of lead gained 28 grains in the same time. R. Boyle inferred that "glass is pervious to the ponderous parts of flame" because tin or lead are partially calcined when heated in hermetically sealed vessels; and he stated that the increase in weight arises from the assimilation of the "extinguished flame" by the calx. It is rather remarkable that R. Boyle did not attribute the increase in weight to the action of the air on the heated body, because, shortly afterwards, in an essay entitled *Suspicions about some hidden qualities of air* (London, 1674), apparently following R. Hooke's experiments, *q.v.*, R. Boyle suggested that "air contains some odd substance, either of a solar, astral, or other foreign nature; on account whereof the air is so necessary to the subsistence of flame;" and he further added that "this substance is not improbably *a volatile nitre* akin to that which seems so necessary for the maintenance of other flames." In opposition to H. Cardan, Boyle also says that **the calx of a metal must be the metal plus, not minus, something acquired during calcination,** and not its *terra damnata*. J. Kunckel (1677), J. J. Becher (1690), J. Homberg (1700),[4] and others also attributed the increase in weight of a metal during calcination to the absorption of what J. Kunckel called *particulæ igniæ*. In an analogous manner, O. Tachen (1666)[5] assumed that the increase is due to the absorption of an acid existing in the flame, and he found that when lead burns to red lead, it increases its weight one-tenth, and returns to its former weight when reduced to the metallic state. H. Boerhaave (1732)[6] must have suspected that something was wrong, since he kept mercury at a slightly elevated temperature for fifteen years in order to find if there was any increase in weight due to the absorption of the alleged fire particles; and, in opposition to Boyle's hypothesis, no increase due to this cause could be detected. He also demonstrated that the weight of certain metals—*e.g.* silver—was the same whether at ordinary temperatures or at a red heat.

A. Cæsalpin, in his *De metallicis* (Romæ, 1596), summarily dismissed the subject by assuming that the increase in weight is due to the deposition of soot in the interior of the metal during calcination, and others supposed the increase was due to the retention of the vapours of charcoal, or the volatile salt of charcoal or the matter removed from the calcining vessel. J. Hartmann, in his *Praxis chymiatrica* (Lipsiæ, 1625), showed that the increase could not be due to the assimilation of soot, or the vapours of charcoal, because antimony increased in weight when heated in the focus of a burning lens with sunlight; and N. le Febvre[7] supposed that when the metal is calcined by means of a burning glass, the increase in weight is due to the absorption of the *matter of light*, which J. Mayow called *particulæ nitro-aeræ*, and which were supposed to be derived, not from the air but from the sun, which he regarded as a chaos of these particles.

Jean Rey appears to have been the first to critically examine the different hypotheses which had been proposed to explain the increase in weight which occurred when the metals are calcined. J. Rey's work was published in an obscure pamphlet entitled *Essays de Jean Rey, docteur en médécine, sur la recherche de la cause pour laquelle l'éstain et le plomb augmentent de poids quand on les calcine* (Bazas, 1630),[8] which at that time does not seem to have attracted much attention from those interested in the subject, since the discovery of the pressure of air, shortly afterwards, diverted the minds of investigators away from a study of the chemistry of air.

1. The facts.—In order to clarify the mind, the facts must be reviewed.

Investigators of nature, said D. Sennertus in his *Epitome naturalis scientiæ* (Oxford, 1664), are warned not to look for the causes of phenomena before there is a complete agreement as to the facts. Four things are present during the calcination of the metal in air: (1) The containing vessel or crucible; (2) The metal being calcined; (3) The air; and (4) The source of heat. Again the metal weighs more after the calcination than it did before.

2. The hypotheses.—In applying the inductive method of investigation to these facts, *it is necessary to review every rational explanation consistent with the facts, and to examine each hypothesis rigorously and impartially*, since, as emphasized above, it is necessary to show that the explanation finally selected is *alone* consistent with the facts. This extension of the inductive process might be called the **method of exhaustion**; its importance was recognized by Epicurus (*c.* 300 B.C.).[9] **It is a mistake to confine the attention to one hypothesis, because that might seriously limit the range of the inquiry.** The mind unconsciously assimilates evidence in favour of a pet hypothesis; and a pet hypothesis is apt to grow from a favoured child to a tyrannical master. Four plausible hypotheses may be suggested to explain the cause of the increase in weight: (1) the gases, etc., from the source of heat unite with the containing vessel; (2) the air unites with the containing vessel; (3) the gases from the flame penetrate the crucible, and unite with the metal; and (4) the air unites with the metal.

3. Testing the hypotheses by experiment.—By heating the crucible alone, without the metal no change in weight occurs. This **blank, dummy, or control experiment** shows that neither the first nor the second hypothesis will account for the increase in weight of the metal. The third hypothesis can be tested by heating the crucible and the metal out of contact with the air. There is then no change in the weight of the metal. The third hypothesis is therefore untenable. This method was not practicable for the early chemists, and hence J. Rey employed a less decisive test. It might be expected that if the results depend upon the absorption of the flame gases, different results must be obtained by using different sources of heat—sun-glass, etc.—but the same results are obtained in every case, and accordingly, the third hypothesis is probably wrong.

4. The conclusion.—Rey thus examined all the previously suggested explanations, and rejected them one by one; the remaining unchallenged factor was air. **The sole invariable antecedent of a phenomenon is probably its cause.** Hence, unless something has been overlooked, it is concluded that **when metals are calcined in air the increase in weight is due to the fixation of air by the metal,** and not to the absorption of furnace gases, nor to variations in the weight of the vessel in which the calcination is made. The idea was not far from F. M. A. de Voltaire's mind[10] a century later, for in 1737 he said:

> Il est très possible que l'augmentation du poids soit venue de la matière répandue dans l'atmosphère, donc dans toutes les autres opérations par lesquelles les matières calcinées acquierent du poids cette augmentation pourrait aussi leur être venue de la même cause, et non de la matière ignée.

Similar remarks apply to R. A. Vogel's *Experimenta chemicorum de incremento ponderis corporum quorundam igne calcinatorum examinat* (Göttingen, 1753) made in ignorance of J. Rey's work.

J. Rey attempted to explain how air alone could produce an increase in the weight of a metal during calcination. J. Rey *imagined* that when air is heated, it separates into a heavier and a lighter part, and that when a metal is calcined in air, the lighter part of the air is distilled off, and the denser portion—*l'air épais*—alone attaches itself to the metal and forms an ash or calx. J. Rey did not prove this subsidiary hypothesis, viz. that only a part of the air attaches itself to the metals to form a calx. The increase in weight which occurs during calcination was compared to the wetting of sand with water—most of the water can be drained away, but a little remains adherent to the sand:

> The condensed air becomes attached to the calx, and adheres, little by little, even to the smallest of its particles. Thus the weight increases from the beginning to the end. When all of it is saturated, it cannot take up more.

J. Rey's explanation proved to be fallacious. The great merit of J. Rey's work lies in his demonstration that air is a ponderable fluid; and the analogy between air and a liquid regarded as ponderable fluids enabled him to grapple with an intangible body, and to reason on that which from its subtlety had hitherto eluded the grasp of the philosophers of all previous ages.[11]

5. Confirmatory experiments.—S. Hales [12] and J. Juncker also explained the increase in weight by assuming that particles of air were absorbed by the metal, and S. Hales showed that when "1922 grains of red lead is heated there arises 34 cubic inches of air." He did not consider it necessary to test the gas expelled from the red lead since he assumed that it was elemental air. J. Rey's idea that the increase in weight which occurs when a metal is calcined in air is due to the fixation of air by the metal, was confirmed by the work of P. Bayen [13] early in 1774. Bayen showed that mercurial calx owes its "calcined state" to its intimate combination with an elastic fluid, the weight of which, in adding itself to that of mercury, "constitutes the cause of the observed increase in weight" of the mercury during calcination. The experiment was made by reversing J. Rey's procedure and heating the calcined mercury until it decomposed into the original mercury and an elastic fluid. The mercurial calx and the revived mercury were weighed before and after the calcination:

Mercurial calx	576 grains
Revived mercury	518 „
Difference	58 „

P. Bayen added: "I cannot state positively that the 58 grains represent the true weight of the elastic fluid, liberated from the 576 grains of mercurial calx, but clearly everything leads to that conclusion."

J. Rey also made the interesting unforeseen observation that "nature, in her inscrutable wisdom, has set limits which she does not overstep"; in other words, **however long a metal may be heated in air, a definite weight of each metal can combine with only a definite maximium amount of air.** Students to-day regularly repeat J. Rey's experiments on the metals, under various guises, as class exercises—Table I. for example.

TABLE I.—ACTION OF AIR ON THE CALCINATION OF THE METALS.

Metal.	Weight of metal (gram).	Weight of calx (gram).	Increase in weight (gram).	Ratio weight air absorbed : metal used.
Magnesium . .	1	1·658	0·658	1 : 1·52
Zinc	1	1·246	0·246	1 : 4·06
Aluminium . . .	1	1·890	0·890	1 : 1·12
Copper . . .	1	1·252	0·252	1 : 3·97
Tin	1	1·269	0·269	1 : 3·72

Hence, one gram of the absorbed air is respectively equivalent to

(Absorbed air).	Magnesium.	Zinc.	Aluminium.	Copper.	Tin.
1	1·52	4·06	1·12	3·97	3·72 grms.

6. Anticipation of new phenomena.– A good hypothesis ought to predict phenomena which have not been observed, and to foretell the results of new experiments; because, if the hypothesis be true, it ought to include all other cases. **A hypothesis which is not illogical and which does not contradict known facts is to be judged by its usefulness. The end justifies the means.** G. J. Stoney has expressed the idea neatly: "A theory is a supposition which we hope to be true;

a hypothesis is a supposition which we expect to be useful. Fictions belong to the realm of art; when allowed to intrude elsewhere, they become either make-believes or mistakes." When the consequences of a hypothesis are logically deduced, **a good hypothesis should not only explain, but it should anticipate new facts.** Rey's hypothesis can be used to predict new results. In his *Mémoire sur la calcination de l'étain dans les vaisseaux fermés, et sur la cause de l'augmentation du poids qu'acquiert ce metal pendant cette opération* (1774), A. L. Lavoisier [14] wrote:

> Thus did I at the beginning reason with myself. . . . If the increase in weight of a metal calx (calcined in a closed vessel) be not due to the addition of fire matter, nor of any other extraneous matter, but to the fixation of a portion of the air contained in the vessel, the whole vessel after calcination must be heavier than before, and must merely be partly void of air, and the increase in the weight of the vessel will not occur until after the air required has entered.

A. L. Lavoisier confirmed this inference experimentally on November 12, 1774, although the gifted Russian chemist, M. W. Lomanossoff,[15] had come to the same conclusion in 1756, eighteen years before A. L. Lavoisier.

§ 14. The Evolution of Ideas regarding the Nature of Burning

> Step by step we cross great eras in the development of thought; there is no sudden gigantic stride; a theory proceeds by slow evolution until it dominates or is destroyed. —G. F. Rodwell (1869).
>
> Slowly, gradually and laboriously one thought is transformed into a different thought, as in all likelihood one animal species is gradually transformed into a new species. Many ideas arise simultaneously. They fight a battle for existence not otherwise than did the Ichthyosaurus, the Brahmin and the horse. Thoughts need their own time to ripen, grow, and develop.—E. Mach.

The beautiful fiction of Greek mythology, as related by Æschylus, tells how Prometheus stole fire from heaven, and gave the sacred gift to man as the most useful of all his necessaries. To many ancient worshippers, fire was a thing divine, the supreme manifestation of God himself, and it soon became the one visible symbol of God. Even to-day the *sacred fire* exists among the races of the Balkans. Accordingly, the Zoroastrian fire worshippers called their god *the one fire*, or *the pure fire*;[1] and the sun was worshipped first as an emblem of the deity—fire—and afterwards as itself a god.[2] Fire thus came to be the first and most potent of all the elements, and it is easy to understand how Heracleitos regarded subtle fire as the sole primal element from which all things were created; and how fire was canonized by Pythagoras and Empedocles as one of the four indispensable and all-sufficient components of the universe.

Some of the early philosophers promulgated a dynamical theory of heat and fire. Epicurus (*c.* 300 B.C.) regarded heat as a result of the rapid motion of minute spherical particles which insinuated themselves in the pores of the densest substances; cold was likewise produced by angular particles moving more slowly. Lucretius (*c.* 80 B.C.) similarly referred heat to the motion of primary particles which penetrated every material thing. H. Cardan[3] (1557) spoke of a *motus ignis* and a *motus caloris*. R. Fludd (1617), F. Bacon (1620), A. Kircher (1644), and others have propounded views which amount to a denial of the elemental nature of fire, since they virtually assumed that heat is a violent motion of the particles of bodies, or that fire is air which has been made to glow by the vehement collision of its particles, and that the heat so generated changes combustible matter into flame.

René Descartes, in his *Principia philosophiæ* (Amsterdam, 1644), assumed that originally all matter consisted of square particles endowed with two kinds of motion: a rotation of each particle about its own centre; and a rotation of groups of particles about a common centre. The angles of the particles were abraded by collisions producing three kinds of particles which he called elements: (1) *Materia primi elementi*, or fine dust, which he also called *materia subtilis*, or *materia cœlestis*, because the sun, stars, and fire were supposed to be composed of this material. (2) *Globuli secundi elementi*, or rounded particles which were supposed to make up the atmosphere and everything between the stars and the earth. (3) *Particulæ tertii elementi*, or particles which retain some of their angles and are partially rounded; these were assumed to make up the earth and all terrestrial bodies. The particles of the *materia cœlestis* were supposed to be in far more rapid motion than the other particles. The different forms of matter were supposed to be determined by the relative proportions and motions of these three elements; and every natural phenomenon, the result of the conduction of motion from one body to another. Fire, according to R. Descartes, consisted of the third element rapidly agitated by the *materia cœlestis*; and the particles of combustible bodies were supposed to be peculiarly adapted to receive the motions of the *materia cœlestis*. It was all a transmission of motion, not substance. N. Lemery adopted the main tenets of thè Cartesian theory in his famous *Cours de chimie* (Paris, 1675):

> I understand by igneous corpuscles—*corpuscles ignées*—a subtle form of matter which having been thrown into rapid motion, still retains the capacity of impetuous motion when it is enclosed in grosser matters; and when it finds bodies which by their texture or figure are easily put in motion, it draws them about so strongly that their parts develop heat by being rubbed violently against one another. . . . The particles of sulphur, for instance, are very susceptible to motion . . . and it seems probable that fire is only violent motion of minute bodies about their common centre.

Flame, said R. Descartes, is directed upwards because it contains much *materia cœlestis* which is lighter than air, and the cause of lightness in bodies generally. Descartes' *materia cœlestis* approximates to the modern conception of an æther more subtle than air, and filling the interstices between the molecules of air with a continuous series of globules which pervade the pores of glass, and of the densest substances without interruption; and propagating light by communicating impulses from one molecule to another so as to produce a kind of pressure without locomotion.

Isaac Newton[4] postulated a similar æther "pervading and lurking in dense bodies, but not yet sufficiently manifested by experiments." R. Hooke introduced the notion of vibratory impulses in this medium, and the idea was elaborated by C. Huygens and T. Young into the undulatory theory of light which is now generally accepted. The communication of the vortex motion of the *materia cœlestis* to the atoms is thus described by R. Boyle:[5]

> The restless agitation of the *materia cœlestis* wherein the particles of air swim, so whirls

> them round that each corpuscle endeavours to beat off all others from coming within the little sphere requisite to its motion about its own centre . . . their elastic power is made to depend upon the vehement agitation which they receive from the fluid æther (*materia cœlestis*) which swiftly flows between them.

Several early observers noticed that fire cannot subsist without air. Theophrastus,[6] for instance, in the fourth century B.C., in his treatise *On Fire*, noticed that air plays an important part in the maintenance of flame; Hero of Alexandria (*c.* 117 B.C.) demonstrated this by placing a lighted lamp in a closed vessel, and showing that under these conditions the flame was extinguished—Hero said that the fire consumed and rarefied the air; and from a similar experiment in the thirteenth century, Roger Bacon inferred that *aer est cibus ignis*—air is food of flame—in agreement with Theophrastus—315 B.C.—who said, "It is not at all irrational to believe that flame is maintained or supported by an aëriform body." Near the beginning of the sixteenth century (*c.* 1500), Leonardo da Vinci[7] clearly recognized that air is necessary for the sustenance of the flame of a burning candle, for he said: "There is smoke in the centre of the flame of a wax candle because the air which enters into the composition of the flame cannot penetrate to the middle. It stops at the surface of the flame and condenses there." Leonardo da Vinci also showed that air is necessary for respiration; and that air is not an element because one part of it alone is concerned in combustion. R. Fludd[8] noticed in 1617 that when a candle is burnt in a glass vessel over water, the water rises in the vessel as the air is consumed, for "air nourishes fire, and in nourishing consumes it." H. Cardan also, in his *De rerum varietate* (Basil, 1557), classified different substances as *combustible* or *incombustible*. Flame, said he, is nourished by a gas—*flatus*—which will ignite a glowing splint, and which exists in saltpetre. H. Cardan was here very near to the discovery of facts which in the hands of A. L. Lavoisier produced *une révolution immense dans la science.*

After his discovery of the air-pump in 1650, one of the first experiments tried by O. von Guericke[9] was to ascertain if a candle would continue burning in an exhausted receiver, and it was found that owing to the want of air the flame of a lighted candle expired more quickly under the exhausted receiver of an air-pump than when the receiver was not exhausted; fire, said Guericke, consumes air. In his first treatise on pneumatics, *New experiments, physico-mechanical, touching the spring of air* (London, 1660), R. Boyle mentions several proofs that combustion cannot proceed in a space void of air; and in 1672, R. Boyle, in an essay *On the difficulty of preserving flame without air* (London, 1672), showed that when placed under the receiver of an air-pump, the flame of burning gas, derived from the action of an acid on iron, is suddenly enlarged on exhausting the air, and finally is extinguished; and he showed that sulphur does not burn if heated in vacuo. These, and other experiments on similar lines, clearly showed that **air is necessary for combustion.**

Robert Hooke outlined a theory of combustion in his *Micrographia* (London, 1665). He noticed the similarity in the actions produced by air and by saltpetre,[10] and hence suggested that **air is mixed with a substance which is like, if not identical with, that which is fixed in saltpetre, and that only this portion of air is required to support combustion and respiration.** A similar conclusion had been hinted at by R. Fludd,[11] who said: "The substance of saltpetre is nothing but air congealed by cold." Again, in his *Lectiones cutlerianæ* (London, 1674–9), Robert Hooke assumed that burning is produced by the solvent action of the surrounding air which is dissolved by the burning body much as water dissolves salt. He said:

> Air is a menstruum that dissolves all sulphurous bodies by burning, and without air, no such dissolution will follow, though the heat applied be never so great, which was particularly tried by charcoal enclosed in an iron case with a screw stopper, which though violently heated yet the coke was not burned nor wasted when taken out. . . . That shining transient body we call flame is but a mixture of air and volatile sulphurous parts of combustible bodies which are acting upon each other as they ascend. . . . The action is performed with so great violence and does so minutely act, and rapidly agitate the

smallest parts of the combustible matter, that it produces in the diaphanous medium of air the action or pulse of light.

J. Mayow (1669)[12] subjected the guess or hypothesis of Hooke to the test of observation. The following experiment is a more refined form of one made by J. B. van Helmont, *circa* 1640 :—

J. Mayow arranged a candle in water so that the wick was between 9 and 10 cm. above the surface of the water. A glass cylinder, *A*, Fig. 6, was lowered over the burning candle so that the level of the water inside and outside the cylinder was the same. A small syphon, *B*, was used for the purpose. Immediately the cylinder was in position, the syphon was removed. The flame of the candle soon expired, and water rose in the jar. Some gas still remained in the jar, but it could not be air because one of the characteristic properties of air is to support the burning of the candle, and the flame of the candle is extinguished in the residual gas. Mayow obtained analogous results by confining a mouse under the jar. The mouse died, and the water rose in the jar.

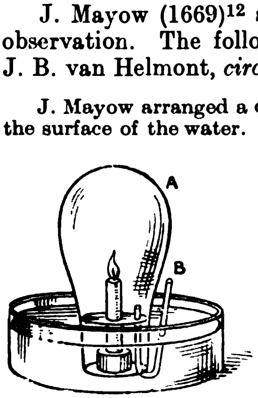

FIG. 6.—Mayow's Experiment on Combustion.

Hence, Mayow inferred that **air contains two kinds of particles, one of which—the nitro-aërial particles—is withdrawn and destroyed by the burning candle.** J. Mayow also stated :

> Though the particles of air are very minute, and are vulgarly taken for an element of the greatest simplicity, it appears to me necessary to judge them to be a compound. . . . It is manifest that the air is deprived of its force by the respiration of animals much in the same manner as by the deflagration of flame.

Mayow does not seem to have quite grasped the idea that the nitro-aërial particles which support combustion actually combine with the burning body, although he correctly inferred that air was a mixture containing nitro-aërial particles as one constituent. The nitro-aërial particles were indiscriminately called fire-air, nitre-air, and nitro-aërial spirit. Mayow's observations appear to show that **air is a mixture of two gases one of which is withdrawn during combustion, and the remaining gas does not support combustion.** Stephen Hales [13] also noticed that in the combustion of phosphorus under a bell-jar, white fumes are produced and air is absorbed. When the experimenters of the seventeenth century spoke of the *destruction of the elasticity of a portion of the air*, they meant that some of the air was lost—presumably by absorption by the confining liquid, etc.

Some modern commentators consider that J. Mayow's *nitro-aërial spirit* represented oxygen, and his *aërial spirit*, nitrogen. It has been said that J. Mayow's nitro-aërial particles were made to explain too much, for he applied them to all sorts of phenomena—*e.g.* the formation of acids, fermentation, the production of nitre, calcination, combustion, and respiration—rather is this a tribute to J. Mayow's genius. J. Mayow considered the nitro-aërial particles to be fixed as the acid component of nitre because the effects produced by nitric acid and by the burning glass on antimony were the same. He extended his views to other substances—particularly the acidification of sulphurous and fermenting substances by exposure to the atmosphere—and thus inferred that his nitro-aërial particles are the active agents in combustion and acidification. When J. Mayow regarded these same particles as the principle by which metals increase in weight when calcined in air ; the principle by which vegetables germinate and grow ; and by which the blood changes its colour in the lungs during respiration, he seems to have generalized with far greater precision from a few facts than the greater part of the next generation did from many.[14]

J. Mayow, however, did mix some fantastic hypotheses with his eminently logical interpretations of ingenious experiments, and in some cases the relevant matter is mixed with so many irrelevancies, that it is difficult to tell which is which unless his statements are interpreted in the light of what is now known to be true. To-day, J. Mayow's brilliant reasoning would be accepted as a logically conclusive proof of the existence of oxygen as a distinct substance; but his demonstration was a century ahead of its time. Instead of his unique experimental talents being encouraged by his contemporaries, they were damped by the coldest of receptions. His work was evidently above the heads of his contemporaries. The historian of science, said G. F. Rodwell,[15] should endeavour to grasp the precise mode of thought of the man of whom he writes, to think as he thought, to view the phenomena in the light of the age in which he lived, and then to reason on them as he reasoned. Evidently, then, R. Hooke and J. Mayow got very near to the present-day theory of combustion, but unfortunately, the latter's ingenious experiments had very little, if any, influence on the subsequent development of chemistry, because the lowering clouds of the phlogiston hypothesis appeared as a grey after dawn and gradually darkened the sky of chemistry until the chemical world appeared to be enveloped in an impenetrable fog. For another century more trust was placed in phantasms of the imagination than in facts obtained by precise observations.

It must be added that in the Far East, the Chinese philosopher Mao-Khoa, who flourished about the eighth century, is said to have had a fairly clear idea of the composition of air, and of the part played by oxygen—which he called *yin*—in combustion and respiration. This historical information, however, played no part in European discoveries since it is but a comparatively short time ago that Mao-Khoa's views were reported, and unfamiliarity with the language and literature has prevented many examining the claims of the Chinese scholar to a proud place in the history of chemistry.

§ 15. The Phlogiston Theory

During the greater part of the eighteenth century, the doctrine of phlogiston was not only the lamp and guide of chemists but it remained the time-honoured and highest generalization of physical chemistry for over half a century.—S. P. LANGLEY.

Phlogiston died as an old king,—once infinitely dominant, somewhat tyrannical, not always just; now deposed, decrepit, utterly senile, forsaken by all.—W. ODLING.

Up to about the middle of the fourteenth century, combustion was explained by the aid of the assumption that all combustible bodies contained a common element, the essence of fire, that is, an inflammable principle which enabled them to burn. This obviously means little more than saying that substances burn because they are combustible. The idea of a subtle fire innate in matter has pervaded philosophy from the earliest times. Zeno (*c.* 450 B.C.) called it ἀτεκνέκον πῦρ—barren fire; Heracleitos (*c.* 450 B.C.), ἀναθυμίαις; Lucretius (*c.* 80 B.C.), *subtilis ignis*, *cœlestis ignis*, or *tenuis ignis;* Paracelsus (*c.* 1500), *sideric sulphur;* H. Cardan (*c.* 1553), *calor cœlestis;* and R. Descartes (*c.* 1664), *materia cœlestis*. The alchemists of the Middle Ages variously styled it *elemental fire*, *astral fire*, *sulphurous principle*, *or materia ignis*.

The empyrean[1] element of the ancient Greeks was consecrated under the classical name **phlogiston** by the hierophants of a newer chemistry. The word phlogiston is derived from the Greek φλογιζω, to inflame, and is related to φλέγω, to burn, and φλὸξ, flame. In some cases phlogiston was believed to resemble that subtle fiction we now call *æther*, and J. Juncker,[2] in 1744, called it *materia ignea ætheræ*. J. Kunckel (1676) thought that the inflammable principle must be sulphur, and wrote *ubi ignis et calor, ibi sulphur*—where there is fire and heat there is sulphur. Virtually all chemists of this period attributed the combustibility of a substance to the presence of sulphur. There were many *sulphurs*—*e.g.* the *sulphur of wood* (carbon), the *sulphur of wine* (alcohol), etc., and Robert Boyle in his essay *On the difficulty of preserving flame without air* (London, 1672), called the fume or gas which is evolved when an acid acts upon iron *the volatile sulphur of Mars;* and in his essay *On the producibleness of chemical principles* (London, 1680), he speaks of the sulphur of the chemist as being a combustible and inflammable principle.

Twenty-five years after the appearance of R. Descartes' *Principia*, and about the time of J. Mayow, J. J. Becher began to publish the chemical side of a theory analogous in many respects with the physical theory of René Descartes. The most important work of J. J. Becher is his *Physica subterranea* (Lipsiæ, 1669), and the three supplements dated 1671, 1675, and 1680 respectively—J. J. Becher's term *subterranea* is probably equivalent to the modern *inorganic*. J. J. Becher advocated the importance of experiment in chemical science. He rejected the four-elements and the quintessence of the ancients, but he did so only to promulgate four elements of his own devising—fire; the earthy principle; the combustible element; and the metallic one. This enabled him to classify material substances into fiery or imponderable bodies, earth, combustibles, and metals. The combustibles and metals were later grouped together, and his system was simplified into fire, the first kind of substance; earths, calces, and acids, the second; and combustibles and the metals, the third; otherwise expressed, J. J. Becher's triad included fire, the products of combustion, and combustibles. It was not the custom, in J. J. Becher's time, to keep one specific technical term for one specific thing. He seems to have used the terms vitrifiable earth—*terra lapida* or *terra vitrescibilis*—inflammable earth—*terra pinguis*—and mercurial earth—*terra fluida* or *terra mercurialis*—almost in the same sense that the alchemists spoke respectively of salt, sulphur, and mercury. He regarded his three elements as three varieties of sulphur; vitrifiable earth was called *fixed sulphur*, *mercurial earth*, or *volatile sulphur;* and *inflammable earth* was indiscriminately called *combustible sulphur*, *sulphur adustible*, *sulphur ardens*, or *phlogistic sulphur*. J. J. Becher said:

> Combustible sulphur is the innate heat of the metals. . . . The base metals contain an inflammable principle which by the action of fire goes into the air, leaving behind a metal calx.

This recalls the hypothesis promulgated by H. Cardan a century earlier. J. J. Becher supposed the different forms of matter to be compounds of one or more of these elements differently arranged with or without water. G. F. Rodwell,[3] in a valuable article *On the theory of phlogiston*, says that J. J. Becher never used the word φλογίστον as a noun to designate the matter or principle of fire. It was reserved for J. J. Becher's disciple G. E. Stahl, near the beginning of the eighteenth century, to employ the term phlogiston for the *materia ignis* of the early writers.

Towards the end of the seventeenth century, G. E. Stahl sketched an outline of the theory of phlogiston in his *Zymotechnia fundamentalis* (Franckfurth, 1697); and in his *Specimene Becheriano* (Franckfurth, 1702), he elaborated J. J. Becher's *Physica subterranea*, a work which he rated very highly, and vaunted it to be *opus sine pari*—a work without a peer; *primum ac princeps*—first and foremost; *liber undique et undique primus*—a book everywhere supreme; etc. G. E. Stahl also wrote his *Fundamenta chymiæ dogmaticæ et experimentalis* (Norimbergæ, 1723) as a text-book of phlogistic chemistry, and he described in his *Experimenta, observationes, animadversiones, CCC numera, chymicæ et physicæ* (Berlin, 1731), a number of experiments in support of the theory, and answers to some questions. Like the ancients, G. E. Stahl believed in the existence of two kinds of fire: (i) ordinary visible fire, or mundane fire, or gross earthy fire which he called *ignis* or flame; and (ii) pure, subtle, invisible fire, *materia ignis*, or phlogiston, which became *ignis* only when associated with material particles which assimilated its motion. It therefore follows that J. J. Becher's *terra inflammibilis*, *terra pinguis*, *combustible sulphur*, *sulphur ardens*, or *phlogistic sulphur*; and G. E. Stahl's *phlogiston* are new names for an old time-honoured principle. The dominant functions of Descartes' *materia cœlestis* were conferred on phlogiston, and some new properties were added. Phlogiston, said G. E. Stahl, is the *materia aut principium ignis, non ipse ignis*. Although the real nature and properties of phlogiston were unknown, its existence was pure conjecture, yet G. E. Stahl did not hesitate to speak very definitely about this creature of the imagination. He said:

> Phlogiston is a very subtle matter capable of penetrating the densest substances; it neither burns, nor glows, nor is visible; it is agitated by a rapid motion—*igneo motu*—and it is capable of communicating its motion to material particles adapted to receive it. The particles when endowed with this rapid motion constitute visible fire. . . . Fire is an aggregate of a great number of particles in vehement motion. The *materia* of fire is phlogiston—a thin all-pervading medium composed of movable particles—the *forma* is the motion itself; the *materia* is passive, the *forma* is active. The motion of phlogiston is *gyratorius seu verticillaris* and not progressive. . . . Heat is an intestine motion of the particles of matter.

G. E. Stahl taught that in the act of combustion, phlogiston, an intrinsic constituent of every combustible body, was set at liberty. Oxidation was said to be due to the escape of phlogiston; deoxidation or reduction to the absorption of phlogiston. When a metallic oxide was heated with a substance rich in phlogiston —*e.g.* charcoal or reducing agents generally—the charcoal supplied the calx or metallic oxide with phlogiston, and reproduced a compound of phlogiston with the metallic oxide which was the metal itself. Metals were thus supposed to be compounds of phlogiston with their calces or oxides. The noble metals were supposed to have their phlogiston so firmly fixed that nothing can take it from them. While the base metals are turned to calces when roasted in air, the royal metals remain intact during the fiercest trial. If phlogiston escaped, the metallic oxide or calx remained. The idea is symbolized

$$\text{Metal} \rightleftharpoons \text{Phlogiston} + \text{Metal calx or oxide}$$

The body from which phlogiston escapes, when no longer capable of supporting combustion, was said to be *dephlogisticated*, and conversely, the body—solid, liquid, or gas—with which the phlogiston was combined, or by which it was absorbed, was said to be *phlogisticated*. Apparently overlooking the theories of R. Hooke (1664) and J. Mayow (1674), which were developed while Stahl was in the nursery, M. E. Chevreul[4] claimed that *on doit à Stahl la première explication de la combustion*.

The phlogistians are said to have been most assiduous in collecting *instantiæ convenientes*, but very reluctant in accepting *instantiæ inconstantiæ*. G. E. Stahl, by denying that the calx of mercury weighed more than the mercury from which it was derived, sacrificed fact to theory. Phlogistic chemistry was thus established in opposition to facts which at first sight appeared to carry its own refutation, for if the calcination of a metal be attended by the expulsion of phlogiston, the calx should weigh *less* than the metal. When the facts that the loss of phlogiston is always associated with a *gain* in weight, and *vice versa*, became too insistent, and could no longer be denied, G. E. Stahl, in his *Fundamenta chymiæ* (Norimbergæ, 1723), frankly evaded the difficulty by introducing another perplexity. He said:

> The fact that metals when transformed into their calces increase in weight, does not disprove the phlogiston theory, but, on the contrary, confirms it, because phlogiston is lighter than air, and, in combining with substances, strives to lift them, and so decreases their weight; consequently, a substance which has lost phlogiston must be heavier than before.

Thus, the phlogistians said that phlogiston also embodied the principle of levity, and conferred a negative weight upon bodies. Consequently, when phlogiston is associated with matter, the weight is lessened, just as inflated bladders lessen the water-weight of a swimmer.

It may not seem rational to postulate the existence of a substance weighing less than nothing. It will be observed, however, that the assertion, *all matter is heavy and possesses weight*, is one way of saying that the attraction of gravitation exists between all masses of matter. This is by no means a self-evident principle, because it is just as easy to conceive of two masses of matter repelling one another, and easier still to imagine two masses of matter neither attracting nor repelling one another. Thus, G. B. Airy [5] said: "I can easily conceive that there are plenty of bodies about us not subject to this mutual action, and therefore not subject to the law of gravitation." Hence, the assumption of a phlogiston weighing less than nothing is not so silly as is sometimes supposed. If phlogiston be a principle of levity, however, with a negative gravity, it would not be attracted but rather repelled by other substances. Consequently, in order to explain how phlogiston becomes fixed in combustible bodies, it would be necessary to invent another force stronger than gravitation. It is quite true that no form of matter with a negative gravity has been detected, and accordingly, it is assumed that a form of matter weighing less than nothing does not exist, and that, other things being equal, **an increment in weight is necessarily an effect of an increment of matter.**

The era of phlogiston presents serious claims to be regarded as the period when chemistry began to take shape as a definite science. It represented a definite attempt to group diverse chemical phenomena about a rational principle which seemed adequate to embrace the then known facts. The doctrine of phlogiston was invented to render chemical phenomena intelligible to the mind; it was founded on fact; and it owed its value in the minds of a race of eminently practical chemists, to the facts which it represented. New facts soon began to accumulate which could not be explained in terms of the original simple hypothesis, and auxiliary hypotheses were framed in quick succession; these made the theory contradictory and unmanageable. In his *Réflexions sur le phlogistique* (Paris, 1783), A. L. Lavoisier [6] said:

> Chemists have turned phlogiston into a vague principle, one not rigorously defined, and which consequently adapts itself to all the explanations for which it might be required. Sometimes this principle has weight, sometimes not; sometimes it is free fire, sometimes it is fire combined with the earthy element; sometimes it passes through the pores of vessels, sometimes the vessels are impervious to it; it explains both causticity and non-causticity, transparency and opacity; colours and their absence; it is a veritable Protean, changing in form each instant.

A. L. Lavoisier's explanation of the increase in weight which occurs when lead is calcined, seems so obvious that it is now difficult to appreciate the difficulty as set forth by P. J. Macquer (1769) [7]:

> The phenomenon is *un vrai paradoxe chimique*. While it is easy to prove the fact, it

> is difficult to find a satisfactory explanation. The phenomenon is outside all physical ideas which we have formed, and it is only in the future that a solution of the difficulty can be expected.

The chief difficulties encountered in the application of the theory of phlogiston were : (i) The increase in weight which occurs when metals are calcined ; (ii) The necessity for the presence of air during combustion ; (iii) The change of mercury calx into a metal without the addition of phlogiston. In the latter case, P. J. Macquer, indeed, used the fact that mercury calx can be converted into a metal by merely heating it *per se* in the absence of a body containing phlogiston, to argue that the mercury calx is not a real calx, but merely a substance which has acquired *par l'action du feu l'apparence d'une chaux métallique*. P. J. Macquer endeavoured to remove the objection by assuming that phlogiston is light and that during combustion, light and air mutually precipitate one another ; during the calcination of a metal, the air unites with the metal and disengages phlogiston ; and during the reduction of a metal calx, light unites with the metal and liberates air. C. W. Scheele[8] supposed that heat, light, and inflammable air were compounds of air and phlogiston which are convertible into one another by the addition or subtraction of phlogiston—inflammable air was assumed to contain most, and heat least phlogiston. During calcination, the metal either attracted air by means of its phlogiston and thus formed heat, or else communicated phlogiston to the air, and attracted heat from the fire ; in either case the air remained in the calx and imparted an overplus of weight. When a calx is reduced by inflammable air, heat, or light, the latter is decomposed and the phlogiston remains united to the reduced metal. The fact that oxygen supported combustion better than air led to the hypothesis that air contains more phlogiston than oxygen, which was hence called *dephlogisticated air*. At one time H. Cavendish (1766)[9] assumed that inflammable air is itself the phlogiston of the ancient chemists, and that a certain amount is fixed in all combustible bodies. Inflammable air, *i.e.* hydrogen gas, was accordingly called *phlogisticated air*. This hypothesis substituted a definite tangible material for a vague principle, but many of the properties of G. E. Stahl's phlogiston were utterly at variance with those of hydrogen, and the hydrogen hypothesis completely failed.

About 1770, it had been definitely proved that there is an increase in weight during the conversion of a metal into a calx by calcination of the metal in air. The fact was qualitatively explained, somewhat clumsily, by the phlogiston hypothesis which was based upon the *subtilis ignis* of the ancients, or the *materia cœlestis* of R. Descartes. R. Hooke, J. Rey, and J. Mayow had recognized that air somehow plays an important part in the process of calcination and combustion, but while their ideas on the general principle were clear, the details were somewhat hazy and indefinite.

§ 16. Lavoisier's Experiments on Combustion and Calcination

Nature is ever making signs to us, she is ever whispering to us the beginnings of her secrets; the scientific man must be over on the watch, ready at once to lay hold of nature's hint, however small: to listen to her whisper, however low.—M. FOSTER.

The beginning and end of every exact chemical process is weighing.—W. NICHOLSON (1808).

In 1772, Antoine Laurent Lavoisier began to publish accounts of a brilliant series of investigations which in a few short years banished phlogiston completely from chemical science. Chemistry had grown too great to be governed by the mystic phantom—phlogiston. In his *Opuscules physiques et chimiques* (Paris, 1774), A. L. Lavoisier first showed that phosphorus and sulphur increase in weight and absorb large volumes of air when they are burnt, and he obtained similar results with lead and mercury in closed vessels. A. L. Lavoisier pursued the subject further in a *Mémoire sur la calcination de l'étain dans les vaisseaux fermés, et sur la cause de l'augmentation de poids qu'acquiert ce métal pendant cette opération* (1774). He found that the vessel containing the air and tin did not increase in weight, although part of the air was absorbed. When the flask was opened, air rushed in, and the increase in the weight of the vessel was found to be equal to the increase in weight which the tin alone had suffered. Hence, A. L. Lavoisier concluded, with J. Rey, that the increase in the weight of the tin was solely due to an absorption of the air in which the calcination had occurred. There was not sufficient air in the flask to saturate all the tin, and yet some air always remained as a residue. Hence, A. L. Lavoisier concluded further that only **part of the air can combine with the metal during the calcination**; he also found that the increase in the weight of the tin during calcination is equal to the decrease in the weight of the air. Hence, it seems as if air contains at least two constituents, only one of which is absorbed by the heated metal. This inference was tested by an important experiment described in his *Traité élémentaire de chimie* (Paris, 1789).

The mercury was confined in a glass retort with an S-shaped neck which dipped under a bell-jar in a trough of mercury, as illustrated in Fig. 7. The air in the retort was in communication with the air in the bell-jar. The level of the mercury in the bell-jar was adjusted at a convenient level, and its position "very carefully marked with a strip of gummed paper." By means of a charcoal furnace, the mercury in the retort was heated—not quite to its boiling point (357°). A. L. Lavoisier said: "Nothing of note occurred during the first day. The second day I saw little red particles swimming over the surface of the mercury, and these increased in number and volume during four or five days; they then stopped increasing and remained in the same condition. At the expiration of twelve days, seeing that the calcination of the mercury made no further progress, I put the fire out." The red particles were identified with the calx of mercury now called red oxide of mercury, or mercuric oxide, and then called *mercurius calcinatus per se*.

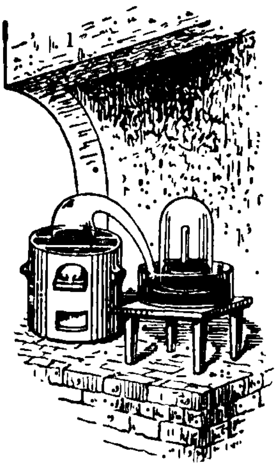

FIG. 7.—A. L. Lavoisier's Experiment on the Combustion of Air.

After making allowance for variations of temperature and pressure, A. L. Lavoisier found that when mercury was calcined with a given volume of air in a closed vessel, 50 cubic inches of air were reduced to between 42 and 43 cubic inches; the difference, 7 to 8 cubic inches, that is, one-fifth or one-sixth of the total volume of the air, was absorbed by the mercury, forming the red calx of mercury. The air which remained in the retort was not absorbed by the excess of hot mercury; it was rather less dense than ordinary air; it extinguished the flame of a burning candle immersed in the gas; and a mouse was quickly suffocated when placed in the gas. Hence, A. L. Lavoisier first called the gas *moufette atmosphérique*, and later **azote,** "from the α privative of the Greeks, and ζωή, life." In France, the gas is still called *azote*, though in Britain it is called *nitrogen*.

By collecting the red mercury calx, and re-heating it in a suitable retort (probably to 400°), Lavoisier obtained between seven and eight cubic inches of a gas which had been previously removed from the air by the hot mercury. The gas was exactly analogous in properties with the *dephlogisticated air*, discovered on August 1st, 1774, by Joseph Priestley, by heating *mercurius calcinatus per se* by means of a burning lens. When a burning candle was immersed in the gas, the candle burnt with *éclat éblouissant*—blinding brilliancy—as Lavoisier expressed it; a smouldering splinter of wood burst into flame when plunged in the gas; and the gas did not suffocate a mouse like azote. A. L. Lavoisier first called this gas *l'air éminemment respirable*, *pur*, *ou vital*, and afterwards *oxygen*. The latter term is its present-day designation. In this manner, A. L. Lavoisier proved that **atmospheric air is made up of two gases—oxygen and nitrogen—of different and even opposite natures, the oxygen alone combines with the metal during calcination, and is the cause of the increase in weight.**

A. L. Lavoisier further showed that the sum of the weights of the mercury and oxygen obtained by heating mercury calx is exactly equal to the weight of the calx; and that the increase in the weight of the mercury in the formation of the calx is equal to the weight of the oxygen taken from the air. In his *Réflexions sur le phlogistique* (Paris, 1783) A. L. Lavoisier said that during the combustion of phosphorus in oxygen gas (vital air):

> There is a total absorption of vital air, or rather of oxygen, in the combustion of phosphorus, and the weight of the phosphoric acid obtained is found to be rigorously equal to the weight of the phosphorus, added to that of the vital air employed in the combustion. The same agreement of weights is observed in the combustion of inflammable air, in the combustion of charcoal, etc.

Hence, the mechanism of combustion according to A. L. Lavoisier is: Metal + Oxygen = Metal calx, and not, as G. E. Stahl supposed to be the case: Metal − Phlogiston = Metal calx. The phenomenon which occurs when oxygen unites with a metal to form a calx is called **oxidation,** and the resulting calx is called an **oxide.** A. L. Lavoisier thus showed that it is not the calces that are simple and the metals compound, but just the reverse; so that the phlogistians have therefore been said to have perceived the relations between these two classes of bodies upside down. In all reductions with charcoal, said A. L. Lavoisier, fixed air is obtained owing to the union of the charcoal with the pure portion of the air—oxygen—which was fixed in the calx during the oxidation of the metal.

> If I take a metallic calx and heat it with carbon in a closed vessel, at the moment the calx is reduced to the metallic state—at the moment, for example, when litharge, the calx of lead, is changed into metallic lead, there reappears the air, which had become fixed when the metallic lead had been made into a calx, and an aerial product—fixed air—can be collected at least a thousand times more bulky than the solid litharge employed. This experiment appears to be one of the most interesting which has been made since the time of Stahl.

Assuming that this interpretation of the experiments is correct, A. L. Lavoisier inferred that by mixing azote and oxygen in the right proportions, it ought to be possible to reproduce atmospheric air. This A. L. Lavoisier did, and the mixture was found to behave with respect to "combustion, respiration, and the calcination of metals similar in every respect to atmospheric air." Lavoisier similarly showed that if the calcination of the metal is attended by the union of the vital air—oxygen—of the atmosphere with the metal, then, when the calcination is effected in an inverted glass vessel containing vital air, the whole should be absorbed. This deduction was "proved by weight and measure."

According to the phlogistians, a lighted candle burns because it is a compound of candle-matter and phlogiston. The compound is decomposed little by little, as the candle burns from tip to base, and the phlogiston passes into the surrounding atmosphere. A. L. Lavoisier inverted *l'ancienne hypothèse.* He supposed the hydrogen and carbon of the candle, during the burning, to unite with the oxygen of the air to form the oxides of carbon and of hydrogen; and generally, when a substance is burned, it does not give out an imaginary levitative phlogiston, but rather takes in real gravitative oxygen.

In his *Mémoire sur la combustion en général* (Paris, 1777), A. L. Lavoisier altogether rejected the principle of combustion advocated by G. E. Stahl, and argued that his own hypothesis "seemed to be more probable, more conformable with the laws of nature, and to involve less strained explanations and fewer contradictions" than the doctrine of G. E. Stahl. About ten years later, A. L. Lavoisier collected and organized such an array of facts in defence of his proposition that he was able to write with much greater confidence in his *Réflexions sur le phlogistique* (Paris, 1783), and he claimed the phlogistic doctrine to be an error fatal to the progress of chemistry:

> If in chemistry everything can be satisfactorily explained without the aid of phlogiston, it thereby becomes eminently probable that phlogiston does not exist, that it is a hypothetical being, a gratuitous assumption.

It is easier to make new discoveries than to eliminate old prejudices. Chemists were painfully slow to recognize the part played by air in combustion and calcination. In his *Réflexions sur le phlogistique* (Paris, 1783), A. L. Lavoisier said:

> Chemists have turned phlogiston into a vague principle, one not rigorously defined, and which consequently adapts itself to all the explanations for which it might be required. Sometimes this principle has weight, sometimes not; sometimes it is free fire, sometimes it is fire combined with the earthy element; sometimes it passes through the pores of vessels; sometimes the vessels are impervious to it; it explains both causticity and non-causticity, transparency and opacity, colours and their absence; it is a veritable Protean, changing in form each instant.

A. F. de Fourcroy began to teach A. L. Lavoisier's theory in 1787; C. L. Berthollet joined the new cause about the same time. Then followed L. B. Guyton de Morveau, and nearly all the French and British chemists. The Berlin Academy abandoned phlogiston in 1792, and the controversy which had waged for some years between the phlogistians was virtually at an end.[1] The downfall of phlogiston, a relic of Egyptian and Chaldean lore, was celebrated by Madame Lavoisier, habited as a Greek priestess, burning the writings of G. E. Stahl upon an altar dedicated to the new positive science. At the beginning of the new century a few petrified spirits, unable to march to the music of the new chemistry, still lingered behind. Robert Boyle's admonition in his *Considerations touching experimental essays in general* (1661), may have been forgotten:

> It ought to be esteemed much less disgraceful to quit an error for a truth than to be guilty of the vanity and perverseness of believing a thing still because we once believed it. . . . Until a man is sure he is infallible it is not fit for him to be unalterable.

The observed facts were sterile and barren before they were vivified by the fire of Lavoisier's genius. Indeed, enthusiasts have said that chemistry as a science was not born until A. L. Lavoisier's theory of burning had been demonstrated. Many writers—*e.g.* S. Brown (1858)[2]—have emphasized that tradition and prejudice were all against A. L. Lavoisier, and however much he owed to his predecessors and contemporaries—J. Rey, P. Bayen, J. Priestley, H. Cavendish, and C. W. Scheele—he scarcely owed them one glimmering ray of thought—rather the reverse. The legacies of fact inherited by A. L. Lavoisier were beclouded and distorted by the false hypotheses through which their discoverers saw them, and it required a master mind to co-ordinate the facts accumulated by many workers into one system. We can feel with A. Wurtz when—following A. F. de Fourcroy (1797)—he opened his *Histoire des doctrines chimiques* (Paris, 1869) thus: *La chimie* *est la science française, elle fut constituée par Lavoisier d'immortelle mémoire;* otherwise expressed, chemistry is a French science, it was founded by Lavoisier of immortal memory. This statement seems to have needlessly irritated some of our own historical writers. Can we wonder that Frenchmen are proud of their Lavoisier? Surely "we can amiably pass without protest this ardent hero-worship."

At first sight, it does seem curious that such a long period of time should have been required to work from P. E. de Sultzbach's note in 1489 to the effect that metals increase in weight when calcined in air, to A. L. Lavoisier's proof in 1774 that the increase in weight is due to the absorption of oxygen from the air. This will occasion no surprise when we remember the difference between the properties of air which cannot be seen, and the properties of solids and liquids which can be readily seen and handled. As G. F. Rodwell has emphasized, the most obvious property of matter is its visibility, and the conception of matter divested of this quality is no small effort to a mind untutored in invisible bodies, which exercise no apparent effect on surrounding objects, and it belongs to an advanced order of experimental philosophy. There were no means of recognizing even the more salient properties of air at the disposal of the chemists until a comparatively late period, and the earlier chemists, accordingly, believed air to be intrinsically different in its essence from more familiar visible substances. To illustrate the ideas about air which prevailed at the end of the eighteenth century, the opening words of A. L. Lavoisier's *Mémoire sur la nature du principe qui se combine avec les métaux pendant leur calcination et qui en augmente le poids* (Paris, 1775) may be quoted:

> Do different kinds of air exist? Is it enough that a body should be permanently expanded for it to be considered a particular kind of air? Are the different airs found in nature or formed by us specific substances, or are they modifications of atmospheric air?

Again, altogether apart from the skill required in the manipulation of gases, it is not at all surprising that writers on chemistry in the Middle Ages failed to interpret the mechanism of the burning of a candle in air when the knowledge required to explain the chemical side of the phenomenon is recalled:

> (i) Air is composed of two gases both sparingly soluble in water; (ii) During combustion one of the gases unites and the other does not unite with the burning body; (iii) Air contains four volumes of the inert gas, and one volume of the gas which unites with the burning body; (iv) A gas soluble in water is produced during the combustion; and (v) The increase in weight of the combustible body during the burning is equal to the decrease in the weight of the air.

The phlogiston hypothesis is sometimes held up to ridicule. It must be borne in mind that the hypothesis was adopted by nearly all the leading chemists in the earlier part of the eighteenth century when it appeared to be as firmly fixed among the root principles of chemistry as the kinetic theory does to-day. Thus, the ardent and devoted J. Priestley could say:

> If any opinion in all the modern doctrine concerning air be well-founded, it is certainly this, that nitrous air is highly charged with phlogiston. If I have completely ascertained anything at all relating to air, it is this;

and the diplomatic P. J. Macquer, in his *Éléments de chymie pratique* (Paris, 1751), that

> We cannot say how phlogiston is fixed by substances; but without pretending to guess the cause of the phenomenon, let us rest contented with the certainty of the fact.

The phlogiston theory represented the most perfect generalization known to the best intellects of its day, and J. J. Becher and G. E. Stahl were the prophets of a new mode of viewing chemical mutations. The doctrine served to give coherence to the thoughts and work of a race of chemists extending from J. J. Becher and G. E. Stahl down to H. Cavendish, J. Priestley, and C. W. Scheele.

The phlogistic hypothesis enabled chemistry to escape in part from mystic and mediæval empiricism,[3] for it introduced a certain amount of order among a chaotic mass of facts. Like phenomena were grouped together, and chemistry thrived and multiplied its proportions while under its sway. Phlogiston prepared the way for A. L. Lavoisier's balance, just as the balance heralded J. Dalton's arithmetic. There is what A. Comte[4] called *la loi de succession* running through history. The early struggles of man in quest of knowledge and truth were not in vain. The sun-worshipper and the phlogistian, each in his own way, had been working to a common end. All generations—past and future—thus seem to be linked in one common service.

It is inconceivable that men like T. Bergmann, H. Cavendish, J. Priestley, and C. W. Scheele would counsel what they considered to be an inconsistent doctrine. Phlogiston was regarded by them, not as a temporary hypothesis, but as a permanent acquisition, an enduring conquest of truth. To-day the word is but an empty symbol.

It must be added that H. St. C. Deville (1860), C. Brown (1866), and W. Odling (1871)[5] have pointed out that phlogiston occupied a similar position in the chemistry of the eighteenth century that potential energy does to-day. Said Deville : *On arrive à admettre que l'affinité (en intensité) n'est pas autre chose que la quantité de chaleur latente ou phlogistique enfermée dans les corps.* Even A. L. Lavoisier, in his *Traité élémentaire de chimie* (Paris, 1. 60, 1793), considered oxygen to be made up of caloric and the matter of oxygen. Lavoisier's *caloric* —a veritable ghost of phlogiston—was supposed to be the matter of heat possessing no weight whatever. Ordinary oxygen thus contained the principle of oxygen plus caloric. The latter has also been identified with potential energy. Here then the old revives in the new. The chemistry of to-day is not materialistic, for it is concerned with both energy and matter.

Theories perish, facts remain.—Much of what we think best in the theories of to-day may to-morrow be rejected, with phlogiston, worthless. There is no reason to suppose that fewer errors are believed to-day than in the days when phlogiston reigned supreme ; and it is not at all improbable that posterity will smile at our inexplicable ignorance in some departments of science. This need cause the student no embarrassment. A fallacious theory may be a valuable guide to experiment. Experiment and labour applied to the explication of the most extravagant hypothesis are not always lost. Guided by wrong hypotheses, men haves ought one thing and found another ; Columbus sought the Indies and found America. W. Whewell has pointed out that when a theory, which has been received on good evidence, appears to fail, the really essential and vital part of it survives the fall, that which has been discovered continues to be true. It is necessary, however, to follow René Descartes advice : **Give unqualified assent to no proposition which is not presented to the mind so clearly that there is no room for doubt.** As Aristotle would have said, we do not need to cultivate the art of doubting, but rather the art of doubting well ; for the art of doubting well is the necessary antecedent of progress. Doubt is the parent of inquiry.

It is not always expedient to follow the history of each hypothesis and each conquest of truth, step by step, as in the case of air. That of course would be an ideal plan of work ; but it is not always a waste of time to study the exploded fallacies once cherished by the potentates of old. The right attitude of mind towards an hypothesis or law can be developed only when history has taught how man has had to climb with slow faltering steps until he obtained a clear view of each new principle of chemical science. J. W. Goethe was quite right : The history of a science is the science itself : The past is key to the present ; although, as A. Comte (1839) expressed it : *On ne connait pas complètement une science tant qu'on n'en sait que l'histoire.* Unfortunately, time cannot always be spared to wander with the original investigators into the byways of knowledge, and a more economical plan must usually be followed. If every one had to pass through all the stages traversed by all who have gone before, it would be impossible to reach the vantage ground gained by the labours of his predecessors.

CHAPTER II

COMBINATION BY WEIGHT

§ 1. What is an Element?

The elements count as simple substances not because we know that they are so, but because we do not know that they are not.—J. von Liebig (1857).

A. L. Lavoisier showed that atmospheric air is no more an elementary principle than the water of the ocean, for it can be resolved into two simpler gases—oxygen and nitrogen. It is further possible to resolve all known substances—air, water, etc.—into about eighty distinct elemental or primitive forms of matter. The present-day concept of an element is one of those ideas which has gradually grown into chemistry. Epicurus, about 300 B.C., held that corporeal things are either composite, or else they are the constituent parts of which the composite things are compounded; and that the continued division of the composite must at last furnish ultimate, indivisible, unchangeable particles of the elements. Aristotle, in his *De cœlo* (**3**. 3), also defined an element. He said:

> Everything is either an element or composed of elements. . . . An element is that into which other bodies can be resolved, and which exists in them either potentially or actually, but which cannot itself be resolved into anything simpler, or different in kind.

This precise and accurate concept was soon beclouded with the idea that all the different varieties of matter observed in nature are composed of a primitive element with varying proportions of wetness or dryness, or of coldness or hotness. This quaternary of attributes gradually materialized into earth, water, air, and fire. All the different forms of matter were vaguely supposed to have been compounded in some inscrutable manner from varying proportions of this quartet.

In 1661, Robert Boyle's attention was arrested by the loose way in which the term element was employed, and in his *The Sceptical Chymist* (Oxford, 1661), he gave a clear concept for an element. He said:

> I mean by elements, as those chymists that speak plainest do by their principles, certain primitive and simple, or perfectly unmingled bodies; which not being made of any other bodies, or of one another, are the ingredients of which all those called perfectly mixt bodies are immediately compounded, and into which they are ultimately resolved. . . . I must not look upon any body as a true principle or element, which is not perfectly homogeneous, but is further resolvable into any number of distinct substances.

N. le Febvre,[1] whom J. B. Dumas called *l'homme d'imagination*, flourished in the seventeenth century about the time of Robert Boyle. N. le Febvre showed that Empedocles' analysis of wood into four elements—flame or fire, smoke or air, moisture or water, and ashes or earth—does not include all the principles of which this form of matter is compounded. By the destructive distillation of wood, he found that water charged with acetic acid and an oily inflammable liquid condensed in the receiver; a gas escaped; and charcoal remained. The charcoal burnt in air, giving fire and ashes; and the ashes were resolved by water into a soluble salt, and an insoluble earth. N. le Febvre thus resolved wood into six ingredients, and he got very near to recognizing that the only proof of an elementary principle is the fact of its yielding nothing else to analysis. He maintained that chemistry is not the doctrine of the four elements, an art of transmutation, or a science of mixts ; but is rather the art of analysis with a view to discover *la connaissance de toutes les choses que Dieu a tirées du chaos par la création*—a knowledge of all the ingredients of all the various kinds of matter which God has created out of chaos.

Even as late as the latter part of the eighteenth century, fire, air, water, and earth were regarded as elemental. Thus, P. J. Macquer, in his *Dictionnaire de chymie* (Paris, 2. 4, 1778), gave a *juste* definition of an element, and added :

> Although fire, air, water, and earth are reputed to be simple, it is possible that they are not so ; they may be very complex, and may result from the union of several other more simple substances . . . but as experience teaches us absolutely nothing on this subject, we may consider without inconvenience, and indeed in chemistry we ought to consider fire, air, water, and earth as *les corps simples*, because they really act as such in all chemical operations.

We are also indebted to A. L. Lavoisier (1789) for further clarifying the concept of an element. A. L. Lavoisier, quite logically, considered lime, magnesia, baryta, and alumina to be elements. We now know that these elements of A. L. Lavoisier are compounds of oxygen with calcium, magnesium, barium, and aluminium respectively. This was not known to Lavoisier, and he rightly said : " We are certainly authorized to consider them simple bodies until, by new discoveries, their constituent elements have been ascertained." Again, in 1811, the question whether chlorine—then called oxymuriatic gas—was really an element or a compound of oxygen with some other element was raised by Humphry Davy. H. Davy claimed that chlorine is an element because, although oxygen was believed to be present, none could be found. " Hence," added H. Davy, " we have no more right to say that oxymuriatic gas (*i.e.* chlorine) contains oxygen than to say that tin contains hydrogen. . . . Until a body is decomposed, it should be considered simple."

It is not possible to improve upon Lavoisier's conception of a chemical element, and I feel compelled to quote his words, although written before 1789 : [2]

> When we apply the term elements or principles to bodies to express our idea of the last point which analysis is capable of reaching, we must admit, as elements, all substances into which we are able to reduce bodies by decomposition. Not that we are entitled to affirm that these substances which we consider as simple, may not themselves be compounded of two, or even of a greater number of more simple principles ; but since these principles cannot be separated, or rather, since we have not hitherto discovered the means of separating them, they are, with regard to us, as simple substances, and we ought never to suppose them compounded until experiment and observation have proved them to be so.

The definition of an element is not founded upon any intrinsic property of the elements, but rather upon the limited resources of the chemist. To find if a given substance is an element or a compound, it is usual to assume that it is a compound and then to apply all known methods for resolving compounds into simple substances. If the methods fail to effect a decomposition, the substance is said to be an element. Hence, the statement that any given substance is an element has been said to be a confession of the impotence of human powers. In fine, element is a conventional term employed to represent the limit of present-day methods of analysis or decomposition.[3] We may, therefore, summarize these ideas in the definition : **An element is a substance which, so far as we know, contains only one kind of matter.** To say the substances we call elements *cannot* be decomposed may be regarded as an unwarranted reflection on the powers of our successors. The moment Auer von Welsbach (1885) proved that didymium was a mixture of praseodymium and neodymium, one element ceased to exist, and two elements were born. If it were found to-morrow that the element chlorine is really a compound of two new elements previously unknown, the fact would be important and it would change the face of chemistry, but it would not render useless any facts we know about chlorine.

The old alchemists sought to transform some of the common metals into gold. Whenever the attempt has been made with materials known to be free from gold, no transmutation has been observed. There is nothing intrinsically absurd in the notion, but at present, no authentic transmutation has been deliberately, or rather intentionally, accomplished. Works like P. J. von Lewinheim Sachs' *Aurum chymicum* (Genevæ, 1702) and K. C. Schmeider's *Geschichte der Alchemie* (Halle, 1832) professed to examine critically the authenticity of the legendary reports by the alchemists of the reality of the transmutation of the metals, and concluded that in some cases the legends are above suspicion, and this in spite of the fact that H. von Osten, in his *Eine grosse Herzstärkung für die Chymisten* (Berlin, 1771), had exposed some forty-five tricks and deceptions practised by alchemical knavery. All the reports now stand discredited. K. C. Schmeider criticized the legends imperfectly, and failed to recognize that fictions may be plausible as well as extravagant. When the evidence has permitted a critical examination, every recorded instance has been traced to a mal-observation; and evidence which cannot be tested is outside the range of scientific methods. In the words of J. M. Wilson (1917), in science, there is no statement of fundamental importance that depends on history or on any testimony which cannot be verified.

The next inquiry arises from the question: What relations subsist between the weights and volumes of the different elements which make up the different kinds of matter known to man ?

§ 2. The Law of Constant Composition—Proust's Law

Nature in her inscrutable wisdom has set limits which she never oversteps.—JEAN REY.

The proportion in which one element can unite with another is fixed by nature, and the power of augmenting or diminishing this *pondus naturæ* is not given to man.—J. L. PROUST (1801).

Attention must now be directed to the singular observation made by Jean Rey (1630) that during the calcination of a metal in air, "the weight of the metal increased from the beginning to the end, but when the metal is saturated, it can take up no more air. Do not continue the calcination in this hope: you would lose your labour." The examples previously quoted—Cap. I, Table I—have shown that one gram, and only one gram, of air is absorbed by definite amounts of the given metals under the conditions of the experiment, and Lavoisier's work proves that the *oxygen* of the air is alone absorbed. Accordingly, one part by weight of oxygen is equivalent to 1·52 parts magnesium; 4·06 of zinc; 1·12 of aluminium; 3·97 of copper; and 3·72 of tin. Instead of taking the weight of oxygen unity, it will be more in accord with general usage to make oxygen 8. Hence, multiply the preceding numbers by 8:

Oxygen.	Magnesium.	Zinc.	Aluminium.	Copper.	Tin.
8	12·16	32·48	8·96	31·96	29·76

When magnesium is calcined in the presence of oxygen, or air, the metal always unites with the oxygen in the proportion of one part of oxygen per 1·52 parts of magnesium, or 8 parts by weight of oxygen per 12·16 parts by weight of magnesium. The same principle obtains when magnesium oxide is made in several different ways; and likewise with the other metallic oxides. The proportions in which two elements unite together do not vary in a fortuitous manner, but in fixed and definite proportions. Hence, as P. J. Hartog[1] puts it: **two like portions of matter have the same composition.** The converse of this statement is not necessarily true, for two portions of matter compounded from the same proportions of the same elements are not necessarily alike.

The exact work of J. S. Stas[2] and T. W. Richards and many others has firmly established the constancy of the composition of the regular type of chemical compounds. J. S. Stas, in his famous *Recherches sur les lois des proportions chimiques* (1860–65), for example, studied among other things, the composition of silver chloride prepared by four different processes at different temperatures. He found that 100 parts of silver furnished 132·8425, 132·8475, 132·8480 parts of silver chloride; and that neither the temperature nor the method of preparation had any influence on the composition of the chloride. The difference between the two extremes is less than 0·006 part per 100 parts of silver. This shows that the errors, incidental to all experimental work, are here remarkably small. J. S. Stas likewise proved that ammonium chloride prepared from quite different sources, and purified in different ways, always contains exactly the same proportion of chlorine. Still further, he proved that *the combining weight of an element is not affected in the slightest degree by the various elements with which it might combine.* For example, silver combines with iodine to form the iodide, and with iodine and oxygen to form the iodate. The ratio of silver to iodine in both compounds is the same, and is not modified by the large quantity of oxygen present in the iodate. Hence, J. S. Stas stated: "If the recognized constancy of stable chemical compounds needed further demonstration, I consider the almost absolute identity of my results has now completely proved it."

The law of constant proportions, however, can never be proved with mathematical exactness. However skilful a chemist may be, it is impossible to make an exact measurement without committing an error of observation or an error of experiment. It is assumed that the small difference 0·005 per cent. between the two extreme results of J. S. Stas (1) is wholly due to the unavoidable errors of experiment, for we cannot expect an exact solution of the problem; and (2) is not due to a very slight inexactitude in the law of constant proportions. In 1860, J. C. G. de Marignac considered that the experiment did not prove definitely that the composition of compounds might not vary within very minute limits:

> I do not consider that it has been absolutely demonstrated that chemical compounds do not normally have an excess of one of the constituents. It is true that this excess is very minute, but it is still appreciable in very delicate measurements.

The composition of a definite compound appears to be independent of its mode of formation, and therefore it is inferred that substances always combine in definite proportions. If an excess of one substance be present, the amount in excess remains uncombined as extraneous matter. This deduction from the observed facts is called **the law of definite proportions,** or **the law of constant composition.** The law is sometimes enunciated: *a particular chemical compound always contains the same elements united together in the same proportions—by mass.* This statement, if interpreted literally, holds good for a particular mixture, as well as for a particular compound; and it has nothing to say as to the distinction between a mixture and a compound. Probably no generalization in chemistry is more firmly established than that like compounds possess the same quantitative composition. So great is the faith of chemists in the truth of this generalization that a few accurate and careful experiments are considered sufficient to settle, once for all, the composition of a substance. For instance, if a substance possessing all the properties of magnesium oxide be given to a chemist, without taking any more trouble, he knows that it will contain 12·16 parts of magnesium for every eight parts of oxygen. The law of constant composition furnishes a kind of *a priori* control over quantitative analysis. Constancy in composition is regarded as a proof of purity, and purity is attended by constancy in composition. Hence arose the concept of a **chemical compound** as distinct from a mixture.[3]

§ 3. History of the Law of Constant Composition

Ce n'est que du conflit des opinions contraires que jaillit la vérité.—F. Hoefer (1843).

The law of constant composition was not discovered by any particular man, but it gradually grew among the doctrines of chemistry. The law was tacitly accepted by many before it was overtly enunciated. This is shown by J. Rey's views (1630), previously stated. In 1699, G. Homberg,[1] in his *Observations sur la quantité d'acides absorbés par les alcalis terreux*, described measurements of the amounts of different acids (vinegar, spirits of salt, aqua fortis, and vitriolic acid) required to saturate a given amount of potassium carbonate (salt of tartar); he evaporated the saturated liquid to dryness and weighed the resulting solid. His results were compiled in the form of a table which has been regarded as embodying the first hint of the law of definite proportions. G. Homberg considered that the quantity of an acid which unites with an alkali is *la mesure de la force passive de cet alcali*, and further added that by *la force des acides* he means the solvent action of the acid, and similarly for the alkalies. F. Hoefer (1843) suggests translating G. Homberg's "solvent action" by "neutralizing," and "solubility" by "neutralizable." Isaac Newton referred to the saturation capacity of acids for different metals in the thirty-first query of his *Opticks* (London, 1704). G. E. Stahl also in his *Fundamenta chymiæ* (Norimbergæ, 1723) spoke of the *pondus naturæ* as the proportions which ought to exist between the masses of the different ingredients in order that a determinate compound be produced. In 1717, E. F. Geoffrey analyzed saltpetre and stated its quantitative composition. A. S. Marggraf (1749); H. T. Scheffer (1750); T. Bergmann (1775-84); R. Kirwan (1790-1800); J. Black (1794); M. H. Klaproth (1795); V. Rose (1803-5); C. F. Bucholz (1799-1802); and L. N. Vauquelin (1812) all based analyses of chemical compounds on the tacit assumption that this law is valid; and W. Higgins' theory of atoms (1789) implies that chemical compounds must have a constant composition. A. L. Lavoisier appears to have had no doubts on the subject. In every oxide, said he, the relation of oxygen to the metal is constant.

In 1767, H. Cavendish said that those quantities of bases—*e.g.* potash and lime—are equivalent which neutralize the same amount of acid; and, in 1788, he showed that this equivalency is independent of the nature of the acid. C. F. Wenzel (1777) had a fairly clear idea that a definite weight of a base neutralized a definite amount of a given acid, and in his *Lehre von der Verwandschaft der Körper* (Dresden, 1777), he gave measurements of the weights of over twenty metals and bases which were required to saturate about a dozen acids; and he also examined quantitatively the products of some reactions—*e.g.* copper sulphate and lead acetate; mercuric sulphide and silver chloride; etc. Shortly after C. F. Wenzel's book had appeared, J. B. Richter, in an important study of this subject, published evidence in his *Ueber die neueren Gegenstände der Chemie* (Breslau, 1791-1802), and in his *Anfangsgründe der Stöchyometrie oder Messkunst chymischer Elemente* (Breslau, 1792-4), which demonstrated conclusively that the weights of the various acids which neutralize certain fixed weights of the bases are the same; and the same numbers hold good for the neutralization of all acids by the bases; otherwise expressed: **Acids and alkalies unite in constant proportions to form salts**—this is **Richter's law of proportionality,** or *Richter's law of equivalent ratios.* Consequently, it is possible to assign equivalent numbers to the acids and bases. For instance, using modern data and terms :

Acids.	Equivalent weight.	Bases.	Equivalent weight.
Hydrofluoric acid	20·01	Ammonium hydroxide	35·05
Hydrochloric acid	36·47	Calcium hydroxide	37·06
Sulphuric acid	49·04	Sodium hydroxide	40·01
Nitric acid	63·02	Potassium hydroxide	56·00

J. B. Richter gave separate tables for the neutralization equivalents of each acid and each base ; but G. E. Fischer, in an appendix to his German translation of C. L. Berthollet's *Recherches sur les lois de l'affinité,* showed that J. B. Richter's data could be reduced to a single table containing twenty-one numbers divided into two columns as just indicated. These tables can be regarded as the first **tables of equivalent weights** published. The weights of the acids in one column represent the amounts required to neutralize the quantity of any of the bases indicated in the other column ; and conversely, the weights of the bases in the second column represent the amounts required to neutralize the quantity of any one of the acids indicated in the first column. Thus 56 grams of potassium hydroxide will neutralize 20·01 grams of hydrofluoric acid, 36·47 grams of hydrochloric acid, 49·04 grams of sulphuric acid, 63·02 grams of nitric acid, etc., and 63·02 grams of nitric acid will neutralize 35·05 grams of ammonium hydroxide, 37·06 grams of calcium hydroxide, etc. Richter claimed that the rule he gave is a true touchstone—*Probierstein*—for the proportions wherewith the acids and bases neutralize one another, because if the observed numbers do not agree with those demanded by the rule, they may be regarded as erroneous.

J. B. Richter mixed up much valuable work with several fantastic hypotheses ; he supposed that the weights of the bases required to neutralize a constant weight of acid are in arithmetical progression ; and the weights of the acids required to neutralize a constant weight of any base are in geometrical progression. Richter appears to have cooked some of his results to make them fit his erroneous hypothesis so that the numbers represent what he thinks he ought to have obtained rather than what he actually observed. Such a procedure is quite antagonistic to the spirit of science, and made chemists reasonably sceptical about the accuracy of the whole of Richter's work. It was thought, wrongly as it happens, *falsus in uno, falsus in omnibus* (false in one, false in all). Consequently, the above generalization did not attract the attention it deserved. On reading J. B. Richter's work on chemical ratios, said J. J. Berzelius (1827), we are astonished that the further study of the subject could ever have been neglected.

It must be added that the validity of the law of definite composition was the subject of an interesting controversy during the years between 1800 and 1808. J. L. Proust [2] maintained that constant composition is the invariable rule ; C. L. Berthollet did not assert that cases of constant composition are non-existent, but he argued that these instances were due to special circumstances, and maintained that constant composition is the exception, variable composition the rule. J. L. Proust's words are worth quoting :

> According to my view, a compound is a privileged product to which nature has assigned a fixed composition. Nature never produces a compound even through the agency of man, other than balance in hand, *pondere et mensura.* Between pole and pole compounds are identical in composition. Their appearance may vary owing to their manner of aggregation, but their properties never. No differences have yet been observed between the oxides of iron from the South, and those from the North ; the cinnabar of Japan has the same composition as the cinnabar of Spain ; silver chloride is identically the same whether obtained from Peru or from Siberia ; in all the world there is but one sodium chloride ; one saltpetre ; one calcium sulphate ; and one barium sulphate. Analysis confirms these facts at every step.

It might be thought that positive assertions of this kind, backed by accurate experimental work, would leave no subject for disputation; but, surveying the battlefield in the light of the present-day knowledge, it seems that another quite different phenomena was confused with the law of constant composition; and the methods of analysis were not very precise. Some, probably from the unfounded belief that "Proust deservedly annihilated Berthollet," call the generalization discussed in this chapter, **Proust's law.** The arguments against the law of constant composition was silenced not by J. L. Proust, but by the work which developed from J. Dalton's atomic theory.[3] J. L. Proust did not satisfactorily answer all C. L. Berthollet's objections.

According to C. Daubeny (1850) it has been stated that something like the theory of constant composition can be found among the dogmas of the old sage Pythagoras (*c.* 520). This philosopher is sometimes supposed to have derived what is the most valuable part of his philosophy from the Egyptian priests during his sojourn in Egypt. Pythagoras taught that number—whatever was meant by that term—is a bond sustaining by its power the permanent existence of everything on the earth. The influence of Pythagoras has been traced in the doctrine laid down by Philo the Jew—or who ever wrote the apocryphal book of wisdom—God ordained all things by measure, number, and weight. It is, however, certain that European chemistry is in no way indebted to the Egyptian priesthood or to the Pythagorean philosophy for the concept of the law of constant composition. It would indeed require the exercise of a good deal of ingenuity to disentangle the law of chemical combination from the conflicting statements which have been made as to the meaning to be attached to Pythagoras' doctrine of numbers.

F. Wald (1895–9)[4] argues that the composition of chemical compounds is variable, and that the observed constancy in the composition of chemical compounds must be attributed to the selection by chemists of special preparations. Hence, says F. Wald, the statement of the law of constant composition is quite empirical, and the assumption that these selected preparations are alone true compounds is quite arbitrary.

§ 4. Pure Substances

> Pure water is never found in nature. One may even say that no man has ever seen or handled absolutely pure water. It is an ideal substance, to which some specimens of highly purified water have nearly approached.—M. M. P. MUIR.
>
> It is only in "tall talk" or in advertisements that any human preparation, elementary or not, can be spoken of as *chemisch rein*.—P. G. TAIT (1881).

The substance we call water has its own properties, but sea-water, spring-water, rain-water, and distilled water show certain differences in their properties. The differences, however, are not due to the water, but to the substances—impurities—which the water has dissolved from its surroundings. If sea-water be distilled, the "impurities"—sodium chloride, magnesium chloride, etc.—remain behind. Sea-water is therefore a homogeneous substance, but, rightly or wrongly, it is often stated to be a mixture, because water and various salts can be separated by simple evaporation or by freezing. Table salt is more or less impure sodium chloride. The presence of a little magnesium chloride in table salt makes the salt more hygroscopic, so that the contaminated table salt deliquesces more readily than if magnesium chloride were absent.

The term **deliquescence**—from *deliquescere*, to melt or dissolve—refers to the process of absorbing moisture from the air so that a salt becomes moist, or even dissolves in the moisture it has absorbed from the air; *e.g.* when potassium carbonate is exposed to the atmosphere it rapidly gains in weight. The term **hygroscopic**—from *ὕγρος*, wet—refers to the absorption or adsorption of moisture from the atmosphere. Most substances, particularly when powdered, are hygroscopic, even if they do not deliquesce. The term **efflorescence** from *efflorescere*, to blossom, refers to the formation of a crust—generally white—on the surface of a body. The phenomenon is very often due to the loss of water from the surface of certain crystalline salts; *e.g.* when crystals of washing soda are exposed to a dry atmosphere, they gradually lose weight.

Air is a mixture of oxygen and nitrogen, with a little carbon dioxide, and it is habitually moist owing to the presence of a varying proportion of water vapour. In a chapter contained in J. B. Porta's *Magiæ naturalis* (Naples, 1589), on the extraction of water from air, it is shown that if a large glass flask be filled with a mixture of ice and nitre, water condenses from the air to the outer walls of the vessel, and trickles down into a basin below as receiver. Isaac Newton[1] said that potassium carbonate deliquesces in air because of an attraction between the salt and the particles of moisture in the atmosphere, and asked: Why does not common salt or nitre deliquesce in the same way except for want of such an attraction? In H. B. de Saussure's *Essais sur l'hydrométrie* (Neuchatel, 1783) there is an excellent study of the moisture which is normally present in atmospheric air. He exposed "equal quantities of salt of tartar, quicklime, wood, lime, etc., all dried as perfectly as possible," to the same air, and found that they "imbibed water and increased in weight in unequal quantities." The salt of tartar took more than the lime, and the lime more than the wood. H. B. de Saussure said that "these differences can only proceed from the different degrees of the affinity of these bodies for water," and he called this affinity, the *hygroscopic affinity* of the bodies for the vapour, so that the amount of vapour imbibed by different substances from the air "is proportional to their affinity for water vapour." H. B. de Saussure also showed that the thirst or the attractive force of the body for aqueous vapour diminishes from moment to moment "in proportion as it drinks the vapour," otherwise expressed, the hygroscopic activity of the body diminishes in proportion as it approaches the point of saturation.

Lavoisier's experiments on the transformation of water into earth.—A compound may be contaminated with impurities in many ways—from the raw materials used in preparing the compound; from the vessels in which it was prepared or stored; by exposure to the atmosphere; by the partial decomposition of the substance when exposed to light, etc. It was once believed that air can be condensed to water, as was thought to be proved by the falling dew; and that water can be changed into an earth, as is evidenced by the residue obtained when rain-water or distilled water is evaporated to dryness in glass vessels. Thus, O. Borrichius in his *Hermetis, Ægyptorum et chemicorum sapientia* (Hafniæ, 1674), said that "when 100 pounds of snow, hail, or of rain-water, are evaporated, the water is transformed into a dusty earth which contains some common salt;" R. Boyle[2] found on distilling and re-distilling pure rain-water, time and again, in glass vessels, a white powdery substance was obtained each time the water was evaporated; and the more the water distilled from a given glass vessel, the larger the amount of white powder. He added that a friend, of unsuspected credit, had distilled water two hundred times "without finding the liquor grow weary of affording the white earth." It seemed to him as if water "might be very nigh totally brought into earth, since out of an ounce of distilled rain-water he had already obtained nearly three-quarters of an ounce, if not more, of the often-mentioned earth." A. L. Lavoisier[3] first traced the true source of this earth. In his paper *Sur la nature de l'eau et sur les expériences par lesquelles on a prétendu prouver la possibilité de son changement en terre* (1770), A. L. Lavoisier described experiments with the object of "settling by decisive experiments whether water can be changed into earth as was thought by the old philosophers, and still is thought by some chemists of the day." By heating water in hermetically sealed glass vessels, after some days, the water became turbid and little white specks separated from the water and floated about. The hermetically sealed glass vessels were weighed before and after the experiment; it was proved: (1) The earth does not come from outside the vessel, because the weight of the vessel *and* its contents does not alter. This is against Boyle's hypothesis that fine igneous particles are able to pass through the glass, and are precipitated in the form of a white powder when they come in contact with water.

> Consequently, I conclude that nothing can pass through the pores of the glass, and these little white particles, be they caused by what they may, are not caused by igneous particles passing through the glass.

Still further, it was shown (2) The earth does not come from the water, because the weight of the water remains the same before and after the experiment; (3) The earth comes from the vessel, because the vessel loses in weight; and (4) The earth comes *wholly* from the vessel, because the loss in weight of the vessel is virtually equal to the weight of the earth formed. Hence, adds Lavoisier, "it follows from these experiments that the greater part, possibly the whole of the earth separated from rain-water by evaporation, is due to the solution of the vessels in which the water has been collected and evaporated." C. W. Scheele (1777) [3] deduced a similar conclusion from other experiments. He analyzed the earth produced during the evaporation of water in glass vessels and showed that it has a similar composition to the stuff of which the vessel was made.

R. F. von Walther (1915) has an interesting experiment to demonstrate the solubility of glass in water, 500 c.c. of water are placed in a common litre flask with sufficient alizarine to produce a pale yellow colour, the colour changes to a reddish-violet owing to the dissolution of alkali from the glass. By adding dilute sulphuric acid from a burette, the colour changes back to pale yellow when the alkali is neutralized. He found that after an hour's boiling, alkali equivalent to 18·3 c.c. of centinormal sulphuric acid had been dissolved from a glass vessel.

The purity of commercial compounds.—The term *pure* or *chemically pure*, is unfortunately used when it is desired to emphasize the fact that the substance has not sufficient impurity to influence appreciably the most exact work for which it is to be employed. There cannot be degrees of purity. A thing is either pure or impure. It may be convenient to use terms like highly pure, all but pure, very impure, etc., but the term, chemically pure, in the sense of nearly pure, is objectionable. This recalls Basil Valentine's statement that water exists in three degrees of excellence—the pure, the purer, and the purest! The labels on commercial reagents with their *pure*, *purissimum*, and *chemically pure*, are almost equivalent. F. Mylius [4] proposed distinguishing degrees of purity as of the first, second, and sixth grades according as they contain one part of total impurity in 10, 10^2, . . . 10^6 parts.

The terms *reagents* and *chemicals* are applied to the substances used in chemistry for producing special reactions with other substances. The former term is more particularly used in analytical work. Chemically pure substances, paradoxical as it may seem, are sold with a statement on the labels indicating what impurities are present as well as how much of each. *Commercial* reagents, on the other hand, have not been specially purified, and hence are sold at a cheaper rate than the chemically pure substances. Purification is an expensive operation, and the cheaper commercial reagents are used whenever specially purified materials are not required. Some hold that "perfectly pure substances are unknown." This is possible, but to establish the proposition, we should be involved in a metaphysical discussion, and we might be led to say with A. Laurent: "Chemistry is the science of substances which do not exist," or perhaps with G. W. F. Hegel: "Pure being is pure nothing."

Positive and negative evidence.—One positive proof may demonstrate an indefinite number of negatives. Thus, if a test proves that a given substance is silver chloride, it at the same time proves that the substance is not metallic copper, arsenic oxide, etc. On the other hand, **inability to prove a direct negative is not to be regarded as equivalent to a positive proof.** Thus, let it be asserted that a third substance, say moisture, must be present when two substances interact chemically. Against this, it can be shown that substances like mercury and chlorine do react when most carefully purified and dried; but it could be, and has been argued that this circumstance is due to the presence of an unrecognized impurity. Similarly, some argue that if the elements could be obtained absolutely free from unknown impurities their atomic weights would be whole numbers. Negative arguments of this type are invulnerable in controversies because they cannot be controverted by proofs to the contrary. True, the most skilful workers with the most refined instruments cannot find an impurity, but still, it can be asserted that better equipped searchers *might* be more successful. This *might*, however, does not prove the thesis in question. Nevertheless, the argument is often used. For instance, H. Davy's quest for oxygen in chlorine; T. Bergmann's proof of the individuality of nickel; W. Ostwald's statement that catalytic agents can change only the velocity of existing reactions; etc.

The effect of traces of impurity on the properties of a compound.—It may be well to emphasize, just here, that sometimes a minute trace of impurity is of vital importance. Some reactions proceed quite differently in the presence, and in the absence of traces of moisture or maybe other impurities. The properties of many substances, too, are modified in a remarkable manner by small traces of impurity. H. Vivian says that $\frac{1}{1000}$th part of antimony will convert the best selected copper into the worst conceivable; Lord Kelvin, that the presence of $\frac{1}{1000}$th part of bismuth in copper would reduce its electrical conductivity so as to be fatal to the success of the submarine cable; H. le Chatelier, that the absorption of a quite imperceptible weight of gas changes the melting-point of highly purified silver nearly 30°; G. le Bon (1900) that the presence of $\frac{1}{10000}$th part of mercury in magnesium makes the metal decompose water at ordinary temperatures; and W. C. Roberts Austin, that $\frac{1}{500}$th part of bismuth in gold will render gold useless from the point of view of coinage, because the metal would crumble under pressure in the die. J. F. W. Herschel (1851) considered the fact that such minute proportions of extraneous matter should be found capable of communicating sensible properties of a definite character to the bodies with which they are mixed, to be perhaps one of the most extraordinary facts that has appeared in chemistry.

§ 5. Physical and Chemical Changes.

> **Most of the substances belonging to our globe are constantly undergoing alteration in sensible quantities, and one variety becomes as it were transmuted into another. Such changes, whether natural or artificial, whether slowly or rapidly performed, are called chemical. Thus, the gradual and almost imperceptible decay of the leaves and branches of a fallen tree exposed to the atmosphere, and the rapid combustion of wood in our fires, are both chemical operations.—H. DAVY.**

The early chemists did not clearly distinguish between uniform mixtures and homogeneous compounds so that many substances now known to be mechanical mixtures were classed with substances known to be homogeneous compounds; again, owing to the fact that they were seldom able to prepare compounds of a high degree of purity, the properties of compounds seemed more or less variable. Even so late as the end of the seventeenth century, chemists were not all clear that substances could be obtained with fixed and invariable properties. The properties of a substance are those qualities, or attributes, by which its nature is manifested. About 1730, H. Boerhaave distilled mercury five hundred times with the idea of finding if its properties thereby suffered any change. About this time, it was recognized that a homogeneous pure substance always has the same properties and behaves in the same way, when the conditions are the same; and generally, that **one element or compound is distinguished from all other elements or compounds in possessing certain specific and characteristic properties**; or, in the words of an old alchemist: " God hath sealed each substance with a particular idea."

First and foremost, a chemical compound has a fixed and definite composition; then again, a compound or element usually melts and boils at definite temperatures; its specific gravity, specific heat, crystalline form, colour, odour, behaviour when in contact with other substances, etc., are characteristic of one particular chemical compound. When the melting-point of, say, pure silver chloride has been once accurately determined, it follows that all other samples of pure silver chloride will melt at the same temperature under the same conditions. Many changes in the properties of matter are not immediately perceptible to the senses; and in the majority of cases, the processes for the identification and differentiation of the different forms of matter are based upon their behaviour towards certain reagents. The more salient characteristic properties of an element or compound are employed for its identification—that is, for distinguishing it from other known elements or compounds. Thus, a student would be probably correct in stating that a solution contained a silver compound if it gave a white precipitate when acidified with hydrochloric acid, and the precipitate was insoluble in hot water, and soluble in aqueous ammonia; and if the spectrum of a burning body has a yellow line in a particular part, the presence of sodium would be inferred. About 1661, Robert Boyle[1] noticed many examples of the use of chemical reagents for the detection or identification of certain substances, and in 1780, T. Bergmann collected together a number of reagents useful for detecting the commoner elements or acids, and described the effects produced. M. H. Klaproth, L. N. Vauquelin, J. J. Berzelius, F. Wöhler, H. Rose, C. R. Fresenius, and others built upon this foundation the present system of qualitative analysis.[2]

Physical changes.—When liquid water becomes ice or steam there is no change in the *chemical* nature of the substance, for the matter which makes steam and ice is the same in kind as that of liquid water. A substance can generally change its state, as when liquid water becomes steam or ice. The idea is further emphasized by the fact that in most cases a substance is called by the same name, whether it be in a solid, liquid, or gaseous state of aggregation. For instance, we speak of *liquid* oxygen, *liquid* air, *molten* silver chloride, etc. Again, matter may change its *volume* by expansion or contraction; it may change its *texture*, as when a porous solid is fused to a vitreous mass; it may change its *magnetic qualities*, as when a piece of soft iron in contact with a magnet attracts other pieces of iron, etc. It is conventionally agreed to say that in none of these cases of physical change is there any evidence of the formation of a new substance; and that the matter does not lose or change those properties which distinguish it from other forms of matter. **A physical change involves an alteration in the properties of a substance without the formation of a new substance.**

Chemical changes.—When magnesium metal is heated in air, a white powder is formed, and when mercuric oxide is similarly treated, mercury and oxygen are obtained. The action of heat in both cases furnishes forms of matter with very different specific properties from those forms of matter employed at the start. **A chemical change involves the formation of a fresh substance with different**

specific properties from the original substance or substances. In both chemical and physical changes the total *weight* of matter before and after the change remains constant, but in chemical changes alone the *kind* of matter alters.

It is not always easy to distinguish between physical and chemical changes, because the only real distinction between the two turns on the question: is there any evidence of the formation of a new substance during the change? The evidence, as we shall soon see, is not always conclusive. When red mercuric iodide is heated above 126° it turns yellow, and the red colour is resumed on cooling. Two chemical changes are involved, because the new substance produced on heating the iodide re-forms the original compound on cooling. So, when water is heated, complex aggregates of simple particles are riven asunder to again coalesce or associate together on cooling. To the physicist, with his attention fixed on the temperature, or volume, the heating of water is a physical process; to the chemist, with his attention on the nature of the constituent particles, it is a chemical process, because when heated the particles of water become less and less complex as the temperature rises. What we call a body, said E. Mach, is a complex of properties which affects the senses in different ways. . . . One or more properties of the complex are altered in a physical change, while in a chemical change, the whole complex is affected.[3]

The distinction between chemical and physical changes is a subject for the end, not the beginning of chemistry. It is remarkable that the first principles of a science are really the most difficult to grasp, because, said J. F. Ferrier, that which is first in the order of nature, is last in the order of knowledge:

> The apotheosis and final triumph of the human reason will be, when, having traversed the whole cycle of thought, she returns—enriched only with a deeper insight and clearer consciousness—to be merged in the glorious innocence of her primitive and inspired *incunabula*.

§ 6. Compounds and Mixtures

> The common operations of chemistry give rise in almost every instance to products which bear no resemblance to the material employed. Nothing can be so false as to expect that the qualities of the elements shall be discoverable, in an altered form, in the compound.—W. WHEWELL (1840).

In his *De generatione et corruptione*, Aristotle regarded the difference between what we call to-day physical and chemical mixtures, as dependent on the distinction between what is potential and what is actual. Aristotle recognized a form of combination—now called physical mixture—in which the elements were supposed to exist actually; and another—chemical combination—in which the elements were supposed to exist potentially—*e.g.* the elements oxygen and hydrogen exist actually as such in a free state, but in water they exist potentially, for they can be educed and become actual only by the destruction of the water or of that special form which in water they actually possessed.[1] Consequently it may be said what is actually one substance may be potentially another. In a mere mixture, said Aristotle, you have only mixture, juxtaposition or σύνθεσις; but in chemical combination you have a mingling or μίξις where the elements disappear as such, but they still remain potentially. This kind of combination—chemical combination—is defined very well by Aristotle as "the unification of mingled elements that have changed their nature as elements."

1. The constituents of a compound are combined in definite proportions.—The law of constant proportions is of fundamental importance in forming a conception of the meaning of the term "chemical compound." If a substance produced in different ways be not constant in composition, it is not considered to be a chemical compound, but rather a mixture. R. Bunsen (1846), for example, showed that the proportion of oxygen to nitrogen in atmospheric air is not constant, because the oxygen varies from 20·97 to 20·84 per cent. by volume, by methods of measurement with an error not exceeding 0·03 per cent. Hence, the oxygen and nitrogen in atmospheric air are said to be simply mixed together, and not combined chemically. The so-called eutectic mixtures and cryohydrates show that substances with a definite composition are not always chemical compounds.

2. Compounds are homogeneous, mixtures are usually heterogeneous.—It is comparatively easy to detect particles of sugar and sand in a mixture of the two; and a simple inspection of a piece of Cornish granite will show it is a mixture of at least four constituents—silvery flakes of mica; black patches of schörl; whitish crystals of felspar; and clear glassy crystals of quartz. Although the particles of felspar, mica, schörl, and quartz differ from one another in size and shape, no essential difference can be detected in the composition and properties of different samples of pure quartz, felspar, mica, and schörl. Hence, it is inferred that the sample of granite is a mixture of schörl, felspar, quartz, and mica; and that each of these minerals is a true chemical compound. Very frequently the constituents of a mixture are too small to be distinguished by simple inspection, and the body appears homogeneous. A microscopic examination may reveal the heterogeneous character of the substance. Blood and milk, for instance, appear to be homogeneous fluids, but under the microscope the former appears as a colourless fluid with red corpuscles in suspension; and milk appears as a transparent liquid containing innumerable white globules (fat). Naturally, too, the stronger the magnification, the greater the probability of detecting whether the body is homogeneous or not. Sometimes the microscope fails to detect non-homogeneity under conditions where other tests indicate heterogeneity.

Before constant composition can be accepted as a proof of chemical combination, it must also be shown that the substance is homogeneous. Chemical individuals are homogeneous. **A homogeneous substance is one in which every part has exactly the same composition and properties as every other part.** A substance may have a fixed and constant composition and yet not be homogeneous—*e.g.* cryohydrates and eutectic mixtures to be described later. A substance may be homogeneous, for all we can tell to the contrary, and yet not have a constant composition—*e.g.* atmospheric air; a solution of sugar in water, etc. This simply means that **all chemical compounds are homogeneous, but all homogeneous substances are not chemical compounds.** Indeed, it is sometimes quite impossible to tell by any single test whether a given substance is a mixture or a true chemical compound. It is therefore not satisfactory to classify matter into (i) homogeneous bodies (meaning elements and chemical compounds), and (ii) mixtures, because some mixtures would have to be included with homogeneous bodies. It might also be added that the term *substance* is used in chemistry in two ways: It is employed as a synonym for body or matter, and also for a specific form of matter which is chemically homogeneous.[2]

3. The constituents of a mixture can usually be separated by mechanical processes.—The properties of a mixture of finely powdered iron and sulphur have been used in chemical text-books from the beginning of the nineteenth century in order to illustrate the difference between mixtures and compounds. It would be difficult to find a better example. If a mixture containing, say, 6 grams of iron and 4 grams of sulphur be rubbed in a mortar, (1) the colour of the mixture is intermediate between the colour of the iron and of the sulphur; (2) the particles of iron and sulphur can be readily distinguished under the microscope; (3) most of the iron can be removed without difficulty by means of a magnet; and (4) the two constituents can be separated quite readily by washing the mixture on a dry filter paper by means of carbon disulphide. The sulphur dissolves in the carbon disulphide; and the former can be recovered by evaporating the carbon disulphide from the filtered solution. Sulphur remains behind as a crystalline residue. The metallic iron remains on the filter paper. Here then the constituents of the mixture have been separated by the mechanical processes—(1) magnetting, and (2) the action of solvents.

In 1826, J. J. Berzelius published analyses of the precipitate obtained when hydrogen sulphide is passed into a slightly acid solution of a salt of tellurous acid, and these showed that the proportions of sulphur and tellurium satisfied the law of constant composition, and hence J. J. Berzelius inferred that a true chemical compound—tellurium sulphide—was formed. Accordingly, tellurium sulphide—with its method of formation and a description of its chemical and physical properties—was regularly described in chemical literature. This sulphide is now considered to be a myth, because half a century later, F. Becker (1876) discovered that when the material was digested with carbon disulphide, the sulphur dissolved and tellurium remained undissolved. Hence it was inferred that Berzelius' sulphide is not a chemical individual, but a mixture of sulphur and tellurium in constant proportions. The assumption is of course made that the carbon disulphide does not decompose the precipitate.

It is generally stated that " a solution of sugar or of salt in water is a mechanical mixture because, though homogeneous, the salt or sugar can be recovered unchanged from the water by the mechanical process of evaporation." This is an unwarranted assumption. The salt and water may have combined, and the product of the chemical combination may be decomposed into salt and water during the process of evaporation. The intervention of a **solvent** sometimes decomposes a compound into its constituents, or conversely, causes the constituents of a mixture to combine in such a manner as to produce compounds which previously did not exist.

The so-called mechanical processes of separation usually include: (1) *Magnetting, hand-picking, sieving,* etc. (2) *Elutriation,* or treatment with water flowing at different speeds such that the lighter particles are carried off by the slower streams, and the heavier particles by the faster streams. *Settling* and *lixiviation* are modifications of this type of separation. (3) *Flotation, or fractional levigation.* If some mixtures be placed in liquids of the right specific gravity, the lighter constituents will float and the heavier constituents will sink; and if some mixtures be treated with oils, etc., the oil so affects the particles of some substances that they are buoyed up in liquids where otherwise they would sink—such substances can be separated in this way from other substances not so affected by the oil. (4) *Fractional solution, or crystallization,* depend on differences in the solubility of the constituents in suitable solvents. (5) *Distillation, evaporation, freezing, liquation, melting, diffusion, cupellation,* etc.

4. A mixture usually possesses the common specific properties of its constituents; the properties of a compound are usually characteristic of itself alone.—The properties of a mixture are nearly always additive, *i.e.* the resultant of the properties of the constituents of the mixture. For instance, a *mixture* of equal parts of a white and black powder will be grey, whereas sodium metal and greenish-yellow chlorine gas give a white pulverulent *compound*—common salt.

Specific gravity is a number which expresses how much heavier a given substance is than an equal volume of a standard substance (say water at 4°) taken at a standard temperature and pressure. In the case of gases, either air=unity, oxygen=16, hydrogen =1, or hydrogen=2 is taken as standard; and in the case of liquids and solids, water at +4°, or at 0°, is taken as unity. The great value of specific gravity data lies in the fact that *specific gravity is a number which enables volume measurements to be converted into weights, and weight measurements to be converted into volumes,* for weight=specific gravity ×volume. Specific gravity may thus be regarded as the weight of unit volume if water =unity be taken as a standard, and the weights are reckoned in grams, and volumes in cubic centimetres. There is no need here to elaborate distinctions between density and specific gravity. The density is the mass of unit volume, so that if D, m, and v respectively denote the density, mass, and volume of a substance, $D=m/v$.

The specific gravity of a mixture of equal volumes of two substances of specific gravity 3 and 5 will be 4, because if one c.c. of water weighs one gram, there will be a mixture of 0·5 c.c. weighing 1·5 gram of one substance; 0·5 c.c. of the other substance weighing 2·5 grams; and $1{\cdot}5+2{\cdot}5=4$ grams per c.c. It must be added that the specific gravities of compounds are not necessarily a mean of the specific gravities of their components; indeed, if elements mix without change in volume that fact alone is strong presumptive evidence that a compound has not been formed. It must be added, too, that a small contraction would not be considered a sufficient proof of chemical action because liquid chlorine and bromine contract a little when mixed together, and this reaches a maximum—2 per cent.—when the mixture corresponds approximately with the atomic proportions $Br + Cl$. The specific gravity of compounds may be greater or less than the average specific gravity of their constituents. This shows that the force which causes compounds to unite chemically is not an attractive force independent of the nature of the combining substances. Hence, although this force is sometimes called chemical attraction, the term is used metaphorically. Some properties of compounds —like weight—are additive, for they are the sum of the properties of their constituents.

EXAMPLES.—(1) What is the specific gravity of air containing a mixture of one volume of nitrogen when the specific gravity of oxygen is 16, and the specific gravity of nitrogen 14·01? One-fifth volume of oxygen weighs 3·2 units, and four-fifths volume of nitrogen weighs 11·2 units. Hence, one volume of the mixture will weigh 14·4 units.

(2) Ozonized air—a mixture of air and ozone—has a specific gravity 1·3698, and it contains 13·84 per cent. by weight of air, specific gravity unity, and 86·16 per cent. of ozone. What is the specific gravity of ozone? Here 13·84 grams of air occupy $13{\cdot}84 \div 1$ volumes; and 86·16 grams of ozone occupy $86{\cdot}16 \div x$ volumes, where x denotes the specific gravity of ozone. Hence, 100 grams of ozonized air occupy $100 \div 1{\cdot}3698 = 73$ volumes; and $73{\cdot}00=(86{\cdot}16 \div x)+13{\cdot}84$; or $x=1{\cdot}46$.

The **law of mixtures** may be stated in symbolic form. If a mixture of two substances contains x fractional parts of a substance of specific gravity s_1, it will contain $1-x$ fractional parts of the other substance of specific gravity s_2. Then if S be the specific gravity of the mixture, $xs_1+(1-x)s_2=S$.

EXAMPLE.—Lord Rayleigh and W. Ramsay (1895) found that a mixture of argon and nitrogen had a specific gravity 2·3102 (air unity), and the specific gravity of nitrogen alone is 2·2990; what is the specific gravity of argon if the mixture contained 1·04 per cent. of argon? Here $x=0{\cdot}0104$; $1-x=0{\cdot}9896$; $s_2=2{\cdot}2990$; $S=2{\cdot}3102$. By substituting these data in the above expression, $2{\cdot}2990+(2{\cdot}3102-2{\cdot}2990) \div 0{\cdot}0104=s_1$, or the specific gravity of argon (air unity), is $s_1=3{\cdot}376$.

If a portion of the mixture of finely divided sulphur and iron be placed in a hard glass test-tube and warmed over Bunsen's flame, the contents of the tube begin to glow and a kind of combustion spreads throughout the whole mass. When cold, break the test-tube, and note that (1) the porous black mass formed during the action is quite different from the original mixture; (2) the microscope shows that the powdered mass is homogeneous; (3) it is not magnetic like iron (provided the iron was not in excess); and (4) it gives up no sulphur when digested with carbon disulphide (provided the sulphur was not in excess). These facts lead to the assumption that there has been a chemical reaction between the sulphur and the iron. *When chemical combination occurs, the reacting constituents appear to lose their individuality or identity more or less completely, and each new substance which is formed has its own distinctive properties.*

5. Thermal, actinic (light), or electrical phenomena usually occur during chemical changes.—Attention must be directed to the fact that a great deal of heat was developed during the combustion of the iron and sulphur. The heat required to start the reaction does not account for the amount of heat developed during the reaction. This point is perhaps better emphasized by placing an intimate mixture of powdered sulphur and zinc on a stone slab. After the flame of a Bunsen's burner has been allowed to play on a portion of the mixture for a short time to start the reaction, the zinc and sulphur combine with almost explosive violence. Large amounts of heat and light are developed during the reaction.

If a plate of commercial zinc be placed in dilute sulphuric acid, bubbles of gas are copiously evolved, and if a thermometer be placed in the vessel, the rise of temperature shows that heat is generated during the chemical action. If the zinc be pure, very little, if any, gas is developed. It makes no difference if a plate of platinum be dipped in the same vessel as the zinc, provided the plates are not allowed to come into contact with one another. If the two plates are connected by a piece of copper wire, a rapid stream of gas bubbles arise from the surface of the platinum plate, and some gas also comes from the zinc plate. The platinum is not attacked by the acid in any way, but the zinc is rapidly dissolved. If a voltmeter and shunt or an electric bell be interposed in the circuit between the two plates, the deflection of the needle or the ringing of the bell will show that an electric current passes from the platinum to the zinc. The electric current is generated by the chemical reaction between the zinc and the acid, which results in the formation of zinc sulphate and a gas. The action will continue until all the acid or the zinc is used up.

For convenience, the zinc **plate** of the cell *B* is conventionally called the **positive plate** and is often represented by a short thick line, and the **platinum plate** is likewise called the **negative plate** and is represented by a longer thinner line as illustrated by the plan, Fig. 1. Here *G* represents the voltmeter or galvanometer and shunt. The vessel of acid with its two plates is called a **voltaic cell**, and this particular combination can be symbolized :

. Platinum | Dilute sulphuric acid | Zinc

The voltaic cell originally used by A. Volta (1800) had copper in place of platinum.

The chemical reaction just indicated is far from being the most economical mode of generating electricity, but all the different forms of voltaic cell on the market agree in this : **Electricity is generated during chemical action.**

The development of heat, light, or electrification are the usual concomitants of chemical action. The absence of such phenomena when substances are simply mixed together is usually taken as one sign that chemical action has not taken place. When nitrogen and oxygen are mixed together in suitable proportions to make atmospheric air, there is no sign of chemical action, and this fact is sometimes cited among the proofs that air is a mixture. The argument is not conclusive because the condensation of steam and the freezing of water are usually cited as physical changes although heat is evolved during both transformations.

The tests for distinguishing chemical compounds from mixtures involve answers to the following questions: (1) Is the substance homogeneous ? (2) Are the different constituents united in definite and constant proportions ? (3) Are the properties of the substance additive ? (4) Were thermal, actinic, or electrical phenomena developed when the substance was compounded ? (5) Can the constituents be separated by mechanical processes ? The list does not necessarily exhaust the available tests, but in spite of what we know, there is sometimes a lingering doubt whether a particular substance is a mixture or a true chemical compound. This arises from the fact that some of the tests are impracticable, others are indecisive. Owing to our ignorance, it is not always easy to state " the truth and nothing but the truth." As P. J. Hartog [3] has emphasized, C. L. Berthollet repeatedly asked J. L. Proust to furnish an experimental distinction between chemical compounds and mixtures, but without success. Even to-day, there is no experimental method of generally distinguishing the two. The usual definition is a theoretical distinction based on molecules, but one can also be adapted from the phase rule (*q.v.*).

§ 7. Circumstantial and Cumulative Evidence

> To find the truth is a matter of luck, the full value of which is only realized when we can prove that what we have found *is* true. Unfortunately, the certainty of our knowledge is at so low a level that all we can do is to follow along the lines of greatest probability.—J. J. BERZELIUS.

Suppose a substance is suspected to be a chemical compound because it appears to be homogeneous; on investigation, we find that it has a fixed definite composition. This verifies our first suspicion, and the joint testimony gives a very much more probable conclusion than either alone. By piling up the evidence in this manner, for or against our suspicion, we can make a chain of circumstantial evidence which enables a highly probable conclusion to be drawn. Each bit of evidence by itself is not of much value, but all the evidence taken collectively has tremendous weight. A successful hypothesis is strengthened by the testimony furnished by diverse facts, and the more numerous and significant the particular instances embraced by the hypothesis the more nearly will their joint testimony mount to the altitude of proof, and plausible hypotheses neatly dovetailed may fit together so well as to apparently strengthen rather than weaken one another. However, it is easy to see that the probability of an hypothesis being valid becomes less as the number of unproved assumptions on which it is based becomes greater. We can even get a numerical illustration. *If* the definite-compound test be right nine times out of ten, the probability that a given substance of definite composition is a true compound is $\frac{9}{10}$; similarly, *if* the homogeneity test be right three times out of four, the probability that the given homogeneous substance is a chemical compound is $\frac{3}{4}$; and the probability that the given homogeneous substance of definite composition is a true compound is $\frac{39}{40}$. **Every bit of additional evidence in favour of a conclusion multiplies the probability of its being correct in an emphatic manner; and evidence against a conclusion acts similarly in the converse way.** Thomas Huxley has stated that one of the tragedies in science is the slaughter of a beautiful hypothesis by one *incongruent fact*; a conclusion based solely upon circumstantial evidence is always in danger of this Damoclean sword.

A writer has said: " When two facts seem to be in conflict, we may be driven to decide which is the more credible of the two." This statement may give rise to a misunderstanding. We cannot admit the possibility of two contradictory facts. Facts can, and often do, contradict hypotheses. Again, a fact is a fact and cannot be disputed; all facts are equally true. Scientific knowledge cannot be arranged in two compartments, one for truth and one for error. The degree of confidence to be placed in a statement can be made only after the evidence has been sifted and weighed. If there be any doubt about the truth of an alleged fact, something is wrong. The laboratory, not the study, is the place to decide if the alleged fact is the result of an incomplete or of a mal-observation. Facts *qua* facts cannot be graded in degrees of probability or credibility, since the difference between *probability* and *certainty* does not represent any quality of the objective fact, it merely describes a state or *attitude of the mind* which ranges from ignorance to knowledge.

§ 8. Analysis and Synthesis

> It is surely not fitting for a chemist to make a large number of experiments with the sole object of rapidly making new products, for he will then overlook phenomena and changes during the operations which might serve as important clues to an explanation of nature's secrets.—M. W. LOMONOSSOFF.

The earliest chemists were familiar with changes due to the *union* of distinct forms of matter to produce a different substance with new properties of its own; and also with the *separation* of two or more definite substances from another quite different substance. The term **spagyric art** (*σπάν*, to separate; *ἀγειρείν*, to assemble), applied to chemistry about the sixteenth century, emphasized the fact that chemical changes were regarded as involving either combinations or decompositions; and as the balance came into more and more extended use, it was gradually recognized that when elements or compounds have suffered a chemical change, the original substances can be recovered, qualitatively and quantitatively the same, by reversing the chemical operation.

The term *synthesis*—from *σύν*, with; *τιθέω*, I place—is employed for the operations involved in the formation of a particular compound from its constituents. The term *analysis*—from *ἀνά*, back; *λύω*, I loosen—is employed for the process of separating the constituents of a compound or mixture. Thus mercuric oxide is broken down into its constituents when heated. The object of the analysis may be to answer the question: What are the constituents of the mixture or compound? The analysis is then said to be *qualitative*. If the relative quantities of the different constituents are to be determined, the analysis is said to be *quantitative*.

There is one period in the history of chemistry when the discovery or synthesis of new substances was considered to be the main aim of the chemist; new substances were made unmeasured and unclothed with properties, which now require to be critically scrutinized all over again. The style of some old text-books on chemistry was not far removed from that of cookery recipe books, for they gave a long dreary list of modes of preparing different substances which led E. J. Mills (1876) to say: Chemistry has become an art of breeding (new compounds). The pioneer work has been useful, for it has furnished modern chemistry with raw empirical material to be worked up into science; indeed a great many more empirical data are now available than chemists have been able to co-ordinate and assimilate into their science. Consequently, we are beginning to recognize the truth of the inspired words of M. W. Lomonossoff, cited above, though written in 1751; and the growing use of tables of measurements and of squared paper in chemical text-books is a sign of the times. In the words of R. Fittig:

> We are now forced to increase the number of compounds, not merely in order to prepare new substances, but in order to discover natural laws.

The solution which remains when the dilute sulphuric acid can dissolve no more zinc, may be filtered and evaporated over a hot plate until a drop of the hot solution crystallizes when placed on a cold glass plate. Crystals of zinc sulphate will separate as the solution cools. By evaporating a large volume of the solution very slowly, crystals over a foot long have been obtained. This experiment illustrates the **synthesis** of zinc sulphate from metallic zinc and dilute sulphuric acid. The earlier alchemists assumed that when a metal dissolves in acid, the metal is destroyed. J. B. van Helmont[1] showed that this assumption is ill-founded because just as when a certain amount of common salt is dissolved in water, the same amount of salt can be recovered from the solvent, so, when silver is dissolved in *aqua fortis*, the metal passes into solution, but is not essentially altered. In the present case, the zinc dissolved by the acid can be recovered as zinc sulphate, and if need be as metallic zinc.

The analysis of aqueous solutions of zinc sulphate by the electric current.—An electric current is developed during the reaction between dilute sulphuric acid and metallic zinc which results in the formation of zinc sulphate and the evolution of a gas.

Place two platinum plates, *E*, Fig. 1, and pure distilled water in the clean glass jar, which will now be called the "electrolytic cell." Connect the two platinum plates with an accumulator or secondary battery, and a voltmeter and shunt as indicated in Fig. 1. The object of the accumulator is to generate an electric current. If the water is pure the needle of the voltmeter moves very little, if at all. Add a concentrated solution of zinc sulphate to the water in the glass jar. The jump of the needle of the voltmeter shows that a current of electricity is flowing through the circuit and hence also through the solution of zinc sulphate. If chloroform, benzene, or an aqueous solution of cane sugar had been used in place of the solution of zinc sulphate in the electrolytic cell, no current would pass through the circuit. Hence, liquids may be either conductors or non-conductors of electricity.

An electric current passing through an aqueous solution of zinc sulphate produces some remarkable changes: (1) a spongy mass of metallic zinc accumulates about one of the platinum plates; (2) if the solution be tested, particularly in the neighbourhood of the other platinum plate, sulphuric acid will be found to be accumulating in the solution during the process of electrolysis; and (3) bubbles of oxygen gas, easily tested by collecting some in a test-tube, rise from the same platinum plate about which the acid accumulates. If the experiment be continued long enough, metallic zinc and sulphuric acid will be produced in appreciable quantities. If the accumulator be disconnected, and the connecting wires be joined together, the zinc will redissolve in the acid, re-producing zinc sulphate; and an electric current will be generated during the dissolution of the zinc.

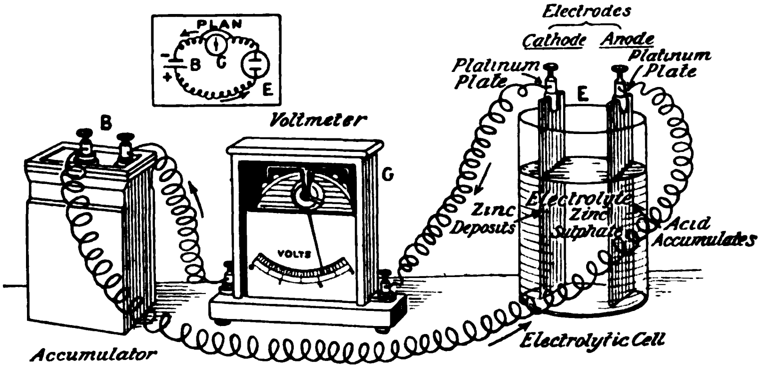

FIG. 1.—Chemical Action induced by Electric Current—Electrolysis.

The process of decomposition or analysis by the aid of the electric current is called **electrolysis.** The liquid which is decomposed is called the **electrolyte.** The passing of the electric current through the conducting copper wires, and through the conducting platinum plates, produces no change in these metals. Hence, we recognize two kinds of conductivity—in one the conducting medium is decomposed by the current—electrolyte; and in the other the conducting medium is not decomposed by the current—non-electrolyte. The plate at which the zinc collects is called the **cathode**—from κατά, down; ὁδός, a path—and the other plate, about which the acid collects, is called the **anode**—from ἀνά, up; ὁδός a path. The anode and cathode together are called the **electrodes.** These terms were suggested to M. Faraday by W. Whewell.[2] With the conventions already indicated as to direction, the electric current is said to enter the electrolytic cell *viâ* the anode, and to leave the cell *viâ* the cathode. The two electrodes are thus "the doors or ways by which the current passes into or out of the decomposing body." It seems as if the electric current first splits the decomposing liquid into two parts which pass to the electrodes. The term **anion**—from ἀνιόν, that which goes up—is applied to those parts of the decomposing fluid which go to the anode; those passing to the cathode are called **cations**—from κατιόν, that which goes down; and when reference is made to both the anions and the cations, the term **ions**—from, ἰών, traveller—is employed. **Ion is thus a general term for those bodies which pass to the electrodes during electrolysis; or for the two parts, no matter how complex, into which the electrolyte is primarily divided during electrolysis.** This notation was proposed by M. Faraday in 1834.

The experiments indicated above illustrate an important principle—**the principle of reversibility: If an antecedent event A produces an effect B, then an antecedent event B will reproduce the effect A.** Thus, chemical action can produce an electric current, and conversely, an electric current can produce chemical action, Fig. 1. The one can undo the work of the other. Many other examples of the principle will be recalled—for example, heat causes gases to expand; conversely, if a gas expands by its own elastic force, the gas will be cooled; a crystal of tourmaline is electrified by uniformly raising its temperature, and Lord Kelvin (1877) showed that the reverse effect can be induced, for a change of temperature occurs when the electrical state of the crystal is changed; etc.

§ 9. Dalton's Law of Multiple Proportions

> If Dalton's hypothesis of multiple proportions be found correct, we shall have to regard it as the greatest advance chemistry has yet made towards its development into a science.—J. J. BERZELIUS (1811).

The formation of chemical compounds is not a capricious and fortuitous process, but it proceeds in an orderly fashion. Chemical combination is restricted to certain fixed proportions of matter. These limitations appear to have been prescribed by nature as part of her scheme in building the material universe. This fact arrested the attention of J. Rey in 1630. J. Rey's conclusion that in the calcination of the metals "nature has set limits which she does not overstep," agrees with many facts; but there are certain limitations. If one gram of lead be calcined for a long time at 500°, never more than 1·103 gram of a red powder—red lead—is obtained. Here, 64 grams of oxygen correspond with 621 grams of lead. If the lead be calcined at about 750°, one gram of lead will not take up more than 0·078 gram of oxygen to form a yellow powder—litharge; otherwise expressed, 64 grams of oxygen correspond with 828 grams of lead. Here then nature has set *two* limits; lead forms at least two definite oxides—a red oxide stable at a dull red heat, and a yellow oxide stable at a bright red heat. A puce oxide can also be obtained by treating the red oxide with nitric acid, and the puce oxide contains 414 grams of lead for 64 grams of oxygen. The relative proportions of lead and oxygen in the three oxides are as follows:

	Oxygen.	Lead.
Puce oxide (lead peroxide) . .	64	$414 = 207 \times 2$
Red oxide (red lead) . . .	64	$621 = 207 \times 3$
Yellow oxide (litharge) . . .	64	$828 = 207 \times 4$

This means that for a given weight of oxygen, the yellow oxide has four-thirds as much lead as the red oxide, and twice as much as the puce oxide. Similarly, carbon forms two well-defined oxides, called respectively carbon monoxide, and carbon dioxide. In these we have:

	Oxygen.	Carbon.
Carbon dioxide	8	$3 = 3 \times 1$
Carbon monoxide	8	$6 = 3 \times 2$

Perhaps the oxides of nitrogen furnish the most convenient illustration of the principles; at least six have been reported (the real existence of the hexoxide has not been established satisfactorily). In these, the relative proportions of nitrogen and oxygen are as follows:

	Nitrogen.	Oxygen.
Nitrogen monoxide	14	$8 = 8 \times 1$
Nitrogen dioxide	14	$16 = 8 \times 2$
Nitrogen trioxide	14	$24 = 8 \times 3$
Nitrogen tetroxide	14	$32 = 8 \times 4$
Nitrogen pentoxide	14	$40 = 8 \times 5$
(Nitrogen hexoxide	14	$48 = 8 \times 6$)

These six compounds of the same elements united in different proportions form a series of substances so well marked and contra-distinguished that it is questionable if the most acute human intellect would ever have guessed *a priori* that they contained the same constituents. Starting from the compound with the least oxygen, we see that for every 14 grams of nitrogen, the amount of oxygen increases by steps of 8 grams. Accordingly, in all six compounds of nitrogen and oxygen the masses of nitrogen and oxygen are to one another as $m \times 14 : n \times 8$, where m and n are whole numbers.

If an aqueous solution of sodium hydroxide be mixed with successive small quantities of hydrochloric acid, the relative proportions of the two substances can be varied at pleasure, but there is not an infinite variety of compounds of soda and acid. The one sole product of the reaction is sodium chloride, and this has always one fixed and definite composition. If an excess of either acid or soda be present, it is assumed that the excess remains uncombined, because, when the solution is concentrated by evaporation, crystals of sodium chloride are obtained along with the excess of soda or of acid if such be present. If sulphuric acid be substituted for hydrochloric acid, crystals of two distinct and definite products can be separated —the one is called *sodium bisulphate*, and the other *normal sodium sulphate*— according as the acid or alkali is in excess. Here then is an apparent exception to the old saw, *natura non facit saltum*, for nature does make jumps. The leaps are shown in the relations by weights between the soda and acid in the two products:

	Soda.	Acid.		Soda.	Acid.
Sodium bisulphate . .	52 .	160	or	52	160
Normal sodium sulphate .	52	80	or	104	160

Hundreds of cases equally simple might be cited. Similar facts helped to establish an idea deduced by J. Dalton (1802–4) from the atomic theory, and now called **the law of multiple proportions: when one substance unites with another in more than one proportion, these different proportions bear a simple ratio to one another.**

There is no difficulty in tracing the simple ratio $m : n$ in the cases which precede, but it is not always easy to detect the *simplicity* of this ratio in perhaps the larger number of cases. For instance, the ratio $m : n$ for compounds of carbon and hydrogen passes from 1 : 4 in methane, up to 60 : 122 in dimyrcyl, and still more complex cases are not uncommon; the methods of analysis are scarcely sensitive enough to distinguish the comparatively simple triacontane where carbon : hydrogen is as 30 : 62, from hentriacontane where this ratio is 31 : 64. Again, the masses of carbon which unite with one of hydrogen, in methane, ethylene, and acetylene are 3, 6, and 12 respectively, but in methane, ethane, propane, hexane, eicosane, and anthracene, they are 3, 4, 4·5, 5·143, 5·714, and 16·8 respectively. Several attempts have been made to get around the difficulty, by rewording the statement of the law. Thus, B. D. Balareff[1] recommends: "The masses of the different elements in a compound are directly proportional to their equivalent weights or to simple multiples of their equivalents," but E. Puxeddu has discussed these various forms and shown that they are intrinsically different in meaning from the original Daltonian law.

Still the Daltonian law is considered to be so well founded that it can be applied to predict the composition of compounds which have never been prepared. Thus, if an oxide of nitrogen containing rather more oxygen than nitrogen hexoxide be made, it may be predicted that it will contain $7\times8=56$ parts of oxygen for every 14 parts of nitrogen by weight. Again, if a substance be found to contain oxygen and nitrogen, not in the proportion 14 : 8 or a multiple of 8, it is in all probability a mixture, not a true compound. Again, air contains oxygen and nitrogen, but the proportions of nitrogen to oxygen is as 14 : 4·29. This is usually given along with other circumstantial evidence to show the probability that air is a mixture and not a chemical compound.

Are solutions chemical compounds or mixtures ?—Our definitions say mixtures, because the composition of solutions follows neither the constant nor the multiple proportion law. We might easily be led to **reason in a vicious circle**—*in circulo probando*—by a rigid application of the so-called constant and multiple proportion laws. Salts dissolve in water in all proportions up to a certain limiting value. The process of solution, in some cases, seems to be otherwise indistinguishable from chemical combination, and C. L. Berthollet (1803) [2] considered that " solution is a true combination " produced by " a feeble combination which does not cause the characteristic properties of the dissolved body to disappear." It is sometimes said that the process of solution cannot be a case of chemical combination because there are no signs of abrupt *per saltum* changes characteristic of combination in multiple proportions. **The composition of homogeneous solutions can vary continuously within certain limits while a chemical compound has one fixed and definite composition ;** accordingly, we refuse to call substances compounds which do not conform with this definition. Hence, in virtue of arbitrarily compiled definitions, solutions are said to be mixtures, not chemical compounds, and this in spite of the fact that the dissolution of salts may be accompanied by those very phenomena which are usually recognized as characterizing chemical combination —changes in volume, specific heat, temperature, etc.—so that the product of the reaction (solution) has different properties from the average of its components.

One writer has said : " Efforts have been made to find compounds which do not conform to the laws of chemical combination, but all attempts have resulted in failure ; " another writer says, " The law of multiple proportions has been tested by the analysis of thousands of compounds, and, like the law of constant proportions, it is one of the perfect laws from which no deviation has been discovered." From what has been said, **if exceptions to the laws of chemical combination were discovered, chemists would refuse to call them compounds, and the quest for exceptions must therefore end in failure.** For the same reason, the .appeal to experience is useless, it can neither establish nor refute the laws of constant and multiple proportions. More bluntly expressed : a prejudice in favour of the definitions in question may warp the judgment to such an extent as to lead to a denial of the possibility of contradictory phenomena. Such a perversion of the judgment must be detrimental to the progress of science. Hence the danger of cherishing a blind faith in our so-called laws of nature, which, at the present day, are little more than conventional definitions. With such definitions one can easily be deluded with the belief that he worships in the temple of certainty as indicated in the above two quotations.

§ 10. The History of the Law of Multiple Proportions

Communities of atoms are called chemical combinations, and they possess every degree of stability. The existence of some is so precarious that the chemist in his laboratory can barely retain them for a moment; others are so stubborn that he can barely break them up. The more persistent or stable combinations succeed in the struggle for life and are found in vast quantities as in the cases of common salt and of the combinations of silicon. Stability is a property of relationship to surrounding conditions; it denotes adaptation to environment. Thus, salt is adapted to the struggle for existence on earth, but it cannot withstand the severer conditions which exist on the sun.—G. H. DARWIN (1905).

William Higgins, in his book *A comparative view of the phlogistic and antiphlogistic theories with inductions* (London, 1789), stated that one particle of sulphur and one of oxygen constitute sulphurous acid, while a particle of sulphur and two particles of oxygen constitute sulphuric acid; he also stated that in the compounds of nitrogen and oxygen, the particles of the two ingredients are to each other respectively in the ratio 1 : 1 or 2, 3, 4, or 5. According to C. Daubeny (1850), owing to imperfections in the available chemical analyses, W. Higgins could not have established the proposition as a general rule; and judging from the cursory manner in which Higgins refers to the relation between the proportions in which the constituents of these compounds unite to form compounds, he did not attach much importance to the principle. W. Higgins here appears to have followed Isaac Newton, who, in his *Opticks* (London, 1704), said:

> The smallest particles of matter may cohere by the strongest attractions and compose bigger particles of weaker virtue; and many of these may cohere and compose bigger particles whose virtue is still weaker, and so on for divers successions, until the progression ends in the biggest particles on which the operations in chymistry depend.

It has been suggested that Newton's idea of chemical affinity, dependent on the successive addition of atoms, may have given W. Higgins and J. Dalton the hint which they needed for producing the law of multiple proportions.

Even before John Dalton enunciated the law of multiple proportions, many observations had shown that compounds unite together in more than one proportion. Indeed, it now seems strange that chemists should have failed to notice the law of multiple proportions when numerous analyses were available. E. von Meyer[1] attributes this to the results being calculated in such a way as to hide the law, but A. N. Meldrum has shown that the data were frequently stated in precisely the way required. J. B. Richter (1792) noticed that certain metals have the power of combining with oxygen to form oxides with two different proportions of oxygen; J. L. Proust (1799) obtained a similar result in connection with copper, but partly owing to inaccurate analyses, and partly owing to the fact that he had no guiding principle, he failed to recognize the law of multiple proportions. A. L. Lavoisier (1789) knew that certain substances united with oxygen in several different proportions each of which corresponded with a fixed and constant relation between the weights of the combining elements. F. Clément and J. B. Désormes (1801) also analyzed carbon monoxide and found that it contained just half the amount of oxygen contained in carbon dioxide, and it afterwards struck J. Dalton as curious that the two French chemists did not take more notice of this remarkable result. J. Bostock's analyses of the lead acetates in 1805 were shown by J. Dalton to be in good agreement with the law. Between 1802 and 1807, J. Dalton gave a number of examples of the law of multiple proportions from his own analyses and those of others.

In 1808, in a memoir *On oxalic acid*, T. Thomson[2] showed that, in the formation of the two potassium salts of oxalic acid, the quantity of potash which reacts with a given amount of oxalic acid is in one case just double the proportion in the other; similar results were obtained with the two strontium oxalates—one of which is obtained by saturating oxalic acid with strontia water, and the other by mixing solutions of ammonium oxalate and strontium chloride. It is remarkable, said

T. Thomson, that thefirst contains just double the proportion of base contained in the second. In a paper *On super-acid and sub-acid salts* (1808), W. H. Wollaston also found that the amounts of carbonic acid relative to a given amount of potash in the two potassium carbonates are related as 1 : 1 and 1 : 2. These two papers are of historical interest, and they attracted some attention because, at that time, so few facts were known which could be employed to test the law of multiple proportions. In 1810, J. J. Berzelius began to publish a series of investigations designed "to find the fixed and simple ratios in which the constituents of inorganic nature are combined;" he gave a number of accurate analyses which enabled him to say that if two substances A and B unite in more than one ratio, the various masses of A which unite with a fixed mass of B bear a simple ratio to one another. These experiments played so important a part in establishing the law of multiple proportions that the law itself has been called *Berzelius' law*. Some years later, in reviewing J. Dalton's hypothesis, J. J. Berzelius said:

> It may be doubted if J. Dalton was sufficiently cautious in applying the new hypothesis to the system of chemistry. It appeared to me that the paucity of analyses given in support of the generalization indicated a desire on the part of the experimenter to obtain a certain result; but this is just the attitude which must be avoided when proofs for or against a preconceived theory are sought. Notwithstanding all this, to Dalton belongs the honour of discovery that part of the doctrine of chemical composition termed the law of multiple ratios, which no one had previously observed.

In the celebrated Proust *v.* Berthollet controversy, C. L. Berthollet showed that some elements unite in more than one proportion, and therefore he argued that compounds do not necessarily have a fixed and definite composition; but J. L. Proust demonstrated that when a metal unites with, say, oxygen in more than one proportion, the proportion in which the two elements combine do not vary in a continuous manner, but they proceed in jumps, *per saltum*, and each of the compounds has then a fixed and definite composition. J. L. Proust, however, failed to recognize the law of multiple proportions subsequently developed by J. Dalton.

§ 11. Richter's Law of Reciprocal Proportions

After long centuries of painful and continuous effort, chemistry has discovered that the elements combine with one another in definite and unchanging ratios of quantity; and that, when their compounds are decomposed, they yield up those identical ratios.—S. BROWN (1843).

Between 1810 to 1812, J. J. Berzelius[1] published the results of a careful study of the quantitative relations of some of the elements—*Versuch die bestimmten und einfachen Verhältnisse aufzufinden nach welchen die Bestandtheile der unorganischen Natur mit einander verbunden sind*. He found that 100 parts of iron, 230 parts of copper, and 381 parts of lead are equivalent, for they unite with 29·6 parts of oxygen forming oxides, and with 58·73 parts of sulphur, forming sulphides. Hence, since 58·73 parts of sulphur and 29·6 parts of oxygen unite respectively with 138 parts of lead, then, if sulphur and oxygen unite chemically, 58·73 parts of sulphur will unite with 29·6 parts of oxygen, or, taking the law of multiple proportions into consideration, with some simple multiple or submultiple of 29·6 parts of oxygen. In confirmation, J. J. Berzelius found that in sulphur dioxide, 58·73 parts of sulphur are united with 57·45 parts of oxygen. The difference between 2 × 29·6 = 59·2 and 57·45 is rather great, but some of the methods of analysis were crude in the time of J. J. Berzelius, and very much closer approximations—very nearly 1 in 50,000—have been obtained in recent years.

J. B. Richter, some twenty years before J. J. Berzelius' work, proved that a similar relation held good for the combination of acids and alkalies. J. J. Berzelius extended J. B. Richter's law to combinations between the elements. The above relations are included in the generalization sometimes called the **law of reciprocal proportions,** or **the law of equivalent weights. The weights—multiple or submultiple—of the various elements which react with certain fixed weight of some other element taken abitrarily as a standard, also react with one another.** If each of two substances, A and B, combines with a third substance C, then A and B can combine with each other only in those proportions in which they combine with C, or in some multiple of those proportions. This law does not mean that if each of the elements A and B combines with C, then the elements A and B will combine with one another. A. L. Lavoisier, in his *Traité élémentaire de chimie* (Paris, **1.** 116, 1789), argued that if two elements have *une grande appétence* for a third element, they should have an affinity for one another: *quæ sunt eadem uni tertio sunt eadem inter se;* and he added: *c'est ce qu'on observe en effet.* Further knowledge has shown that the direct converse is more nearly in accord with facts.

The law of reciprocal proportions may be regarded as a corollary of the law of multiple proportions on the further assumption that A, B, and C can form binary compounds—AB, BC, CA—with one another. Consequently it follows that if a compound be formed by the union of two elements A and B, it is only necessary to find the proportions in which a third element C unites with one of the two elements, say A, to be able to predict the proportions in which C will unite with B; if the law of reciprocal proportions did not hold, this prediction would be impossible. These numerical relations come out very clearly by comparing the proportions in which the different members of a series of elements, selected at random, combine with a constant weight of several other elements. Suppose the analysis of a substance shows that its ingredients are not in those proportions which we should expect from the known combinations of each of its components with another substance, we might safely infer that the substance analyzed is a mixture, and not a single compound. At ordinary temperatures, alcohol mixes in all proportions with ether and with water, but ether and water cannot be mixed in all proportions.

Example.—If one gram of hydrogen unites with eight grams of oxygen to form water, and if one gram of hydrogen unites with 35·5 grams of chlorine to form hydrogen chloride, in what proportion will oxygen and chlorine be likely to combine? Ansr.—If oxygen and chlorine unite at all, they will be likely to do so in the proportion of 8 grms. of oxygen to 35·5 grms. of chlorine, or some multiple or submultiple of this ratio. As a matter of fact, 8 grms. of oxygen do unite with 35·5 grms. of chlorine to produce chlorine monoxide.

The laws of constant, multiple, and reciprocal proportions are wonderful examples of the beauty and harmony of nature; and yet, we have glimmering hints that these are but symbols of a sublimer generalization which, when discovered,

> Will make one music as before
> But vaster.

§ 12. Combining, Reacting, or Equivalent Weights

> Since it is already settled for us by custom that quantities of different substances are to be called equal when or because they are equivalent gravimetrically, we have no choice. but also, from the chemical point of view, to call those quantities of substance equal which interact in single chemical changes.—E. Divers (1902).

The following numbers represent the results obtained by the chemical analysis of a number of substances selected at random :

		Per cent.		Per cent.
Silicon dioxide	Silicon	46·93 ;	Oxygen	53·07
Hydrogen chloride	Hydrogen	2·76 ;	Chlorine	97·23
Magnesium chloride	Magnesium	25·53 ;	Chlorine	74·47
Water	Hydrogen	11·18 ;	Oxygen	88·81
Silver chloride	Silver	75·26 ;	Chlorine	24·74
Silver fluoride	Silver	70·05 ;	Fluorine	29·95

Analyses are generally calculated so that the sum of all the constituents is 100 (per cent.) within the limits of experimental error. This is simply a convention of the analyst, for the results could be just as intelligibly summed to any other number. Taking any one of the elements as a standard, let us calculate what amount of each of the other elements will combine with a given quantity of the selected element. To save time, take oxygen = 8 as the standard. Starting with silicon, 53·07 parts of oxygen are combined with 46·93 parts of silicon. Consequently, we have the proportion $53·07 : 8 = 46·93 : x$; or, $x = 7·07$, for silicon when the unit oxygen is 8. Similarly, for water, hydrogen is 1·008 when oxygen is 8. Again, in hydrogen chloride when hydrogen is 1·008, chlorine is 35·45 ; in silver chloride, silver is 107·88 when chlorine is 35·45 ; when silver is 107·88, fluorine is 19·0 ; and when chlorine is 35·45, magnesium is 12·16. Collecting together the results of these calculations, we get

Oxygen.	Silicon.	Hydrogen.	Chlorine.	Silver.	Fluorine.	Magnesium.
8	7·07	1·008	34·45	107·88	19	12·16

We have previously obtained a number of results for some metals for the standard oxygen 8 by a different process, and the number for magnesium obtained by an indirect process : Oxygen → Hydrogen (water) → chlorine (hydrogen chloride) → magnesium (magnesium chloride) gives the same results within the limits of experimental error as was obtained by a totally different process. Similar results are obtained in all cases, subject, of course, to the greater risk of experimental error when a long chain of compounds is involved. As a rule, there is no need to follow such an extended series as we have done, for fluorine and for magnesium. Most of the elements unite directly with oxygen ; and with the other elements, one intermediate step usually suffices.

We are therefore able to deduce an important generalization : The combining weights of the elements are specific constants, *i.e.* they change from element to element, but for each element, the combining weight is fixed and invariable. Otherwise expressed: **A number can be assigned to each element ; this number—called the combining, reacting, or equivalent weight—represents the number of parts by weight of the given element which can enter into combination with 8 parts by weight of oxygen, or one part by weight of hydrogen.** All combining weights are relative numbers, and they are conventionally referred to oxygen 8, or hydrogen unity. When an element unites with another element in more than one proportion, the higher proportions will always be simple multiples of the combining weights—one for each element. This is the so-called **law of combining or reacting weights : when a substance enters into chemical combination it always does so in quantities which are proportional to its combining weight ;** and the law of multiple proportions becomes :[1] The quantities of the different elements in a compound are simple multiples of their equivalent weights. The term *equivalent weight* is generally attributed to W. H. Wollaston (1814), and *combining weight* to T. Young (1813).[2]

If the combining weights of the elements are fixed, as they undoubtedly are, and since the elements can combine to form compounds which, in turn, can form compounds with other elements and with one another, it follows that the compounds themselves also have combining weights if they also can enter into chemical combination. Hence the so-called **law of compound proportion—the combining weight of a compound body is the sum of the combining weights of its components.** This deduction from the law of combining weights is as firmly established experimentally as the law of combining weights itself. The neutralization of acids by bases, and numerous other chemical reactions, can be cited in illustration.

The experimental results, indicated in § 2, raise the suspicion that **there is a difference between chemical and gravimetric equality.** E. Divers (1902) has pointed out that in the latter, equal quantities of the different forms of matter are represented by equal weights; whereas, in a chemical sense, equal quantities of matter are the weights or masses of different forms of matter which unite with one another chemically. Consequently, chemical union may be regarded as a measure of the amounts of the different forms of matter which are chemically equivalent. Chemical equality is thus as clearly defined as gravimetric equality. The former is a measure of chemical and the latter a measure of physical phenomena; the latter is wholly independent of, and the former mainly dependent upon the nature of the substances compared.

§ 13. The Perdurability of Matter

The annihilation of matter is unthinkable for the same reason that the creation of matter is unthinkable, the reason namely that nothing cannot be an object of thought.—H. SPENCER (1851).

I cannot see what warrant there is for assuming that when a weight A of one substance combines with another whose weight is B, the weight of the resulting compound is universally and necessarily $A+B$.—A. D. RISTEEN (1895).

In 1774, A. L. Lavoisier heated tin with air in a closed vessel and found that the weight of the whole system, before and after the calcination of the tin, was the same, thus showing that the whole system neither gained nor lost in weight during the oxidation of the metal. H. Follinus also noticed, in 1613, that mercury could be transformed into the sulphide and the product transformed back to the metal without a change in the weight of the mercury, and Jean Rey was very emphatic, for he said in 1630:

> I now give a flat denial to the erroneous maxim which has been current since the birth of philosophy—that the elements mutually undergoing change, one into the other, lose or gain weight according as in changing they become rarefied or condensed. With the arms of reason I boldly enter the lists to combat this error, and to sustain that weight is so closely united to the primary matter of the element that they can never be deprived of it. The weight with which each portion of matter was endowed at the cradle will be carried by it to the grave.

J. R. Glauber, in his *Furni novi philosophici* (Amsterdam, 1648), described the reaction between a solution of gold in *aqua regia* and a solution of silica in potash lye, by stating:

> The potash paralyses the action of the acid with the result that the gold and silica are respectively deprived of their solvents, and are accordingly precipitated. The weight of the precipitate so obtained is the sum of the weights of the silica and gold originally taken.

These experiments are here mentioned because they emphasize very well the fact that, in spite of the most painstaking care, every time all the substances taking part in a chemical reaction are weighed before and after the change, there is no sign of any alteration in the quantity of matter. The need for assuming the perdurability or constancy of matter emphasized in the so-called *law of the indestructibility of matter* has been recognized from the very beginning of the Ionian physics; for example, Democritus said twenty-four centuries ago: Nothing can ever become something, nor can something become nothing—*ex nihilo nihil fit, et in nihilum nihil potest reverti*. J. B. van Helmont's experiment on the transformation of water into vegetable substances, and the analytical work indicated in connection with the law of constant composition, all tacitly assume the principle of the indestructibility of matter. A. L. Lavoisier is generally supposed to have first demonstrated the law in 1774 by experiments like that cited above, but the law is very much older; it was definitely enunciated in 1756 by M. W. Lomonossoff; and the law must have been at the back of J. Black's mind when he worked on the alkaline earths in 1755. The alleged demonstrations that "in all changes of a corporeal nature, the total *quantity* of matter remains the same, being neither created nor destroyed," illustrate but do not prove the proposition, and they assume that no new substance can possibly come into or go out of existence.

The chemist's law of "indestructibility of matter" really means that, in all cases which have been examined, the total *weight* of the elements in any reacting system remains constant through all the physical and chemical changes it is made to undergo; although the observed facts are better generalized as **the law of persistence of weight: no measurable change in the total weight of all the substances taking part in any chemical process has ever been observed.** If A and B represent respectively the weights of two compounds which form two other compounds M and N; and if the symbol = be employed in place of "produces," and + for "together with," the law of persistence of weights can be symbolized algebraically $A + B = M + N$. If the weight of one of these four compounds be unknown, it can be computed by solving the equation. Chemists constantly use this principle in their work, for, as A. L. Lavoisier said in 1774:

> Experiments can be rectified by calculations, and calculations by experiments. I have often taken advantage of this method in order to correct the first results of my experiments, and to direct me in repeating them with all proper precautions.

When faith in magic was more prevalent than it is to-day, many believed that by some potent incantation or charm, matter could be called out of nothingness, or could be made non-existent.[1] Superficial observation might lead to the belief that a growing tree, the evaporation of water, and the burning of a candle prove the creation and the destruction of matter, but a careful study of these and innumerable other phenomena, has shown that the apparent destruction of matter is an illusion. Matter may change its state as when liquid water is vaporized, and when a candle is burnt. In the case of a growing tree, the nutrition the tree receives from the soil and from the air (carbon dioxide) is overlooked. There is an old demonstration experiment commonly used to illustrate the fact that the apparent destruction of matter in the burning of a candle is illusory:

> A candle is fixed on one pan of a balance below a cylinder fitted with wire gauze, quicklime, soda lime, and glass wool. Weights are added to the right scale-pan until the beam of the balance is horizontal. The candle is lighted. The gases rising from the flame pass through the cylinder where the products of combustion are absorbed by the soda lime. In 3 or 4 minutes the pan carrying the candle is depressed. The increase in weight is due to the fixation of the products of combustion by the soda lime. The products of combustion are formed by the combination of the carbon and hydrogen of the candle with oxygen from the air; this oxygen was not included in the first weighing. The fact illustrated by this experiment is undoubtedly true, but the experiment, though popular, is inconclusive because quicklime and soda lime both absorb moisture and carbon dioxide from the air. Hence, to make the experiment conclusive, it would be necessary to remove these compounds from the air used in the burning of the candle, or else to make due allowance for them. This would involve complicated operations; the test has been made, and the result is qualitatively the same as with the simpler experiment.

Every time a chemical reaction takes place in a closed vessel, which permits neither the egress nor the ingress of matter, the total weight remains unchanged within the limits of experimental error. The more carefully the experiments are made, the more nearly do the values approach identity. Both A. Heydweiller (1901) and J. J. Manley (1912) have tried to find if a loss in weight occurs during chemical action, taking the most extreme precautions known to man in order to secure the utmost accuracy.

The experiment may be illustrated by introducing a solution of silver nitrate into one limb of the λ-shaped tube by means of a suitable funnel and a solution of potassium chromate in the other limb. The opening of the tube is then sealed, the tube is weighed and tilted so as to mix the solutions and start the reaction. The tube is again weighed. When the reaction is over and the conditions of temperature, etc., are the same as when the first weighing was made (for illustrative work on the lecture table, the opening of the tube may be corked and the solutions mixed). Other pairs of solutions are: a solution of potassium iodate, slightly acidulated with hydrochloric acid, and potassium iodide; lead acetate and sodium sulphide; acidulated potassium chromate and sodium sulphite; etc.

No difference has been detailed in the weights of the initial and final products of the reaction within the limits of experimental error—0·000006 grm. After an examination of fifteen different reactions, H. Landolt (1909) [2] again failed to detect a variation in weight; and added, " since there seems no prospect of pushing the precision of the experiments further than the degree of exactness attained, the experimental proof of the law may be regarded as established."

The law of the persistence of weight or the so-called law of the indestructibility of matter means that a **variation in the total weight of the substance taking part in chemical reactions, greater than the limits of experimental error, has never been detected.** Hence it is inferred that **in chemical reactions, substance persists while matter changes its form.** It might also be added that the many and varied determinations of the atomic weights of the elements furnish valuable illustrations of the law in question. The law of persistence of weight is quite empirical like the law of excluded perpetual motion. It is shown later, that if a real difference of weight in the substances taking part in a reaction could be detected, perpetual motion would be possible.

If immeasurably small and trifling differences be taken into consideration, as is sometimes done in theoretical speculations, objection might be made to the statement that the weight of a compound must be equal to the weight of the separate constituent elements, for, as I. Todhunter [3] pointed out in 1876, the converse is the strict truth. The weight of a body depends upon the positions of the component particles, and, in general, by altering the *positions* of the particles, the resultant effect which we call weight is altered, though it may be to but an inappreciable extent. Moreover, even the *time* at which the weighing is performed is theoretically important, for the weight must change to a trifling extent with the changing position of the sun and moon in the sky. It is quite conceivable, too, that the weight of the iron in, say, magnetic oxide of iron might *appear* to be greater than the same amount of iron in, say, potassium ferrocyanide because of the effect of the *earth's magnetic field* upon the former. But if such an effect were observed, it would not interfere with our faith in the law as soon as the disturbing effect was recognized.

H. Spencer considers that all the so-called experimental proofs by weighing tacitly assume the object being proved, since weighing implies that the matter forming the weights remains unchanged in quantity; or as H. S. Redgrove puts it, " weight measures matter because matter is indestructible, and matter is indestructible because weight measures matter."

§ 14. The Atomic Theory of John Dalton

> It seems probable to me, that God in the beginning formed matter in solid, massy, hard, impenetrable, movable particles, of such sizes and figures, and with such other properties, and in such proportion to space, as must conduce to the end for which He formed them ; and that these primitive particles, being solids, are incomparably harder than any porous body compounded of them, even so hard as never to wear or break in pieces ; no ordinary power being able to divide what God Himself made one in the first creation. . . . The changes of corporeal things are to be placed only in the various separations and new associations and motions of these permanent particles. . . . These principles I consider not as occult qualities, but as general laws of nature by which the things themselves are formed ; their truth appearing to us by phenomena, though their causes be not yet discovered.—ISAAC NEWTON.

The three laws of chemical combination : (1) the law of constant composition ; (2) the law of multiple proportions ; (3) the law of reciprocal proportions ; and the law of the persistence of weight, summarize observed facts. They exist quite independently of any hypothesis we might devise about their inner meaning ; but we have an intuitive feeling that there must be some peculiarity in the constitution of matter which will account for the facts.

An atom is the unit of chemical exchange.—Chemists in imagination have invested matter with a granular structure. Matter is supposed to be discrete, and built up of corporeal atoms. The imagination can subdivide matter indefinitely ; the chemist says that however true this may be, nothing less than an atom ever takes part in a chemical reaction. The atom is the limiting size so far as chemical combination is concerned. An atom cannot be subdivided by any known chemical process. What A. Kekulé wrote in 1867 applies equally well to-day, in spite of some interesting though abortive attempts to eliminate atoms from chemistry. Should the progress of chemistry lead to a different view of the constitution of matter, it will make little alteration to the chemist's atom. The chemical atom will always remain the chemist's unit. As a chemist, continued A. Kekulé,[1] the assumption of atoms appears to be not only advisable but absolutely necessary provided that the term be understood to denote those particles of matter which undergo no further division in chemical transformations.

Compare this hypothesis with observation. Fix the attention on the facts: Elements combine with one another either in amounts which correspond with their combining weights (law of constant composition), or with multiples of their combining weights (law of multiple proportions). Otherwise expressed, definite amounts of matter—the atoms—corresponding with the combining weights, act as chemical units. Reactions between different elements are reactions between these units. Atoms of the same element all have the same constant weight, and atoms of different elements have different weights. All this is in agreement with the law of constant combining weights. It is not the mass *per se* but the constituent particles of the elements which combine each to each.

Fractions of an atom do not take part in chemical changes.—The proportions in which one element combines with another can alter only by steps one atom at a time ; 1, 2, 3, . . . atoms of one element can combine with 1, 2, 3, . . . atoms of another element. This is but one way of stating the laws of multiple and reciprocal proportions. The weight of an atom of each element is a constant quantity, and therefore elements can only combine with each other in certain constant proportions or in multiples thereof. The atoms of the elements are the units from which nature has fashioned all the different varieties of matter in the universe. One atom of mercury unites with one atom of oxygen to form mercuric oxide. If two atoms of mercury united with one atom of oxygen, the result would not be mercuric oxide, but some other oxide of mercury—if otherwise, the law of constant composition would be false. As a matter of fact, such a compound is known, but it is mercurous oxide. Mercurous oxide has its own specific properties which are different from those of mercuric oxide.

The analyses of C. F. Wenzel (1777), J. B. Richter (1791) J. L. Proust (1800), J. Dalton (1801), J. J. Berzelius (1810), and a host of followers are summarized in the laws of chemical change, and these laws, in turn, are rendered luminous and coherent by the hypothesis which assumes that all the different forms of matter in the universe are aggregates of insensibly small homœomeric particles which all the powers of chemistry cannot further subdivide. We thus adopt the view of J. B. Dumas and of M. Faraday that whether matter be atomic or not, this much is certain, granting it be atomic, it would behave in chemical transformations as it does now; A. Kekulé expressed similar views in 1867:

> The question whether atoms exist or not has but little significance from a chemical point of view; its discussion belongs rather to philosophy. In chemistry we have only to decide whether the assumption of atoms is a hypothesis adapted to the explanation of chemical phenomena, . . . and to advance our knowledge of the mechanism of chemical phenomena.

It remains to find the canons by which chemists have been able to fix the relations between the weights of the atoms of different elements.

Atomic weights are relative.—The combining weights of the atoms can be expressed in any desired units; it is quite immaterial whether a grain or a ton be imagined. **In dealing with combining or atomic weights, the conception of absolute quantity is irrelevant.** Given sufficient oxygen, 100 tons, kilograms, pounds, grams, or grains of mercury will give respectively 108 tons, kilograms, pounds, grams, or grains of mercuric oxide—no more, no less. Several different lines of argument, given by O. E. Meyer in his *The Kinetic Theory of Gases* (London, 1899), indicate that there are about 1280,000000,000000,000000 or $12\cdot8 \times 10^{20}$ hydrogen atoms in a milligram, so that the weight of an atom of hydrogen is not far from $\frac{1}{1280,000000,000000,000000}$th or $12\cdot8 \times 10^{-20}$ of a milligram. This estimate may not be exact, and it is not here emphasized as a fact, although it is probably not far out. Suppose for the sake of illustration it is true, then, with the evidence so far adduced, an atom of mercury will weigh $100 \times 12\cdot8 \times 10^{-20}$th milligram, and an atom of oxygen $8 \times 12\cdot8 \times 10^{-20}$ mgrm. We do not know the absolute weights with any degree of precision, but the relative weights are known with a fair degree of accuracy. Given the relative weights, and the weight of an atom of one of the elements, the absolute weights of the atoms of all the other elements can be computed, for the masses of the other elements bear the same ratios to one another that are assigned to them in the table of atomic weights. The ratio of the weights of the different kinds of elements in a compound represents the relation between the weights of the several different kinds of atoms (or aggregates of atoms) which make up the compound.

J. Dalton's atomic hypothesis.—It is impossible to say who invented the atomic theory, because it has grown up with chemistry itself. It certainly did not arise by one effort of modern science, as W. Nernst supposes, "like a phœnix from the ashes of the old Greek philosophy." In the work of William Higgins and his predecessors, the hypothesis was little more than an inanimate doctrine. It remained for Dalton to quicken the dead dogma into a living hypothesis. John Dalton's atomic hypothesis explains the structure of matter and of chemical combination upon the following postulates, which may be regarded as a very brief statement of what is called Dalton's atomic theory:

> 1. Atoms are real discrete particles of matter which cannot be subdivided by any known chemical process. 2. Atoms of the same element are similar to one another, and equal in weight. 3. Atoms of different elements have different properties—weight, affinity, etc. 4. Compounds are formed by the

union of atoms of different elements in simple numerical proportions—1 : 1; 1 : 2; 2 : 1; 2 : 3; etc. This led Dalton to deduce the law of multiple proportions which was later confirmed by experiments. 5. The combining weights of the elements represent the combining weights of the atoms.

J. Dalton seems to have assumed that the atoms are in perfect repose, unless disturbed by mechanical or chemical forces.[2]

Some defects in Dalton's atomic theory.—The hypothesis of Dalton's respecting atoms, and more particularly atomic weights, is not quite that which prevails in modern chemistry. According to the atomic theory: **an atom is the smallest particle of an element which can enter into or be expelled from chemical combination.** The assumption that the combining weights of the elements represent the combining weights of the atoms has caused some difficulty. How is the smallest combining weight of an atom to be fixed? In carbon monoxide, for example, we have oxygen and carbon in the following proportions by weight: Oxygen : carbon 8 : 6, and in carbon dioxide: Oxygen : carbon 8 : 3 or as 16 : 6. What is the atomic weight of carbon if the atomic weight of oxygen is 8? Obviously, the evidence now before us would be consistent with many different views. Carbon monoxide may be a compound of one oxygen atom with two carbon atoms each with a combining weight of 3; or a compound of one oxygen atom with one carbon atom with a combining weight of 6. In the latter case, carbon dioxide is a compound of one carbon atom of combining weight 6 with two oxygen atoms, and the same combining weights would have been obtained if any number n of carbon atoms were combined with $2n$ oxygen atoms. Again in, order to ascertain the complexity of a combination of atoms, J. Dalton[3] stated that

> If only one combination of two elements exist, it must be presumed to be binary; if two combinations exist, one will be a binary compound and the other a ternary compound.

This hypothesis was also adopted by J. J. Berzelius,[4] but in the case of the so-called carbon dioxide or carbon monoxide, there is at present nothing to show which is the binary and which the ternary compound. Similar difficulties arise when the idea of atoms so far developed is applied to other combinations of the elements. There is therefore some confusion. The concept of the atom becomes more or less indistinct and vague when the attempt is made to develop a consistent system on the basis of the atomic hypothesis as propounded by Dalton. **Dalton's theory is defective because it lacks a standard for fixing the atomic weights of the different elements.** The difficulty was removed only when chemists had learned the value of Avogadro's hypothesis in fixing a definite standard for evaluating atomic weights. Chemists then conventionally came to an understanding as to the relation between the composition and specific gravity of a vapour or gas.

§ 15. The Evolution of the Atomic Theory up to the time of Dalton

> Il est regrettable que les traitées modernes négligent l'histoire et présentent comme des monuments achevés des sciences en perpétuelle évolution.—F. OSMOND (1906).

The atomic theory seems to have been born in the twilight of history. The earliest philosophers of the Eastern fore-world made many quaint guesses at the constitution of matter. Among these guesses, there is one which appears to have been promulgated by Kanada as a doctrine among the ancient Hindus [1] long prior to the rise of Grecian philosophy. This doctrine assumed that the world of sensible matter is produced or constituted by the concourse of substantial or concrete monads or atoms moving more or less freely about one another. A similar guess was propounded by Leucippus about 450 B.C., and advocated as a doctrine about thirty years later—420 B.C.—by his disciple Democritus.[2] About 300 B.C. the same guess was elaborated by Epicurus into a definite system, and the same guess still lives, more or less modified, in modern chemistry.

From the imperfect fragments which have been transmitted to us, it is scarcely possible to dissociate the ideas of Leucippus from those of Democritus. Epicurus taught Democritus' views, which thence passed to Lucretius, and were summarized in an immortal poem *De rerum natura* (written about 80 B.C.). According to C. Daubeny,[3] a Phœnician named Mochus promulgated similar views before Leucippus time; and it has also been stated that the ideas of Pythagoras (*c.* 500 B.C.) about corpuscular monads, mentioned by Aristotle, in his *Metaphysics* (**12**. 6), were derived from the Egyptian priests. E. Zeller [4] has argued that the available evidence does not justify the assumption that Leucippus derived his hypothesis from Mochus, and he further considers that Democritus adopted nothing but mathematics from Pythagorean sources, since there is no affinity between the two philosophies. Democritus, however, travelled extensively on his own account; and it is probable that he visited the Egyptian priests, the Chaldeans, and the Persians. There are traces of atomistic views in the writings of Empedocles (*c.* 500 B.C.), Anaxagoras (*c.* 450 B.C.), and Heracleitus (*c.* 450 B.C.). P. Gomperz [5] has emphasized his belief that the atomic theory of Leucippus and Democritus was a resultant of the labours of their predecessors, and that it "was the ripe fruit on the tree of the old doctrine of matter which has been tended by the Ionian philosophers."

In the fifth century before Christ, Anaxagoras' attempt to compress an inflated bladder led him to recognize the impenetrability of matter. If matter be continuous it was not so easy to see how movement without appreciable hindrance could be possible in air, and yet be impassably resisted by a rock. The atomic theory of Leucippus provided a satisfactory explanation. Motion in a medium is easy or difficult according to the disposition of the constituent atoms which makes it easy or difficult for the atoms to be displaced. The Hellenic theory of atoms seems also to have been opposed as a counter-proposition to the idea of Zeno (*c.* 460 B.C.) that matter is infinitely divisible. Zeno argued that whatever be the dimensions of matter, it must be geometrically divisible, for however small a particle may be, it can be supposed to be halved, quartered, or split into a thousand parts. The atomicians, however, postulated that the monads or atoms could not be cut, bruised, broken, or frayed; otherwise they would wax old, crumble, and lose their shape. Consequently, substances formed by the aggregation of wearable atoms would gradually change their characteristics. Water and earth, said Isaac Newton, composed of old worn particles would not be the same in nature and texture as water and earth originally composed of unworn particles. There is no reason to suppose that there has been any change in the character of water and earth in past ages, and hence, in order that nature may be enduring and permanent, it was inferred that the atoms must be adamantine and perdurable. Zeno's concept is quite different from that of the atomicians'. The latter could have readily admitted with Zeno that atoms are capable of geometrical subdivision, but reserved the right to hypothecate that further subdivision does not occur. Consequently, with those apparently opposing tenets, said S. Brown, the disputants did not argue in answer to one another at all. They crossed swords without touching one another. Each fought his own shadow.

Among other names for atoms, Democritus employed ἄτομα, but Lucretius does not use this term. Lucretius' favourite expression is *primordia* or *rerum primordia*, which is translated "the first elements" or "the first beginnings of things." Lucretius also uses *figuræ*, *semina*, or *semina rerum*—the seeds of things; *materia corpora genitalia* or *prima*; *corpora* or *corpora rerum* or *corpora materia*; *elementa*; and *corpuscula*—but never atom. Cicero used Democritus' term *atomi* for these primitive corpuscles. The derivation of the term *atom*—ἀ, not; τέμνω, I cut—means something which cannot be subdivided. The present-day definition of an atom says nothing about its ultimate nature. John Dalton certainly considered the atom to be indivisible, and this is illustrated by his favourite aphorism: "Thou knowest no man can split an atom." Thomas Graham (1842) defined the atom, not as a thing which cannot be divided, but as one which has not been divided. The term atom was once used for a small interval of time—according to Ducange, the $\frac{15}{54}$th part of a second—a moment. Thus, in the Greek text of Paul's *First Epistle to the Corinthians* 15. 52), there is an expression: ἐν ἀτόμῳ, ἐν ῥίπῃ ὀφθαλμοῦ—in an atom or moment, in the twinkling of an eye.

Concrete indivisible atoms.—The more characteristic features of the Hellenic theory of the atomic constitution of matter, as expounded by Lucretius,[6] are best illustrated by quotations from H. A. J. Munro's translation of Lucretius' poem.

1. Matter is discrete, not a continuum.

> However long you may hold out by urging many objections, you must needs in the end admit that there is a void in things. . . . Wherever there is empty space which we call void, there body is not. . . . If there were no empty void, the universe would be solid . . . for without void, nothing seems to admit of being crushed in, broken up, or split in two.

2. All substances are formed of solid atoms which are separated from one another by void space. Each atom is a distinct individual.

> First beginnings are of solid singleness, massed together and cohering closely by means of least parts, not compounded out of a union of those parts, but, rather, strong in everlasting singleness. . . . First beginnings are strong in solid singleness, and by a denser combination of these all things can be closely packed and exhibit enduring strength.

3. The atoms are impenetrable, indivisible, and indestructible. They are as perfect and fresh to-day as when the world was new.

> There are therefore certain bodies which can neither be broken in pieces by the stroke of blows from without, nor have their texture undone by aught piercing to their core, nor give way to any other kind of assault. . . . Since by the laws of nature it stands decreed what these things can do and what they cannot do, and since nothing is changed, but all things are constant . . . they must sure enough have a body of unchangeable matter also. Therefore, if first bodies are as I have shown solid and without void, they must be everlasting. . . . For if the first beginnings or things could in any way be vanquished and changed it would then be uncertain too what could and what could not rise into being, in short on what each thing has its powers defined, its deepest boundary mark. . . . From these parts nature allows nothing to be torn, nothing further to be worn away, reserving them as the seeds of things.

4. The atoms differ from one another in shape, size, and weight.

> Next in order apprehended of what kind and how widely differing in form are the beginning of things, how varied by manifold diversities of shape. . . . The things which are able to affect the senses pleasantly consist of smooth round elements; while all those, on the other hand, which are found to be bitter and harsh, are held in connexion by particles that are more hooked and for this reason are wont to tear open passages in our senses, and on entering in to break through the body. . . . And quickly as we see wines flow through a strainer, sluggish oil on the other hand is slow to do so, because sure enough it consists of elements either larger in size or more hooked and tangled in one another. . . . Again things which look hard and dense must consist of particles more hooked together, and be held in union because compacted throughout with branch-like elements. . . . Those things which are liquid and of fluid body ought to consist more of smooth and round elements.

5. There is a finite number of different kinds of atoms, but an infinite number of homœomeric atoms of each kind.

> The first beginnings of things have different shapes, but the number of shapes is finite. If this were not so, then once more it would follow that some seeds must be of infinite bulk of body. . . . Wherefore you cannot possibly believe that seeds have an infinite variety of forms, lest you force some to be of monstrous hugeness. . . . The first beginnings of things which have a like shape one with another, are infinite in number. For since the difference of forms is finite, those which are like must be infinite or the sum of matter will be finite, which I proved not to be the case. . . . It is clear then that in any class you like the first beginnings of things are infinite, out of which all supplies are furnished.

6. The properties of all substances depend upon the nature of the constituent atoms, and the way the atoms are arranged. In his *Metaphysics*, Aristotle illustrated the effect of shape, arrangement, and position by examples borrowed from the Greek alphabet, and his illustration may be interpreted: The difference of *shape* is illustrated by the opposition of A and N; the difference of *arrangement* or contact, by AN and NA; and that of *position*, by the conversion of N to Z by turning the former on its side.

> It often makes a great difference with what things and in what position the same first beginnings are held in union and what motions they mutually impart and receive; for the same make up heaven, sea, lands, rivers, sun; the same make up corn, trees, living beings; but they are mixed up with different things and in different ways as they move. Nay, you see throughout even in these verses of ours many elements common to many words, though you must needs admit that the lines and words differ one from the other both in meaning and in the sound wherewith they sound. So much can elements effect by a mere change of order, but those elements are the first beginnings of things can bring with them more combinations out of which different things can severally be produced.

7. The atoms are in constant motion; motion is an inherent property of atoms.

> Solid bodies of matter fly for ever unvanquished through all time. . . . The first beginnings of things move of themselves. . . . No rest is given the first bodies through the unfathomable void, but driven on rather in ceaseless and varied motion they partly, after they have been pressed together, rebound leaving great spaces between, while in part they are so dashed away after the stroke as to leave but small spaces between. . . . Herein you need not wonder at this, that though the first beginnings of things are all in motion, yet the sun is seen to rest in supreme repose, unless where a thing exhibits motions with its individual body. For all the nature of first things lies far away from our senses beneath our ken; and therefore since they are themselves beyond what you can see, they must withdraw their motions from sight also; and the more so that the things which you can see, do yet often conceal their motions when a great distance off. For often the woolly flocks as they crop the glad pastures on a hill, creep on whither the grass jewelled with fresh dew summons and invites each, and the lambs, fed to the full, gambol and playfully butt; all which objects appear to us from a distance to be together and to rest like a white spot on a green hill.

8. Combination or aggregation is due to the coalescence of moving particles. Democritus supposed the particles to move in straight lines, and the collisions to be accidental. In order to better the account for the coalescence, Epicurus supposed that the atoms moved in paths which deviated slightly from the rectilineal.

> When bodies are borne downwards sheer through void, at quite uncertain times and uncertain points of space they swerve a little from their equal poise; you just and only just can call it a change of inclination. If they did not swerve, they all would fall down, like drops of rain, through the deep void, and no clashing would have been begotten, nor blow produced among the first beginnings; thus nature never would have produced aught.

A. A. Cournot[7] believes that none of the ideas bequeathed to us by the ancients has had a greater or even a similar success to the atomic doctrine of Leucippus and Democritus. So far as the experimental evidence available to the Grecian philosophers in support of this particular doctrine is concerned, its long life, in the form of the chemist's atomic theory, can be attributed to chance, for if a sufficient number of thinkers speculate about the structure of matter, without checking their conclusions with facts, it is but in accord with the laws of probability that some of them will approximate to the truth. As C. Daubeny has said:

> The earliest philosophers appear to have often lighted upon the most sublime truths, astonishing us with an intermixture of the noblest views of nature with the most crude and vulgar conceits, and often leaving to their successors little more than the task of selecting from the mass of error, the grains of truth which are disguised by and confounded with it.

The modern theory, unlike the older speculation, is based upon the observed laws of chemical change, and can scarcely stand apart from them.

There is almost an historical continuity in the treatment of the doctrine from Leucippus to John Dalton (1801)—with a break during the dark ages. The atomism of Democritus and Epicurus grew into the corpuscular mechanics of the seventeenth century, and into the atomic theory of the nineteenth century. Francis Bacon[8] was one of the first of the Renaissance philosophers of the seventeenth century to recognize the importance of Democritus' doctrine of atoms; but he later regarded the study as unprofitable:

> Men do not cease from dissecting nature until they arrive at the atom; a thing which if true, can do but little for the welfare of mankind.

The atomic hypothesis was accepted with minor modifications by Robert Boyle,[9] who said in his *Sceptical Chymist* (Oxford, 1661):

> There are clusters wherein the particles do not stick so close together, but they may meet with corpuscles of another denomination, disposed to be more closely united with them than they were among themselves; and in such case, two corpuscles thus combining, losing that shape, size, or motion upon whose account they exhibited such a determinate quality, each of them really ceases to be a corpuscle of the same denomination as it was before; and from the coalition of these, there may result a new body, as really one as either of the corpuscles before they were confounded.

If this were paraphrased into the language of to-day it would be taken to embody the idea of a chemical affinity uniting atoms into compounds. Robert Hooke (1665), John Mayow (1669), Nicolas Lemery (1675), and most of the philosophers of the Renaissance—R. Descartes (1644), Pierre Gassend (1647), C. Huygens (1690), G. Amontons (1702), N. de Malebranche (1712), and M. N. Lomonossoff (1741)—were atomicians.[10] René Descartes seems to have believed in the existence of atoms, but he substituted in place of an interatomic void, a subtle imponderable atomic fluid, the *materia cœlestis*, which occupied the space between the atoms of matter. Therefore, while a given space could be freed from ponderable matter, the *materia cœlestis* still remained. This is equivalent to the more modern statement that an æther-vacuum is impossible. N. de Malebranche (1712) dogmatically asserted that

> The *matière subtile* or *éthérée* is necessarily composed of *petits tourbillons*—small vortices—which are the natural cause of all material changes, and of the most general phenomena—*e.g.* hardness, fluidity, weight, buoyancy, the refraction and reflection of light, etc.

Isaac Newton (1675)[11] assumed that the atoms of a compound were held together by attractive forces so long as they did not approach within a certain limiting distance; within this limit repulsive forces were supposed to come into play which prevented absolute contact and gave rise to the resilience of the particles during impact. Newton also tried to explain Boyle's law on the assumption that gases were made up of mutually repulsive particles, which recede from one another as far as the pressure of the superincumbent atmosphere will let them; and he referred chemical changes to different associations of atoms.

R. Kirwan (1783), Bryan Higgins (1776), and William Higgins (1789),[12] with more or less confidence, explained the constant composition of salts in terms of atoms. Bryan Higgins recognized seven elements composed of "atoms homogeneal, impenetrable, immutable, in figure inconvertible, and globular;" and he appears to have held the view that two different atoms combine in the proportions of 1 : 1, and in that proportion only. William Higgins imagined a combination in multiple proportions, but believed that the binary combination 1 : 1 was the most stable. Thus, he said:

> In volatile vitriolic acid, a single ultimate particle of sulphur is united only to a single particle of dephlogisticated air; and in perfect vitriolic acid, every single particle of sulphur is united to two of dephlogisticated air, being the quantity necessary to saturation.

This idea appears to have arisen in Higgins' mind because it was assumed that atoms of the same kind are mutually repulsive and that a combination containing two similar atoms would have a greater tendency to disruption on account of the assumed mutual tendency of similar atoms to break apart. About this time, W. Nicholson [13] defined chemistry as a science of atoms, for he said :

> Chemistry, as a science, teaches the methods of accounting for the changes produced in bodies by the motions of their parts amongst each other which are too minute to affect the senses individually ; and, as an art, it consists in the application of bodies to each other in such situations as are best calculated to produce those changes.

Then followed John Dalton's announcement of the atomic theory and the law of multiple proportions at a lecture delivered at the Royal Institution, London, in 1803–4 ; the theory was described in T. Thomson's *System of Chemistry* (Edinburgh, 1807), and by Dalton himself in the following year, in the first part of his remarkable book, *A New System of Chemical Philosophy* (Manchester, 1808–10), where he says :

> It is one great object of this work to show the importance and advantage of ascertaining the relative weights of the ultimate particles, both of simple and compound bodies, the number of simple elementary particles which constitute one compound particle, and the number of less compound particles which enter into the formation of one or more compound particles.

Quite a number of different suggestions have been made to explain how Dalton came to give to the atomic hypothesis he had no doubt imbibed from Isaac Newton, the distinguishing features which led to its being called Dalton's atomic theory. Dalton's own accounts of the genesis of the hypothesis are not always consistent, so much so, that H. Debus [14] has breathed an improbable suspicion that J. Dalton deliberately made a mystery of the evolution of the theory. In his *System of Chemistry*, 1807, T. Thomson stated that the theory was suggested to J. Dalton by a comparison of the analyses of marsh gas and olefiant gas ; but J. Dalton's notebooks show that the experiments on these gases were made in the summer of 1804, nearly a year after the first table of atomic weights had been compiled. H. E. Roscoe and A. Harden,[15] in opposition to H. Debus,[16] attempted to prove that Dalton was influenced in the development of the theory by experiments on the diffusion and solubility of gases, which led him to try to find the relative sizes of the particles of different gases. This involved a determination of the relative weights of the particles of each gas, which, in turn, necessitated a determination of the chemical composition of the gas. The results so obtained led J. Dalton to deduce the atomic theory. In a series of important papers on *The Development of the Atomic Theory* (1909–11), A. N. Meldrum [17] showed that the facts admit of a somewhat different interpretation.

At the beginning of the nineteenth century, the diffusion of gases was supposed to be the work of chemical affinity, and the oxygen and nitrogen in the atmosphere were supposed to be chemically combined. In 1801, J. Dalton [18] argued that the phenomenon is physical and that the mixture of oxygen and nitrogen gases in atmospheric air is mechanical because the "nitric acid gas" formed by the union of these two elements is "an elastic fluid totally distinct in its properties from either of the ingredients." Dalton frequently quoted Newton's views on the attraction and repulsion of atoms, and, in a lecture in 1810, Dalton explained that he did not at first consider a possible difference in the sizes of the particles of the two elastic fluids, but he said that in 1805, he considered that the sizes must be different because no equilibrium can be established by particles of different sizes pressing against each other. In Dalton's notebooks, these views are dated Sept. 14th, 1804. According to H. E. Roscoe and A. Harden, these dates are wrong, for they assume that, having established a difference in the sizes of the particles of the elastic fluids,

> Dalton thence proceeded to determine the relative *sizes* and *weights*, together with the relative *numbers* of atoms in a given volume. This led the way to the combination of gases. . . . Thus a train of investigation was laid for determining the *number* and *weight* of all chemical elementary principles which enter into any sort of combination with one another.

Otherwise expressed, it is assumed that Dalton *first* satisfied himself that the atoms of different gases have different sizes, and *then* devised the chemical theory.

A. N. Meldrum (1911), however, has shown that J. Dalton did not conclude that the atoms of different gases were different in size until *after* the chemical theory had been formed. In J. Dalton's notebook, dated Sept. 6th, 1803, the first table of atomic weights appears in the annexed form :

Ult. at.	hydrogen	1	Ult. at.	nitrous oxide	13·66
,,	oxygen	5·66	,,	nitric acid	15·32
,,	azote	4	,,	sulphur	17
,,	carbon	4·5	,,	sulphurous acid	22·66
,,	water	6·66	,,	sulphuric acid	28·32
,,	ammonia	5	,,	carbonic acid	15·8
,,	nitrous gas	9·66	,,	oxide of carbon	10·2

A. N. Meldrum has also indicated that John Dalton probably arrived at the law of multiple proportions as a result of experiments on the combination of nitric oxide and oxygen whereby he was able to write in his notebook, Aug. 4th, 1803, that 100 measures of air could take 36 or 72 of nitric oxide. J. Dalton then probably framed the rule that atoms combine in the proportion 1 : 1, and on considering the more complex cases, he tested the possibility of combination in other proportions by the available analytical data, so that, in the following month, Sept. 6th, he was able to draw up the table of atomic weights.

Punctual atoms or centres of force.—The Lucretian school has never receded from the primary assumption that matter is composed of ultimate, solid particles—potentially divisible, but physically incapable of further subdivision ; but another school of atomicians has assumed that there is no limit to the divisibility of the particles of matter, and that the smallest conceivable particle still consists of an infinitude of smaller particles. René Descartes has said :[19]

> It is very easy to recognize that there can be in substance no atoms, that is to say parts of bodies or matter which are by nature indivisible, as some philosophers have imagined ; in as much as however small we may suppose these parts to be, yet, since they must be extended we see there is not one of them that cannot be further divided into two or more others, of smaller size, and is accordingly divisible ;

and I. Kant (1781), in his *Observations on the Second Antinomy*,[20] argued that those who object to the infinite sub-divisibility of matter do not recognize the clearest mathematical proofs as propositions relating to the constitution of space. Zeno (460 B.C.) previously argued that matter must be made up of indivisible and unextended points. Some such particles as these—*points de substance*—were imagined by G. W. von Leibniz (1695), and called **monads**—μονάς, a unit—a term which was employed by Pythagoras, and which is said to have been suggested to Leibniz by G. Bruno's *De monade* (Frankfurt, 1591), or during his intercourse with F. M. van Helmont. Leibniz's ideas were described in his posthumous *La monadologie* (Berlin, 1840) :[21]

> Material atoms, still composed of parts, are contrary to reason, for the inviolable attachment of one part to another—if we could reasonably conceive or suppose such a thing—would not destroy their diversity.

Newton himself seems to have had some misgivings about the indivisibility of atoms, for he said in his *Philosophiæ naturalis principia mathematica* (Londoni, 1687) :

> Whether these parts, distinct, and as yet undivided by material forces, are able to be divided and sundered in their turn is uncertain.

The main difficulty with Leibniz's animated points is to understand how a body can possess extension in space if it be made up of components which have no spatial dimensions, for, as J. C. Maxwell (1877) observes, that which has neither figure nor extent can have no existence. The Democritians—Newton, etc.—assumed that it is necessary to suppose that the ultimate particles must possess some bulk, otherwise they could not produce bulk by aggregation ; on the contrary, Zeno, Wolf, Schelling, etc., do not consider this assumption necessary, for a number of self-repulsive points in limited space can also communicate bulk to the body they compose. For instance, if a point were endowed with the irresistible power of repelling the hand from a radius of one inch, the result would be the same as if the hand were to grasp a 2-inch ball of adamant.

R. J. Boscovich,[22] in 1763, attempted to improve Leibniz's ideas by assuming that matter is made up of unextended points which mutually *attract* one another, but which never come into contact because, as soon as they approach within a certain limiting distance, they mutually *repel* one another; the repulsive forces increase more and more in intensity as the points approach closer and closer together, so that they never come into absolute contact. Extension in space is an effect of this repulsion, and the aggregation of matter is an effect of the attractive forces. He said:

> Matter is not mutually penetrable, but each atom-centre extends, so to say, throughout the whole of the solar system, yet always retaining its own centre of force.

R. J. Boscovich assumed that when attraction predominates, the body is a *solid*, and a *gas* when repulsion predominates, while if the two forces are more equally balanced, a *liquid* results.

A great deal has been written in favour of both hypotheses—Newton's that an atom is a solid nucleus surrounded by spheres of repulsive and attractive forces; and Boscovich's that an atom is a mathematical point with a sphere of a repulsive force surrounded by a sphere of an attractive force. In 1844, in *A speculation touching electrical conduction and the nature of matter*, M. Faraday [23] points out that in the ordinary atomic theory it is assumed that solids, liquids, and gases are composed of material atoms occupying a definite space, and are held together by cohesive forces; and further, in order to explain the contraction in volume which occurs on cooling or compressing solids, liquids, or gases, it is assumed that atoms cannot be in actual contact, but must be separated by an intervening space. These assumptions involve the following dilemma: If space is a non-conductor of electricity in non-conducting bodies, and a conductor in conducting bodies, we are compelled to assume that space possesses opposite and contradictory qualities, for if space be an insulator, it cannot exist in conducting bodies, and if it be a conductor, it cannot exist in insulating bodies. Hence, M. Faraday wrote:

> I feel a great difficulty in the conception of atoms of matter with intervening spaces not occupied by the atoms. . . . The atoms of Boscovich appear to me to have a great advantage over the more usual notion. His atoms are mere centres of forces or powers, not particles of matter in which the powers themselves reside.

There is a similar dilemma involved in connection with the transmission of light, and the physicists, A. M. Ampère (1835), A. L. Cauchy (1836), and M. Seguin (1853), have accordingly regarded atoms as centres of force infinitely small, without extension in space. Cauchy's punctual atoms were supposed to vibrate differently in different directions so that the elasticity varied accordingly. J. F. Redtenbacher (1857) [24] regarded this as an impossible assumption. The atoms, said Ampère, regarded as *les centres d'actions moléculaires, ne doivent pas être considérées seulement comme très petites relativement aux distances qui les séparent, mais comme rigoureusement nulles.*

The difference in the two sets of hypotheses turns on whether cohesive or other forces emanate from immaterial points of zero volume, or from material particles each occupying a definite volume. Which hypothesis is to be accepted? It must be remembered that we can persuade ourselves that matter itself can be spirited away by trying to conceive the residuum which remains when each property known to be a manifestation of energy is subtracted from matter. An extended nothing, said G. W. von Leibniz, is meaningless, an extended something must have quality, and to call that quality extension is to cover up the difficulty with a name. J. Locke (1690), and G. Berkeley (1713), M. Faraday (1844), W. Ostwald (1892), as well as earlier and later philosophers, have emphasized how impossible it is to conceive or imagine the existence of matter independent of energy; we have evidence of the existence of energy, and therefore, the supposition that a material world really exists apart from energy is undemonstrable and false. The chemist, however, progresses with his work on the assumption that he lives in a material world which it is his business to investigate.

The atomic theory is the only satisfactory hypothesis which has correlated the numerous facts relating to the transformations of matter. It may be perfectly true, Lord Kelvin (1874) has pointed out, that the assumption of atoms can explain no property of a body which has not previously been attributed to the atoms themselves. This, added H. von Helmholtz, is not evidence against the existence of atoms, but is rather against efforts to derive the foundations of theoretical physics from purely hypothetical assumptions as to the atomic structure of natural bodies. The assumption of atoms has none the less proved an invaluable aid in forming vivid mental pictures of the different phases of a chemical reaction; it has served as a wonderful stimulus to the chemical explorer, for it has enabled chemists to anticipate successfully the results of experimental research. The vitality of this time-honoured theory is remarkable; it is ever assimilating new facts, and ever enticing the chemist to fresh fields and pastures new. Innumerable prophecies based on the atomic hypothesis have been completely verified so that the atomic theory is now regarded as a pyramid of truth. Consequently, although no one has ever seen an atom, A. R. A. Smith (1884) could say: We believe in atoms because, so far as we can see, nature uses them. **The greater the number of facts consistently explained by one and the same theory, the greater the probability of its being true.** The overwhelming mass of circumstantial evidence, direct and indirect, which modern chemistry and physics offer, has justified the faith of Dalton; and almost, but not quite, demonstrated the real existence of tangible atoms.

§ 16. The Language of Chemistry

However certain the facts of any science, however just the ideas derived from these facts, we can only communicate false or imperfect impressions to others, if we want words by which these may be properly expressed.—A. L. LAVOISIER.

Words are the footsteps of reason.—FRANCIS BACON.

The nomenclature of a science, that is, the group of technical terms peculiar to that science, is of vital importance. It is virtually impossible to separate the nomenclature from the science itself. Lavoisier emphasized the importance of this in his classical *Traité élémentaire de chimie* (Paris, 1789). Every science consists of three things: (1) the facts which form the subject-matter; (2) the ideas represented by those facts; and (3) the words in which those ideas are expressed. Like three impressions of the same seal, said Lavoisier, the word ought to produce the idea; and the idea ought to be a picture of the fact.

Special technical words have been invented to fix and describe the ideas and principles of chemistry—as of all other sciences. Technical terms should be precise and clear, and not tainted with ambiguity and vagueness. Such technical terms form part of the current language of chemistry, and they are of international value.

Technical terms are obtained in two ways: (1) Owing to the poverty of language, words in colloquial every-day use are commandeered, and are given, by a special definition, a specific meaning. Such words are a prolific source of error and confusion, and they ofttimes lead to needless controversies because they have a variety of different meanings—energy, force, atom, etc., are examples. (2) Terms are specially invented for a specific purpose—electron, and telegraph, are examples. These terms are much less liable to misapprehension than adaptations of every-day words which possess several meanings. However strange the special terms may appear at first, they soon grow familiar to the ear, and they can be used without effort. W. Whewell has pointed out, very aptly, that "technical terms carry the results of deep and laborious research. They convey the mental treasures of one period to the generations that follow; and laden with this, their precious freight, they sail safely across the gulfs of time in which empires have suffered shipwreck, and the language of common life has sunk into oblivion." Witness: some of the terms used in the chemistry of to-day were coined by the early Arabian chemists—*e.g.* alcohol, alkali, borax, elixir, lac, etc.

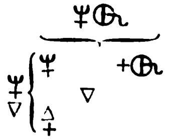
Naming the elements.—A great number of the elements have been endowed with names which refer to some salient property or characteristic, *e.g. iodine*—from its violet vapour; *chlorine*—from its green colour; *chromium*—from the colour of its compounds; *rhodium*—from the rose colour of its salts; *osmium*—

from its smell; *argon*—from its indifference to chemical reagents; similarly with platinum which refers to the silvery appearance of the metal—from the Spanish *plata*, silver. Likewise with the names phosphorus, radium, quicksilver, bromine, nitrogen, oxygen, hydrogen, argon, glucinum, iridium, praseodymium, thallium, indium, cæsium, and rubidium. Other elements have been named more or less capriciously; thus some elements are named after particular localities—*strontium*, from Strontian (in Scotland); *ruthenium*, from Ruthenia (Russia); *yttrium*, *ytterbium*, *erbium*, and *terbium* are all derived from Ytterby (in Sweden). Some elements have been named in honour of some country or from association with some other event at the time of their discovery—*e.g.* *helium*, from its occurrence in the sun; *gallium*, from Gallia (Gaul); *germanium*, from Germany; *lutecium*, from Leutéce, an old name for Paris; *palladium* was named after the planetoid Pallas discovered about the same time; *uranium* was likewise named in honour of the discovery of the planet Uranus; etc. Some names refer to the minerals in which they occur; *beryllium* is derived from the name of the mineral beryl; *zirconium*, from the mineral zircon; similarly with *molybdenum*, and many others. Some names refer to renowned personages—*e.g.* *victorium*, from Queen Victoria; similarly with *gadolinium*, from J. Gadolin; and *mosandrum*, after G. Mosander. Other names refer to mythological personages—*e.g.* *thorium*, from Thor, the son of Odin, a god in Scandinavian mythology; *vanadium*, from a Scandinavian goddess, Vanadus; *tantalum*, from Tantalus in Grecian mythology; *niobium*, from Niobe, daughter of Tantalus;[1] and similarly with cerium, titanium, palladium, and uranium. Some names are emblematic—*e.g.* selenium, cobalt, and nickel.

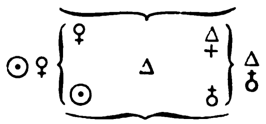
Unfortunately some elements have not yet been christened with a name recognized by all. *Niobium*—symbol Nb—and *columbium*—symbol Cb—are two different names for one element; *glucinum*—symbol Gl—and *beryllium*—symbol Be—are two different names for another element. There is at present a struggle for existence between these terms, no doubt the fittest will survive. The first terms here employed were recommended by the International Association of Chemical Societies, September, 1913; and F. W. Clarke wrote a strong protest, and claimed columbium in place of niobium for historical reasons.

Symbols.—The old alchemists used to represent different substances by quaint sometimes fantastic symbols—an example is given in Fig. 1, Cap. I. The hieroglyphs of the Hermetic priests in Egypt, and the fantastic symbols of the alchemists of the Middle Ages, were attempts to hide knowledge from the vulgar, and to surround the study of nature with difficulties and mysteries. The symbols of the modern chemist, on the contrary, are intended to facilitate the study of chemistry by abbreviating complicated expressions so that their meaning can be seen at a glance. Some of the older symbols did come under this category; for example, gold has been represented by the picture of a king on his throne; by the symbol ○ or ☼, for the sun, etc.; silver, by ☾, the moon; etc. Fantastic symbols, like that indicated in Fig. 1, Cap. I, could lead only to confusion. Symbols were employed by Raymond Lully somewhat frequently in the thirteenth century. Possibly the alchemists intended the symbols to convey some idea of the peculiarities of the metals they represented; indeed, it has been suggested that the circle which appears in certain of the symbols was intended to illustrate the perfection of the metallic state, and the half circle, an approximation thereto. In any case the alchemists were very fond of symbols, and of obscuring their meaning by using mystic triangles and special hieroglyphs so as to make their writings like cryptograms which required a key before the meaning could be deciphered.[2] Thus, Raymond Lully in his *Testamentum, duobus libris universam artem chimicam complectens* (Colon, 1568), used the symbol *A* to represent God the Creator, *B* stood for mercury, *C*, for saltpetre. . . . These symbols were not in general use, and each writer devised his own. The alchemists of the thirteenth century also represented Aristotle's four elements by triangles: △, fire; 🜁, air; ▽, water, and 🜃, earth. Other symbols gradually came into more or less general use; thus, about the fourteenth century the symbol △ for sulphur was fairly common in the writings of the alchemists.

At the beginning of the eighteenth century, symbols for chemical compounds began to be used more frequently, not with the idea of making the literature obscure and unintelligible to the uninitiated, but rather for conciseness, brevity, and clearness. St. F. Geoffroy, in his *Table de différents rapports observés en chimie entre différentes substances* (1718), used the ordinary alchemical symbols for the metals and introduced a number of others, *e.g.* ⊖ for salt; >⊖ for hydrochloric acid; >⏀ for nitric acid; >⏀⊣ for sulphuric acid, etc. In his *De attractionibus electiviis* (Upsala, 1775), T. Bergmann represented chemical reactions by symbols and signs. The two subjoined diagrams illustrate T. Bergmann's method. The symbols to the right and left, outside the brackets, represent the substances which react together; and those above and below, the products of the reaction, if any, which separate from the system. The symbols within the brackets represent the reacting components; and the disposition of the brackets is intended to indicate whether the products of the reaction are solid, or solution, or volatile. Thus,



Represents the action which occurs when an aqueous solution (▽) of calcium sulphide (♆) is treated with sulphuric acid (⏀). The lime (♆) and sulphuric acid (⏀) unite together to form calcium sulphate (♆⏀) which is precipitated (⏝) and the sulphur (🜍) also remains as a solid. (⏝).



Represents the action which occurs when an alloy of gold and copper (⊙♀) is fused (△) with antimony sulphide (🜍♁); The copper (♀) and gold (⊙) are separated; the copper (♀) and sulphur (🜍) unite together to form a solid (⏝), and the gold (⊙) and antimony (♁) also unite to form a solid (⏝).

A. F. de Fourcroy[3] employed a similar method in 1784. It must be added that, about 1756, W. Cullen is said to have been the first to employ diagrams to illustrate chemical reactions. A. L. Lavoisier used the symbol ▽ for water; ⊕ for oxygen; etc., and, like T. Bergmann (1775), he represented chemical reactions by combining these symbols in various ways.

John Dalton, in his *New System of Chemical Philosophy* (Manchester, 1808), made a step in advance by representing the atoms of the elements by symbols, and combining these symbols so as to show the elements present in a compound. Thus, ⊙ represented hydrogen; ○ oxygen; ● carbon, etc. Water was represented by ○⊙; carbon monoxide by ○●; carbon dioxide by ○●○; etc. These symbols have all been abandoned. They are too cumbrous. To-day, we follow J. J. Berzelius' method, suggested in various editions of his *Larbok i Kemien* (Upsala, 1811), and use one or two leading letters from the recognized name of the element to represent any particular element. The first letter is always a capital; the second, if present, is always a small letter.

Thus, O represents oxygen; H, hydrogen; C, carbon; N, nitrogen; Cl, chlorine; etc. The names of ten elements start with C, and to prevent the possibility of confusion, a second leading letter is selected either from the name, or from the alternative Latin name of the element. Thus C (carbon), Ca (calcium), Cb (columbium), Cd (cadmium), Ce (cerium), Cl (chlorine), Co (cobalt), Cr (chromium), Cs (cæsium), and Cu (*cuprum*), copper). The elements with alternative Latin names are symbolized: Sb for antimony (*stibium*); Cu for copper (*cuprum*); Au for gold (*aurum*); Fe for iron (ferrum); Ag for silver (*argentum*); Pb for lead (*plumbum*); Hg for mercury (*hydrargyrum*); K for potassium (*kalium*); Na for sodium (*natrium*); and Sn for tin (*stannum*).

Naming the compounds.—Each element forms with other elements a group of compounds which are said *to contain* the respective elements, because the elements in question can be obtained unchanged from the compounds. Consequently, **every compound has an elementary or ultimate composition.** Compounds are symbolized by joining together the letters corresponding to the different elements in the compound. Thus, HgO represents mercury oxide, a compound of mercury and oxygen. When only two elements are united to form a compound, the name of the second element is modified so that it ends in **ide.**

The symbol for the element also represents one of its atoms. If more than one atom is present in a compound, a small figure is appended to the bottom—in France, generally at the top right-hand—corner of the symbol of the element, to indicate the number of atoms present. Thus, H_2O represents a molecule of water, *i.e.* a compound containing two atoms of hydrogen and one of oxygen; CO represents a molecule of carbon monoxide—a compound containing one atom of carbon and one atom of oxygen; Na_2CO_3 represents a molecule of sodium carbonate a compound containing two atoms of sodium, one atom of carbon, and three atoms of oxygen. A letter affixed in front of a group of symbols represents the number of times that group is contained in the given compound. Thus, crystallized sodium carbonate is symbolized: $Na_2CO_3.10H_2O$, meaning that this compound contains one equivalent of Na_2CO_3, and ten equivalents of the group H_2O.

J. J. Berzelius (1814)[4] represented two atoms of an element in a compound by drawing a bar through the symbol of the element; for instance, $\cancel{\mathrm{H}}\mathrm{O}$ represented H_2O; $\cancel{\mathrm{Fe}}\mathrm{O}_3$: Fe_2O_3; $\cancel{\mathrm{Cu}}\mathrm{O}$ represented Cu_2O; etc. J. J. Berzelius also represented an atom of oxygen united with an element by placing a dot over the symbol of the element, and an atom of sulphur by a dash in a similar position; thus, $\dot{\mathrm{C}}\mathrm{u}$ represented CuO; $\ddot{\mathrm{P}}\mathrm{b}$, PbO_2; $\dot{\mathrm{C}}\mathrm{a}\ddot{\mathrm{C}}$, $CaOCO_2$; $\mathrm{CuS}+5\cancel{\mathrm{H}}$ represented CuO, SO_3+5H_2O; and Fe represented FeS_2. This system did not last long in chemical literature, although the mineralogists used it for a longer time.

Compounds of an element with oxygen are called **oxides,** and the process of combination is called **oxidation.** When an element forms more than one oxide, a Greek numerical suffix is often prefixed to the word oxide. Thus SO_2 is sulphur dioxide; SO_3, sulphur trioxide; CO, carbon monoxide; CO_2, carbon dioxide; PbO, lead monoxide; PbO_2, lead dioxide or lead peroxide. The Anglicized Latin and Greek numerical prefixes are indicated in Table I.

TABLE I.—LATIN AND GREEK NUMERICAL PREFIXES.

	Latin.	Greek.		Latin.	Greek.
1	Uni-	Mono-	17	Septemdeci-	Heptadeca-
2	Bi-	Di-	18	Duodeviginti-	Octodeca-
3	Ter-	Tri-	19	Undeviginti-	Enneadeca-
4	Quadri-	Tetra-	20	Viginti-	Icosi-
5	Quinqui-	Penta-	21	Unviginti-	Henicosi-
6	Sexa-	Hexa-	22	Duoviginti-	Docosi-
7	Septa-	Hepta-	23	Treviginti-	Tricosi-
8	Octo-	Octo-	24	Quattuorviginti-	Tetracosi-
9	Nova-	Ennea-	25	Quinviginti-	Pentacosi-
10	Deca-	Deca-	26	Seviginti-	Hexacosi-
11	Undeci-	Henadeca-	27	Septemviginti-	Heptacosi-
12	Duodeci-	Dodeca-	28	Duodetriginta-	Octocosi-
13	Terdeci-	Trideca-	29	Undetriginta-	Enneacosi-
14	Quattuordeci-	Tetradeca-	30	Triginta-	Triaconta-
15	Quindeci-	Pentadeca-	31	Untriginta-	Henitriconta-
16	Sedeci-	Hexadeca-	32	Duotriginta-	Dotriconta-

	Half	Whole	Equal	Many	One and a half	One third	Four thirds
Latin . .	Semi-	Omni-	Equi-	Multa-	Sesqui-	Tertia-	Quadritertia-
Greek .	Hemi-	Holo-	Homo-	Poly-	Hemitri-	Trita-	Tetratrita-

It is considered bad style to mix Latin and Greek root words and prefixes. Consequently we usually try to keep Greek with Greek, and Latin with Latin. Thus, we say "diatomic," not "biatomic"; "bimolecular," not "dimolecular"; "bivalent," not "divalent"; and "bivariant," not "divariant"; because "atomic" is derived from the Greek word, while "molecular," "variant," and "valent," are derived from Latin words. There are, however, many hybrids universally recognized. *E.g.* millimetre, centimetre, etc. Monovalent, divalent, etc., are also used in spite of their hybrid character. In the application of the Greek numerals in organic chemistry, some hybrids are used—*e.g.* in the methane series of hydrocarbons, Greek numerals are generally employed excepting for C_9H_{20}, $C_{19}H_{40}$, $C_{29}H_{60}$, . . . and for $C_{11}H_{24}$, $C_{21}H_{44}$, . . . where Latin numerals are used. The series thus runs pentane, C_5H_{12}; hexane, C_6H_{14}; heptane, C_7H_{16}; octane, C_8H_{18}; nonane, C_9H_{20}; decane, $C_{10}H_{22}$; undecane, $C_{11}H_{24}$; etc. For consistency nonane should be enneadecane, and undecane, hendecane, etc. The custom is so general, and so deeply rooted in the literature of organic chemistry, that, as F. Beilstein[5] says, the rectification *gegenwärtig nicht mehr empfehlenswert erscheint*. This state of crystallization has not yet been attained in the naming of inorganic compounds, and the Greek numerical prefixes can be consistently used if thought desirable; but "sesqui" is generally used whether Greek or Latin affixes are employed. However, we cannot always be purists without defying custom, which, as Horace has said, decides the language we must use.

Sometimes the termination **-ic** is affixed to the name of the metal for that oxide which contains the greater proportion of oxygen, and **-ous** for the oxide containing the lesser proportion of oxygen. For instance, SnO is either stannous oxide, or tin monoxide, and SnO_2 is either stannic oxide or tin dioxide; FeO is ferrous oxide; and Fe_2O_3 ferric oxide. For historical reasons, the names of some compounds do not conform to this system because the affix "ic" was assigned to the compound first discovered, and the compounds subsequently discovered were named accordingly. Consequently, when only one series of compounds is known, the use of either termination is now avoided—thus, potassium, sodium, and magnesium are preferred to potassic, sodic, and magnesic respectively. The method of naming the compounds now under discussion is not always satisfactory when the elements form more than two compounds. To get over the difficulty, a prefix **hypo-** (under, or lesser) is sometimes added to a compound less rich in oxygen than the **-ous** compound, and **per-, hyper-, or super-** (beyond, above) is added to the one with more oxygen. Thus,

Persulphuric acid	$H_2S_2O_8$	Perchloric acid	$HClO_4$
Sulphuric acid	H_2SO_4	Chloric acid	$HClO_3$
Sulphurous acid	H_2SO_3	Chlorous acid	$HClO_2$
Hyposulphurous acid	$H_2S_2O_4$	Hypochlorous acid	$HClO$

The six nitrogen oxides—nitrogen monoxide, dioxide, trioxide, tetroxide, pentoxide, and hexoxide—would be awkwardly named by this system.

It will be observed that *ous* from the Latin *osus* means "richness," so that *stannous* means *rich in* tin, and etymologically stannous oxide means an oxide *richer in* tin than stannic oxide, and by implication *poorer in oxygen*. In actual use, therefore, the etymological meaning is inverted, and the implied signification has been universally adopted. Etymologically the term *hypo* means *less rich*, so that hypochlorous means less rich in chlorine than chlorous—in practice the very opposite is the case, for hypochlorous acid has less oxygen than chlorous acid, and it contains a higher proportion of chlorine. Similar remarks apply to the prefixes *per*, *super*, and *hyper*.

Oxides like alumina—Al_2O_3; ferric oxide—Fe_2O_3, etc., are sometimes called **sesquioxides** (*sesqui*, one-half more). Compounds which have less oxygen than the normal are sometimes called **suboxides** (*sub*, below) instead of hypo-oxides, *e.g.* while CuO represents cupric oxide, Cu_2O represents cuprous oxide, and also copper suboxide; similarly, while AgCl represents the normal silver chloride, Ag_2Cl represents silver *sub*chloride. Custom has restricted the use of *hypo-* to the acids or acidic oxides, and *sub-* to the basic or indifferent oxides. The oxides can be roughly divided into two classes. Some oxides, with water, form acids, and others act as bases. It is not very easy to draw a sharp line of demarcation between the two. The *acidic oxides* have a sour taste, and turn a solution of blue litmus red; the *basic oxides* usually turn a solution of red litmus blue, and have a soapy feel.

The nomenclature of inorganic chemistry is thus based upon the principle that the different compounds of an element with other elements can be named by a simple change in the beginning or termination of the word—witness ferric and ferrous oxides; and also by the addition of a numerical suffix showing the relative number of atoms of the corresponding element in its compounds. The systematic name of a compound thus indicates its composition.[6] These little artifices, apparently trivial, are really important advances in the language of chemistry. The method has some defects, but when the necessity for a modification becomes acute, it will probably not be difficult to change. Language generally lags in the wake of progress.

§ 17. The Evolution of the Chemist's Nomenclature

> For a language to be perfect, it is not sufficient that each substance, each idea, each modification of form, time, place, etc., should be represented by one word, or by one invariable symbol, it is necessary in addition, both to aid the memory and to facilitate the operations of the mind, that analogous words should designate analogous substances, analogous ideas, and modifications of ideas. It is thus that the words of our language represent to us by similar terminations or augments, similar modifications of ideas represented as when we say: *je vois, j'aperçois, je reçois; nous voyons, nous apercevons, nous recevons.* In like manner do chemists make use of the expressions sulphate, nitrate, chloride, etc.—A. LAURENT (1854).

In the British Association's *Report on Chemical Nomenclature*,[1] it is shown that the evolution of the chemist's nomenclature is largely conditioned by the history of chemistry itself. No attempt to name substances systematically appears to have been made before the time of Geber—about the thirteenth century. The names in vogue for chemical substances up to the middle of the eighteenth century were more or less arbitrary, for they were (i) relics of alchemists' terms—for instance, *aqua fortis* (nitric acid), *aqua regia*, etc.; or derived (ii) from the name of their discoverer—for instance, *Cadet's fuming liquid* (alkarsine); or (iii) from one who had made a special study of the substance—for example, *Glauber's salt* (sodium sulphate); or (iv) from the name of the locality where they occurred—for example, *Epsom salts* (magnesium sulphate); or (v) from some prominent property or quality they possessed—for instance, *tartar emetic* (potassium antimony tartrate); or (vi) the names were based upon some superficial resemblance, and thus what J. B. A. Dumas called *le langue des cuisinières*—the language of the kitchen—was applied; for instance, antimonious chloride was called *butter of antimony* because of its buttery appearance; zinc chloride for the same reason was called *butter of zinc*; and arsenic chloride, *butter of arsenic*. On account of this superficial resemblance, these substances for a time were classed along with butter from milk! Similarly, *oil of vitriol* (sulphuric acid), *oil of tartar* (deliquesced potassium carbonate), *olive oil*, and the fatty oils generally were classed together; so also were such unlike substances as *spirit of wine* (alcohol), *spirit of salt* (hydrochloric acid), *Libavius' fuming spirit* (stannic chloride), *Boyle's fuming spirit* (ammonium sulphide), *Glauber's fuming spirit of nitre* (nitric acid), and *spirits of hartshorn* (ammonia) were included in one class. This virtually means that the names of the compounds were the basis of the classification. The names were arbitrarily assigned, and hence the classification was almost as arbitrary and confusing as if the compounds had been classified according to the number of the letters in their names. Liquids were once called mercurys—mercury itself was *mercurius communis*, alcohol, *mercurius vegetabilis*, etc. Salts were distinguished by their taste—*salis acida*, *salis alcalina* —and by their volatility—*salis alcalina fixa*, *salis alcalina volatila*, etc. There are here, however, signs of a feeble attempt at a truer classification.

Towards the end of the seventeenth century, chemists began to assign similar names to salts having the same origin—more particularly in reference to the acidic component of the salts. Thus, salts derived from sulphuric acid were called *vitriols ;* and those from nitric acid were called *saltpetres.* A century later, P. J. Macquer and A. Baumé, in their *Plan d'un cours de chimie expérimentale et raisonnée* (Paris, 1757), emphasized the need for designating substances similar in composition by similar names so as to enable chemists to cope with a rapidly growing list of new compounds. The confused state of chemical nomenclature, even at the beginning of the nineteenth century, is shown by an illustration from Joseph Black's *Lectures on the Elements of Chemistry* (Edinburgh, 1803), where sometimes a dozen synonyms for a salt are listed.

About 1770, T. Bergmann advocated a new system of nomenclature which was described in his *Meditationes de systemate fossilium naturali ;* the system was based as far as possible on the terms then in use, and founded on the phlogiston theory. T. Bergmann also proposed to represent substances of analogous composition by similar symbols, and so compounded the symbols that each substance had its own special symbol. For instance, he called potassium sulphate, *alkali vegetabile vitriolatum ;* sodium chloride, *alkali fossile salitum ;* ammonium nitrate, *alkali volatile nitratum ;* and similarly for sodium nitrate, sulphate, etc. His system was excellent for its time, and shortly afterwards (1782), Guyton de Morveau [2] gave a consistent nomenclature for the salts which he described as compounds of acids and bases, and he illustrated the advantages of his system by applying it to 474 substances—*e.g. vitriol de barote* (barium sulphate) ; *nitre de mercure* (mercury nitrate) ; *muriate de calce* (calcium chloride) ; *fluor de calce* (calcium fluoride); etc. In the choice of names for chemical compounds, said G. de Morveau, the following five principles should be observed :

(1) A phrase like *liqueur alkaline saturée de la matière colorante de bleu de Prusse* is not a name and it should be replaced by *l'alkali prussien.* Both terms were then in vogue. (2) The name should correspond as nearly as possible with the object. When a name is made up of a noun and an adjective, the former should be applied to the least changeable and more essential constituent. The names of discoverers should be excluded from the system. (3) If the constitution of a body is not known, a term with no meaning is better than one which may ultimately prove to be a wrong one. Hence *l'alkali prussien* is preferable to *l'alkali phlogistique.* (4) New names are best derived from roots of the best known dead languages—Greek and Latin. (5) Names should be adapted to the peculiarities of the particular language in which they are to be used.

G. de Morveau's system, like Bergmann's, was founded on the phlogiston theory. These two schemes were probably the first attempts to devise a complete system of naming inorganic compounds so that each name indicates the qualitative composition of the substance for which it stands. These two systems are not very different, and are not much unlike the one in use to-day.

In 1787, A. L. Lavoisier and G. de Morveau, with the assistance of C. L. Bertholet and A. F. de Fourcroy, presented details of a new *Méthode de nomenclature chimique* to *l'Académie des Sciences* [3] in Paris. The proposed method was really an elaboration of T. Bergmann's and G. de Morveau's systems adapted to the dualistic hypothesis. Most chemists felt the need for a precise nomenclature independent of the phlogiston which the French chemists were rapidly driving out of chemical science. In the proposed system the names assigned to the various compounds were intended (i) to indicate the compound ; (ii) to define the compound ; (iii) to recall its constituent parts ; (iv) to classify it according to its composition ; and (v) to indicate the relative proportions of its constituents.

The French report laid the foundations of the chemical language of to-day—of course, after making due allowance for the development of the science which has necessitated many modifications. The terms *ic* (ique) and *ate, ous* (eux) and *ite,* for respectively distinguishing the higher and lower acidic oxides and their salts, are employed for the first time. In 1804, T. Thomson [4] introduced the plan of distinguishing the different oxides of an element by prefixing the Greek suffixes *proto*, first; *deuto*, second, . . . for the first, second, . . . compound of a series—*e.g.* CuCl would be the *proto*-chloride of copper; and $CuCl_2$ the *deuto*-chloride. In 1808, J. Dalton explained his notation in his *New System of Chemical Philosophy* (Manchester, 1808). J. J. Berzelius' modifications [5] followed in 1811 as indicated above. Berzelius introduced the term *ide*, or French *ure*, as a termination for simple compounds.

Various other systems of nomenclature have been proposed from time to time in which artificial words replace the arbitrary names applied to well-known substances—each vowel or consonant of the artificial word representing either a substance or a number.[1] These systems have been found to be unworkable. There are also systems based on M. Dewey's *Decimal Classification and Relativ Index* (Boston, 1885); for example, A. L. Voge, in his *The Inorganic Compounds* (Zurich, 1911), arranges 14,000 inorganic compounds on Dewey's system. He gives

	N_2O	NO	N_2O_3	NO_2	N_2O_4	N_2O_5
Symbols . .	133211	133311	133411	13351181	13351182	133611

These systems have possible uses in libraries and for card indexes.

The *Méthode de nomenclature* contained as appendices two *Mémoires sur de nouveaux caractères à employer en chimie* devised by J. H. Hassenfratz and P. A. Adet. In these, 54 straight and curved lines representing the combining units, were arranged in various ways to represent possible compounds. The appearance of the combined symbols, in many cases, recalls some of the modern systems of shorthand writing. The idea of using "shorthand systems" is revived every now and again, but has never come into general use.

CHAPTER III

HYDROGEN AND THE COMPOSITION OF WATER

§ 1. The History of Pneumatic Chemistry

The history of human knowledge is a history of false inferences and erroneous interpretations of facts.—MAX NORDAU.

THE attention of the early workers in chemistry was mainly directed to visible and tangible liquids and solids, while the gases—spirits, fumes, vapours, and airs, as they were variously called—which escaped when different substances reacted together, were usually considered to be unwholesome effluvia, best avoided. Indeed, about the middle of the eighteenth century J. Black [1] could say :

> In their distillations, chemists have often observed that part of a body has vanished from their senses, notwithstanding the utmost care to retain it ; and upon further inquiry, they have always found that subtle part to be air, which, having been imprisoned in the body under a solid form, was set free and rendered fluid and elastic by the fire.

In the third century, Clement of Alexandria believed that the suffocating properties of some gases were manifestations of a diabolical nature, and J. B. van Helmont, who was the most advanced student of gases at the beginning of the seventeenth century, appears to have had a hazy belief that the gases he had discovered were in some senses living spirits—diabolic or divine. Even as late as the middle of the seventeenth century, G. Agricola [2] hinted that the gases in mines were manifestations of malignant imps ; and the idea had not been altogether exorcised at the beginning of the eighteenth century.

The old chemists used the term *spirit* or *air* where we use the term *gas* generically for aëriform elastic fluid. Thus, in the first century of our era, Pliny, in his *Historia natura* (2. 4), spoke of that *spiritus* which both the Greeks and the Romans called *aĕro*. The terms *spiritus*, *flatus*, *halitus*, *aura*, and *emanatio nubila* were also applied to aëriform fluids disengaged by heating other substances, and they are common in the writings of the alchemists of the Middle Ages. J. B. van Helmont, in speaking of the *spiritum sylvestrem* which he had obtained by the combustion of carbon, etc., said, " This spirit, unknown up to the present, I call by a new name *gas*," and he says elsewhere [3] that in order to distinguish the vapour given off by water at ordinary temperatures from the vapour which is derived from boiling water, " by the licence of a paradox, for want of a name, I call the vapour rising from water at ordinary temperatures, a *gas*, being not far severed from the *chaos* of the auntients (ancients)." Just as the " chaos of the auntients "—Hesiod's *χαος*—was a confused mixture of elements from which the Creator produced the universe ; so, to van Helmont, the vapour of water was a confused mass of elements from which all material substances could be produced. The word *chaos* was very frequently used by Paracelsus with a similar meaning. " Chaos," said he, " is an air like the wind. Air is nothing more than a chaos. What air is, that is chaos. The element air is named chaos." Stephen Hales (1727 also said that atmospheric air is a veritable Proteus and a chaos. It is an easy transition from *chaos* to *chas*, which has the sound of *gas*. According to M. Speter, the *ch* and *ao* of chaos when converted into Netherland speech become respectively *g* and *a*, so that van Helmont transformed Paracelsus' term to suit the language of his country. Some derive the word from the *geest*—spirit, volatile liquid, or refined fluid—of the Dutch ; or from the *gäscht*—yeast—of the Germans.[4]

Near the beginning of the seventeenth century, J. B. van Helmont, in his essay *De flatibus*, distinguished *gas sylvestre*—given off by fermenting liquids—from the inflammable gases which he named *gas pingue*, *gas sicum*, or *gas fuliginosum*. J. B. van Helmont seems to have adopted the common opinion that gases are different combinations of elastic air with various exhalations or impurities, for at that time chemists regarded the different gases as chaotic mixtures of various substances with atmospheric air. The term *sylvestre* was intended to imply that the artificial gases which he had prepared were untameable and uncondensable. In a letter to R. Boyle [5] in 1678, Isaac Newton stated that he considered that the ferrous gas (hydrogen) which R. Boyle had obtained by the action of acids on iron, and the cuprous gas (nitrogen oxide), which C. Huygens [6] had obtained by the action of nitric acid on copper, contained ultimate particles respectively of iron and copper brought to a state of aërial elasticity; but the idea of a *ferrous gas* from iron, and a *cuprous gas* from copper was disproved when H. Cavendish [7] demonstrated the identity of the gases obtained by the action of acids on iron and on zinc. According to J. Priestley, " Boyle [8] was the first who discovered that what we call fixed air, and also inflammable air, are really elastic fluids capable of being exhibited in a state unmixed with common air." R. Boyle extended his experiments on factitious (artificial) airs separable from fixed bodies to a variety of substances, and he noticed the condensability of hydrogen chloride (1676); the orange colour of nitrogen peroxide (1672); and the evolution of an air by heating red lead in the focus of a burning glass (1678). He also obtained an air from oyster shells and red coral (1661), and noted the inflammability of hydrogen obtained by the action of acids upon iron (1671). R. Boyle employed the term *air* generally (1676) in the same sense that the word gas is used to-day. *Tout corps invisible et impalpable,* said R. Descartes (1664), *se nomme air.* J. Mayow [9] examined the relative elasticities of the two gases obtained by R. Boyle by the action of nitric and sulphuric acids on iron, and decided that *there exist various elastic fluids other than air.* J. Mayow's conclusion was opposed by the elder Bernoulli,[10] who claimed that there are no other elastic fluids besides air; and, overlooking the constant diminution of volume which Mayow found to occur when air is breathed or burnt, J. Bernoulli further claimed that animals are suffocated and flames are extinguished in certain airs because the airs are charged with miasmata inimical to life and combustion.

It is sometimes said that S. Hales, in his *Vegetable Staticks* (London, 1727), confused the different gases which he prepared with atmospheric air. This erroneous idea has appeared because Hales focussed his attention on the generic physical properties of gases rather than on their specific chemical characteristics. Thus, W. V. Harcourt [11] has pointed out that when Hales states that " the airs generated by effervescences . . . resemble true permanent air " he really means that they are true elastic fluids with the same permanence of constitution, and the same elastic force as common air. Hales heated a number of substances in vessels arranged so that the gases evolved could be collected over water, and he measured the proportion of gas furnished by definite weights of different substances. He also collected airs furnished by fermentation processes, and airs generated by the action of acids on metals. S. Hales did not make any special experiments on the chemical properties of different gases—hydrocarbons, carbon dioxide, nitrogen oxides, oxygen, nitrogen, hydrogen, cyanogen, and chlorine—which he probably collected, nor on the aqueous solutions of the more soluble gases—hydrogen chloride, sulphur dioxide, and ammonia—which he must have prepared. In spite of the experimental facts which S. Hales thus accumulated, his attention was so preoccupied with their generic physical properties that he did not observe their specific chemical differences —*oculos habuit et non videbat*—and he was thus prevented from making many capital discoveries.

J. B. van Helmont seems to have believed that while gases could be prepared artificially in many ways, they could not be caught and held in vessels—*gas, vasis incoercible, foras in aerem prorumpit.* S. Hales is generally credited with the invention of the gas-collecting or **pneumatic trough.** J. B. van Helmont did not know how to isolate and preserve the *gas sylvestre* which he discovered near the beginning of the seventeenth century, and he distinctly stated that the gas cannot be confined in any vessel, since it overcomes all obstacles and mixes with atmospheric air.

R. Boyle (1661) and J. Mayow (1669) used a glass globe, Fig. 6, Cap. I, inverted in a basin of water for confining air: they filled the globe with water and inverted it in the basin of water so that the gas generated by the action of an acid on some scraps of iron in the basin displaced the water and collected in the globe. M. d'Elèment, in a brochure [12] published at Paris in 1719, had already shown that air could be manipulated and measured like other bodies by confining it in vessels over water; and in 1621, J. C. Drebbel had noticed the bubbling of gas from a retort heated with its beak dipping in water. S. Hales devised the apparatus indicated in Fig. 1, for collecting the gases evolved when different substances are heated in a retort—a glass vessel was used for generating the gases at low temperatures, and a bent gun barrel for high temperatures. The vessels used for collecting the gas were hung by strings mouth downwards below the surface of the water. H. Cavendish (1766) used a similar device. W. Brownrigg [13] used a shelf with two holes larger than the gas jar and above the level of the liquid in the trough; the latter were prevented sinking too deeply by means of wedges. J. Priestley introduced the use of a perforated shelf below the level of the liquid in the trough for supporting the vessel to be filled with gas. Modifications of S. Hales' and J. Priestley's pneumatic troughs were employed very effectively in chemical researches on gases by C. W. Scheele (1770) and A. L. Lavoisier (1772). Joseph Priestley also substituted mercury for water; and, by means of the **mercury pneumatic trough,** he collected and isolated gases—ammonia, hydrogen chloride, sulphur dioxide, silicon fluoride—which are so soluble in water that their existence had been overlooked when water was the confining liquid.

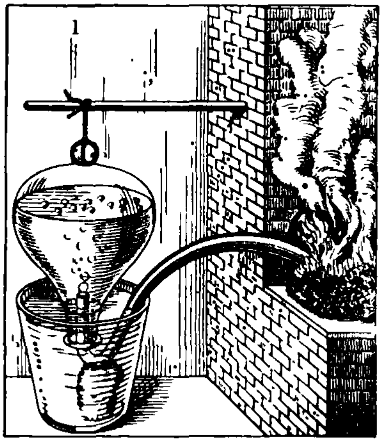

Fig. 1.—S. Hales' Pneumatic Trough.

The study of gases began to occupy serious attention towards the end of the eighteenth century, so that in 1779, although "only eight gases were certainly known with respect to their composition," yet chemists were so proud of their knowledge that T. Bergmann was able to write: "During the last ten years chemistry has not only soared into regions of invisible aerial substances, but it has dared to explore the nature of these substances, and to search into their constituent principles." The nineteenth-century chemists devoted a great deal of time and attention to the imperceptible, intangible gases ignored by the earlier workers. Indeed, chemistry could never have progressed very far if the gases and vapours had been ignored. The work of Joseph Priestley, between 1770 and 1780, gave such a stimulus to the study of gases that G. Cuvier, in his *Éloge historique de Priestley* (Paris, 1806), called him *un des pères de la chimie moderne.*

§ 2. Hydrogen—Preparation and Properties

> It can scarcely be said that pneumatic chemistry was properly begun till Mr. Cavendish published his valuable paper on carbonic acid and hydrogen gas, in the year 1766 —T. THOMSON (1813).

The discovery of hydrogen.—It is inconceivable that the alchemists knew nothing about this gas, for they were perpetually operating with various metals in contact with acids. It must therefore have been known for a very long time that an inflammable air or gas is produced when iron is dissolved in dilute sulphuric acid. Paracelsus, in the sixteenth century, described the action somewhat quaintly. He said that when the acid acts on iron "an air arises which bursts forth like the wind." Near the beginning of the next century, J. B. van Helmont described this gas as a peculiar variety of air which was combustible and a non-supporter of combustion, but his ideas were somewhat hazy, for he confused it with other inflammable gases; indeed, up to about 1766, writers generally used **inflammable air** as a general term to include this gas, as well as the hydrocarbons, hydrogen sulphide, carbon monoxide, and other combustible gases. Hydrogen was sometimes specifically distinguished as the *inflammable air from the metals*. In 1650, T. Turquet de Mayerne [1] reported that the fumes evolved when dilute oil of vitriol acts on iron are inflammable, and in 1671 Boyle [2] observed that the flame was extinguished when placed under the receiver of an air-pump, but R. Boyle's chief concern was to show that the gas, which he called the *volatile sulphur of Mars*, was dilatable and compressible, and that it was really an air. Nearly a century later, J. Priestley also experimented with the gas, and S. Hales [3] found that iron filings and oil of vitriol gave scarcely any air, but on adding water, there was a copious evolution of the aëriform fluid. In 1766, H. Cavendish [4] showed that the combustible gas produced by the action of dilute sulphuric or hydrochloric acid on metals like iron, zinc, and tin is a distinct substance with definite properties peculiar to itself; hence, hydrogen was called *inflammable air*. Cavendish measured the amount of hydrogen obtained from a given weight of the different metals; he also measured the specific gravity of the gas, and found it to be seven times lighter than atmospheric air; he also showed that the specific gravity of the gas was the same whether zinc or iron were used in the preparation. F. de Lassone and C. W. Scheele discovered almost simultaneously that a solution of zinc in caustic lye furnishes the same gas. J. Watt (1783), R. Kirwan (1781), H. Cavendish (1766), and J. Priestley (1784) identified the gas with the evanescent phlogiston, and they called it *phlogiston*, or *phlogisticated air;* but neither this name nor *inflammable air* persisted very long, for both terms were ousted by the cognomen *hydrogen* which A. L. Lavoisier applied to the gas in 1783. In his *Considérations générales sur la dissolution des métaux dans les acides* (1784),[5] A. L. Lavoisier, following a suggestion of P. S. de Laplace, traced the source of the hydrogen which is evolved when a metal dissolves in a dilute acid, to the decomposition of the water. He assumed that the oxygen of the water united with the metal to form a calx, and the hydrogen escaped in the free state. The calx united with the acid to form water and a salt.

The preparation of hydrogen.—Hydrogen obtained by the action of dilute sulphuric or hydrochloric acid on metallic iron is not very pure, and it possesses a distinct smell owing to the presence of hydrocarbon gases, etc., formed by the action of the acid on the carbon compounds associated, as impurities, with commercial iron. The solution remaining after the action of sulphuric acid on the iron, when put aside in a cool place, soon forms beautiful pale green crystals of ferrous sulphate. Magnesium and aluminium furnish a fairly pure gas; with aluminium the acid should be warmed to start the reaction. In these cases, not only is hydrogen gas evolved but crystals of magnesium sulphate and of aluminium sulphate can be obtained from the liquids in which the respective metals have been dissolved. The action of the acid on tin is rather slow; granulated zinc is used for general laboratory work.

Hydrogen gas is made in small quantities in the laboratory by placing granulated zinc in a bottle fitted with a stopper with two holes—one to take a funnel tube, the other to take an L-shaped tube for conducting away the gas. Instead, the granulated zinc may be placed in a two-necked Woulfe's bottle—so named because these bottles were first described by Peter Woulfe (1784). The one tubulure is fitted with a one-hole stopper carrying a tube funnel, and the other, with the gas exit tube. The zinc is covered with water, and sulphuric acid is added a little at a time through the tube funnel until the gas begins to come off vigorously. For many purposes there is no need to use the pneumatic trough for collecting hydrogen, since by bringing the gas-jar mouth downwards over a jet of hydrogen the gas will collect in the upper part of the jar, and displace the air downwards—hence the term collecting gases by the downward displacement of air—many writers call this *collecting the gas by upward displacement.* Hydrogen gas so prepared is always tested before use by collecting a test-tube of the gas, and while holding the tube upside down, applying a lighted taper. If the gas burns quietly at the mouth of the test-tube, all is well.

Hundreds of different forms of apparatus[6] have been devised for supplying an intermittent stream of gas by the action of a liquid—*e.g.* hydrochloric or sulphuric acid—on a solid—*e.g.* zinc, ferrous sulphide, or marble. They are all based on the principle applied by J. W. Döbereiner in his hydrogen lamp. When the gas is no longer free to escape, the pressure generated by the gas drives the acid away from the solid; this stops the further generation of gas. When the pressure is relieved by allowing the gas to escape, the acid again comes in contact with the solid. In the better types of apparatus (i) the freshest acid is brought in contact with the solid; (ii) the emptying and recharging is simple; and (iii) a great over-pressure is avoided.

The properties of hydrogen.—Hydrogen gas is colourless and odourless—the impure gas may have a smell. The hydrogen gas streaming from the generating flask can be lighted, and a flame of burning hydrogen is obtained which was formerly called *lumen philosophicum*, or the *philosopher's flame.* To get the flame to burn steadily it is best to interpose between the exit tube and the jet, a wider tube loosely packed with granulated calcium chloride to arrest by absorption the water vapour carried along with the gas. The hydrogen flame is very hot and melts ordinary glass; a jet of hard glass, quartz glass, or platinum can be used. When a lighted taper is plunged into a jar of hydrogen held mouth downwards, the gas burns with a scarcely visible blue flame at the mouth of the jar, and the taper is extinguished showing that the gas is combustible and a non-supporter of combustion. When J. Black (1766) heard that H. Cavendish had found hydrogen to be much lighter than air, he thought that possibly a thin bag made from the allantois of a calf, when filled with hydrogen, would be buoyed up by air. Modifications of Black's idea are used as illustrative experiments on the lecture table, and not long afterwards the gas was used for filling balloons. The gas can be poured upwards from one jar to another, and it can be proved that the gas has actually been transferred from the one vessel to the other by testing the contents of each jar with a lighted taper before and after the pouring.

The extreme lightness of hydrogen and its combustibility enable many ingenious experiments to be performed with the gas. For instance, a cardboard box or a light glass vessel can be counterpoised bottom upwards, on a balance; the beam will ascend when hydrogen is poured upwards into the inverted vessel. Soap-bubbles blown with the gas, or collodion balloons filled with the gas, rise to the ceiling very quickly. The gas may be syphoned upwards from one vessel to another, or, the gas may be syphoned from, say a bell-jar and burnt at the long leg of the syphon. An explosive mixture with air is formed when the hydrogen has nearly all been syphoned away, and the flame at the top of the long leg of the syphon will then rush back and produce a loud but harmless explosion.

The explosive character of a mixture of hydrogen with oxygen of air can be illustrated by mixing two volumes of hydrogen gas with either one volume of oxygen or five volumes of air in a soda-water bottle. A lighted taper applied to the mouth of the bottle causes the gas to detonate. The combustion of the whole mass is almost instantaneous. The explosion is so violent that we can understand why N. Lemery, in his *Explication physique et chimique des éclairs et du tonnère* (1700), tried to show that thunder and lightning are produced by the fulminations of hydrogen.[7] The sound obtained when a long glass tube is placed about the flame of burning hydrogen led to W. Higgins (1777) calling the experiment the *chemical harmonicon*. The tones vary with the diameter, thickness, and length of the tube and on the nature of the jet. The sound appears to be the effect of an extremely rapid series of explosions. M. Faraday obtained a similar *musical flame* with inflammable gases and vapours other than hydrogen. M. Faraday's explanation is that a strong current of air is established; this lengthens the flame, and small portions of air are mixed with the hydrogen in such a manner as to form small quantities of detonating gas, which, when set on fire, produces slight explosions succeeding each other quickly and regularly. C. Wheatstone found that while producing sound within a glass tube, regular intermissions in the intensity of the flame are observed, and these present a chain-like appearance on a revolving mirror, indicating alternate contractions and dilations of the flame corresponding with the sonorous vibrations of the column of air.

Joseph Priestley[8] has told us that in 1776 his friend, J. Warltire, had noticed that when a flame of hydrogen is allowed to burn in air confined under a bell-jar, the whole of the receiver appears to be filled with "a fine powdery substance like a whitish cloud," when the flame was extinguished; and the air left in the glass was found to be "perfectly noxious." In the same year P. J. Macquer[9] inquired whether the flame of hydrogen evolved smoke or soot. He thus described his experiment:

> By placing a saucer of white porcelain in a jet of inflammable gas (hydrogen) burning tranquilly at an orifice, I found that the part of the saucer which the flame licked was moistened by small drops of liquid as clear as water, and which, in fact, appeared to be nothing but pure water.

It is probable that J. Warltire's white cloud was not produced by a finely powdered solid, but by minute drops of water. In 1779, J. R. Sigaud de la Fond also mentioned the formation of water during the combustion of inflammable air. P. J. Macquer did not stop to inquire: Whence came the water? He has been blamed because he felt no astonishment at that which is really astonishing, for he merely mentions, without comment, the appearance of the water. P. J. Macquer did not see before him a great discovery begging for recognition. Hence, asks F. J. Arago (1839),[10] is genius in the observational sciences to be reduced to the faculty of asking an appropriate Why? The inquiry can be made, (1) What happens to the surrounding air during the burning of a jet of hydrogen? and (2) Is the product of the action really water?

J. Warltire's 1776 experiment can be modified by making a jet of dried hydrogen burn under a bell-jar containing a measured volume of air standing over water. At first, there is a momentary expansion of the air due to the heating of the confined air by the flame; immediately afterwards, the water rises in the jar, and the hydrogen flame gradually expires. Immediately this occurs the stream of gas is stopped to prevent it passing into the air in the bell-jar. The gas remaining in the jar has quite similar properties to the nitrogen gas remaining after mercury is calcined in air. It is the "perfectly noxious air" alluded to by J. Warltire. In 1777, C. W. Scheele described an analogous experiment in his *Chemische Abhandlungen von der Luft und von dem Feuer* (Upsala, 1777), but with other combustible agents. The experiment shows that **when hydrogen burns in air, it unites with the oxygen and leaves nitrogen behind.** If the experiment be carefully made, nearly four-fifths of the original volume of air remains. The burning hydrogen removes nearly one-fifth of the original volume of air. Hydrogen does not burn in the residual nitrogen—although about 7 or 8 per cent. of oxygen is still present. A certain amount of dew collects on the inner walls of the bell-jar, but that, of course, may come from the water in the dish below. In fine, the facts give reasons for supposing that hydrogen, in burning, combines with oxygen to form an oxide of hydrogen in the same sense that mercury, when calcined in air, combines with oxygen to form mercuric oxide. It remains to try and isolate a sufficient quantity of the hydrogen oxide whose existence has just been inferred, but not proved, in order that its properties may be examined more closely.

The experiment of P. J. Macquer (1778) can be modified so that a jet of dried hydrogen is burned under a funnel, the stem of which is curved so that it passes into a two-necked globe; the other neck of the globe is connected with an aspirator so that the products of combustion from the hydrogen flame can be aspirated through the system. The glass bulb is kept cold and a clear colourless liquid collects therein. This liquid has all the properties of water; it is a clear, colourless, and tasteless liquid with no smell; it freezes at 0°, and boils at 100°. The water does not come from the condensation of the moisture already present in the gas as it rises from the generating vessel, because the gas is dried by the "scrubbing" it receives as it passes along the tower of calcium chloride; this statement can be tested by making a blank experiment with the un-ignited gas. It is therefore inferred that water is burnt hydrogen, or the *calx of hydrogen;* otherwise expressed, **water is hydrogen oxide formed when hydrogen burns in air.** Hydrogen and oxygen are both gases, and it is therefore more difficult to find the combining ratio Hydrogen : Oxygen in the formation of hydrogen calx, by direct weighing, than is the case with the metallic calces. It remains therefore to show how chemists have solved the problem.

§ 3. Dumas' Experiment on the Composition of Water by Weight

After very careful examination of all the analytical researches made for the determination of atomic weights, I emphatically declare that the researches of Dumas are the most important of all, marking as they do the beginning of the analysis of precision, and offering also the first instance of a true series of determinations, such as is required to furnish the absolute values of the atomic weights.—G. D. HINRICHS.

Several determinations of the combining weights of hydrogen and oxygen in the formation of water have been made. Prior to J. B. A. Dumas' work, there were the pioneer attempts to find the combining ratio of hydrogen and oxygen by M. Monge, A. L. Lavoisier, and M. Meusnier[1] about 1786. They admitted measured volumes of hydrogen and oxygen into a globe, exploded the mixture, and after repeating the process 372 times, weighed the water produced, and calculated the weights of oxygen and hydrogen employed from the densities of the gases. It was found that in water the ratio of the weight of hydrogen to that of oxygen is as 1 : 6·61. In 1791, A. F. de Fourcroy, L. N. Vauquelin, and M. Séguin repeated M. Monge's work and found the ratio to be 1 : 6·17. In 1803, John Dalton estimated the ratio of hydrogen to that of oxygen to be 1 : 5·66, a result further removed from the truth than the ratios found by the French savants. J. Dalton corrected his first result in 1808, and gave the ratio 1 : 7. In 1814, from J. L. Gay Lussac and A. Humboldt's observation that two volumes of hydrogen and one volume of oxygen unite to form water, and J. B. Biot and F. J. Arago's observation of the relative densities of these two gases, W. H. Wollaston calculated the ratio of the weights of hydrogen and oxygen in water to be 1 : 7·545. This was followed by the work of P. L. Dulong and J. J. Berzelius in 1819, and of J. B. A. Dumas in 1842.

Hydrogen does not combine readily with many of the elements, but it readily combines with oxygen, chlorine, fluorine, lithium, and a number of others. So great is the attraction of hydrogen for oxygen that it will very often remove oxygen from its combinations with the other elements. For instance, on March 6th, 1783, J. Priestley[2] reported that he had confined lead oxide (minium or red lead) in a tall cylinder containing inflammable air standing over water; the red oxide of lead was heated in the focus of a burning glass. He observed:

> The minium became black, and then ran in the form of perfect lead; at the same time the air diminished at a great rate, and the water ascended within the cylinder. . . . Seeing that metal to be actually revived, and that in a considerable quantity, at the same time that the air was diminished, I could not doubt that the calx was actually imbibing something from the air; and from its effects in making the calx into a metal, it could be no other than that to which chemists had unanimously given the name phlogiston. . . . Consequently, phlogiston is the same thing as inflammable air.

The experiment was varied by confining the gases over mercury in place of water, and using other calces—*e.g.* the oxides of tin, bismuth, mercury, silver, iron, and copper. He further found that "1 oz. of lead was revived by 108 oz. measures of inflammable air, and 1 oz. of tin by 377 oz. measures." The 108 oz. and 377 oz. measures of inflammable air would weigh nearly 4·4 and 15·4 grains respectively. Priestley's measurements are good, because these numbers are close to their ideal values, 4·6 and 16·3 grains respectively. This remarkable experiment might have opened J. Priestley's eyes to the insufficiency of the phlogiston hypotheses. A. L. Lavoisier[3] has pointed out that J. Priestley did not notice that there was a decrease in the weight of the solid during the reduction, and that water was a product of the reaction. The true interpretation of the reduction observed by J. Priestley is due to A. L. Lavoisier.

In J. Priestley's experiment, the hydrogen is said to be oxidized; and the metallic oxide, *reduced* or *deoxidized*. The hydrogen is called a *reducing agent*, that is, a *reducer* or *deoxidizer*; and the copper oxide an *oxidizing agent* or *oxidizer*, because it oxidizes hydrogen to water. The reaction under consideration is both an oxidation and a reduction process. All depends upon whether the hydrogen or the copper be under consideration. In the fifteenth century, Paracelsus applied the term *reduction* to the preparation of the metals. During a reduction, the reducing agent is usually, not always, oxidized; and during an oxidation, the oxidizing agent, reduced. If a known amount of copper oxide be reduced by hydrogen, and the water formed be collected and weighed, the weight of the reduced copper oxide will show how much oxygen has been used in forming a definite amount of water. This was done by P. L. Dulong and J. J. Berzelius[4] in 1820, and by J. B. A. Dumas in his celebrated *Recherches sur la composition de l'eau* in 1843. J. B. A. Dumas' experiment is not the best of its kind, although it was the best of its time, and it has long and deservedly held an honoured place in chemical text-books. The experiment illustrates some important principles, and it is therefore here described in outline. The first stage of the work involved the purification of hydrogen.

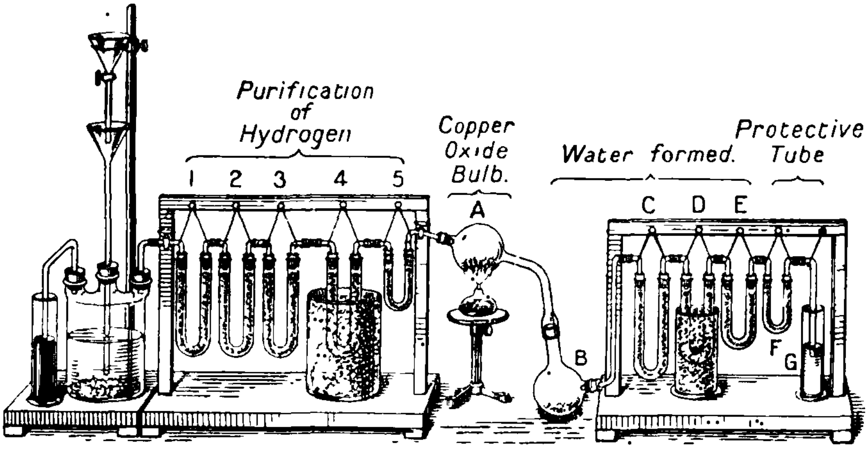

FIG. 2.—Dumas' Experiment (abbreviated).

The hydrogen was prepared by the action of zinc on sulphuric acid. It might be thought that pure zinc and pure sulphuric acid should be used. Experiment shows, curiously enough, that under these conditions the action is so very, very slow that some have jumped to the conclusion that "absolutely pure sulphuric acid, even when diluted with pure water, has no action on perfectly pure zinc." Moreover, it is exceedingly difficult to prepare pure zinc and pure sulphuric acid. Hence, pure reagents were not used for the preparation of the hydrogen. Accordingly, the gas may contain nitrogen and oxygen derived from the air; sulphur dioxide and hydrogen sulphide derived from the reduction of the sulphuric acid by the hydrogen; carbon dioxide; arsenic hydride (if the acid or the zinc contained arsenic); hydrogen phosphide (if the zinc or the acid contained phosphorus); nitrogen oxides (if the acid contained nitrogen oxides); and water vapour. Accordingly, J. B. A. Dumas (1842) used sulphuric acid, which had been well boiled, to get rid of dissolved air, and then passed the hydrogen through a series of U-tubes—Fig. 2—containing: (1) pieces of glass moistened with lead nitrate to remove hydrogen sulphide; (2) solution of silver sulphate to remove arsenic and phosphorus compounds; (3) solid potassium hydroxide to remove sulphur dioxide, carbon dioxide, and nitrogen oxides; and (4) phosphorus pentoxide to remove moisture not absorbed by the solid potassium hydroxide. J. B. A. Dumas used three potassium hydroxide tubes, and two phosphorus pentoxide tubes—like (4)—only one of each is in the diagram. The phosphorus pentoxide tubes were placed in a freezing mixture. The tube marked (5) in the diagram contained phosphorus pentoxide, and it was assumed that the hydrogen passing through was quite dry—this tube is accordingly called a *témoin tube* (*témoin*, a witness) because it can be employed as evidence that the hydrogen which passed through gave up no moisture to the desiccating agent.

J. B. A. Dumas passed the purified hydrogen over red-hot copper oxide, and determined the loss of weight (oxygen) which occurred. He then weighed the amount of water produced.

The purified hydrogen was passed through a weighed bulb, *A*, containing copper oxide, and heated by the spirit lamp underneath. Most of the water condensed in the bulb *B*, and the remainder was absorbed in the U-tube *C* containing solid potassium hydroxide, and in *D* and *E* containing phosphorus pentoxide. The phosphorus pentoxide tube *D* was kept cool by a freezing mixture. The three tubes *C*, *D*, *E*, and the bulb *B*, were weighed before and after the experiment. The last U-tube, *F*, containing phosphorus pentoxide was followed by a cylinder, *G*, of sulphuric acid through which hydrogen escaped. The vessels *F* and *G* were not weighed; they served to protect the other tubes from the external atmosphere.

The average of nineteen experiments by J. B. A. Dumas (1842) gave:

Copper oxide lost in weight	44·22 grams
Water produced	49·76 „
Hydrogen (by difference) . .	5·54 „

Hence, he inferred that 15·97 parts of oxygen united with two parts of hydrogen to form water, or 16 parts by weight of oxygen combined with 2·004 parts by weight of hydrogen to form water. His nineteen values ranged between 15·892 and 16·024, and his mean value for hydrogen is usually considered to be rather low, or the mean value for oxygen rather high. A later determination by E. W. Morley gave 16 : 2·016. In approximate work, we may take it that 2 parts by weight of hydrogen combine with 16 parts by weight of oxygen to form 18 parts of water; indeed, J. B. A. Dumas himself expressed his belief that the true value of the ratio Hydrogen : Oxygen is probably 2 : 16.

It is common to append to the arithmetical mean of a series of observations the so-called **probable error.** For example, the mean of Dumas' nineteen determinations of the relative weights of hydrogen and oxygen in water is given as: Oxygen, 15·96 ± 0·007, when hydrogen is 2; and O. L. Erdmann and R. F. Marchand's eight determinations by a similar method are represented by the average 15·973 ± 0·011. The probable error in the one place is ±00·07 and in the other ±0·011. This does not mean that J. B. A. Dumas' results were nearer the true value than O. L. Erdmann and R. F. Marchand's. The probable error does not tell how nearly the average of a given number of similarly conducted experiments would approach the average actually found. In J. B. A. Dumas' result, the chances are even that the true average of the determination by his method lies between (15·96 + 0·007 =) 15·967 and (15·96 − 0·007 =) 15·953. If an unrecognized constant error affected all the results, the average actually found would still differ from the true value by this amount. As a matter of fact, when J. B. A. Dumas had nearly finished his work, he did find that his numbers were affected by a curious error, previously unrecognized, so that the concordance of his individual determinations did not prove that his average was right. This error, if not corrected, makes the result appear a little low. The reduced copper retains some hydrogen very tenaciously;[5] similarly, when copper oxide is made, as is usually the case, by calcining the nitrate to redness in a current of air, it retains an appreciable amount of nitrogen. As a result, when the oxide is reduced in a current of hydrogen, the weight of the water formed is less than that which corresponds with the loss of weight which has occurred during the reduction of the copper oxide, assuming that water is really formed by the union of hydrogen and oxygen.

The main objections to J. B. A. Dumas' work turn on the following facts: (1) There is a great difficulty in thoroughly removing all the air from a large complicated apparatus; (2) The absorption of air by sulphuric acid which is slowly evolved along with the hydrogen when the acid acts on zinc; (3) M. Melsens showed that there is a retention or occlusion of hydrogen by the reduced copper; (4) T. W. Richards and E. F. Rogers showed that the copper oxide was probably contaminated with occluded nitrogen and other gases; (5) W. Dittmar and J. B. Henderson showed that there is a slight reduction of sulphuric acid by hydrogen to form gaseous sulphur dioxide (which is later absorbed by the potash); (6) The difficulty in drying the gas, etc., completely. The last is considered by T. W. Richards (1911) to be one of the most fertile sources of error in the determination of accurate equivalents. (7) Before the hydrogen reached the copper oxide, J. B. A. Dumas dried it with sulphuric acid and phosphorus pentoxide, and used calcium chloride to remove the aqueous vapour from the excess of hydrogen which left the copper oxide bulbs. Since phosphorus pentoxide removes more moisture from a gas than calcium chloride, it is possible that some aqueous vapour escaped. This would tend to give high results. (8) E. W. Morley has shown that hydrogen from sulphuric acid and zinc always contains carbon compounds which cannot be removed by absorption; (9) J. J. Berzelius emphasized the fact that the displacement of hydrogen by air at the end of J. B. A. Dumas' experiment, saturated the liquid water with air and made its weight too large; and (10) W. Dittmar has stated that J. B. A. Dumas did not correct his weighings for the buoyancy of air. This would make his weighing of the water produced appear too low.

In 1892 G. D. Hinrichs[6] argued that the combining ratio of oxygen in J. S. Stas' determinations is a function of the amount of potassium chlorate employed, such that with 30–35 grms. of chlorate the atomic weight is 16, and with 100 grms. of chlorate, 15·98. Similar results were obtained with the determinations of J. B. A. Dumas, J. S. Stas, and J. P. Cooke of the atomic weight of sulphur, chlorine, bromine, etc. Hence G. D. Hinrichs argues that the atomic weight should be calculated not from the mean, but from the limiting value corresponding with zero weight of the substance. P. A. Guye and E. Moles have shown that the relation observed by G. D. Hinrichs is confined to determinations in which the quantities of substances employed have been weighed in air and the reduction to vacuum effected by calculation; and the results are satisfactorily explained by assuming that the anomaly is due to the surface condensation of air and moisture, and should therefore disappear when the weighings are conducted in vacuo. The average deviation due to this cause is between 1 in 10,000 and 1 in 20,000. P. A. Guye and E. Moles found that with silver the error due to surface condensation is 2×10^{-5} gram per gram of metal.

§ 4. E. W. Morley's Experiment on the Composition of Water by Weight

In the determination of atomic weights, a small number of values are to be regarded as fundamental. They are the standards of reference; and by comparison with them all the other atomic weights are established. The atomic weights of hydrogen and oxygen are primary; that is, one or other of them is the basis of the entire system of atomic weights.—F. W. CLARKE.

It will be observed that P. L. Dulong and J. J. Berzelius, and J. B. A. Dumas weighed the oxygen and the water, and estimated the hydrogen by difference. Then followed the work of J. Thomsen, J. P. Cooke and T. W. Richards, and E. H. Keiser, in which the hydrogen and water were weighed, and the oxygen estimated by difference. W. A. Noyes and Lord Rayleigh weighed the oxygen and hydrogen, and estimated the corresponding weight of water. In his memoir *On the Density of Hydrogen and Oxygen, and the Ratio of their Atomic Weights* (Washington, 1895), E. W. Morley first made what J. S. Stas called a *synthèse complète* by weighing all three quantities—oxygen, hydrogen, and water. He synthesized water by burning hydrogen in oxygen, and weighed both gases separately and afterwards in combination. In this way he was able to determine the combining ratio of hydrogen and oxygen. Since the combining ratio of oxygen with a number of metals has already been determined, the combining ratios of the same metals with respect to hydrogen can be computed when once the ratio Hydrogen : Oxygen is accurately known.

Known weights of pure dry hydrogen and pure dry oxygen were stored in two large glass globes. The vessels containing the hydrogen and oxygen were weighed separately. The hydrogen was prepared by heating palladium hydride, and the oxygen by heating potassium chlorate. The hydrogen was weighed as palladium hydride, and the oxygen was weighed in a compensated glass globe. The apparatus for storing and drying the hydrogen and oxygen is not shown in Fig. 3. The globe containing oxygen was connected with the apparatus, and the oxygen passed through a layer of phosphorus pentoxide, and thence into the glass chamber *M*, *viâ* one of the jets *A*; the globe containing hydrogen was similarly connected with the other tube containing phosphorus pentoxide, and the hydrogen led into the chamber *M viâ* one of the jets *A*. The phosphorus pentoxide was not intended to dry the *entering* gases—these had already been dried. The chamber *M* was previously evacuated and weighed. One of the gases, say oxygen, was allowed to enter *M*, and electric sparks were passed across the terminals *F* just over the jets *A*. Hydrogen was led into the apparatus and ignited by the sparks. The rates at which hydrogen and oxygen entered the chamber were regulated so that the formation of water was continuous. The water formed was condensed, and collected in the lower part of the chamber. To hasten the condensation the apparatus was placed in a vessel of cold water—dotted in the diagram. When a sufficient amount of water was formed, the apparatus was placed in a freezing mixture. The mixture of unconsumed oxygen and hydrogen remaining in the tube was pumped away, and analyzed. The weights of hydrogen and oxygen so obtained were added to the weights of unconsumed hydrogen and oxygen remaining in the globes. The phosphorus pentoxide tubes prevented the escape of water vapour. The amount of water formed was determined from the difference in the weights of the system *M* before and after experiment. The amounts of hydrogen and oxygen were determined from the weights of the corresponding globes before and after the experiment. The amount of water formed was determined from the increase in the weight of the above described vessel before and after the combustion.

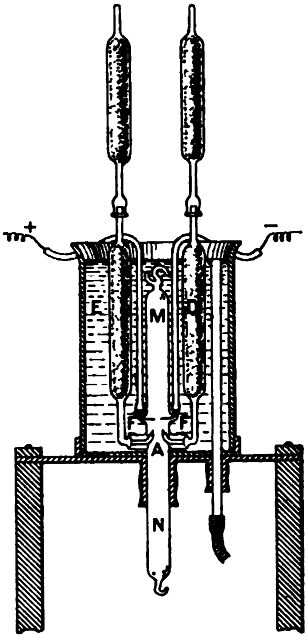

FIG. 3.—Morley's Experiment —Synthesis of Water.

E. W. Morley, as a mean of eleven experiments, found that:

Hydrogen used	3·7198 grams
Oxygen used	29·5335 ,,
Water formed	33·2630 ,,

Hence, taking oxygen = 16 as the unit for combining weight, it follows that **16 parts by weight of oxygen combine with 2·016 parts by weight of hydrogen**

to form 18·016 parts of water—within the limits of the small experimental error, and, adds E. W. Morley: "Until further light is obtained concerning the sources of error which doubtless affect all these experiments, this value is the most probable that can be derived from existing data." It might be added that the ratio Oxygen : Hydrogen = 16 : x for twenty-five sets of determinations by other workers, made since 1821, using different methods, has values of x ranging between 2·003 and 2·018.

§ 5. The Decomposition of Water by Metals

> If, as I have tried to demonstrate, water is really a compound of hydrogen with oxygen . . . in order to obtain hydrogen, it is only necessary to bring water in contact with a substance for which the oxygen has more affinity than it has for hydrogen, in order to liberate the hydrogen as a gas. Iron is commonly used for this purpose, and it is necessary to raise the temperature to a red heat in order to effect the separation. . . . There is *une véritable oxidation du fer par l'eau*. . . . The oxygen is fixed by unity with the iron, and the hydrogen is disengaged as an inflammable gas.—A. L. LAVOISIER (1789).

Water remains permanent and stable so long as the balance of the forces between its constituent elements is maintained, but in the presence of a metal which can unite with one of these elements, the water may be decomposed. One element—say hydrogen—is set free, while the other element—oxygen—unites with the agent of destruction to form a new compound—oxide of the metal. The application of this principle was suggested to A. L. Lavoisier by the illustrious P. S. de Laplace; and as a result, the first conscious analysis of water was made by A. L. Lavoisier, assisted by M. Meusnier, about 1784. This particular process has the disadvantage of isolating only one of the two elements of water. In their *Mémoire où l'on prouve par la décomposition de l'eau, que ce fluide n'est point une substance simple, et qu'il y a plusieurs moyens d'obtenir en grand l'air inflammable qui y entre comme principe constituant*, A. L. Lavoisier and M. Meusnier (1771)[1] passed steam over hot **iron,** and found that the metallic iron was converted into a "black oxide precisely similar to that produced by the combustion of iron in oxygen gas"; otherwise expressed, *the iron is oxidized by the water, and the water is reduced by the iron*, forming "a peculiar inflammable gas," which Lavoisier named hydrogen, because "no other term seemed more appropriate." The word signifies the generative principle of water, from the Greek ὕδωρ, water, and γεννάω, I generate or produce. The German word for hydrogen is *Wasserstoff*—the stuff from which water is made.

The following is a modernized form of M. Meusnier and A. L. Lavoisier's experiment:—Fill an iron, porcelain, or hard glass tube—60 cm. long and 1·5 cm. diameter—with bright **iron** turnings or bright iron nails. In Fig. 4 a hard glass tube is used. This is drawn out at one end as shown in the diagram. This end is fitted with a delivery tube dipping in a gas trough. A roll of previously ignited asbestos paper, 6 cm. long, is inserted in the opposite end. This end is closed with a red rubber stopper and the exit tube of the flask so arranged that it passes a short distance into the core of the asbestos paper. The asbestos roll, later on, prevents the liquid water from coming into contact with the hot glass and breaking the tube. Water is boiled in the flask, and the steam passing through the iron turnings is decomposed. When all the air has been driven out of the apparatus, hydrogen may be collected in the gas jar.

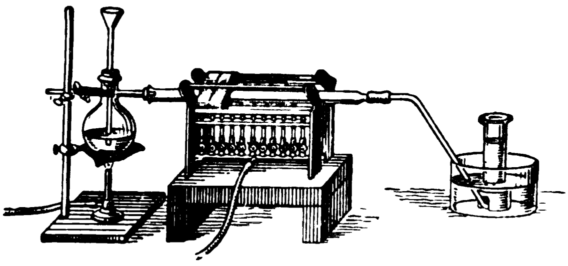

FIG. 4.—Decomposition of Steam by Hot Iron—A. L. Lavoisier and M. Meusnier's Experiment.

If **zinc** be used in place of iron, the temperature need not be much higher than the boiling point of water, since zinc reduces steam and forms zinc oxide at a comparatively low temperature. H. V. Regnault[2] found the zinc oxide is crystalline if the reaction occurs at red heat. If a strip of **magnesium** ribbon be placed in a bulb of a hard glass tube and heated, in a current of steam, at a red heat, the metal appears to burst into flame, forming magnesium oxide. The resulting hydrogen can be ignited if the jet of steam be not too vigorous. According to A. Ditte (1871), magnesium decomposes water slowly at 70°; and according to H. Fleck and H. Bassett (1895), magnesium amalgam decomposes cold water. In A. W. Knapp's experiment (1912) powdered magnesium is added to ten times its weight of water with a little palladious chloride in solution; metallic palladium is formed and this metal acts catalytically or electrolytically on the water. The decomposition is then so vigorous that the water appears to boil, and the escaping hydrogen ignites spontaneously. Metallic **calcium** decomposes cold water and gives off hydrogen, but the action slows down very soon, probably because the calcium hydroxide is not all dissolved by the water, and in consequence a protective crust of this substance forms over the surface of the metal. The calcium can be advantageously warmed with water in a flask which is connected directly with a delivery tube leading to the gas trough. If the water is not free from carbonates, a crust of calcium carbonate also forms over the surface of the metal. Calcium hydroxide is formed as well as hydrogen. The reaction with **strontium** is rather more vigorous than with calcium; and with **barium** more energetic than with strontium. The metal **sodium** decomposes cold water, giving off hydrogen, and forming sodium hydroxide. So much heat is generated during the reaction that the metal melts, showing that its temperature has risen over 95°. The experiment is liable to unpleasant explosions when the sodium is confined so as to enable the resulting hydrogen to be collected. The cause of the explosion has not been definitely established; it has been attributed to the formation of a dioxide or a hydride.[3] It is more likely to be due to the formation of a film or bubble of water superheated above its boiling point. **Potassium** alone reacts so violently with water that the temperature rises high enough to set fire to the hydrogen. The hydrogen burns with a violet-tinged flame, owing to the presence of the vapour of potassium; the hydrogen produced by the action of sodium on water burns with a yellow flame, owing to the contamination of the hydrogen with the vapour of sodium. According to J. J. Berzelius, a solution of metallic sodium in mercury—**sodium amalgam**—decomposes water much less turbulently than sodium alone; the result is similar when a small piece of **potassium amalgam**—3 or 4 mm. diameter—is placed on water. J. J. Berzelius says the gas obtained by the alkali amalgam is odourless, but if an acid or ammonium chloride is also present, the product smells like the gas derived from the dissolution of zinc in acids.

This set of experiments gives a series of metals which appear to react with water with increasing violence; the metals—iron, zinc, magnesium, calcium, sodium, potassium—seem to have an increasing avidity or affinity for oxygen so that they are able to tear the whole of the oxygen from the water, fix the oxygen, and thus liberate half or all the hydrogen as a gas. Under suitable conditions, by treatment with fluorine, chlorine, or bromine, the hydrogen is fixed and the oxygen liberated as a gas. Still further, by passing an electric current through water, both components are liberated in the gaseous state.

§ 6. The Decomposition of Water by Electricity

Electricity is a key which will open a way into the innermost parts of nature.—J. W. Ritter (1798).

In 1758, G. B. Beccaria [1] exposed water to powerful electric sparks, and although he must have decomposed this substance, he does not seem to have been aware of it; in 1789, the Dutch chemists P. van Troostwijk and J. R. Deiman noticed that when an electric charge from a powerful electric machine was passed through water, bubbles of gas were obtained. They showed that the gases were not due to the expulsion of air dissolved by the water, since the same result was obtained by using distilled water, and water freed from dissolved air by a prolonged boiling. Hence, it can be inferred that **water is decomposed into its constituent gases by the electric discharge.** On May 2nd, 1800, W. Nicholson and A. Carlisle [2] happened to put a drop of water in contact with two wires from a voltaic battery, and noticed the formation of small bubbles of gas about the tips of the wires provided the wires were not in contact. They then immersed the two wires in a glass of water, and found that gases were formed about both wires; the gas collected about one wire was hydrogen, and about the other wire, oxygen. Hence, **hydrogen and oxygen are produced during the electrolysis of water.** The gases were mixed and exploded. The result was water. This is very interesting—chemical combinations can produce an electric current; here an electric current is used to produce chemical decomposition. H. Davy (1807) also showed that the hydrogen and oxygen liberated during the decomposition of water are in the proportions in which they combine to form water.

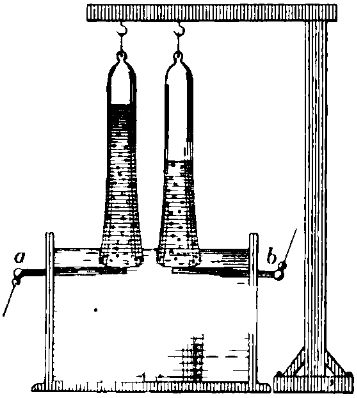

Fig. 5.—J. W. Ritter's Apparatus (1800) for the Electrolysis of Water—Gases separated.

The experiment of W. Nicholson and A. Carlisle appears to have excited a great deal of attention at the time, and many substances were treated in a similar manner. This culminated in the brilliant discovery of the alkali metals by H. Davy in 1807. J. W. Ritter's form of apparatus, shown in Fig. 5, is the prototype of the many ingenious forms of apparatus which have been devised for illustrating W. Nicholson and A. Carlisle's experiment. In place of J. W. Ritter's electrodes *a* and *b*, Fig. 5, adapted for the discharge from an electric machine, plates of gold or platinum, in communication with an accumulator or galvanic battery, are used. During the passing of the electric current, bubbles of gas accumulate on the metal plates and then rise into the test-tubes. More gas is given off at one plate than the other. In fact, the volume of the oxygen obtained approximates very closely to half the volume of the hydrogen. The gas in each tube can be identified by means of a lighted taper or otherwise. In the one tube, the taper burns with the "blinding brilliance" characteristic of oxygen; and the gas in the other tube burns with the blue flame characteristic of hydrogen.

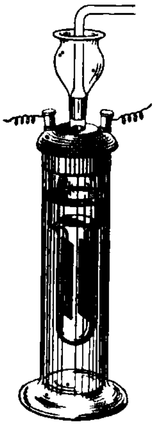

Fig. 6.—Electrolysis of Water—Gases mixed.

The water to be decomposed or electrolyzed is usually acidified with a few drops of, say, hydrochloric or sulphuric acid. Some of the water disappears during the electrolysis, but no change can be detected in the amount of acid mixed with the water. Hence it is inferred that the water, not the acid, has been decomposed. The experiment succeeds equally well if a solution of sodium or potassium hydroxide be used with nickel or iron electrodes. Here again the water, not the alkali, is decomposed. The acid or alkali is used because water alone does not conduct an electric current very well. In fact, pure water is said to be a non-conductor of electricity. Dilute solutions of acids or alkalies are good conductors. If iron electrodes are used in the acidulated liquid much of the oxygen formed during the decomposition of the water is used in oxidizing the metal.

A mixture of one volume of oxygen and two volumes of hydrogen, called **electrolytic gas** or **detonating gas**—A. Volta (1776) called it *aura tonante*—is often wanted in gas analysis, etc. This is easily provided by placing both electrodes under one receiver. The apparatus illustrated in Fig. 6 is often used for this work—it explains itself. The outer jacket keeps the electrolyte cool. Many forms of apparatus have been devised for the electrolytic preparation of small quantities of hydrogen and also of the mixed electrolytic gas.[3]

Are hydrogen and oxygen the sole products of the electrolysis of water?—Electrolytic oxygen often contains a little ozone and the electrolyte some hydrogen peroxide; both these compounds are formed by the electrolysis of acidulated water, but not if a solution of barium hydroxide be electrolysed. Besides oxygen and hydrogen, the early chemists noticed that an acid and an alkali are respectively formed about the positive and negative poles during the electrolysis of water. W. Cruickshank (1800) supposed the acid to be nitrous acid, and the alkali ammonia; J. B. Désormes (1801) considered that hydrochloric acid and ammonia were the products; while M. Brugnatelli (1802) explained the phenomenon by asserting that it is the nature of electricity to produce these substances, and he called the acid product *electric acid*. In 1807, Humphry Davy sought the origin of the acid and the alkali, and published an account of his experiments in a most important memoir entitled, *On Some Chemical Agencies of Electricity*. T. Thomson has styled this investigation "the finest and completest specimen of inductive reasoning which has appeared in the age in which Davy lived."

While accepting H. Cavendish's demonstration that water is a compound of oxygen and hydrogen, H. Davy considered the possibility that some product might result from the unexpected decomposition of oxygen and hydrogen, and he then divested the common experiment of every imaginable source of fallacy. It seemed to H. Davy that the acid and alkali are most likely produced: (1) from the water; or (2) by the decomposition of the glass; or (3) by the electrolysis of sodium chloride derived from the hands touching the instruments; or (4) from substances derived from the ambient air which are decomposed by contact with the electrical apparatus. Instead of conducting the electrolysis in glass vessels, Davy tried vessels of gold, and by taking precautions to eliminate disturbances produced by the contact of the vessels with the hands, and by the presence of impurities in the water, H. Davy found that while an acid still continued to be formed, no alkali appeared, and he showed that the alkali is derived from the solution of the glass vessels during the electrolysis. H. Davy next conducted the electrolysis in an atmosphere of hydrogen, and he then found that neither an acid nor an alkali was developed, and hence he inferred that the acid which appears in the electrolyte is derived from the nitrogen in the atmosphere. Consequently, **when precautions are taken to prevent the introduction of impurities from external sources, no acid or alkali is produced during the electrolysis of water.** It has since been found that the volume of oxygen obtained during the electrolysis of a solution of lithium, potassium, sodium, barium, or calcium hydroxide is sensibly less than half that of the corresponding hydrogen. The hydrogen obtained is rather more than double the volume of the oxygen when an electric current of low density is used for the electrolysis.

It must be emphasized that the decomposition of water by the electric current is not the same in kind as that produced by the disruptive discharge of an electric machine in P. van Troostwijk and J. R. Deiman's experiment. In the latter case, oxygen and hydrogen are evolved at both the poles dipping in the liquid, while in the former case, oxygen is evolved at the one pole, and hydrogen at the other. The electrolysis of water by the disruptive discharge is largely masked by the thermal decomposition of the water (A. L. Lavoisier and M. Meusnier's experiment). J. W. Ritter decomposed water the same year as W. Nicholson and A. Carlisle, but apparently in ignorance of their work. J. W. Ritter modified the experiment. He half-filled the two legs of a **V**-tube with concentrated sulphuric acid, *aa*, Fig. 7, so as not to wet the sides of the tube with acid; he then carefully poured distilled water, *ww*, into each leg of the tube so as not to disturb the acid, when he found the water in the upper part of the legs of the tube did not affect litmus paper. When gold wires, *gg*, connected with a battery were dipped in the water, hydrogen collected at one pole, oxygen at the other. J. W. Ritter said that the water in one leg of the tube is not in communication with the water in the other leg. He therefore inferred that water is an elementary body, and that about the one pole *water unites with negative electricity to form oxygen, and with positive electricity to form hydrogen*, about the other pole. This conclusion conflicts with the evidence obtained when water is decomposed by agents other than electricity, and it was explained by Faraday's experiment on electrolysis.

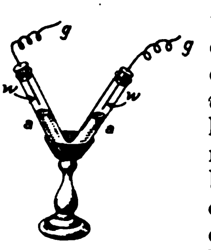

FIG. 7.—J. W. Ritter's Experiment.

The formula for water used to be written HO when the atomic weight of hydrogen was taken unity, and oxygen 8. This agrees quite well with the determinations of E. W. Morley and of J. B. A. Dumas. But we naturally ask for an explanation of the result of the electrolysis of water. Does an atom of hydrogen occupy twice the volume of an atom of oxygen ?

§ 7. Cavendish's Experiments on the Synthesis of Water by Volume

> It is curious to note the changing fortunes of water in the history of chemistry. First the matrix of the whole universe; then only one of the four elements, though the chief of the quaternion; and at last discovered to be itself nothing but a liquid product of combustion, one oxide among many, the mere ash, rust, or calx of so much burnt hydrogen.—S. BROWN (1851).

From the earliest dawn of scientific speculation, water has been regarded by natural philosophers as one of the four primal elements, and they were quite right, so far as their knowledge went, because they did not know how to decompose it into simpler substances. The dogma had been reiterated so frequently that, down to the days of the first French revolution, no one appears to have entertained any doubts of the simple elementary nature of this liquid; Basil Valentine called it "the mother of the metals." At the beginning of the seventeenth century the sagacious J. B. van Helmont[1] planted a sprig of willow in a vessel suspended in air, and fed it on nothing but water; he found the plant to grow apace—new branches, leaves, and roots sprouted forth. He said:

I placed 200 livres of dried soil in an earthenware pot, and planted therein a sprig of willow weighing 5 livres. At the end of five years, the willow had increased to nearly 69 livres, 3 onces. The vase had never been watered with anything but rain water or distilled water.

Hence it was inferred that the constituents of plants—wood, foliage, acids, salts, and earths—are embodied within elemental water in some mysterious inscrutable way. The experiment seemed to him a crucial one, but J. Woodward's researches[2] showed the conclusion was fallacious because the parts played by the substances dissolved in the water, and by the atmospheric air surrounding the plant, were not recognized. The composite nature of water was not suspected until over a century after J. B. van Helmont's time. Even the shrewd Robert Boyle in his *Sceptical Chymist* (Oxford, 1661) lauded, beyond his predecessors, the importance of water:

It seems evident that water may be transmitted into all the other elements . . . not only plants, but animals and minerals may be produced out of water.

Near the end of the seventeenth century, Isaac Newton[3] noticed that while the refractive indices of various non-combustible substances increase proportionally with their densities, the increase with the refractive indices of combustibles—camphor, turpentine, oils—is greater than corresponds with their densities. "Water has a refractive index in a middle degree between those two sorts of substances, which consist as well of sulphureous, fat, and inflammable parts, as of earthy, lean and alcalizate ones." After the compound nature of water had been discovered, commentators read into Newton's statement a prediction that water would be found to contain an inflammable substance as one of its constituents, although it may be questioned if Newton intended to make any such assertion.

In 1782, J. Priestley[4] thought that he had proved that water is converted into "air of the same purity as the atmosphere" by heating it in porous earthenware vessels so long as there is free access of air to the outside of the retort, but he found the following year, in agreement with a hint he had received from Josiah Wedgwood, that the supposed conversion was a mal-observation, because the air was transmitted from the outside to the interior through the pores of the retort.

In 1776, P. J. Macquer[5] noticed the formation of a liquid resembling water when hydrogen burns in air, and the flame is allowed to impinge on a cold slab of porcelain. Soon after the discovery of oxygen, J. Priestley (1775) noticed that when hydrogen is mixed with certain proportions of oxygen, a violent detonation occurs when ignited by a flame. In the spring of 1781, J. Priestley[6] made what he called "a random experiment to entertain a few philosophical friends," in which a mixture of inflammable air with dephlogisticated air or oxygen was exploded in a closed vessel by means of an electric spark, as had been effected by A. Volta in 1777. The sides of the glass vessel were found to be bedewed with moisture after the explosion. Neither P. J. Macquer nor J. Priestley appears to have paid any particular attention, at the time, to the phenomena; they both seem to have thought that the dew "was nothing else than the mechanical deposit of the moisture dispersed in common air." According to J. Priestley, John Warltire repeated this experiment with a copper vessel, and obtained a slight loss of weight which he thought might be due to the escape of ponderable matter in the form of heat, through the pores of the vessel. In the light of subsequent events, *il est clair*, said A. L. Lavoisier (1781), *que M. Priestley a formé de l'eau sans s'en douter*. Meanwhile, H. C. Cavendish[7] looked upon the deposition of the dew as a fact "well worth examining more closely"; H. Cavendish also wished to find what became of "the air lost" during the combustion of hydrogen in common air. He tried (i) if the air had been changed into carbon dioxide; (ii) if it had been changed into nitric acid; and (iii) if it had been changed into sulphuric acid. He negatived these hypotheses one by one. In the summer of 1781, H. Cavendish followed up the subject by exploding mixtures of dephlogisticated air with inflammable air in closed vessels. A certain amount of the gaseous mixture lost its elastic form, and produced a certain amount of liquid water. In the fourth experiment on exploding gases—dated July 5th, 1781, in his laboratory notebook—H. Cavendish demonstrated the relations between the volumes of inflammable air and common air consumed in the formation of water, for he showed that by exploding a mixture of 7,344 volumes of inflammable air (from zinc and an acid) with 17,361 volumes of common air, there was a contraction of 10,630 volumes, and a gas $\frac{1}{62}$nd of the specific gravity of common air remained. Before the end of the month, H. Cavendish had proved the liquid product to be pure water, for his notebook says:

> The liquid was not at all acid, nor gave the least red colour to paper tinged with red flowers, it yielded no pungent fumes on evaporation, and yielded scarce any sediment on evaporation to dryness.

H. Cavendish stated his conclusion from these experiments when they were described in his paper *Experiments on Air* (London, 1784):

> When inflammable air (hydrogen) and common air are exploded in proper proportion, almost all the inflammable air, and near one-fifth of the common air, lose their elasticity, and are condensed into dew. And by this experiment it appears that this dew is plain water, and consequently that almost all the inflammable air and about one-fifth of the common air, are turned into pure water.

Cavendish repeated the experiment with a mixture of inflammable air (hydrogen) with nearly twice its volume of pure dephlogisticated air (oxygen), and found that almost the whole of the mixture in the globe formed pure water; a quantity of water was collected by repeatedly introducing more gas into the globe and exploding the mixture. The vessel and its contents underwent no change in weight or parted with anything ponderable during the explosion, while a certain volume of gas was replaced by a certain weight of water. Hence, as A. L. Lavoisier[8] has expressed it: *l'eau n'est point une substance simple, et qu'elle est composée poids pour poids d'air inflammable et d'air vital*—otherwise expressed, **water consists, weight for weight, of the hydrogen and oxygen gases lost in its production.** The results of H. Cavendish's experiments, 1781–2, were communicated to J. Priestley not later than March, 1783, and also to A. L. Lavoisier in June, 1783, and published in 1784; the delay in publication was occasioned by the need for investigating the puzzling appearance of nitric acid along with water when oxygen was substituted for atmospheric air. There appears to have been some extensive alterations in Lavoisier's paper before it was published, but there is no means of determining precisely the extent of the additions. J. Watt wrote a letter to J. Priestley, April 26th, 1783, containing an outline of a theory of the composition of water, and on June 19th, 1783, Joseph Priestley[9] read a paper before the Royal Society in which he stated in reference to the bedewed glass in his experiment:

> I carefully weighed a piece of filter paper, and then, having wiped with it all the inside of the glass, weighed it again, and always found, as nearly as I could judge, the weight of the decomposed air in the moisture acquired by the paper.

H. Cavendish's public statement that he had previously communicated to J. Priestley every experiment which was needed to determine the composition of water was publicly acknowledged by J. Priestley. These facts have never been impugned, and they are supported by the entry in the Minute Book of the Royal Society[10] which was confirmed at the meeting on the 26th June, 1783. J. Priestley said:

> These arguments received no small confirmation from an experiment of Mr. Cavendish, tending to prove that the reconversion of air into water, in which pure dephlogisticated air and inflammable air were decomposed by an electric explosion, and yielded a deposit of water equal in weight to the decomposed air.

The work of H. Cavendish was soon confirmed by M. Monge,[11] in a memoir *Sur le résultat de l'inflammation du gas inflammable et de l'air déphlogistiqué dans des* *vaisseaux clos*. M. Monge exploded measured volumes of hydrogen and oxygen in an exhausted glass globe, and by admitting fresh quantities of gas for explosion, he collected a relatively large amount of water. He calculated the weight of the original gases from their known densities, and weighed the liquid product. The results showed :

	Onces.	Gros.	Grains.
L'air inflammable	–	6	10·03
L'air déphlogistiqué . . .	3	0	58·53
Total weights of components . .	3	6	68·56
Total weight of product . . .	3	5	1·01
Deficit		1	67·55

Owing to the use of moist gas, M. Monge over-estimated the weight of the hydrogen which he had employed, and consequently there was a small deficiency between the observed weight of water and the estimated weights of gas required for the synthesis. The water produced was very slightly acid, and he assumed that the acidity is due to " the small quantity of vitriolic (sulphuric) acid which inflammable air carries when prepared by the dissolution of iron " in that acid ; H. Cavendish had already proved that nitric acid is a by-product of the reaction under certain conditions. M. Monge concluded (i) that the volume of hydrogen required for the formation of water is about twice as great as that of the oxygen ; and (ii) that " when inflammable air and dephlogisticated air, both pure, are exploded, there is no other product but pure water, heat, and light." Experiments similar in principle, but with highly purified materials, were made by A. Scott and E. W. Morley[12] over a century later.

J. Watt's claims to the first true conception of water.—In 1783, James Watt,[13] of engineering fame, expressed the opinion that " according to J. Priestley's experiments, dephlogisticated air unites completely with about twice its bulk of inflammable air . . . and therefore water is composed of dephlogisticated air and phlogiston." It is possible, though doubtful, that J. Watt had in mind inflammable air or hydrogen when he used the term phlogiston, and by dephlogisticated air, what is now called oxygen. In his *Thoughts on the constituent parts of water and of dephlogisticated air* communicated to the Royal Society, November, 1783, J. Watt said that he was convinced by the arguments of R. Kirwan and J. Priestley that inflammable air is either wholly pure phlogiston or at least that it contains no admixture of any other matter ; but he added that in his opinion inflammable air contains a small quantity of water and much elementary heat. He regarded heat as a material substance, and invested it with the capacity of combining with other substances like other material elements, and of becoming the basis of those sensible qualities by which bodies are permanently distinguished from each other. According to his theory, dephlogisticated air is composed of water deprived of its phlogiston and united to elementary heat. He believed that dephlogisticated air and phlogiston can unite in certain degrees to form, not water, but fixed air, while under other circumstances they can unite to form neither water nor fixed air, but rather phlogisticated air. In spite of this, it has been claimed that J. Watt was the first to form the conception that water is a compound of dephlogisticated and inflammable air, and that H. Cavendish made the proposition good by unassailable experiments. Naturally, J. Watt's claims have been disputed, and the so-called *water controversy* has been waged upon the rival claims of J. Watt, A. L. Lavoisier, and H. Cavendish.

The controversy is exceedingly involved. The three rival claimants almost simultaneously arrived at analogous conclusions by different paths. H. Cavendish was at work on the products of the combustion of hydrogen ; J. Watt was speculating on the latent heat of steam ; and A. L. Lavoisier was studying the production of acids by the oxidization of inflammable substances. All these paths ultimately converged into the one line of inquiry which culminated in the discovery that water is a compound of hydrogen and oxygen. The issue is confused by the fact that, while the date of publication or receipt by a scientific society is usually taken to be decisive in questions of priority, this is not always satisfactory. In the present case, the observed results of the one were communicated to others before they were published, and alterations were made in some of the original papers, after they had been read and before they were published. Lord Jeffrey has shown that the case cannot be decided by those narrow and jealous canons of evidence derived from the rigid maxims of law or the precedents in cases of patent:

> Courts of law must proceed on inflexible rules, and can make no distinction of persons; and are forced therefore peremptorily to reject all evidence proceeding from the parties concerned, or from those having any interest in the issue; though it is certain by so doing they must occasionally decide against the truth, and against the conviction of all unprofessional observers. The question in a court of law, in short, is never really what the truth of a case is, according to the actual and conscientious belief of the judges or jury, after considering every atom of producible evidence that is in existence, but merely what is the import of the *evidence that is legally admissible*. . . . In all questions before the public no evidence is inadmissible.

J. Priestley tried to repeat the experiment on the formation of water which he said had been described to him by H. Cavendish. In order to ensure the absence of moisture, Priestley prepared his dephlogisticated air from nitre; and his inflammable air, by heating what he called " perfectly made charcoal " in a retort. The gas from the charcoal would obviously be obtained by the diffusion of air and furnace gases through the walls of the retort and the reaction between these gases and the charcoal. J. Priestley failed because, through an extraordinary blunder, the wrong inflammable air was used. According to W. V. Harcourt (1846), " neither the phlogiston nor the inflammable air of Priestley and Watt were convertible terms for hydrogen, their notion of the change of air into water, and of water into air, had no reference to hydrogen, but first to nitrogen, and afterwards to a mixture of gases, the chief of which was carbon monoxide. J. Priestley's paper was communicated to the Royal Society on April 19th, 1783; H. Cavendish's communication to J. Priestley must therefore have been *anterior* to the speculation which J. Watt addressed to J. Priestley on the 26th of the same month, as well as to Lavoisier's experiments the following June." J. Priestley thus comes as an intermediate link, for through him an account of the experiments and conclusions of H. Cavendish were transferred to Watt.

Lavoisier's claims to the discovery of the composition of water.—For a time, some claimed A. L. Lavoisier to have discovered the composition of water independently of H. Cavendish. According to M. Berthelot, the laboratory journal shows that as early as March, 1774, the attention of A. L. Lavoisier was directed to the product of the combustion of hydrogen since he believed that every inflammation ought to be attended by an increase in weight, and in 1777, he burnt hydrogen in air, and, in 1781, oxygen in hydrogen; but A. L. Lavoisier's mind was preoccupied with the conviction that oxidation means acidification, and the production of water, which must have occurred, seems to have passed unheeded. Lavoisier said afterwards that he did not then know about Macquer's experiment. A. L. Lavoisier was always on the alert as to the nature of the products of the combustion of hydrogen, and in 1783 he was in such a position that the slightest hint would enable him to comprehend its true nature. This hint was furnished by the rumours of H. Cavendish's experiment which spread through the scientific world in the spring of 1783. C. Blagden communicated the result of H. Cavendish's experiment to A. L. Lavoisier, at Paris, on June 24th, 1783. A. L. Lavoisier confirmed the fact with a single hasty experiment made a few days after C. Blagden's communication, and described before the French Academy—partly in November and partly in December, 1783. Although the account of H. Cavendish's *Experiments on Air* was not read before the Royal Society until January 15th, 1784, Lavoisier[14] said that on

June 24th, 1783, "Mr. Blagden has informed us that Mr. Cavendish had burnt inflammable air in closed vessels, and that he had obtained a very sensible quantity of water." Consequently, H. Cavendish was undoubtedly first in the field, and he furnished his rivals with the grounds of their conclusions—J. Watt through J. Priestley, A. L. Lavoisier through C. Blagden.

H. Cavendish was certainly not clear about the character of the reaction involved in his synthesis because his mind was unconsciously mystified by the phlogiston hypothesis. He seems to have rather inclined to the opinion that the indifference of hydrogen to oxygen at ordinary temperatures implied the presence of some substance in the former which lessened the intensity of its affinity for oxygen, and he conceived that this substance could be water alone, because water is the sole residue of the combustion of hydrogen and oxygen. Thus, H. Cavendish remarked:

> From what has been said, there seems the utmost reason to think that dephlogisticated air is only water deprived of its phlogiston, and that inflammable air, as was before said, is either phlogisticated water, or else pure phlogiston, but in all probability the former.

The indifference of free hydrogen and oxygen to one another at ordinary temperatures was a source of perplexity to others besides H. Cavendish. Thus, J. Watt[15] said:

> Priestley accounts for the facts by supposing that the two kinds of air, when formed at the same time and in the same vessel, can unite in their *nascent state*; but that, when fully formed they are incapable of acting upon one another, unless they are first set in motion by external heat.

It certainly required Lavoisier's system to give a significance to Cavendish's capital discovery, by showing that water is a definite oxide or calx of hydrogen formed whenever hydrogen is burnt in air or oxygen.

The synthesis of liquid water.—The following is a modernized form of H. Cavendish's elegant experiment, although it is not any more demonstrative. In Cavendish's original experiment, the explosion vessel was weighed before and after the gases were exploded:

A stout glass vessel, *A*, Fig. 8, is fitted with a stopcock, *C*, at one end, and with a piece of strong pressure tubing, *D*, connected with a reservoir, at the other end. A pair of platinum wires, *T*, are sealed into the stout glass measuring vessel just below the stopcock. These wires are put in communication with an induction coil, which in turn is connected with an accumulator. The tube *A* is called the *eudiometer*, or the explosion tube. This is filled with mercury by adjusting the levelling tube *B* and the stopcock *C*. A mixture containing one volume of oxygen and two volumes of hydrogen is introduced into the explosion tube *viâ* the stopcock *C* and by depressing the levelling tube. When the explosion tube is about half or three-fourths filled, read the volume of its contents by bringing the mercury to the same level in both levelling tube and explosion tube. Then depress the levelling tube so that the mercury falls nearly to the bottom of the explosion tube. Pass a spark from the induction coil through the wire terminals of the explosion tube. The gases explode, and the level of the mercury is again adjusted after the apparatus has stood for a few minutes in order to regain the temperature of the room. The mercury rises nearly to the level of the stopcock. The mixed gas probably

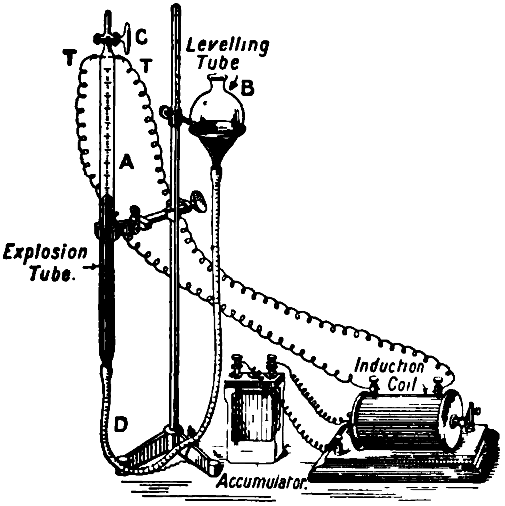

FIG. 8.—Modern Form of Synthesis of Liquid Water by Volume—Cavendish's Experiment.

contained a trace of air, and probably also a slight excess of either oxygen or hydrogen. The advantage of this form of explosion vessel lies in the fact that the explosion takes place under diminished pressure, and is not so liable to fracture the apparatus because it is less violent.

The result shows that two volumes of hydrogen unite with one volume of oxygen to form water. Suppose the experiment be repeated a number of times with, say, one volume of oxygen and three volumes of hydrogen—one volume of hydrogen remains after the explosion; again try the experiment with two volumes of oxygen and two volumes of hydrogen—one volume will remain uncombined after the explosion. It is inferred from this experiment, that **two volumes of hydrogen and one volume of oxygen combine to form water, and if an excess of either oxygen or hydrogen be present, the excess will remain uncombined after the reaction.**

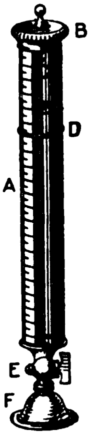

Fig. 9.—Volta's Eudiometer.

Gas analysis.—If a known volume of gas containing hydrogen be mixed with an excess of air or oxygen; or if a known volume of a gas containing oxygen be mixed with an excess of hydrogen and exploded in a eudiometer, the contraction represents the volume of water formed, and the corresponding amount of the gas under investigation can be computed. A. Volta [16] utilized these facts in devising a process to estimate the two gases. A metal cap, *B*, was fitted to the upper part of a graduated tube, *A*, Fig. 9, which constituted J. Priestley's eudiometer. The metal cap carries an insulated wire, *C*, which enabled a spark to be passed in the interior of the tube. A rubber ring, *D*, was used in reading the level of the liquid in the tube. The funnel, *F*, connected with the stopcock. *E*, was used in filling the eudiometer with gas in the pneumatic trough. The limits of explosibility of mixtures of hydrogen and oxygen are approximately Hydrogen : Oxygen=5·4 : 94·6; and 94·7 : 5·3. No explosion occurs if the proportions of these two gases are outside these limits.

Example.—20 c.c. of air were mixed with 20 c.c. of hydrogen and exploded. The mixed gases, after the explosion, occupied 28 c.c. Hence, the contraction shows that 12 c.c. of the mixture combined to form water. Of this two-thirds must have been hydrogen, and one-third oxygen. Hence, the original 20 c.c. of air contained 4 c.c. (*i.e.* one-third of 12 c.c. of oxygen). This illustrates an important principle used in gas analysis.

J. Priestley was led astray by the presence of nitric acid in the water formed by the union of hydrogen with oxygen. According to H. Cavendish's notebooks,[17] he found in September, 1781, that the liquid formed by exploding oxygen with twice its volume of hydrogen contained some nitric acid. H. Cavendish also found that this acid was obtained whether the oxygen was prepared from mercury nitrate, from mercuric oxide, or from plants under the action of solar light; and consequently he inferred that the nitric acid was not present as an impurity in the oxygen. In January, 1783, he showed that, if hydrogen is burnt in the presence of an excess of oxygen slightly contaminated with nitrogen, the excess of oxygen unites with the nitrogen forming nitric acid; but if the hydrogen is burnt with oxygen mixed with a large proportion of nitrogen, "the heat of the explosion is so much diminished that though the affinities of hydrogen and oxygen are sufficient to determine at that temperature the formation of water, the affinities of nitrogen and oxygen are not sufficient to determine the production of nitric acid." H. Cavendish thus demonstrated that the only product of the explosion of hydrogen and oxygen is water.

R. Bunsen (1857) [18] noticed that when electrolytic gas is exploded with air, some nitric oxide is formed, and if an excess of oxygen be present, some nitrogen peroxide is also formed. According to K. Finckh (1905), the amount of nitric oxide so formed depends upon the temperature and pressure of the admixed gases. For instance,

Initial pressure of mercury . . .	450	460	455	750 mm.
Electrolytic gas per 100 vols. air .	88	124	220	210 vols.
Nitric oxide formed	0·22	1·02	2·45	3·01 per cent.

To reduce the proportion of nitrogen oxides formed during the explosion of hydrogen (or hydrocarbons) with air, R. Bunsen found it best to keep the amount of pure hydrogen between 3·81 and 1·55 per cent., for the resulting error is then negligibly small If wider eudiometer tubes than those employed by R. Bunsen are used, these limits must be raised. According to A. Schuller (1882), when hydrogen is exploded with an excess of oxygen, some hydrogen peroxide is formed at the same time.

The volumetric synthesis of steam.—When hydrogen unites with oxygen to form water, is the product equal to the joint volume of the constituents when measured in the same state of aggregation, without allowing the gaseous water to condense to the liquid state? Water is a gas—often called *steam*—when its temperature is a little above 100° at ordinary atmospheric pressures. In 1865 A. W. Hofmann modified an old experiment of J. L. Gay Lussac (1808) by placing a hot vapour jacket about the explosion tube so that the water remains in the gaseous condition and does not condense to a liquid after the explosion. A. W. Hofmann's experiment was described in his *Introduction to Modern Chemistry* (London, 1865), and a modification is illustrated in Fig. 10.

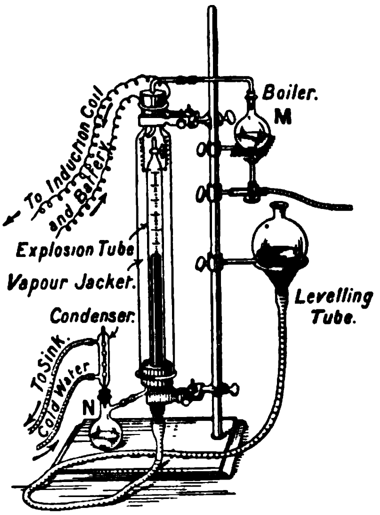

FIG. 10.—Synthesis of Steam by Volume.

The upper end of the glass jacket surrounding the explosion tube, Fig. 10, is connected with a flask, *M*, containing toluene, boiling at about 110°, or amyl alcohol, boiling at about 130°. The lower end of the jacket is connected with a flask and condenser, *N*, so that the amyl alcohol can be recovered. When the amyl alcohol is steadily boiling, and the explosion tube has been filled as described in the preceding experiment, the gases are sparked. In a few minutes, when the temperature has had time to adjust itself, bring the levelling tube in position for a reading.

The result of this experiment is to demonstrate that two volumes of hydrogen unite with one volume of oxygen to form two volumes of steam, for the steam occupies just two-thirds the original volume of the mixed gases. Hence, A. W. Hofmann's form of J. L. Gay Lussac's experiment demonstrates that **when water is synthesized at a temperature above its point of condensation—100°—two volumes of hydrogen react with one volume of oxygen to form two volumes of steam.** Several types of chemical problems are based on this fact. It is necessary to correlate the different results obtained when water is synthesized by volume and by weight.

CHAPTER IV

THE PHYSICAL PROPERTIES OF GASES

§ 1. The Atmosphere

> The atmosphere in which we live and breathe is really a part of the globe on which we stand. We are not surrounded by mere empty space. On the contrary, we live and move at the bottom of a vast ocean of air, which is just as material as the water which surrounds the flat-fish living at the bottom of the sea (1914).

Air was once considered to be a thin, pellucid, evanescent, inscrutable, and imponderable spirit—the spirit of life. Even to-day, air is still used as a symbol for what is spiritual and divine; but to early man the analogy between the impalpable breath of the physical heavens and the inscrutable spirit of God, was very real. It was quite a long time before air was recognized to be a gravic material essentially ponderable like earth and sea.[1]

The physical properties of air were studied long before its chemical properties were investigated. Anaxagoras, who lived about the sixth century B.C., cited two experiments to show that air is material: (i) A blown bladder resists compression, and (ii) the inside of an inverted drinking glass when plunged beneath the surface of water remained dry showing that the presence of air prevented the ingress of the water. These are among the earliest experiments on record. Aristotle (B.C. 384), in spite of some confused ideas on the nature of gases, considered air to be a material substance which possessed weight, because he found that a blown bladder weighed less when empty than when inflated with air. Simplicius, a writer of the sixth century, commenting on Aristotle, said that Ptolemy showed that air has no weight when weighed in air, and that Aristotle's conclusion was vitiated by the condensation of moisture in the bladder derived from the air blown from the lungs during the inflation of the bladder. About a century before Christ, Hero of Alexandria, in an important work on *Pneumatics*, described some experiments to prove that air is a material substance. For instance, he said:

> Let a vessel which seems to be empty be inverted, and, being carefully kept upright, pressed down into the water; the water will not enter it even though it be entirely immersed; so that it is manifest that the air, being matter, and having itself filled all the space in the vessel, does not allow the water to enter. Now if we bore the bottom of the vessel, the water will enter through the mouth, but the air will escape through the hole. Again, if before perforating the bottom, we raise the vessel vertically, and turn it up, we shall find the inner surface of the vessel entirely free from moisture, exactly as it was before immersion. Hence, it must be assumed that the air is matter.

A similar experiment was mentioned by Empedocles[2] (*circa* 430 B.C.), and a correct explanation given. The same experiment was also described in the essay, *De ingeniis spiritualibus*, by Philo of Byzantium, about 300 B.C.

The weight of air.—In his *Book of the balance of wisdom*, written in the fifteenth century, the Arabian Al-Khazoni recognized clearly that air has weight. He said:

> When a heavy body of whatever substance is transferred from a rarer to a denser air, it becomes lighter in weight; and when transferred from a denser to a rarer air, it becomes heavier. . . . Although the weight of a substance in air does not appear to vary, there is an actual variation, owing to a difference of atmospheres at different times.

However, Galileo dei Galilei, in 1632, is usually credited with having first demonstrated satisfactorily that air possesses weight; and he made a rough determination of the specific gravity of air by comparing the relative weights of equal volumes of air and water. G. Galilei found water to be 400 times heavier than air; and twenty or thirty years later, R. Boyle (1661) found water to be 938 times heavier than air. Both measurements were very crude, and are quite unreliable; G. Galilei's result is too low, R. Boyle's too high. Refined experiments show that 1000 c.c. of dry air weigh 1·293 grms. under standard conditions—760 mm. pressure, 0°, and at sea level in latitude 45°. Hence the specific gravity of air is 0·001293 if water be unity. This means that **a normal litre of dry air freed from carbon dioxide and at 0° and 760 mm. weighs 1·2930 grams at sea-level and a latitude of 45°.** The actual numbers are: 1·29276 (H. V. Regnault, 1847); 1·293085 (P. von Jolley, 1879); 1·29284 (Lord Rayleigh, 1888–93); 1·29273 (A. Leduc, 1898); 1·2930 (P. A. Guye, J. Kovacs, and E. Wourtsel, 1912)—*vide* Cap. on atmospheric air.

The accidental or experimental errors affecting the number 1·2930 amount to less than one in ten thousand. The variations which have been observed show that the density of air is not constant but variable both with respect to place and time. This conclusion is in harmony with the variations which have been observed on the relative proportions of oxygen and nitrogen in air. Thus, P. A. Guye, J. Kovacs, and E. Wourtsel found the weight of a normal litre of air, collected during a rising barometric pressure, to be 1·2927 grm., and 1·2932 grm. when collected during a falling barometric pressure. The former number is taken to mean that the air has a slight deficit in the proportion of oxygen, and the latter, a slight deficit in the proportion of nitrogen—when the normal litre is taken as 1·2930 grms. The specific gravity of air, referred to the standard hydrogen 2, is taken to be 28·75; or it oxygen 32 be the standard, 28·95.

The terms **atmosphere** and **air** are sometimes taken to be synonymous and interchangeable, but the word air is often used when reference is made to a limited portion of the atmosphere. The word *air* was formerly used in the same general sense that the word *gas* is to-day. Later, the meaning of the word air was narrowed to connote the *atmosphere*. The word atmosphere is derived from the Greek ἀτμός, vapour; σφαίρα, the sphere. The term atmosphere is also applied to the gaseous envelope or medium surrounding any body, whatever be the nature of the gas—air, oxygen, carbon dioxide, etc. Hence the term *atmospheric air* is often used to emphasize the fact that *air* is the enveloping medium.

Both Anaxagoras and Aristotle believed that *there is no vacuum* and this belief crystallized into the phrase: Nature abhors a vacuum. For instance, when a glass cylinder, closed at one end, is filled with water; then closed at the open end with the hand; turned upside down; and the hand removed while the open end of the cylinder is under water, the water remains in the cylinder. The rise of water in pump barrels was explained by the same hypothesis. When it was found that water could not be pumped higher than about 34 ft., it followed that the hypothesis required modification, for nature's horror of a vacuum obviously could extend only to the equivalent of 34 ft. of water.

The pressure of the air.—In 1644, E. Torricelli,[3] a pupil of G. Galilei, published an account of an experiment which puzzled the philosophers of the time because they were obsessed by the hypothesis that nature abhorred a vacuum.

In E. Torricelli's experiment, a glass tube—about four feet long, and closed at one end—was filled with mercury, the open end was closed with the thumb, and the tube inverted so that, when the thumb was removed, the open end was immersed in mercury. No air was allowed to enter the tube during the operation. Instead of the mercury remaining suspended in the tube, the column of mercury fell to such an extent that its height above the surface of the mercury in the dish was nearly 30 inches, or 760 mm. The vacuous space in the tube above the mercury is called Torricelli's vacuum.

Nature's horror of the vacuum at the top of the tube extended only to the equivalent of 30 inches of mercury. It did not appear probable that nature should have a particular whim of this character, and E. Torricelli suggested the alternative hypothesis that *the column of mercury was maintained by the air pressing on the surface of the mercury in the outer vessel.* B. Pascal, in his *New experiments concerning the vacuum* (1647), argued that since mercury is nearly 13½ times as heavy as water, 30 inches of mercury will be equivalent to 34 ft. of water, and he accordingly repeated E. Torricelli's experiment with a tube 46 ft. long, using water instead of mercury. He obtained a column of water 34 ft. long. When the experiment was repeated with other liquids, he found, in every case, that the height of the column was inversely as the density of the liquid. Hence, it was inferred that **the height of the column of mercury is a measure of the pressure of the atmosphere,** and that fluctuations in the pressure of the air are accompanied by a corresponding rise or fall in the column of mercury. R. Boyle (1665) applied the term *barometer* to Torricelli's instrument—from the Greek βάρος, weight ; and μέτρον, a measure.

In 1647, B. Pascal persuaded M. Perier to repeat Torricelli's experiment at the bottom and at the summit of the mountain Puy-de-Dôme. On September 23rd, 1648, M. Perier wrote that the result *nous ravit tous d'admiration et d'étonnement,* for the mercury sank lower in the tube the higher up the mountain the vessel was carried. This confirmation of what was anticipated by Torricelli's hypothesis was taken to prove that the pressure of the air per sq. cm. is greater at the bottom than on the top of the mountain, and not as Aristotle and his followers would teach that Nature has a greater horror of a vacuum at sea-level than at higher altitudes. In a posthumous work, *On the weight of the mass of air,* published in 1663, B. Pascal summarized arguments which proved conclusively that *all those effects, previously attributed to Nature's horror of a vacuum, are really produced by the pressure, that is, by the weight of the air.*

After the discovery of Torricelli's vacuum a group of philosophers—Thomas Hobbes, Franciscus Linus,[4] etc.—refused to abandon a favourite hypothesis they had formed that the world is everywhere full and a vacuum is impossible. They were called *plenists* in contradistinction to the *vacuuists*—O. von Guericke, B. Pascal, Robert Boyle,[5] etc.—who believed that a vacuum was possible, and capable of being obtained by certain physical processes. A controversy followed, not always in the choicest of language; thus, Thomas Hobbes, addressing Drs. Ward and Wallis, said :

> But I here dismiss you both together. So go your ways, you uncivil Ecclesiastics, inhumane Divines, Dedoctors of morality, unasinous Collegues, egregious pair of Issachars, most wretched Vindices and Indices Academiarum, and remember Vespasian's law (*maledici senatoribus non opportere ; remaledicere fas et civile esse*) that it is uncivil to give ill language first, but civil and lawful to return it.

The facts finally conquered an erroneous hypothesis.

Units of pressure.—The pressure of the air in any given locality varies within comparatively narrow limits. **The normal or standard pressure of the atmosphere** is equal to the weight of a column of mercury of unit area, and 760 mm. high. This pressure is sometimes called " one atmosphere." It is merely necessary to know the height of the barometric column to know the weight or pressure of the air per unit sectional area. The standard corresponds with a weight of (76 × 13·596 =) 1033·3 grms. per sq. cm., or 14·7 lbs. per sq. in. The word *pressure* is generally used in preference to *weight,* because air, like all other fluids, not only presses downwards, but also equally in all other directions.

The selection of the atmosphere as the unit of pressure is quite arbitrary, and other units are used—*e.g.* the kilogram per sq. cm., and the pound per sq. in. The pressure of a dyne per sq. cm. was recommended by the International Physics Congress at Paris in 1900, because it is consistent with the C.G.S. system of units. This unit was called a *barie ;* a similar unit, the *barad,* was proposed by a committee of the British Association in 1888, and there has been some controversy as to whether the unit had better be referred to a dyne per sq. cm. or to a pressure a million times greater. The density of mercury is 13·596, and in latitude 45° the force of gravity is equivalent to 980·6 dynes. Hence, a barometer column 76 cm. high will be maintained by a pressure equivalent to $76 \times 13{\cdot}596 = 1033{\cdot}3$ grms., or $1033{\cdot}3 \times 980{\cdot}6 = 1{,}013{,}300$ dynes per sq. cm., or in round numbers, 10^6 dynes per sq. cm. This number—called a **megabar**—may be inconveniently large, and a ten-thousandth part of 10^6 is called a **bar**, hence, a bar is equivalent to 100 dynes per sq. cm. ; a

centibar to one dyne per sq. cm.; and a **millibar** to 0·1 dyne per sq. cm. This unit, the millibar, has been recommended for recording barometer readings. One megabar is equivalent to 750 mm. of mercury, under standard conditions. The approximation is correct to one part in 5000. Since $13·596 \times 980·6 = 13332$; and one ten-thousandth of this is 1·3332, it follows that **to convert centimetres into bars, multiply by 133·33**; and, **to convert bars into centimetres, multiply by 0·0075.** Since there are nearly 2·54 cms. in an inch, $133·33 \times 2·54 = 338·63$, therefore *to convert inches into bars, multiply by* 338·63. A pressure of one megabar is almost 2 per cent. greater than a kilogram per sq. cm.; and 1·3 per cent. less than the atmosphere unit.

The extent of the atmosphere.—The air gets less and less dense at higher and higher altitudes, and I. Newton (1704) estimated air to be four times rarer at an elevation of about 7½ miles than at sea level; 1,000,000 times rarer at a height of 76 miles; and 1,000,000,000,000,000,000 times rarer at an altitude of 228 miles; and so on. If p_0 be the pressure and D_0 the density of air at sea level, E. Halley's formula [6] becomes

$$\text{Pressure of air at an altitude } h = p_0 e^{-\frac{D_0 h}{p_0}}$$

Variations in the value of the gravitation constant, g, and the rotation of the planet are neglected. Under actual conditions, the earth's atmosphere is incessantly agitated by convection currents—winds and storms—so that there is a continual transfer of air from one part to another. The limiting height at which the atmosphere is in convective equilibrium is about 29 kilometres, and the temperature falls roughly about 10° per kilometre as we ascend. Above this region, the temperature of the air is constant. It is indeed impossible to place a limit to the height the atmosphere extends. G. J. Stoney showed that, because the molecules of some gases attain certain high velocities, these gases are able to escape from the atmosphere of the earth and the other planets. At a height of 100 to 125 miles, there is sufficient air to offer enough resistance to the passage of meteorites to raise their temperature to incandescence. Whatever be the height, the weight of the normal barometric column (per square centimetre of mercury) measures the normal weight of a column of air of the same sectional area and extending from sea level upwards. B. Pascal (1663) appears to have been the first to calculate the total weight of all air about the globe. His estimate is 8,283889,440000,000000 livres—where a *livre* is equivalent to 1 lb. 1 oz. 10¾ dr. avoirdupois.

§ 2. The Influence of Pressure on the Volume of Gases—Boyle's Law

> At the bottom of all cosmic order lies the order of mathematics, the law that twice two is always four.—P. CARUS.

The quantity of matter in a gas is most frequently determined by the measurement of its volume. The volume of a gas is very sensitive to changes of pressure, and it is therefore very pertinent to inquire: What is the effect of variations of pressure on the volume of a gas? About the time Pascal and Torricelli demonstrated the weight and pressure of the atmosphere, O. von Guericke (1650) invented the air pump. The new instrument attracted much attention, and the effect of the "vacuum" (reduced pressure) was tried on all kinds of animate and inanimate objects. In his memoir, *Nova experimenta physico-mechanica de vi aeris elasticæ* (London, 1660), Robert Boyle says that he placed a partially inflated lamb's bladder in the vacuum produced by the air pump, and noticed that the bladder became fully distended to its former size. Boyle thus established the important fact that the less the pressure exerted upon a given mass of air, the greater its volume. In 1661, Boyle continued his work on the elasticity or spring of air, as he called it, and stated that R. Townley,[1] after reading about Boyle's experiments on the determination of the density of air from the height of a column of mercury which it supports, propounded the view that "the pressures and expansions are in reciprocal proportions." On August 2nd, 1661, R. Hooke made some experiments which confirmed Townley's hypothesis, and W. Croone and R. Boyle, at a meeting of the Royal Society on September 11th, 1661, gave an account of some experiments on the same subject. In his *Defense against Linus* (London, 1662), Robert Boyle published an account of the experiments which clearly established R. Townley's hypothesis. Accurate experiments of this nature, said Boyle, "have not been previously made (that I know) by any man." Boyle's result can be expressed in words: **the volume of a gas kept at one uniform temperature varies inversely as the pressure.** This is **Boyle's Law.** Some years afterwards, E. Mariotte, in his *Discours de la nature de l'air* (Paris, 1679), reported analogous results which he and M. Hubin obtained in 1676 by means of an apparatus similar to that employed by Robert Boyle, which led him to take it *pour une régle certaine ou loi de la nature, que l'air se condense à proportion des poids dont il est chargé*, and thus to confirm R. Boyle's deduction made fourteen years earlier. On the Continent, ignoring a priority of at least fourteen years, the law is sometimes improperly designated *la loi de Mariotte*, or *Mariottesches Gesetz.* At the time of the discovery of the law, air was the only gaseous body known, and therefore the accuracy of the law was established by Boyle and Mariotte for one body only. The law of Boyle may therefore be expressed: **The product of the pressure and the volume of a gas kept at one uniform temperature is always the same.** Or, for a given mass of air, $pv =$ **constant.** The numerical value of the constant, of course, depends upon what units are selected for representing the pressures and volumes. Pressures may be expressed in atmospheres, millimetres of mercury, pounds per square inch, etc.; and the volume in litres, cubic centimetres, cubic feet, etc. Boyle's law assumes yet another guise. If p_1 be the pressure of a gas occupying a volume v_1; and p, the pressure when the volume is v, then, since the products pv and p_1v_1 are equal to the same constant, they are equal to one another. Consequently $pv=p_1v_1$. If any three of these magnitudes be known, the fourth can be calculated directly. A large number of measurements are summarized in these formulæ, any one of which, indeed, contains the essence of all Boyle's observations condensed into a simple equation.

EXAMPLE.—A eudiometer holds 4·5 litres of gas when the barometer reads 755 mm. What will be the volume of the same body of gas when the barometer stands at 760 mm.? Here, $p_1=755$, $v_1=4{\cdot}5$, $p=760$, hence, $v=4{\cdot}47$ litres. The most common problem is to calculate—reduce—the volume of a gas at any observed pressure, to the corresponding volume at normal pressure, 760 mm. Given 4·5 litres of gas at 755 mm. pressure, there is no need for any formula to calculate the corresponding volume at 760 mm. The pressure 760 mm. is greater than 755 mm., hence the volume will be less, hence multiply 4·5 by the fraction $\frac{755}{760}$ and the result is 4·47 litres.

When the volume of gas, collected over mercury, is to be measured when the pressure of the atmosphere is 760 mm., and the difference in the levels of the mercury in the gas jar and in the pneumatic trough is 56 cm., it follows that the pressure of the gas in the narrow tube is 760 mm. less 560 mm.=200 mm. Whenever practicable, of course, the mercury inside and outside is brought to the same level before the gas is measured.

Suppose that the confining liquid is water, not mercury. Water is frequently used when the gases are not appreciably soluble in that liquid. Suppose that the external pressure is 760 mm. (barometer), and there is a difference of 10 cm. between the level of the water exposed to the gas, and the level of the water exposed to the air. The weight of 10 cm. of water is not the same as the weight of 10 cm. of mercury. Mercury is 13·596 times as heavy as water, hence, a 10 cm. column of water is equivalent to the weight of a column of mercury 10÷13·596 or 0·74 cm. or 7·4 mm. high. The pressure of the gas is therefore 760 — 7·4 = 752·6 mm. But water vapour exerts a definite pressure at any given temperature, and a still further reduction must be made if we want the pressure actually due to the gas and not to the mixture of vapour and gas. This will be investigated later.

Test for the equilibrium of gases.—If the gas be confined under such conditions that the product pv at any fixed temperature is not constant, the system will not be in a state of equilibrium. If a gas were confined in a cylinder with a sliding piston moving without friction and if the constant in Boyle's equation be p (in atm.) v (in litres)=12, then, if the piston supports a weight of 6 atms., the gas will expand or contract until the product pv satisfies the test. Consequently, **Boyle's law describes the necessary condition for the volume and pressure of a gas to be in a state of equilibrium when the temperature is invariable.** In practice there is no such thing as a frictionless piston, and if Boyle's law were to be tested in a real cylinder an allowance would have to be made for the friction of the piston by putting an extra weight α on the descending piston and a less weight β on the ascending piston; Boyle's law would then be $(p+\alpha)v$ or $(p+\beta)v$ is equal to a constant.

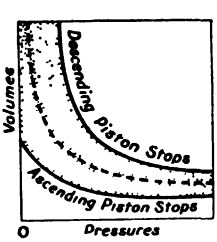

FIG. 1.—Duhem's Experiment.

P. Duhem (1902)[2] has used an interesting illustration. The dotted curve, Fig. 1, represents the relation between pressure and volume as defined by Boyle's law. If the volume corresponding with any given pressure be observed when the rising piston has come to rest, the observed volume will appear to be less than that corresponding with the pressure as defined by Boyle's law, because friction will prevent the piston rising to the point corresponding with the equilibrium position on the dotted curve. Similarly, on a descending piston, friction prevents the volume attaining that indicated on the equilibrium curve.

The friction thus corresponds to what J. W. Gibbs (1876) called the **passive resistance** of a system to assume a state of equilibrium. The nature of the passive resistance can here be recognized, but in some cases we feel sure that something analogous retards the movement of a system to the condition called stable equilibrium, although we know nothing of the character of the passive resistance or **hysteresis**—from ὑστερέω, I lag behind—which opposes the change.

§ 3. Deviations from Boyle's Law

Experimentally we do not know of any gas behaving in strict conformity to the law of Boyle; but in the case of many gases, and of nearly all gases at very high temperatures, the deviation from uniformity is very slight.—J. B. STALLO.

The pressures used by Boyle extended over a range varying from 3 cm. to 300 cm. of mercury. It is hazardous to infer that because the product pv is constant over a limited range of pressures, it will remain constant for pressures widely different from those actually measured. The method of measurement used by R. Boyle, though excellent for its time, is now considered somewhat crude. In the middle of the eighteenth century, P. van Musschenbroeck (1729), J. H. Sulzer, and J. Robinson tried to find if Boyle's result could be extended to all pressures, but with no very definite results. In 1799, M. van Marum[1] called attention to the deviation of ammonia from Boyle's law at high pressures. H. C. Oersted and C. Suensson (1826), and C. Despretz (1827) extended the observations to other gases, and it was found that the easily condensable gases like ammonia, hydrogen sulphide, and cyanogen began to deviate appreciably from Boyle's law at pressures exceeding two atmospheres, and with air, the constancy of the product began to fail at pressures exceeding 20 atm., for it diminished with increasing pressures. Similar conclusions were established for other gases by F. J. D. Arago and P. L. Dulong (1831) and by C. S. M. Pouillet (1844).

Later on, many careful investigations were made by H. V. Regnault (1847), J. O. Natterer (1850–4), L. Cailletet (1870–9), E. H. Amagat (1869–93), and others, to find if the simple law of R. Boyle correctly describes the behaviour of gases at pressures far removed from the normal pressure of the atmosphere—76 cm. of mercury. The general results show that *no two gases behave precisely in the same way*. The deviations for many gases are significant. By differentiating the relation pv = constant, k, or rather $v = k/p$, $dv/dp = -k/p^2$, and if k be taken unity, and $p = 2, 3, 4, \ldots$ be substituted,

$$-\frac{dv}{dp}=\frac{1}{p^2}; \quad \therefore \quad -\frac{dv}{dp}=\frac{1}{4}, \frac{1}{9}, \frac{1}{16}, \ldots$$

meaning that the greater the pressure to which a gas is subjected the less the corresponding decrease in volume, $-dv$, for any subsequent increase of pressure. With most gases, the concentration increases more, that is, the volume increases less than Boyle's law describes; and at high pressures, the concentration increases less, that is, the volume is greater than Boyle's law indicates. This is illustrated by plotting Boyle's law. Boyle's law, when graphed, furnishes the continuous curve shown in Fig. 2. This curve is a rectangular hyperbola. The deviations with nitrogen from this ideal condition are indicated by the dotted line in the same Fig. 2. If it were not for this phenomenon, the density of the gas would increase so that while oxygen at one atm. pressure weighs about 0·0014 grm. per c.c., at a pressure of 3000 atm. the gas would be four times as heavy as water, and at 10,000 atm. pressure over 13 times as heavy as water.

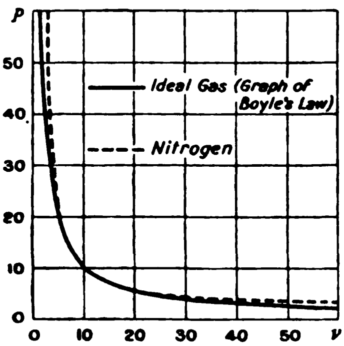

FIG. 2.—Volume : Pressure Curves.

According to Boyle's law, the volume of a gas should diminish indefinitely as the pressure is increased, and in time the volume would approach zero, or become indefinitely small. This is absurd. Pressure can diminish only the space between the molecules and not the actual substance of the molecules. Hence, if b denotes the volume occupied by the molecules the changes in the volume of the gas with variations of pressure will be represented by $p(v-b)$=constant, not by pv=constant. It does not follow that b represents the actual volume of the space occupied by the matter in the molecules. The effect of the volume of the molecule on the compressibility of a gas was dimly recognized by D. Bernoulli, 1738; and by M. W. Lomanossoff, 1750; it was studied by A. Dupré, in 1865; and by J. D. van der Waals in 1872.

In his important *Mémoires sur l'élasticité et la dilatabilité des fluides jusqu'aux* *très hautes pressions*, embodying the results of work extending from 1878 to 1893, E. H. Amagat showed that while the product pv remains fairly constant at low pressures for many gases, the numerical value of pv changes in a remarkable manner as the pressures increase in magnitude. E. H. Amagat's measurements for carbon dioxide show that the product pv is not constant, for when

p . .	1	50	100	125	150	200	500	1000 atms.
pv . .	1	0·92	0·49	0·31	0·31	0·50	1·02	1·81

Notice how the product pv at first diminishes in magnitude and then steadily increases. This is brought out very clearly on plotting the numbers. If the products pv were constant for all values of p, we should get the straight line, dotted and marked *ideal gas line* in Fig. 3; with carbon dioxide, however, the curve descends below the line for an ideal gas, and then steadily rises, passing above the ideal gas line when the pressure is nearly 500 atmospheres.

The curves for hydrogen, helium, argon, and neon, at ordinary temperatures, do not descend below the ideal gas line, but take a path resembling the hydrogen line shown in Fig. 3. However, even these gases exhibit the same peculiar behaviour at lower temperatures. Thus, according to H. K. Onnes and C. Braak (1907), with hydrogen at —140°, the product pv reaches a minimum when the pressure is about 25 atmospheres; at —195°, 45 atmospheres; and at —213°, 51 atmospheres. In 1886, C. Bohr reported that oxygen behaved in a peculiarly abnormal manner at a pressure of about 0·7 mm. of mercury. The pressure-volume curve gave an abrupt change of direction which was ascribed to the transformation of oxygen into another variety; but some careful measurements by Lord Rayleigh (1907) and M. Thiesen (1901) indicate that the statement is probably based upon a mal-observation. To summarize these results at a constant temperature:

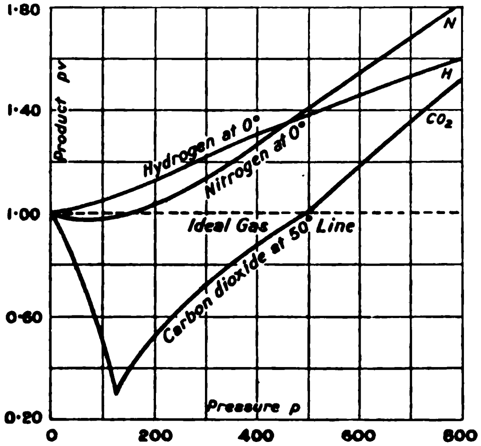

Fig. 3.—pv-Pressure Curves (Amagat).

(1) With small pressures, the product pv decreases with increasing pressure showing that the volume of gas, at relatively small pressures, is less than is described by Boyle's law. At very low pressures, the gas will follow Boyle's law $pv = p_1v_1$. Lord Rayleigh (1901–2) found no appreciable variation with oxygen, hydrogen, and nitrogen between 0·01 and 1·5 mm., showing that between these pressures the deviations from Boyle's law are too small to be detected.

(2) With large pressures the product pv increases with increasing pressure, showing that the volume of the gas, at relatively great pressures, is greater than is described by Boyle's law.

(3) All gases, in consequence, show a minimum value for the product pv. At 0°, for example, the minimum value of pv for air and nitrogen occurs at 100 atm. pressure; for oxygen at about 200 atm.; for carbon dioxide, at about 35 atm.; and for ethylene at about 42 atm. The pressure corresponding with the minimum depends on the nature of the gas and on the temperature. The minimum is less prominent with the more permanent gases than with the more condensable gases.

Gases which obey Boyle's and Charles' laws under ordinary atmospheric conditions usually remain gaseous at comparatively low temperatures and are accordingly called *permanent gases.*

§ 4. Dalton's Law of Partial Pressures

> Accurate and systematic investigation has brought to light the infinite complexity of nature; the fineness of the dovetailing of every event into many others; the never-ending response of all things to changes in the conditions that encompass them; the universal orderliness of natural occurrences; and the absolute interdependence of cause and effect. —M. M. P. MUIR (1894).

When two gases, which do not act chemically on one another under the conditions of the experiment, are brought together, the gases mix intimately, by diffusion, so as to form a homogeneous mixture. Furthermore,[1] John Dalton (1802) found that each gas seemed to exert the same pressure as if it occupied the space alone, and the total pressure of the mixture of gases was the sum of the several pressures due to each gaseous component of the mixture. If P be employed to denote the total pressure of a mixture of gases, and p_1 the partial pressure exerted by one of the gases, p_2 the partial pressure exerted by another gas, p_3 the partial pressure of a third gas, Dalton's discovery means that: $P = p_1 + p_2 + p_3 + \ldots$ In words, **in a mixture of gases which exert no physical or chemical action on one another, each gas exerts the same pressure as if it alone occupied the entire vessel, and the total pressure is the sum of the partial pressures due to each of the gases.** This is Dalton's law of partial pressures. If the four volumes of nitrogen and one volume of oxygen in the atmosphere be under normal pressure, the nitrogen gas will sustain a pressure approximately 608 mm. and the oxygen gas 152 mm. of mercury. J. Dalton added:

> Since two gaseous fluids which exert neither attraction nor repulsion on one another, distribute themselves so that their united pressure is equal to the pressure of the atmosphere, all the components of the atmosphere are arranged together at a given pressure and temperature, and by a paradoxical though true disposition, each of them occupies all the space destined for the aggregate.

It might be added that Dalton's partial pressure law is quite independent of Boyle's law, and can be extended to mixtures of any number of gases.

Examples.—(1) Moist hydrogen gas is confined over water under a pressure of 747·2 mm. of mercury at 15·3°, the partial pressure of water vapour at that temperature is 12·9 mm. of mercury. Then, from Dalton's law of partial pressures, it follows that the hydrogen gas itself is under a partial pressure equivalent to 747·2 less 12·9, or 734·3 mm. of mercury.

(2) If atmospheric air contains a mixture of four volumes of nitrogen and one volume of oxygen, show that if the manometer records a pressure p, the partial pressure of the oxygen gas will be $\frac{1}{5}p$, and of the nitrogen gas $\frac{4}{5}p$.

(3) If a moist gas of volume v_1 be confined in a vessel at a pressure p_1, show that the volume v of dry gas at normal pressure, 760 mm., and the volume v_2 of the water vapour at normal pressure, are respectively $v=v_1(p_1-f)/760$, and $v_2=v_1f/760$, where f denotes the vapour pressure of the water at the temperature of observation.

There are many reasons for supposing that the molecules of a substance exert some kind of attraction on one another. This intermolecular attraction gives rise to phenomena of cohesion, viscosity, capillarity, surface tension, etc. The intermolecular attraction is probably very powerful in solids, weaker in liquids, and very small with gases; but it is highly probable that the molecules of nearly all gases do exert some attractive influence on one another, and the gases, in consequence of this *physical* action, "deviate" from Dalton's law to an extent dependent upon the magnitude of the intermolecular attraction. Many mixtures of gases show slight, but not marked deviations from the law, *e.g.* carbon dioxide and sulphur dioxide; hydrogen with air, and with nitrogen; etc.

P. Fuchs[2] has investigated the change in volume which occurs on mixing chemically indifferent gases—nitrogen with nitrous oxide, carbon dioxide, or oxygen; nitrous oxide with carbon dioxide or oxygen; and oxygen with carbon dioxide. In every case there is an expansion which is greater the more the two components differ in physical properties. The change in volume does not correspond with the ratio of the two gases, but reaches a maximum which is beyond the 1 : 1 ratio, so that the maximum change occurs with mixtures containing more than 50 per cent. of the gas with the lower critical temperature; and the maximum lies nearer to the 1 : 1 ratio, the more the components resemble one another. The change in volume δv is qualitatively but not strictly quantitatively represented by J. D. van der Waals' equation

$$\delta v = x(1-x)\left(\frac{a_1+a_2-2a_{12}}{MRT}-(b_1+b_2-b_{12})\right)$$

where x denotes the number of gram-molecules of the one gas, and $(1-x)$, of the other; a_1 represents the attraction constants of the molecules of the one component; a_2, of the other component; and a_{12}, of the molecules of the different components for one another; b_1, b_2, and b_{12} represent the corresponding volume constants. Accordingly, the theoretical results agree more closely with the observed results when an allowance is made for the effect of the attraction of the molecules for one another.

J. Dalton's law is thus a limiting law for ideal gases. A. Leduc[3] prefers to state the law for actual gases in the form: *The volume occupied by a mixture of gases is equal to the sum of the volumes which the component gases would separately occupy at the same temperature and pressure as the mixture.* If two gases, originally at the same pressure, are mixed so that the temperature and total pressure remain unaltered, the pressure of the mixture can be calculated if the coefficients of deviation from Boyle's law, A, be known between the common pressures p and p_1 for the mixture and for each of the two gases, where

$$A_1^2=\left(\frac{p_1v_1}{p_2v_2}-1\right)\left(\frac{1}{p_2-p_1}\right)$$

There is usually found to be a slight increase of pressure on admixture which is scarcely measurable with the less condensable gases. The value of A at 16° between

1 and 2 atm. is 0·000143 for a mixture of nearly equal volumes of carbon and sulphur dioxides; 0·000005 for air; −0·000002 for equal volumes of hydrogen and oxygen.

The law had been applied to test if chemical action occurs on mixing certain gases, *e.g.* to find if any sign of chemical action occurs when nitric oxide (NO) is mixed with nitrogen peroxide (NO_2) resulting in the formation of nitrogen trioxide (N_2O_3). It is assumed that if no chemical combination takes place, the mixture will obey Dalton's law, and conversely.[4] The conclusion can be valid when it has been shown that the molecules of the two gases exert neither attraction nor repulsion upon one another. If they did, the test might lead to wrong conclusions with respect to chemical action. A slight contraction, for instance, might be evidence of molecular attraction, not of chemical combination.

§ 5. The Laws of Nature

We must confess that physical laws have greatly fallen off in dignity. No long time ago they were commonly described as the Fixed Laws of Nature, and were supposed sufficient in themselves to govern the universe. Now we can only assign to them the humble rank of mere descriptions, often erroneous, of similarities which we believe we have discovered. —J. H. Poynting (1899).

Nature, always working by law, is always consistent, always inexorable; her laws are invariable.—A. Simmons.

This is a convenient place to further emphasize the meaning of the term "law" in chemistry. The laws of a country may be the enactments of a ruling power, the ukases of a czar, or the regulations of the police superposed upon a people compelling them to act in particular ways, but it is of course absurd to say that Dalton's law and Boyle's law *must* be obeyed, implying that these laws are commands imposed upon gases which they are compelled to obey. The laws of nature describe, they do not compel. A substance does not act in a particular way because there is a law, but the law originated when it was found that substances acted in that particular way. Consequently, law is a useful term which the careless sometimes personify; it is a figure of speech, and is employed by scientific men purely in a metaphorical sense. The term has led to some confusion, for it has led to the belief that the uniformity described by the law has been imposed on nature by the will of a rational being—God himself. As previously indicated, a law in science is a kind of summary of the present state of our knowledge of the phenomena described by the law, and it is always subject to revision with the growth of knowledge. **Laws do not necessarily establish facts.** Consequently, the term would be replaced by another word, if we could think of a better. *Rule* would perhaps lead to less misunderstanding. The German equivalent—*Gesetz*, statute—is perhaps worse. A law of nature can have authority only in so far as it is based on facts. As indicated previously, the term "law of nature" is applied to a comprehensive generalization which "methodically and systematically describes certain natural phenomena." The laws of chemical combination describe what the elements do under definite conditions; and generally, **the laws of chemical and physical phenomena are collocations of those circumstances**

which have been found by experiment and observation to accompany all chemical and physical changes included in the statement of the law. The test of the "law" is that the statement holds good without exception. A broken law, said J. H. Poynting, is a false description.

It is sometimes said that a law of nature has never been disproved; this can only mean that if a law of nature is disproved, it ceases to be a law. The common meaning attached to the saying, "The exception proves the rule," is wrong, and it is an instance of confusion arising from the double meaning of words. In the old Latin form, *Exceptio probat regulam*, the word *probat* means tests, just as to-day proving wines means testing them. The proverb therefore meant that the apparent exception furnishes a means of trying, testing, or proving the rule, and if the exception cannot be explained, then the rule breaks down, for the **exception disproves the rule.** The exception annihilates the rule, for, said J. W. Ritter in 1798, a law must be abandoned immediately a real exception is discovered—it is no longer a law.

When the exact conditions are set up, the law describes the phenomenon without variableness or shadow of turning. The law is then regarded as an objective power. This power is called a force, and further, the force is said to be the cause of the phenomenon. Thus gravitation is regarded as an attractive force causing one particle to attract every other particle in the universe; chemical affinity is regarded, in this sense, as a selective chemical change. If therefore we find a gas deviating from Boyle's law, or a mixture of gases "disobeying" Dalton's law, the alleged laws may be false, incomplete, or imperfect descriptions, or some perturbing influence is at work which masks the simple phenomena described by these laws.

§ 6. The Influence of Temperature on the Volume of Gases—Charles' Law

> According to the schools of philosophy, it has been proved that the effect of cold is to make bodies contract while heat makes them expand.—G. GALILEI (1615).

The expansion of air by heat has long attracted the attention of chemists. Hero of Alexandria (*c.* 117 B.C.), G. B. Porta (1616), C. Drebbel (1608), and G. Galilei (1615) experimented on the subject. H. Boerhaave considered the effect of temperature on the volume of gases, and, in his *Elementa chemiæ* (Lugduni Batavorum, 1732), he stated that when air is heated, it becomes so rare that neither the measure nor the limit of its dilation has been yet discovered; and added:

> Air of unequal masses but of the same density, is always expanded in the same measure by the same degree of fire; so that these expansions in the same density of air, by a constant law of nature, are always proportional to the augmentations of heat.

Influence of temperature on the volume of gases—pressure constant.—In 1790, Joseph Priestley concluded "from a very coarse experiment" that "fixed and common air expanded alike with the same degree of heat;" J. Dalton, in 1801, inferred from his experiments: "Upon the whole, I see no sufficient reason why we may not conclude that all elastic fluids, under the same pressure, expand equally by heat;" and J. L. Gay Lussac,[1] in 1802, quoted some experiments in support of the generalization: **The same rise of temperature produces in all gases the same increase in volume, provided the pressure and mass be kept constant.** This law is generally designated **Charles' law,** in honour of J. A. C. Charles, who, according to Gay Lussac, made some crude experiments on the subject fifteen years before Gay Lussac's publication. Some call this relation *Gay Lussac's law.* It might, perhaps, with more propriety be called **Volta's law,** because A. Volta,[2] described it in his *Memoria sulla uniforme dilatazione dell'aria,* in 1793. G. Amontons had an inkling of this law in 1702.

The increase in volume which occurs when one litre of nitrogen at 0° is heated in a suitable vessel is shown in the following table (R. Chappius, 1888):

TABLE I.—THERMAL EXPANSION OF NITROGEN.

Temperature $\theta°$.	Volume v litres.	Expansion per litre per degree.
0	1·0000000	0·0036778
10	1·0367781	0·0036770
20	1·0735396	0·0036763
30	1·1102875	0·0036761
40	1·1470244	

The numbers in the last column—called **the coefficients of thermal expansion**—mean that the volume v of a litre of nitrogen, when heated through $\theta°$ can be represented very closely by the expression : $v=(1+0·003676\theta)$ litres. In other words, nitrogen increases 0·003676, or very nearly $\frac{1}{273}$rd part of its volume at 0° for every degree rise of temperature. More generally, if v_0 be used to denote the volume of gas at 0°, we have, instead of the preceding expression, $v=v_0(1+\frac{1}{273}\theta)$, or $v=v_0(1+\alpha\theta)$. This is very nearly true for most of the common gases, and it therefore represents a condition which must be satisfied by the temperature and volume of a gas, under constant pressure, in order that the system may be in stable equilibrium.

While solids and liquids have their own characteristic coefficient of expansion, gases have nearly the same coefficient of thermal expansion. This is the meaning of Charles' law. The coefficients of thermal expansion (pressure constant) for the gases run something like this for one atmosphere pressure and variations of temperature between 0° and 100° :

Air	0·003671
Hydrogen	0·003661
Carbon dioxide	0·003728
Carbon monoxide	0·003669
Sulphur dioxide	0·003903
Nitrous oxide	0·003719

These numbers are close enough to $\frac{1}{273}$ for most practical purposes. In general, the more easily a gas is liquefied and the greater its molecular weight, the greater the deviation from the constant 0·003665 found for air—witness carbon dioxide, 0·003728 ; hydrogen bromide, 0·00386 ; etc.

For every degree centigrade the temperature falls, the volume of the gas decreases by $\frac{1}{273}$rd. If $\frac{1}{273}$rd part of a gas be taken away 273 times, no more gas remains. This is illustrated by plotting the above equation.

If the temperature be less than $-273°$, the gas would have a negative volume, that is, a volume less than nothing ! If the temperature be $-273°$, the gas would occupy no volume ! It is impossible to imagine a substance occupying no space, but such is a logical conclusion from Charles' law. Where is the fallacy ? Whenever a natural process is represented by mathematical symbols, it is well to remember that the artificial statement often expresses more than actually obtains in nature, because, in the physical world, only changes of a certain kind occur. We must therefore limit the generality of the mathematical expression. Charles' law includes a simplifying assumption. The apparent volume of a gas may be resolved into at least two parts . (1) *the volume occupied by the molecules of the gas ;* and (2) *the space between the molecules.* If b denotes the space occupied by the molecules, and v the observed volume of the gas, the space between the molecules will be represented by $v-b$. Although for the sake of simplicity, we assume v to represent the *total volume* occupied by the gas, Charles' law refers to $v-b$, that is, to the space between the molecules, and in that case, the conclusion that $v=0$ when the temperature is $-273°$ involves no absurdity. Moreover, the gas would liquefy before the temperature $-273°$ was attained, and the simple gas law of Charles would not then be applicable.

It has been urged that J. L. Gay Lussac's statement of Charles' law means that the increase in the volume of a gas at any temperature, for a rise of 1°, is a constant fraction of its initial volume at 0°—in symbols, $v=v_0(1+\alpha\theta)$; while J. Dalton's statement of the law means that the increase in the volume of a gas at any temperature, for a rise of 1°, is a constant fraction of its volume at that temperature—in symbols $dv/d\theta=\alpha v$; hence by integration, $v=v_0e^{\alpha\theta}$. If the latter expression be expanded, $v=v_0(1+\alpha\theta+\frac{1}{2}\alpha^2\theta^2+\ .\ .\ .)$, and if the second and higher powers be outside the range of measurement, the two statements amount to the same thing. R. Mewes and L. Neumann[3] proposed to replace $v=v_0(1+\alpha\theta)$ by $v=x+(v_0-x)(1+\alpha^\theta)$, or approximately $v=v_0(1+\alpha)^\theta$. The results at ordinary temperatures are good, but they become less accurate with decreasing temperatures. The discrepancies are in fact attributed to errors in the measurements at low temperatures which are introduced by surface condensations, etc.

Influence of temperature on the pressure of a gas—volume constant.—About 1682, R. Boyle made some experiments on the influence of " cold and heat " on the pressure, or the spring of air, as he called it, and found that the effect of the greatest degree of cold he could produce did not " weaken the spring by anything near so considerable as one would expect." The subject did not attract much attention until G. Amontons (1702–3)[4] published two memoirs in which he demonstrated that equal masses of air, measured at the same initial pressure, acquire equal increments of pressure when heated to the boiling-point of water provided the volumes are maintained at their initial value; and if the pressure of the air before heating be doubled or tripled, the additional pressure produced when the air is heated to the boiling-point of water is likewise doubled or tripled. Otherwise expressed, the ratio of the total pressures (p and p_1) of air at two definite temperatures (T and T_1), and kept at a constant volume, has always the same value R and is independent of the initial pressure. In symbols, $p/T=p_1/T_1$; which can be written $p=RT$, where R is the constant of proportion. In words, **the same rise of temperature produces the same increase of pressure provided the volume and mass of the gas be maintained constant.** This relation might be called **Amontons' law.** It can be very simply deduced from Charles' and Boyle's laws, expressed in an analogous form, $p=p_0(1+\frac{1}{273}\theta)$, or $p=p_0(1+\beta\theta)$, where β denotes the coefficient of increase of pressure (volume constant). J. L. Gay Lussac thought that all gases had the same values of α and β; and it was thought that $\alpha=\beta$. More exact measurements have shown that neither statement is true. The coefficient β for the above-named gases between 0° and 100° are:

Air	0·003665
Hydrogen	0·003663
Carbon dioxide	0·003688
Carbon monoxide	0·003845
Nitrous oxide	0·003676

Absolute zero.—J. Amontons (1703)[5] argued that air would exert no pressure at all if it were cooled below freezing-point of water to about 2½ times the range of temperature between the freezing- and boiling-points of water. In 1779, J. H. Lambert[6] repeated Amontons' experiment and estimated that air would occupy no volume at all, if cooled to −270°; more accurate measurements make this temperature −273°. This temperature, −273°, is supposed to be a *non ultra plus*, or limiting temperature —the nadir or lowest possible temperature—a kind of *primum frigidum*. Hence, −273° is sometimes called the **absolute zero**; and temperatures reckoned from this zero are called **absolute temperatures.** *L'Association Internationale de Froid*[7] recommended that the letter K—from Lord Kelvin—be employed to denote absolute temperatures so that 0° C.=32° F.=273° K. On the absolute scale of temperatures, 0° C. will be 273° K. If T be employed to denote the temperature on the absolute scale, and θ the temperature on the centigrade scale, we have $T=273+\theta$. Hence, if v be the volume of a gas when the absolute temperature is T, and v_1 the volume when the temperature is T_1, from the preceding equation (3) $v:v_1=T:T_1$, which is but another way of stating Charles' law. The volume of a gas varies directly as the temperature, so that $v=RT$, where R is the constant of proportion. The arbitrary nature of the absolute zero deduced from the coefficient of thermal expansion of air, will appear when it is remembered that a similar train of reasoning would furnish −5000° as the absolute zero, if the coefficient of expansion of mercury were made the standard. It must be remembered, however, that the coefficient of thermal expansion of all gases, unlike liquids and solids, has nearly the same value; and further, the gaseous state probably represents the simplest form in which matter can exist. There are, however, other reasons for selecting −273° as the absolute zero which are discussed in works on thermodynamics.

The combined influence of temperature and pressure on the volume of a gas.—According to Boyle's law, the volume of a gas varies inversely as the pressure, so that if a pressure p_1 and volume v_1 change to a volume x at a pressure p_2, then, from the relation $p_1v_1=p_2x$ (Boyle's law). Again, according to Charles' law, the volume of a gas varies directly as the absolute temperature, so that if a gas whose volume is x at a temperature T_1 changes to a volume v_2 when the temperature rises to T_2, we have from the above relation, $xT_2=v_2T_1$. On substituting the value of x from the preceding relation

$$\frac{p_1v_1}{T_1}=\frac{p_2v_2}{T_2}$$

If p_2, v_2, T_2 represent the volume of the gas under standard conditions of temperature and pressure, p_2v_2/T_2 will have a constant numerical value, say R; and it follows at once that when both temperatures and pressure vary, the effect on the volume will be given by the equation **pv=RT**, where R is the constant of proportion—generally called the **gas constant.** An equation which attempts to express the relation between the pressure, temperature, and volume of a gas is sometimes called the **equation of state**—*Zustandsgleichung*, or *équation caractéristique*—or the *characteristic equation* or the *gas equation*. The equation of state is applicable to ideal gases. If an arbitrary value be assigned to the constant R, and corresponding values of p and v be plotted for a series of values of T, say $T=1,2,3,\ldots$, a series of curves, Fig. 4, are obtained. These curves may be supposed to have been drawn on a surface *abcd*. While a *plane* suffices for showing the relation between *two* variables, a *surface* in three dimensions is needed for *three* variables. These formulæ are used a great deal in calculations involving the variations in the volumes of gases owing to variations in temperature and pressure. For instance, in reducing the volume of a gas at any observed temperature and pressure to the corresponding volume at **the standard or normal pressure and temperature**—0° C. and 760 mm. pressure—often represented by n.p.t., or N.P.T., or S.T.P., or S.T., S.P.

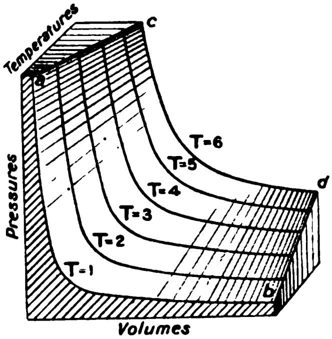

FIG. 4.—Surface showing the Relation between the three variables: Temperature, Pressure, and Volume of Gases.

EXAMPLE.—(1) If a gas measures 170 c.c. at a pressure of 735 mm. mercury, and a temperature of 15°, what is the volume of the gas at normal temperature and pressure? Here it is required to find v in the preceding formula where $p=760$; $T=273$; $T_1=288$; $v_1=170$; and $p_1=735$; hence, $v=\frac{273}{288}\times\frac{735}{760}\times170=155{\cdot}8$ c.c.

(2) Show that 13·8 c.c. of a gas at 747·6 mm. pressure at 19° reduce to 12·4 c.c. at 760 mm. and 0°.

Approximations can be used for general calculations,[8] and books on gas analysis have tables for converting unit volume at $\theta°$ and pressure p to its volume under standard conditions. It will be observed that the fraction T/T_0 for θ and θ_0 is $(273+\theta)/(273+\theta_0)$, and if θ_0 be 0°, the fraction reduces to $1+\frac{1}{273}\theta$, or $1+0{\cdot}003367\theta$.

The numerical value of the gas constant R.—The numerical value of R depends upon the units of pressure and volume; if unit mass of gas be taken, the value of R will depend upon the molecular weight of the gas. If one gram-molecule be taken, $pv=RT$, and if n gram-molecules be taken, $pv=nRT$. *If the litre be taken as the unit of volume and the atmosphere as unit of pressure,* and since a gram-molecule of gas occupies nearly 22·4 litres at 0° and under one atmosphere pressure, $1\times22{\cdot}4=1\times R\times273$; or $R=0{\cdot}082$ litre-atmosphere. *If the gram and cubic centimetre* be taken as unit, it follows that if v_1 represents the volume of a gram-molecule of any gas at n.p.t., $v_1=22{,}400$ c.c.; p_1 is 1033·3 grms. per sq. cm.; and $T_1=273$. Hence, $R=pv/T=(1033{\cdot}3\times22{,}400)/273=84{,}760$ gram-centimetres of energy. From measurements of the mechanical equivalent of thermal energy, it is known that one gram-centimetre of mechanical energy is equivalent to 42,650 calories. Hence, $R=pv/T=1{\cdot}9$ cals., or 2 cals. nearly.

§ 7. Deviations from Charles' Law

Nature abhors the straight line.—R. Ross (1914).

We have already seen that the coefficients of thermal expansion of all gases are only approximately the same. The coefficients for the individual gases differ a little among themselves as indicated above. The variation in the coefficient of thermal expansion at temperatures and pressures not far removed from normal atmospheric temperatures and pressures, is not very marked, and for regular gas calculations can be ignored. It remains to indicate the variation, if any, in the coefficient of thermal expansion with large variations of temperature and pressure. H. Fläugergues (1825) showed that the coefficient of expansion of moist air is rather larger than that of dry air. Charles' law was also tested by P. L. Dulong and A. T. Petit (1815), F. Rudberg (1837), H. V. Regnault (1841), G. Magnus (1842), E. H. Amagat (1873), P. Jolly (1874), P. Chappius (1888), H. K. Onnes and M. Boudin (1900), etc.[1] The more important results are as follows:

(1) **The exact coefficient depends on the nature of the gas.**—H. V. Regnault, about 1850, proved that different gases have not the same coefficients of thermal expansion, as Charles' law assumes, but that each gas has its own specific constant. For ordinary calculations, particularly with gases which cannot be liquefied in the neighbourhood of atmospheric temperatures, the coefficient is taken to be $\alpha=\beta=\frac{1}{273}$.

(2) **The influence of pressure.**—The coefficient of expansion of most gases is increased by augmenting the pressure of a gas until a maximum value is attained, after that, the coefficient diminishes with increased pressure. For instance, E. H. Amagat (1893) found that the coefficients of expansion of carbon dioxide at temperatures between 50° and 60° assumed the following values when the pressure changed from 30 to 1000 metres of mercury:

Pressures .	30	60	125	200	500	1000 metres
Coefficients .	0·0069	0·0085	0·0410	0·0085	0·0033	0·0018

Carbon dioxide thus shows a marked variation in the coefficient of thermal expansion at high pressure. In agreement with these facts, the coefficient also diminishes as the pressure is reduced, even as low as 0·077 mm. of mercury. The variation is not so marked with gases like nitrogen, oxygen, and hydrogen which are not easily condensed to the liquid condition. The general result of H. V. Regnault's and Amagat's work is to show that if a gas is more compressible than is represented by Boyle's law, the coefficient of thermal expansion is increased by pressure; and conversely for gas less compressible than is indicated by Boyle's law, the coefficient of thermal expansion decreases with an increase of pressure. The value p which furnishes the greatest coefficient of thermal expansion is that same value of p which gives the minimum product pv. At ordinary temperatures, therefore, hydrogen and helium do not exhibit this variation in the value of their coefficients of expansion. With these gases, the coefficient of expansion steadily diminishes with increasing pressure; although even these resemble other gases if the temperature be low enough. Consequently, *at high enough pressures, when the minimum pv is reached, the coefficient of thermal expansion of all gases decreases with an increase of pressure.*

(3) **The influence of temperature.**—The general effect of raising the temperature is to lower the coefficient of expansion. For instance, Hirn (1862) found that for water vapour from 0° to

	118·5°	162°	200°	246·5°
Coefficient of expansion .	0·004187	0·004071	0·003938	0·003799

Similarly, L. Troost and P. Hautefeuille (1876) found the coefficient for silicon tetrachloride fell from 0·00449 between 100° and 125° to 0·00399 between 125° and 180°; while between the same temperatures the coefficient for carbon tetrachloride fell from 0·00470 to 0·00414; and for phosphorus trichloride, from 0·00489 to 0·00417.

The changes in the coefficient of expansion with increasing pressure become less and less as the temperature is raised, and finally disappear. So does the minimum value of the product pv become less and less marked as the temperature is raised. The gradual flattening of the carbon dioxide curves as the temperature rises from 40° to 100° is brought out very clearly in Fig. 5. All gases exhibit a minimum value for pv. The pressure required for a minimum depends on the temperature as well as on the nature of the gas. The minimum is most marked when the gas is near its temperature of liquefaction. If the temperature is much above this critical point, the minimum is very small—with hydrogen the minimum is inappreciable at 0°—Fig. 3. All other gases show a minimum at ordinary temperatures. Hence, H. V. Regnault, who discovered this peculiarity of hydrogen, was led to say ironically that hydrogen is a gas *plus que parfait*—a gas more than perfect; but hydrogen also shows a minimum at reduced temperatures. Similar remarks apply to helium and neon.

§ 8. The Critical State of Gases

> The ordinary gaseous and liquid states are only widely separated forms of the same condition of matter, and may be made to pass into one another by a series of gradations so gentle, that the passage shall nowhere present any interruption or break of continuity. Gas and liquid are only distinct stages of a long series of continuous physical changes.—T. ANDREWS (1869).

The fact that some elements occur as gases, others as liquids, and yet others as solids is a mere accident of temperature or pressure. Similar remarks apply to chemical compounds which do not decompose when the temperature is augmented. If the prevailing atmospheric temperature were 100° higher than it is, water would be a gas; and if 100° lower, water would be a solid. Similarly, if the atmospheric pressure were ten times as great as it is, chemistry books would describe sulphur dioxide and many other so-called gases either as liquids or solids; while if the pressure were much less than it is, many so-called liquids would be styled gases. **Every substance is potentially solid, liquid, and gas.** The solid, liquid, and gaseous states of matter are merely phases assumed by virtually all kinds of matter as the temperature rises from absolute zero upwards. The three forms which the elements and their compounds can assume are called the **three states of aggregation.** The three states of water are: *Gas* above 100°; *liquid* between 100° and 0°; and *solid* below 0° under ordinary atmospheric pressure. These facts are symbolized:

$$\text{Water}_{\text{ice}} \overset{0°}{\rightleftharpoons} \text{Water}_{\text{liquid}} \overset{100°}{\rightleftharpoons} \text{Water}_{\text{steam}} \quad (760 \text{ mm.})$$

Investigators who have special facilities for working at high temperatures, report that gold has a melting point, 1062°, and a boiling point, 2530°, or:

$$\text{Gold}_{\text{solid}} \overset{1062°}{\rightleftharpoons} \text{Gold}_{\text{liquid}} \overset{2530°}{\rightleftharpoons} \text{Gold}_{\text{gas}} \quad (760 \text{ mm.})$$

Similarly, those working in laboratories specially equipped for measurements at low temperatures, report that oxygen has a melting point, —227°, and a boiling point, —182·5°, or

$$\text{Oxygen}_{\text{solid}} \overset{-227°}{\rightleftharpoons} \text{Oxygen}_{\text{liquid}} \overset{-182·5°}{\rightleftharpoons} \text{Oxygen}_{\text{gas}} \quad (760 \text{ mm.})$$

M. Faraday (1819) [1] emphasized the fact that when any form of matter passes from the solid to the liquid state, or from the liquid to the gaseous state, its physical properties diminish in number and variety. Thus, solids in becoming liquids lose their hardness, crystalline form, etc.; and in passing to the gaseous state, the phenomena are still more marked, thus, all gases have nearly the same coefficient of thermal expansion. "The varieties of density, hardness, opacity, colour, elasticity, and form which render the number of solids and fluids almost infinite, are in gases supplied by a few slight variations in weight, and some unimportant shades of colour."

The critical state.—T. Andrews demonstrated in his paper *On the continuity of the gaseous and liquid states of matter*,[2] in 1869, that if gaseous carbon dioxide be gradually compressed in a vessel suitable for the observation, the volume diminishes more rapidly than would occur if Boyle's law correctly described the behaviour of the gas; and when the pressure attains a certain value, the gas begins to liquefy. A further decrease in the volume does not change the pressure, but only increases the quantity of gas liquefied. At length, when all the gas has liquefied, a large increase of pressure only causes a minute decrease in the volume of the liquid, since liquids in general undergo but a small change of volume on compression.

If the experiment be made with carbon dioxide at 0°, the gas commences to liquefy when the pressure has attained 35·4 atmospheres; if at 13·1°, liquefaction commences at 49·8 atmospheres pressure; if at 30°, 70 atmospheres pressure; while if the temperature exceeds 31°, or, more accurately, 31·35°, no pressure, however great, will liquefy the gas. Other gases exhibit analogous phenomena. This is in agreement with M. Berthelot's conclusion[3] in 1850 that pressure will not liquefy gases under all conditions of temperature. **For each gas there is a particular temperature above which liquefaction is impossible however great be the applied pressure.** Andrews called this the **critical temperature of the gas**; the corresponding pressure, or the **critical pressure,** is the least pressure which will liquefy the gas at the critical temperatures; the volume of unit mass of the substance at the critical temperature and pressure is the **critical volume**; and the reciprocal of the volume is the **critical density.** Consequently, a substance at the critical temperature and pressure is at its critical density, and is said to be in its **critical state.** The critical constants of a few substances are indicated in Table II., where the atmosphere is the unit of pressure; and the volume refers to one gram of the gaseous substance in litres at 0°, and 760 mm. is the unit of volume; and the density is referred to water at 4°.

TABLE II.—CRITICAL CONSTANTS OF SOME GASES.

Substance.	Critical pressure.	Critical temperature.	Critical density.	Critical volume.
Hydrogen	14·0	−240·8°	0·043	0·00264
Nitrogen	35·0	−146·0°	0·400	0·00517
Oxygen	50·8	−118·8°	0·650	0·00426
Carbon dioxide	77·0	31·35°	0·450	0·00660
Nitrous oxide	74·5	38·8°	0·454	0·00436
Sulphur dioxide	78·9	155·4°	0·520	0·00249
Water	194·6	364·3°	0·208	0·00386
Carbon disulphide	75·0	273·0°	0·377	0·00900
Air	35·9	−140·7°	0·344	0·00468
Helium	2·3	−267·8°	0·066	0·00299
Argon	52·9	−117·4°	0·509	0·00404
Ammonia	110·3	131·0°	0·239	0·00481
Methane	45·6	−82·85°	0·1623	0·00488
Acetylene	64·5	35·25°	0·2346	0·00690
Ethylene	54·0	11·0°	0·210	0·00752
Tin tetrachloride	32·9	318·7°	0·7414	0·00060
Hydrogen chloride	83·0	52·3°	0·462	0·00520
Nitric oxide	71·2	−93·5°	0·524	0·00347
Chlorine	93·5	146·0°	0·547	0·00615

In 1883, J. Dewar[4] showed that the ratio of the critical temperature to the critical pressure of many gases is nearly proportional to the molecular volume, and that the quotient T_c/p_c for the common gases generally lies between 3½ and 5. Other dependent relations have been indicated by E. Ariès and W. R. Fielding.

T. Andrews' critical temperature was forshadowed by D. I. Mendeléeff in 1861 in a paper on the expansion of liquids above their boiling points,[5] when he said:

> The absolute boiling point of a liquid is the temperature at which the cohesion and heat of vaporization become zero. At this temperature, the liquid changes to vapour regardless of pressure and volume.

D. I. Mendeléeff's **absolute boiling point** thus corresponds with T. Andrews' critical temperature. D. I. Mendeléeff estimated the absolute boiling point of water to be 580°, and of ethyl alcohol, 250°. It is interesting to notice the influence of temperature on carbon dioxide, partly liquid, partly gaseous. Observe the upper surface of the gas confined in a glass tube containing partly liquefied carbon dioxide over mercury at 18°. The surface of the liquefied gas has a sharply defined meniscus. On raising the temperature, the meniscus of the liquid becomes flatter and flatter, until, at 31·35°, the surface of the liquid seems to disappear. The sharp line of demarcation between the liquid and gas vanishes at the critical temperature. In the words of T. Andrews, as the temperature of the liquefied gas approaches 31°:

> The surface of demarcation between the liquid and the gas became fainter, lost its

curvature, and at last disappeared. The space was then occupied by a homogeneous fluid, which exhibited when the pressure was suddenly diminished, or the temperature slightly lowered, a peculiar appearance of moving or flickering striæ throughout the entire mass.

At 40°, the tube contains a homogeneous gas. Liquid carbon dioxide cannot exist at this temperature, however great the pressure. Small tubes of liquid carbon dioxide for illustrating the phenomena by lantern can be obtained. Thin sections of quartz found in many granites contain cavities with liquid carbon dioxide which can be seen to pass through the critical point when the sections are warmed on the stage of a microscope.

A blue opalescent mist appears in the tube before the meniscus of the liquid can be detected when the temperature of the gas is gradually lowered. The converse series of changes occur on heating. According to D. Konowaloff (1902),[6] the **critical opalescence** is due to the scattering of light by fine particles of liquid spontaneously formed about dust particles ; or, according to M. von Smoluchowsky (1908), to accidental aggregations of molecules produced by molecular collisions. The appearance of the blue mist is connected with slight disturbances which have been observed in the equation of state when applied to observations in the neighbourhood of the critical temperatures. P. de Heen (1888) argues that there are two kinds of molecules—*molécules liquidogéniques*, and *molécules gasogéniques*—and that the former can persist in the vapour phase. I. Traube (1892) and P. Villard favoured this view. If P. de Heen means that the pressure of a saturated vapour of a pure substance, like that of a mixture, depends upon the relative masses of liquid and vapour phases, the hypothesis is contrary to all experience. This was emphasized by G. G. Stokes and M. Prud'homme. According to M. von Smoluchowsky, the ceaseless to-and-fro agitation of the molecular particles of a gas will produce, spontaneously and continuously, minute inequalities in the density of different parts. A given cube of dimensions μ, for example, will contain sometimes more and sometimes less molecules. Usually these differences are inaccessible to measurement. The case is different when the fluid is not rarefied such as occurs when it is near the critical state. There is then a permanent condition of fine-grained heterogeneity where contiguous regions of notably different density are almost in equilibrium. Owing to molecular agitation, the denser swarms of molecules break up slowly, and, at the same time, others are forming elsewhere. The opalescence is produced by the molecular swarms causing a lateral diffraction of the light. The fluctuations of density increase as the compression increases and are very much more accentuated with a compressed gas than with a gas of normal density. The smaller the aggregates, the shorter the wave length of the light undergoing diffraction. Hence the opalescence may appear blue. M. von Smoluchowsky's theory has been extended by A. Einstein and confirmed by the work of H. K. Onnes and W. H. Keesom. It has also been applied to explain the opalescence of liquid mixtures in the neighbourhood of the point of critical miscibility, and the blueness of the sky.

The relation between the pressure and the volume of, say, carbon dioxide, at different temperatures—T, T_0, T_1, T_2—is represented diagrammatically in Fig. 6. The portion of the curve K_2T_2, or K_1T_1, represents the behaviour of the gas when liquid is present ; the portion K_2M_2, or K_1M_1, the behaviour of the gas in the presence of its own liquid and M_2p_2, or M_1p_1, the behaviour of the liquid when no gas is present. It will be observed that K_2M_2 or K_1M_1 is the **line of constant vapour pressure** which is horizontal with the v-axis. It illustrates in a graphic manner the well-known law : At any fixed temperature, the pressure of a gas in the presence of its own liquid is always the same. The curve $T_0K_0p_0$ represents the relation between pressure and volume at the critical temperature ; and the curve T, the relation between p and v at a temperature when the gas does not liquefy. The line $K_0K_1K_2B$ represents the condition under which the gas, compressed at the stated temperatures T_0, T_1, and T_2, begins to liquefy, and hence it is the curve for saturated vapour, and also the curve for the liquid at its vaporization temperature ; it is not quite accurately called the **dew curve,** or *ligne de rosée*, because a gas under a gradually increasing pressure, first shows signs of liquefaction under conditions represented by a point on this line; similarly, the line $K_0M_1M_2A$ is called the **boiling curve,** or *ligne d'ébullition,* because a liquid under a gradually diminishing pressure first shows signs of vaporization under conditions represented by a point on this line. Note also that the lines K_0A, K_0B, and K_0p_0 divide the plane of the paper into three regions Every point to the right of BK_0p_0 represents a homogeneous gas; every point in the region AK_0B represents a heterogeneous mixture of gas and liquid; and every point to the left of AK_0p_0, a homogeneous liquid. The gas in the region K_0BVT_0 is below its critical temperature, and, in consequence, is sometimes called a *vapour* as distinct from a *gas.* The diagram, Fig. 6, thus represents the conditions of equilibrium of a liquid or gas under different conditions of temperature, pressure, and volume.

The continuity of the liquid and gaseous states.—It is interesting to note historically that C. Caignard de la Tour (1822),[7] long before Andrews' experiment, noticed that when a liquid is heated in a sealed tube there is a definite temperature at which the surface of separation between the gas and liquid disappeared and the whole contents of the tube become homogeneous. C. Caignard de la Tour's experiments thus demonstrate that the critical temperature is the upper limit of the liquid state; and Andrews' experiments prove that the critical temperature is the lower limit to the homogeneous gaseous state. The passage from the one state to the other proceeds in a continuous manner. **The liquid and gaseous states are continuous, not abrupt.** The properties—density, surface tension, viscosity, refractive power, heat of vaporization, compressibility, etc.—of a liquid gradually lose their distinctive character as the temperature is raised, until, at the critical temperature, the properties of liquid and gas are the same.

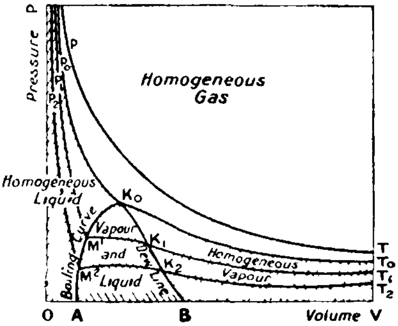

FIG. 6.—Pressure · Volume Curves for Carbon Dioxide.

There is no evidence of a change in molecular structure when, say, carbon dioxide passes from one state of aggregation to another; nor is there any evidence of a polymerization of the molecules when the common gases condense to liquids. Nitrogen peroxide, water, and some other substances, however, do appear to polymerize and form compound molecules on passing from the gaseous to the liquid state of aggression. The properties of the condensing gases do not then exhibit that continuity shown by carbon dioxide and other gases which do not polymerize or dissociate.

The difference between liquids and gases *below* the critical temperature seems to be a question of molecular attraction. If the molecules of a substance in the liquid state have essentially the same motions as in the gaseous state, the specific heat of a vapour should be nearly the same as that of the corresponding liquid. This is by no means the case. For example, the specific heat of liquid mercury is twice as large as that of the vapour; and the specific heat of liquid water is three times that of steam. There is, however, usually less difference between the specific heats, densities, and coefficients of thermal expansion of solids and the corresponding liquids.

The condensation of binary mixtures of gases.—In a posthumous memoir presented to the Royal Society in 1886, T. Andrews[8] showed that some extraordinary phenomena occur when certain binary mixtures of gases are subjected to a gradually increasing pressure. A mixture of 6 parts of carbon dioxide and one of nitrogen commences to liquefy at 3·5° under a pressure of 48·3 atm. Here nitrogen condenses to a liquid at a temperature nearly 150° higher than its critical temperature, and at 102 atm. pressure, the whole of the nitrogen liquefies along with the carbon dioxide. The individual properties of the gases are thus profoundly modified in the presence of other gases which are supposed to be chemically indifferent. The conception which has crystallized from Dalton's law of partial pressures, namely, that the two components of a mixture of gases are perfectly independent of one another, each preserving its own individuality, and each behaving as if it were an isolated individual, is quite erroneous. The explanation turns on the existence of a definite relation between the composition of a condensed liquid and of the vapour during, say, the distillation of a binary mixture of two volatile liquids which exert no chemical action on one another. L. P. Cailletet discovered this remarkable phenomenon during his *Expériences sur la compression des mélanges gazeux* in 1880. If a mixture of one volume of air and nine volumes of carbon dioxide be subjected to a gradually increasing pressure at about 2°, the gas begins to liquefy at a pressure of about 72 atm.; and on increasing the pressure, still keeping the temperature constant, the liquid again passes into the gaseous state when the pressure reaches 149 atm. ; and the liquid does not reappear again however great the pressure. If the pressure at which the liquid appears and disappears be plotted with the corresponding temperature, we get the dew curve *BKC*, Fig. 7. For the same abscissa T_1, there are two ordinates, p_1 and p_2, between which the mixture is in a heterogeneous condition. At temperatures above T_0, no condensation will occur at all ; below T_1, only normal condensation takes place ; at temperatures between T_1 and T_0, both normal and **retrograde condensation** as P. Kuenen (1893) named the phenomenon, will occur. The dotted line *AC* represents the boiling curve ; above *AC*, the system will be in the liquid state. *K* corresponds with the critical temperature of the mixture ; *C* is called a **plait-point.** For mixtures of two gases, therefore, (1) there is a critical zone of temperature above which complete or partial liquefaction is impossible. (2) Within the temperature of the critical zone itself a part of the mixture can be brought by pressure to the liquid state, and in the region of retrograde condensation, condensation is produced by diminution of pressure, and evaporation by an increase of pressure. The phenomena with mixtures thus appears quite different from what obtains with single gases. (3) Below the temperature of the critical zone, the whole of the mixture can be liquefied by pressure.

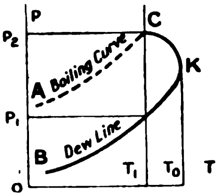

Fig. 7.—Diagrammatic.

The phenomenon occurs only with mixtures of a certain composition ; above and below these limits, the dew curves are quite normal. The curves can be taken in three dimensions with the three variables—pressure, volume, and temperature. The two dew points of a given mixture approach one another as the temperature rises. Thus, F. Caubet (1901) found with a mixture of 74·58 per cent. of carbon dioxide and 25·42 per cent. of sulphur dioxide gases :

TABLE III.—RETROGRADE CONDENSATION OF MIXTURES OF CARBON DIOXIDE AND SULPHUR DIOXIDE.

70°		72°		74·2°	
Pressure.	Volume of liquid.	Pressure.	Volume of liquid.	Pressure.	Volume of liquid.

105·0	0				

One asterisk * represents the first dew point—1er *point de rosée ;* and two asterisks ** the second dew point—2^{e} *point de rosée.*

L. P. Cailletet and E. Mathias (1866) [9] found empirically that the mean values of the densities of a liquid, D_l, and of its saturated vapour, D_v, at a constant pressure, vary with the temperature in a very simple manner. If the densities be plotted with the temperature, a closed curve *AKB*, Fig. 8, is obtained. The mean values of the densities of the co-existing liquid and vapour, plotted against the temperatures, fall on a straight line, *KC*, Fig. 8. The density of the liquid decreases while that of the vapour increases as the temperature rises, until, at the critical point, *K*, the two densities are equal to the critical density. Hence, the rule was called the *loi du diamètre rectiligne*, or Cailletet and Mathias' **law of rectilinear diameters.** According to this empirical rule, **the mean values of the densities of a liquid and of its saturated vapour is a linear function of the temperature**; so that if D represents the mean value of the two densities, $D=a+b\theta$, where a and b are constants, and θ denotes the temperature on the centigrade scale. For argon, the equation of the mean density curve is $D=0{\cdot}20956-0{\cdot}0026235\theta$; and in cases where the curve has a slight curvature, the equation $D=a+b\theta+c\theta^2$ usually represents the observed results. The law has been tested with carbon dioxide, sulphur dioxide, nitrous oxide, hydrocarbons, alcohols, carbon tetrachloride, tin tetrachloride, oxygen, helium, xenon, etc. In all cases the empirical law was found to be remarkably exact, except in the case of those substances—*e.g.* the alcohols, fatty acids, etc.—which are known to exhibit molecular aggregation. The curvature of the line is taken to indicate molecular association, although the absence of curvature does not necessarily mean that molecular association is absent. E. Mathias and H. K. Onnes' results for oxygen are indicated in Fig. 8; the curve is plotted from the following observations:

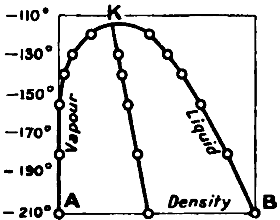

FIG. 8.—Variations in the Densities of Co-existing Liquid and Gaseous Oxygen.

Temperature . .	−210·4°	−182·0°	−154·5°	−140·2°	−129·9°	−123·3°	−120·4°
Density of liquid, D_l .	1·2746	1·1415	0·9758	0·8742	0·7781	0·6779	0·6032
Density of vapour, D_v .	0·0001	0·0051	0·0385	0·0805	0·1320	0·2022	0·2701
Mean density, D . .	0·6373	0·5733	0·5072	0·4773	0·4550	0·4400	0·4366

The mean densities calculated from the linear expression, $D=0{\cdot}1608-0{\cdot}0022656\theta$, do not deviate from the observed values more than ±0·003. The law does not hold good for substances whose molecules in the liquid and gaseous states have a different complexity.[10]

CHAPTER V

COMBINATION BY VOLUME

§ 1. Gay Lussac's Law of Combining Volumes

Omnia mensura et numero et pondere disponsuisti—Thou hast ordered all things in measure, and number, and weight.—LIBER SAPIENTIAE.

NOT very long after John Dalton had directed the attention of chemists to the relations subsisting between the weights of bodies which combine in different proportions, J. L. Gay Lussac[1] established a similar correspondence between volumes of combining gases. A. von Humboldt, the naturalist and explorer, collected samples of air from different parts of the world, and with the aid of J. L. Gay Lussac, analysed the different samples with the idea of finding if the composition of air was variable or constant. J. L. Gay Lussac used Cavendish's process—explosion of a mixture of air and hydrogen gas. As a preliminary, A. von Humboldt and J. L. Gay Lussac investigated the proportion by volume in which hydrogen and oxygen combine, and found the ratio of hydrogen to oxygen, by volume, to be nearly as 2 : 1. If either hydrogen or oxygen was in excess of these proportions, the excess remained after the explosion, as a residual gas. A. von Humboldt and J. L. Gay Lussac (1805) found :

Vols. of oxygen.	Vols. of hydrogen.	Vols. of residue.
100	300	101·3 hydrogen
200	200	101·7 oxygen

After making corrections for impurities, etc., in the gases, J. L. Gay Lussac and A. von Humboldt stated that "100 volumes of oxygen required for complete saturation 199·89 volumes of hydrogen, for which 200 may be put without error." A. Scott (1893) found, as the result of twelve experiments on the volumetric composition of water, that oxygen and hydrogen combine very nearly in the ratio 1 : 2·00245 by volume.

Struck by the simplicity of the relation thus found, J. L. Gay Lussac (1808) followed up the subject by numerous experiments with different gases. As a result, in his *Mémoire sur la combinaison des substances gazeuses, les unes avec les autres* (1809), he concluded that "gases always combine in the simplest proportions by volume." For instance, one volume of hydrogen combines with one volume of chlorine forming two volumes of hydrogen chloride ; two volumes of hydrogen combine with one volume of oxygen forming two volumes of water vapour (which condenses to liquid water if the temperature be below 100°).

There are slight deviations with the gases which show deviations from the laws of Boyle and Charles, but the experimental results are such as to leave no doubt that J. L. Gay Lussac's generalization is valid, and accordingly, we define **Gay Lussac's law : when gases react together, they do so in volumes which bear a simple ratio to one another, and to the volume of the gaseous product of the action.** It is assumed, of course, that the initial and final products of the reaction are under the same conditions of temperature and pressure.

The remarkable way in which elements unite by weight was traced to a peculiarity in the constitution of matter ; so here, we are tempted to make a similar quest. It follows at once (1) if elements in a gaseous state unite in simple proportions by volume, and (2) if the elements also unite in simple proportions by atoms, then the number of atoms in equal volumes of the reacting gases must be simply related. With John Dalton, in his *A New System of Chemical Philosophy* (Manchester, 1808), let us make a guess. Assume that equal volumes of the different gases under the same physical conditions contain an equal number —say n—of atoms. Then, when two volumes of hydrogen react with one volume of oxygen to form two volumes of steam, we have $2n$ atoms of hydrogen reacting with n atoms of oxygen to form $2n$ " compound atoms " of steam. Hence, two atoms of hydrogen react with one atom of oxygen to form two " compound atoms " of steam. In that case, every atom of oxygen must be split into half to make two " compound atoms " of steam. This contradicts the fundamental postulate of the atomic theory expressed in John Dalton's aphorism : " Thou knowest no man can split an atom," meaning that atoms are assumed to be indivisible in chemical reactions.[2] Similar contradictions are encountered in nearly every case of combination between gases, hence J. Dalton regarded J. L. Gay Lussac's law as untenable : *Equal volumes of homogeneous gases, under like conditions of temperature and pressure, do not contain the same number of atoms.* There is such a marked uniformity in the deportment of elementary and compound gases with respect to variations of temperature and pressure, that it is not very probable any essential difference will be found in their constitution.

§ 2. Amadeo Avogadro's Postulate

Advances in knowledge are not commonly made without the previous exercise of some boldness and licence in guessing.—W. WHEWELL.

J. J. Berzelius [1] thought it strange that J. L. Gay Lussac should have contented himself with having determined the combining ratios of gaseous substances, and should make no attempt to extend his discovery. Clearly with J. Dalton the faculty of speculation was predominant, and with J. L. Gay-Lussac experimentation. An epoch-making memoir entitled, *Essai d'une manière de déterminer les masses rélatives des molécules élémentaires des corps, et les proportions selon lesquelles elles entrent dans les combinaisons*, was published in 1811 by Amadeo Avogadro,[2] an Italian physicist. In his memoir A. Avogadro said—

> J'ai proposé une hypothèse pour expliquer le fait découvert par M. Gay Lussac, que les volumes des substances gazeuses qui se combinent entre elles, et des gaz composés qui en résultent, sont toujours dans les rapports très simples entre eux.

He pointed out that the difficulty with Dalton's hypothesis can be avoided if we distinguish clearly between elementary atoms and the small particles of a gas. Assume that the small particles of a gas are aggregates of a definite number of atoms ; then, using A. Avogadro's own words :

> Les molécules constituantes d'un gaz simple quelconque, c'est-à-dire celles qui s'y tiennent à une distance telle à ne pouvoir exercer leur action mutuelle, ne sont pas formées d'une seule molécule élémentaire mais résultent d'un certain nombre de ces molécules réunies en une seule par attraction.

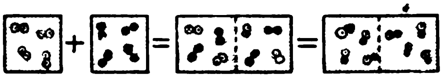
A. Avogadro called these aggregates molecules, in order to distinguish them from the ultimate atom. His actual term was *molécules constituantes* or *molécules intégrantes*—the former term was used for molecules of elements, the latter for molecules of compounds. The one term molecule (the diminutive form of the Latin word *moles*, a mass) is now applied to both Avogadro's *molécules constituantes* and *molécules intégrantes*. Each molecule of an elementary gas is supposed to contain the same number and kind of elementary atoms. What J. Dalton called atoms A. Avogadro called *molécules élémentaires*. The word "atom" does not occur in the latter's memoir. The modern meanings of the terms *atom* and *molecule* were clearly stated by A. M. Ampère[3] in 1832, and by A. Gaudin in the same year. Some years later these distinctions were emphasized by A. Laurent (1846) and employed in his posthumous book *Méthode de chimie* (Paris, 1854). A. M. Ampère used the term particle for an aggregate formed by the juxtaposition of molecules. He said:

> In the passage from liquid to the gaseous state, the molecules are separated from one another; and conversely, in passing from the gaseous to the liquid state, the molecules are drawn together. In the passage from the liquid to the solid state, I think that two or more molecules are drawn together. Mechanical forces alone can separate the particles; chemical forces are required to split the molecules.

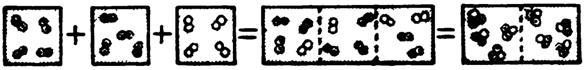
For the sake of simplicity, assume that each molecule of hydrogen gas is composed of two atoms of hydrogen, and make a similar assumption for oxygen gas; and assume with A. Avogadro that **equal volumes of all gases, at the same temperature and pressure contain the same number of molecules.** This postulate is now known as **Avogadro's hypothesis.** In A. Avogadro's own words:

> L'hypothèse qui se présente la première à égard et qui parait même la seule admissible, est de supposer que le nombre des molécules intégrantes dans la gaz quelconque est toujours le même à volume égal, ou est toujours proportionnel aux volumes. . . .

Suppose that two volumes of hydrogen contain $2n$ molecules of hydrogen, then one volume of oxygen will contain n molecules. These react to form $2n$ molecules of steam—each molecule of steam contains two atoms of hydrogen and one atom of oxygen. The idea can be more clearly illustrated by means of the subjoined diagrams. Each square represents one volume of a gas. Each volume contains n molecules. We do not know the numerical value of n, but, for the sake of simplicity, take $n=4$. It makes no difference to the final conclusion what numerical value we assign to n. Then we have:



Hence, although the atoms of oxygen cannot be split, yet a 2-atom molecule of oxygen can be subdivided so that one atom of oxygen enters the composition of each of two molecules of water. Again, with hydrogen and chlorine,



Diagrams similar in principle to these were used by M. A. Gaudin about 1832 in his *Recherches sur la structure intime des corps inorganiques définis.* It must not be supposed for one moment that what may be called Gaudin's diagrams are intended as pictures of the actual molecules. They are to be regarded as aids to the understanding of how Avogadro's hypothesis has led chemists to conclude that the molecules of gaseous elements are really compounded atoms, and how Avogadro's hypothesis reconciles the observed volume relations during the combination of gases with the atomic theory.

It has been assumed for the sake of simplicity, that the molecule of water contains three atoms, and that each molecule of hydrogen and oxygen contains two atoms. As a matter of fact, all we can infer from the observed facts is that the molecule of oxygen is split into halves, and, in the absence of evidence to the contrary, we assume for every substance the simplest molecular structure consistent with the observed facts.

A. Avogadro extended J. Dalton's atomic hypothesis and adapted it particularly to gases. We owe to the former the conception of two orders of minute particles : (1) the atom or unit of chemical exchange ; and (2) the **molecules are the smallest particles of an element or compound which exist free in a gas.** This definition of a molecule is usually extended into the less satisfactory definition : A molecule is the smallest particle of an element or compound which exists in a free state ; otherwise expressed, the molecules of an element or compound are particles so small that the specific properties of the substance depend upon the particles remaining intact. Hence, if molecules be subdivided the parts no longer have the specific properties of the original substance. If the molecules of steam, H_2O, be subdivided, two atoms of hydrogen and one atom of oxygen would be formed per molecule ; the atoms unite in pairs to form molecules.

Diatomic molecules for gaseous chlorine, hydrogen, and oxygen at ordinary temperatures furnish a satisfactory explanation of what we know to-day, but it is possible that at some future date, the evidence will compel us to consider these molecules to be tetra- or hexa-atomic. This will not materially affect the principle as indicated above. The molecule of mercury is supposed to be monatomic ; and the molecule of sulphur, hexatomic.

In 1814, A. M. Ampère advocated views similar to those of A. Avogadro, but he complicated the latter's simple hypothesis by an unsuccessful attempt to apply his conception of molecules to crystalline solids. Avogadro considered Ampère's extension unjustifiable. A. M. Ampère clearly emphasized the hypothetical nature of A. Avogadro's conception in a letter to M. le Comte Berthollet in 1814, when he said : If the consequences of the hypothesis be confirmed by further experiments, and the hypothesis be in agreement with known facts, *elle pourra acquérir un degré de probabilité qui approchera de ce qu'on nomme en physique la certitude.* Increasing knowledge has made A. Avogadro's hypothesis more and more probable ; it has been tested in hundreds of experiments, and never found wanting. The hypothesis has done such good service in giving a rational explanation of many different phenomena that it has been accepted as a fundamental truth. It gave chemists a clear definition of the atom, a method of determining the relative weights of the atoms, and of estimating the number of atoms in the molecule.

§ 3. The Relative Weights of the Molecules

In order to bring into harmony all the branches of chemistry, we must have recourse to the complete application of the theory of Avogadro in order to compare the weights and the numbers of the molecules.—S. CANNIZZARO.

John Dalton in 1807 raised the query : " Are there the same number of particles of any elastic fluid in a given volume and under a given pressure ? " It is curious that in answering " No," J. Dalton[1] abandoned an hypothesis which afterwards proved to be one of the most fruitful suggestions in the development of chemistry, for, under the name of Avogadro's hypothesis, it has correlated what appeared antagonistic and contradictory, and has harmonized what seemed discordant and confused; it made Dalton's atomic hypothesis a clear, intelligible, and fertile theory. As C. A. Wurtz said in his *The Atomic Theory* (London, 1880), had it not been for this development, J. Dalton's hypothesis was in a fair way of being sentenced to sterility and oblivion. A fellow countryman of A. Avogadro, namely S. Cannizzaro, seems to have seen, more clearly than any other, the importance of A. Avogadro's hypothesis in putting J. Dalton's on a firm basis.

S. Cannizzaro's ideas were first published in a letter to S. de Luca embodying a *Sketch of a Course of Chemical Philosophy*,[2] given in the Royal University of Geneva in 1858. Before S. Cannizzaro published his paper, rank confusion prevailed in chemical literature. The terms atomic weight, molecular weight, and combining or equivalent weight were used and abused in every conceivable way. J. B. A. Dumas lost faith in the atomic theory and wrote in despair:

> Si j'en étais le maître j'effacerais le mot atome de la science, persuadé qu'il va plus loin que l'expérience : et jamais en chimie nous ne devons aller plus loin que l'expérience.

Avogadro's hypothesis was necessary for salvation; it lay dormant in chemical literature for nearly half a century; S. Cannizzaro brought the awakening, and showed chemists that the atom must be defined with reference to A. Avogadro's molecule. After reading S. Cannizzaro's pamphlet, Lothar Meyer (1860) thus describes his own conversion: "the scales fell from my eyes, my doubts disappeared, and a feeling of tranquil security took their place." A. Avogadro's hypothesis was thus made the basis of the current theory of chemistry.

By definition, the relative density of a gas is a number which represents how much heavier any volume of the gas is than an equal volume of the standard gas—generally hydrogen—measured at the same temperature and pressure—generally at 0° and 760 mm. pressure. Thus, the relative density of steam is 8·95. This means that any volume, say a litre of steam, is nearly nine times as heavy as the same volume of hydrogen.

Strictly speaking, the density of a gas is the weight of 1 c.c. of the gas at 0° and 760 mm. The density of a gas is usually expressed in terms of a litre of the gas because the number representing the weight of 1 c.c. would be inconveniently small. One litre of hydrogen at n.p.t. weighs very nearly 0·0896 grm. "So important is this standard weight-unit," said A. W. Hofmann in his *Introduction to Modern Chemistry* (London, 1865), "that a name is needed to denote it." He suggested *crith* (κρίθη, a barley corn, or small weight) to denote the weight of a litre of hydrogen at n.p.t. The weight of the same volume of oxygen would then be 16 criths, of nitrogen 14 criths, etc. The term has now dropped out of use, although for a time it served a useful purpose.

By Avogadro's hypothesis, equal volumes of gases, under like conditions of temperature and pressure, contain the same number of molecules, consequently, **the specific gravity or relative density of a gas is proportional to its molecular weight.** Let n represent the number of molecules in a volume v of each of two different gases, and if the molecules of each gas are all alike with the respective molecular masses M_1 and M_2, then the one gas will have a mass nM_1 and the other a mass nM_2. Let the densities of the respective gases be D_1 and D_2, then since density denotes the mass of unit volume, $D_1 : D_2 = nM_1/v : nM_2/v$; that is, $D_1 : D_2 = M_1 : M_2$ or

$$\frac{D_1}{D_2}=\frac{M_1}{M_2};\ \text{or}\ \frac{M_1}{D_1}=\frac{M_2}{D_2}\quad . \quad . \quad . \quad . \quad . \quad (1)$$

or the relative densities of any two gases are proportional to their respective molecular weights; and **the quotient of the molecular weight by the density is the same for all gases.** It is convenient to employ the term *molecular volume* for the quotient obtained by dividing the molecular weight M of a gas by its relative density

D; consequently, from the second of equation (1), **the molecular volumes of all gases are the same.**

If we accept this deduction, it enables us to determine the molecular weights of gases, once we have fixed an arbitrary standard for the density. Cannizzaro's unit, hydrogen=2, is frequently taken as the standard, or else hydrogen unity, that is, as S. Cannizzaro expressed it, "the quantity of hydrogen contained in a molecule of hydrogen chloride" is taken as unity. **The determination of the molecular weight of a gas is thus reduced to a laboratory measurement—the determination of the relative density of the gas.** Methods for measuring vapour densities are outlined later.

It has been shown within certain limitations, that the numerical values for the molecular weight and relative density of a gas referred to *the standard hydrogen*, 2, are the same. That is,

$$\text{Molecular weight} = \text{Relative density } (H_2=2) \quad . \quad . \quad . \quad (2)$$

For example, the observed density of steam is 18 ($H_2=2$), the molecular weight of steam is therefore 18 likewise. Again, if the relative density be referred to the standard *hydrogen unity, or oxygen* 16, the relative density is half the molecular weight; or the molecular weight is twice the density.

$$\text{Molecular weight} = 2 \times \text{Relative density } (H=1) \quad . \quad . \quad . \quad (3)$$

For instance, the density of steam is 9 ($H=1$), the molecular weight is therefore twice 9 or 18 as before. When the relative density is referred to oxygen 32, as is common in recent years, it is virtually assumed that there is an imaginary gas whose relative density is unity; and to avoid the hypothesis implied in the term molecular weight, the term **molar weight** is applied to the relative density of a gas referred to oxygen 32.

If the relative density be determined, as is frequently the case, with reference to *the standard air unity*, then, since the density of air with respect to hydrogen is 28·75 ($H_2=2$); or with reference to oxygen 28·98 ($O_2=32$), it follows that

$$\text{Molecular weight} = 28{\cdot}75 \times \text{Relative density (Air unity)} \quad . \quad . \quad (4)$$

For example, the relative density of cyanogen is 1·806 (air unity), the molecular weight is therefore $1{\cdot}806 \times 28{\cdot}75 = 51{\cdot}92$ ($H_2=2$). This is in agreement with the formula C_2N_2.

It is unfortunate that these different units are employed, even though all give the same final result. It shows the necessity for clearly understanding the particular meaning of terms employed before elaborating an argument. The method of determining the relative density of a gas by weighing a globe full of gas and then full of air, led to the use of air as a standard of reference. Thus, J. L. Gay Lussac (1815) found a 2½-litre globe weighed $w+2{\cdot}738$ grms. when filled with air, and $w+4{\cdot}946$ grms. when filled with cyanogen; consequently the relative density of cyanogen, air unity, is $4{\cdot}946/2{\cdot}738=1{\cdot}806$. The custom of referring all gas densities to air as a standard was gradually adopted. The system has been shown in recent years to be faulty when very accurate results are required because there are undoubtedly slight variations in the composition of air, and this causes the density of air—the standard of reference—to vary in a corresponding manner.

If the specific gravity of a gas is to be referred to water as *standard*, the relative density, air unity, is multiplied by the weight of one c.c. of air, *viz.* 0·001293; by 0·00008996 if hydrogen unity be the standard; and by 0·00004469 if oxygen be 32. Thus, the relative density of carbon dioxide is 1·57 (air unity); 22 (hydrogen unity); and 44 if oxygen 32 be the standard. Hence, also, the specific gravity with respect to water as standard is $1{\cdot}57 \times 0{\cdot}001293 = 0{\cdot}00203$.

It will be noted that if W denotes the weight of a litre of a gas of molecular weight M, and D denotes the relative density, air unity, $W=\frac{1}{2}M \times 0{\cdot}08996$; $D=M/28{\cdot}75$, and therefore $100(W-D)=M$, or *the molecular weight of a gas, is nearly* 100 *times the difference between the weight of a litre of the gas at n.p.t. and the relative density of the gas, air unity.*

Returning to S. Cannizzaro's important paper, S. Cannizzaro gave the following numbers, among others, for the densities of the different gases referred to hydrogen taken as 2, or to a semi-molecule of hydrogen taken as unity :

	Relative densities
Hydrogen	2·0
Oxygen	32·0
Chlorine	71·0
Nitrogen	28·0
Water vapour	18·0
Hydrogen chloride	36·5

If, therefore, the molecules of hydrogen, oxygen, nitrogen, and chlorine contain two atoms, the atomic weights of these gases will be half the respective molecular weights. Hence, making a selection from S. Cannizzaro's tables :

Table I.—S. Cannizzaro's Table of Atomic Weights.

Element.	Relative density of gas.	Atomic Weight, or Density ÷ 2.
Hydrogen	2	1·0
Oxygen	32	16·0
Chlorine	71	35·5
Nitrogen	28	14·0

In the case of compounds, if the molecule of hydrogen chloride contains an atom of chlorine and an atom of hydrogen, the molecular weight will be $35·5+1=36·5$; and the molecule of water vapour containing two atoms of hydrogen and one atom of oxygen—or, as A. Avogadro (1811) expresses it, *une demi-molécule d'oxygène avec une molécule ou, ce qui est la même chose, deux demi-molécules d'hydrogène*—will have a molecular weight of $16+2=18$. Hence, given the molecular weight of a compound gas, and the weights of the atoms of all but one of the elements, it is possible to compute the weight of the atom or atoms of that element in the molecule in question. The *modus operandi* will be discussed in two later sections.

A. Avogadro explicitly guarded against the assumption that the number of constituent atoms in the molecule of a gas must always be 2. There is really nothing in the facts to justify the assumption that the atoms themselves are simple particles. For all we know to the contrary, the atoms may be clusters of *n* particles. Indeed, we shall soon review some cogent evidence which has led many chemists to abandon Newton's solid impenetrable atoms, and to infer that **Dalton's atoms are not nature's irreducible minima.** Even if this inference be valid, each cluster of *n* particles which forms an atom has a definite weight—atomic weight—and enters into and is expelled from chemical combination as if it were a simple particle. If an atom be a cluster of particles, each cluster, so far as we can tell, has up to the present time behaved in chemical reactions as if it were an individual particle. The actual weight of a molecule is certainly not the molecular weight. When it is said that the molecular weight of hydrogen chloride is 36·5, this number simply means that we have conventionally agreed to fix the molecular weight of, say, oxygen as 32 units, and that the molecular weight of hydrogen chloride is to that of oxygen as 36·5 : 32. Consequently, like atomic weights, **molecular weights denote ratios, they are relative not absolute numbers.**

To deduce Avogadro's law from the relation between the relative densities and the molecular weights of the gases. Let M_1 and M_2 denote the weights of the molecules of two gases—A and B respectively ; further, let n_1 and n_2 respectively denote the number of molecules in unit volumes of the two gases. The weights of unit volumes (*i.e.* the densities) of the two gases will be M_1n_1 and M_2n_2. The observed fact is that the molecular weights (M_1 and M_2) of the gases are proportional to the densities (M_1n_1 and M_2n_2) of the gases ; or $M_1n_1 : M_2n_2=M_1 : M_2$, from which it follows that in unit volumes of the two gases $n_1 = n_2$. This is the symbolic way of stating Avogadro's rule. Hence, it has been claimed that Avogadro's postulate can be deduced from the relation between the molecular weights and the densities of two gases. It is easy to be misled by the apparent precision and rigorous accuracy conveyed to the mind by reasoning expressed in mathematical symbols, and to assume that the conclusions of such reasoning are certainties. Some affirm, on the strength of the simple demonstration just indicated, that "Avogadro's hypothesis is true." The reasoning is perfectly sound, but what about the premises, or statements upon which the reasoning is based? Avogadro's method for the determination of molecular weights tacitly assumes that the hypothesis is true. Hence, if the mathematical demonstration be employed to *prove* that Avogadro's hypothesis is true, the argument proceeds in a vicious circle. It is assumed in the premises what is "proved" in the demonstration. A conclusion proved by mathematics cannot be any more certain than the premises on which the reasoning is based.

§ 4. The Formulæ of Compounds

Avogadro's hypothesis affords a bridge by which we can pass from large volumes of gases, which we can handle, to the minuter molecules, which individually are invisible and intangible.—W. A. Shenstone.

Since S. Cannizzaro's time, an enormous number of molecular weights have been determined by the vapour density method. If the molecule cannot be decomposed, it must be assumed that it is composed of one kind of matter only. If the substance is compound, it must be analysed so as to find the ratio, by weight, of its component elements referred to the oxygen standard (16). For instance, suppose that the analysis of a gaseous compound furnished: Nitrogen, 82·35 per cent.; hydrogen, 17·65 per cent. Using S. Cannizzaro's data, if hydrogen has an atomic weight of unity and nitrogen 14, the compound has the equivalent of $17{\cdot}65 \div 1$, or 17·65 hydrogen atoms for every $82{\cdot}35 \div 14$ nitrogen atoms; or 5·9 nitrogen for every 17·65 hydrogen atoms. By hypothesis we cannot have fractions of atoms. The nearest whole numbers are 3 hydrogen atoms for one nitrogen atom. Since the sum of the atoms in the compound must represent the molecular weight, it follows that the molecular weight must be $3n + 14n$, that is, the molecular weight is 17×1; 17×2; 17×3; . . . or $17n$. The formula is N_nH_{3n}. We can get no further until we know the molecular weight. If the vapour density of the compound (hydrogen $=2$) be 17, the molecular weight is 17. Hence, $17 = 17n$, or $n = 1$. The compound analysed can therefore be represented by the formula NH_3.

Examples.—(1) E. W. Morley (1895) found, in some careful experiments on the synthesis of water: Hydrogen used, 3·7198 grms.; oxygen used, 29·5335 grms.; water formed, 33·2530 grms. That is, one part by weight of hydrogen combines with 7·94 parts by weight of oxygen to produce 8·94 parts by weight of steam. A molecule of steam must contain n atoms of hydrogen, because parts of an atom do not take part in chemical changes. Hence, n parts by weight of hydrogen per $7{\cdot}94n$ parts by weight of oxygen give a molecule of steam of weight $8{\cdot}94n$. This all follows from the atomic theory. To apply Avogadro's hypothesis, with Cannizzaro's standard, the density of the steam must be determined. It lies between 16 and 20. It is difficult to determine the number exactly. If $n=1$, the density of the steam molecule will be near 8·94. This does not agree with the observed density 16 to 20. If $n=2$, the density of the steam will be 17·88; and if $n=3$, the density of steam will be 26·82. Hence, $n=2$. This means that each molecule of water vapour contains 2 atoms of hydrogen, atomic weight 1, and one atom of oxygen, atomic weight 15·88; or if we make our unit oxygen = 16, the atomic weight of hydrogen will be 1·008.

(2) Two different compounds have the same ultimate composition, namely: carbon 92·31 per cent., hydrogen 7·69 per cent., but the one has a relative density 26, and the other a relative density 78 (H = 2). What is the formula of each compound? There are 92·31 ÷ 12 = 7·7 carbon atoms per 7·7 ÷ 1 = 7·7 hydrogen atoms; but we cannot have fractions of atoms, hence dividing by 7·7 we get the ratio 1 : 1. That is, the formula of the compound is C_nH_n. The molecular weights of this series of compounds is $(12+1)n$ or $13n$. If $n = 2$, the molecular weight will be 26. Hence, one of the compounds is C_2H_2, and the other is C_6H_6.

In calculating formulæ for substances which cannot be vaporized, and one of the methods to be described later cannot be applied, it is usual to assume that the molecule has the simplest formula. In that case the formula is said to be *empirical*. Some prefer to use the term **formula weight** in place of molecular weight when the actual molecular weight has not been determined. The formula weight, like the molecular weight of a compound, is the sum of the atomic weights of the elements represented in the known or assumed formula of the compound.

EXAMPLES.—(1) 10 grams of pure tin when oxidized in air gave 12·7 grams of oxide. What is the formula of tin oxide? The atomic weight of tin is 119, and of oxygen 16. Hence, the ratio: Tin : oxygen = 10 ÷ 119 : 2·7 ÷ 16 = 0·084 : 0·17 = 1 : 2. The formula is therefore written SnO_2, although there is nothing to show why it is not Sn_2O_4; Sn_3O_6; . . . Sn_nO_{2n}.

(2) A sample of crystallized sodium carbonate furnished on analysis 37·2 per cent. of Na_2CO_3, and 62·8 per cent. of H_2O. What is the formula of the compound? The ratio $Na_2CO_3 : H_2O$ = 37·2 ÷ 106 : 62·8 ÷ 18 = 0·35 : 3·49 = 1 : 10. Hence, the formula is taken as $Na_2CO_3.10H_2O$, although there is nothing to show why it is not some multiple of this, say, $nNa_2CO_3.10nH_2O$.

(3) A. Jones (1892) analysed a sample of electric calamine, and found: Silica, SiO_2, 25·33; zinc oxide, ZnO, 67·15; and water, H_2O, 7·47 per cent. Show that this corresponds very nearly with the formula $Zn_2SiO_4.H_2O$.

(4) W. F. Hillebrand and W. H. Melville (1892) analysed some crystals obtained by the action of sulphuric acid on uranium oxide, and found: UO_2, 53·99; SO_3, 36·95; H_2O, 14·13 per cent. Show that the molecular ratio of these three constituents is 1 : 2 : 3·94, and that this corresponds with the formula $UO_2(SO_3)_2$, $4H_2O$ or $U(SO_4)_2.4H_2O$.

(5) G. Fernekes (1902) analysed a salt obtained by treating a solution of mercuric chloride with potassium ferrocyanide, and found: Potassium, 15·82 per cent.; mercury, 40·63; iron, 11·45; and cyanogen, C_2N_2, 31·78. Show that the simplest empirical formula for the compound is $K_2HgFe(CN)_6$.

§ 5. The Relative Weights of the Atoms

> Atoms are so inconceivably little that their aggregates are alone the ostensible subject of experiments.—S. BROWN.

It has already been stated that the conceptions molecular weight and atomic weight are quite independent of our theories about the nature of atoms and molecules; nor are the conceptions much affected by the actual weights of the atoms and molecules because the terms under consideration are definite expressions of Avogadro's hypothesis coupled with observed facts. It might therefore have been misleading to head this paragraph: *Weighing the Atoms*. There are reasons for supposing that the molecular weight of some compounds in the liquid or solid condition is a multiple of the molecular weight of the same substance in the gaseous condition. The molecule of steam approximately corresponds with the formula H_2O; but in liquid water there are reasons for supposing the molecule is either $(H_2O)_3$ or $(H_2O)_4$, that is, the formula for liquid water is not H_2O, for it contains molecules corresponding with H_4O_2, H_6O_3, or H_8O_4.

Refer back to the difficulty in fixing the atomic weight of carbon from the ratio of the weights of carbon and oxygen in the two oxides of carbon which we encountered in applying J. Dalton's atomic theory. Suppose that we do not know the atomic weight of carbon, but that we do know the composition of a number of volatile carbon compounds as well as their relative densities or molecular weights, Table II.

TABLE II.—MOLECULAR WEIGHTS OF SOME CARBON COMPOUNDS.

Volatile compound of carbon.	Composition by weight.	Molecular weight.	Amount of carbon per molecule.
Carbon monoxide	Carbon 12; oxygen 16	28	12
Carbon dioxide	Carbon 12; oxygen 32	44	12
Methane	Carbon 12; hydrogen 4	16	12
Ethylene	Carbon 24; hydrogen 4	28	12×2=24
Propylene	Carbon 36; hydrogen 6	42	12×3=36
Carbon disulphide	Carbon 12; sulphur 64	76	12

The smallest weight of carbon in a molecule of any of its known compounds is 12, and consequently this number is assumed to be the atomic weight of carbon. The atomic weights of a great number of the elements have been determined in a similar manner.

The determination of atomic weights.—According to J. Sebelin's *Beiträge zur Geschichte der Atomgewichte* (Braunschweig, 1884), when J. J. Berzelius was asked how he was able to get such excellent analyses, analyses which have been the admiration of generations of chemists, he answered:

> Try to find that method of analysis in which the accuracy of the result is least dependent upon the skill of the operating chemist; and when this method has been selected, consider what unavoidable conditions are present which are likely to affect the result with errors; and then ascertain whether the errors will increase or diminish the result. Then make another determination in which the opposite effects can alone be produced. If the two results are the same, the determination was correct.

The actual method used in finding the atomic weight of an element really requires:

(1) An exact analysis of a series of compounds containing the given element; and consequently the compounds investigated must be such as lend themselves to exact analysis, and which can be prepared in a highly purified condition.

(2) It is an advantage if the compound be volatile without decomposition, so that its vapour density can be determined. There are several other methods of computing the molecular and hence also the atomic weights of the different elements; and in several, the compound need not be volatile. Fortunately, atoms and molecules possess other qualities besides mass, which are dependent upon their atomic weights and which can be readily measured. Some of these will be described later.

(3) The smallest proportion of the element under investigation contained in all the compounds whose molecular weights are known is finally selected as the atomic weight of the given element.

J. A. Wanklyn (1894)[1] once claimed to have discovered a series of hydrocarbons, one member of which contained carbon 102 parts by weight, and hydrogen 17 parts, and had a vapour density of nearly 116 (hydrogen 2). Assuming the atomic weight of carbon is 12, and of hydrogen 1, these numbers give formula $C_{8\cdot5}H_{17}$. If this statement had been corroborated, and we were quite sure that Wanklyn's hydrocarbons were not mixtures, it would be necessary to make the atomic weight of carbon = 6, and write the formula of the compound in question $C_{17}H_{17}$, and this in spite of the fact that thousands of compounds of carbon are known, and all agree with the number 12 for the atomic weight of carbon. The formula of carbon monoxide—CO—would then be written C_2O, etc.—but J. A. Wanklyn's claim has never been established.

These remarks emphasize the importance of examining as large a number of volatile compounds as possible when fixing the atomic weight of an element. The importance of this principle was recognized as early as 1859, for F. A. Kekulé then wrote:

> It is of exceptional importance for chemists to determine the relative masses of particles which are not subdivided in chemical reactions. In order to determine the atomic or molecular weights of the elements and their compounds with some degree of probability, it is necessary to investigate a very great number of compounds and a very great number of chemical reactions.

If only a small number of compounds be examined, there is always a possibility, and perhaps a probability, that the actual minimum weight does not occur amongst the set of compounds taken. It follows, therefore, that the **atomic weight of an element is the least amount of that element—relative to the standard oxygen, 16—which is present in any molecule of all its known volatile compounds.** The value so obtained is the maximum possible value; the real value may afterwards prove to be a submultiple of this. The atomic weight must be equal to a whole multiple or submultiple of its combining weight. Owing to the fact that the molecular weights of so many volatile compounds of carbon are known, it is not very probable that the atomic weight of carbon is less than 12.

§ 6. Methods for Measuring the Vapour Densities of Gases, and of Volatile Liquids and Solids

> The history of science shows that even during that phase of her progress in which she devotes herself to improving the accuracy of the numerical measurement of quantities with which she has long been familiar, she is preparing the materials for the subjugation of new regions, which would have remained unknown if she had been contented with the rough methods of her early pioneer.—J. C. MAXWELL.

When determinations of molecular weights are made to decide between quantities widely different, minor corrections, necessary for exact values, are not required. For instance, if chemical analysis showed that the molecular weight of a compound is some multiple of 20, then a molecular weight of 83, by vapour density methods, indicates that $4 \times 20 = 80$ is the molecular weight of the substance. With ordinary vapour density determinations, therefore, the weight of 22·4 litres of the gas or vapour at 0° and 760 mm. is to be computed from measurements with hydrogen $= 2$ or oxygen $= 32$ as standards of reference. No new principle is involved. If an intermediate value between two possible values for the molecular weight of a substance is consistently obtained, there is a disturbance—possibly association or dissociation—which must be investigated more closely.

These remarks do not apply when the molecular weights of gases are estimated from their densities in order to serve as a control for the atomic weights. The densities are then determined with as great an accuracy as possible. In the fourth century B.C., Aristotle made an unsuccessful attempt to determine the weight of air contained in a bladder; and, about 1632, G. Galilei established the fact that air has weight; R. Descartes (1638) said that G. Galilei's primitive method of weighing air *n'est pas mauvaise*. Robert Boyle, in his *Hydrostatics* (Oxford, 1666), gives the specific gravity of air 0·00125—with water unity as standard. The air of tartar, which consists of a mixture of carburetted hydrogen and carbonic acid gases, was weighed in a bladder by S. Hales,[1] and he compared the weight so obtained with that of the same bladder filled with air; F. Hauksbee determined the specific gravity of the mixture of carbon dioxide and nitrogen obtained by passing air over red-hot iron. The specific gravity of these mixed gases was so near that of air that the experimenters, by their methods, did not establish a difference. J. Mayow supposed but did not prove that the nitro-igneous constituent of air was heavier than the residual air from which it was separated. H. Cavendish, however, in his *Experiments on Factitious Airs*, in 1766, first established the difference in the specific gravities of air, carbon dioxide, and hydrogen, and this has been cited as the first conclusive proof of a plurality of elastic fluids. J. Priestley tried to weigh the different kinds of air in glass flasks by the displacement of water in a pneumatic trough, but the drops of water which adhered to the inside of the flask introduced too many errors. J. Priestley then used a bladder, and added that although the determination "cannot be done with precision in a bladder, as used by Mr. Cavendish, because the degree of distension cannot be measured with much accuracy, yet the circumstance is more than counterbalanced by being able to change the air, with compressing the bladder, without wetting it." J. Priestley found the bladder filled with—

	dwts.	grains.
Phlogisticated air weighed	7	15
Nitrous air	7	16
Common air	7	17
Dephlogisticated air	7	19

The early chemists apparently thought the determination of the density of a gas to be so simple an operation that details would be redundant; and they considered it was necessary merely to weigh a bladder or a flask first evacuated, and then filled with the required gas. Towards the end of 1779, F. Fontana [2] devised a much better method of measuring the specific gravities of different gases.

The stoppered globe *A*, Fig. 1, of known capacity is unscrewed from the gas stoppered receiver *B*, exhausted, weighed, and again screwed to the receiver; meanwhile, the receiver is filled over a mercury pneumatic trough with the gas under investigation. The stopcocks are opened, the cylinder *B* depressed in the mercury until the surface of the mercury is the same inside and outside the cylinder. The stopcocks are then closed, the difference of the two weighings is taken to represent the weight of the gas in the globe This result, divided by the capacity of the vessel expressed in cubic inches, gives the weight of a cubic inch of the gas in question.

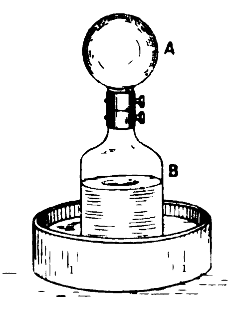

FIG. 1.—Fontana's Apparatus for Measuring the Density of Gases.

J. B. Biot and F. J. Arago (1806) determined the density of undried gases by means of a globe between 5 and 6 litres capacity. The results were corrected for the air displaced by the globe; the residual air in the evacuated flask; the cubical expansion of glass; and the hygroscopic moisture in the gas. The results were reduced to normal temperature and pressure, to sea-level, and to a latitude of 45°. For a long time J. B. Biot and F. J. Arago's measurements were considered to be a model for the work of others. J. J. Berzelius and P. L. Dulong (1820) and J. B. A. Dumas and J. B. J. D. Boussingault (1841) followed J. B. Biot and F. J. Arago's method, but they dried the gases.

A new era was inaugurated by H. V. Regnault in 1847. He introduced many vital improvements in J. B. Biot and F. J. Arago's procedure—chiefly in the use of a counterpoise balloon, and in the filling and exhausting of the globes while they were surrounded by a bath of melting ice. Modern work follows closely on the lines marked out by H. V. Regnault. Every known precaution which will conduce to the accuracy of the result is taken: (1) Attention is paid to the extreme purification of the gases to be measured; (2) the difference in the buoyancy in air of the weight and of the substance to be weighed is eliminated by reducing the weighings to the vacuum standard; (3) Lord Rayleigh's correction (1893) for the difference in the volume of the evacuated and filled balloon holding the gas is applied; (4) the expansion of the glass with variations of temperature is considered; (5) corrections are made for the deviations of the gas under investigation from Boyle's and Charles' laws; (7) an allowance is made for a slight condensation of gas on the inner walls of the measuring vessel; etc. In measuring the relative density of a substance which is gaseous at ordinary temperatures, three methods are available:

A. Weighing a known volume of the gas. The balloon method was worked out by H. V. Regnault (about 1847), and it has been much used in more recent work, where the general tendency has been to reduce the size of the balloons. H. V. Regnault worked with balloons about 10 litres capacity; E. W. Morley (1896)[3] with balloons 8–21 litres capacity; A. Leduc (1897), 2·3 litres; Lord Rayleigh (1888–95), 1·8 litres; P. A. Guye and C. Davilla (1905) used globes of capacity 0·38 to about 0·82 litre for nitric oxide; E. P. Perman and J. H. Davis (1906), 0·5 litre; and R. W. Gray (1905), 0·267 litre. The determinations made with small balloons are quite as concordant among themselves as those made with balloons of larger volume.

In this method the glass globe of volume v is counterpoised on the balance by a second tare balloon of approximately the same volume so as to eliminate corrections necessary for the buoyancy of the air. By repeated exhaustions and re-fillings, the balloon is filled with the gas under investigation. The temperature and pressure are respectively θ and p. Let w denote the difference between the weights of the full and empty balloon. The volume v_0 of the gas at 0° and 760 mm. pressure is first calculated in the ordinary manner:

$$v_0 = v\left(\frac{p}{760}\right)\left(\frac{273}{273+\theta}\right); \text{ or } v_0 = \frac{0\cdot3592vp}{273+\theta} \quad . \quad . \quad . \quad (1)$$

From Avogadro's hypothesis the molecular weight of a gas represents the weight of 22·3 litres of a gas if hydrogen $= 2$ be taken as the standard. Consequently, if w grams of a gas occupy v_1 c.c. at 0° and 760 mm. pressure, 22,300 c.c. will weigh $22{,}300w \div v_1$ grms., and this represents the molecular weight, or the uncorrected relative density of the gas, hydrogen $= 2$. For a high degree of accuracy, it is of course necessary to include correction terms as indicated above.

EXAMPLES.—(1) 585 c.c. of carbon dioxide measured at 18° and 756 mm. pressure weighed 1·076 gram. What is the molecular weight of the gas? 585 c.c. of gas become, at 0° and 760 mm., 546·1 c.c. Hence, the molecular weight is $22{,}300 \times 1\cdot076 \div 546\cdot1 = 43\cdot9$.

(2) H. V. Regnault (1845) filled a 10-litre globe with air at a pressure of 761·19 mm. at the temperature of melting ice. In addition to the tare balloon 1·487 grms. were required to balance the globe. The globe was then exhausted to a pressure 88·43 mm., and 14·141 grms. were now required to restore equilibrium. The globe was then filled with dry oxygen at 0° and 750·22 mm. pressure, 0·172 grm. was needed in addition to the tare to balance the globe. The globe was then exhausted to 4·59 mm. pressure and weighed, again 14·033 grms. were required. The globe lost 12·654 grms. of air at $761\cdot19 - 8\cdot43 = 752\cdot76$ mm. pressure and 0°. This corresponds with 12·776 grms. of air at 760 mm. Similarly with the oxygen: 14·1281 grms. at 760 mm. and 0°. The weights refer to equal volumes, and therefore the relative density of the oxygen (air unity) is $14\cdot1281 \div 12\cdot776 = 1\cdot10563$.

B. Measuring the volume of a known weight of the gas.—The volume occupied by a known weight of gas is measured in a suitable voluminometer, and the gas required to fill the balloon is weighed in another vessel either (*a*) by finding the loss of weight due to the escape of gas from the generating apparatus, or (*b*) by absorbing the gas in suitable apparatus. In the former case, given the temperature and pressure of the confined gas, the capacity of the balloon, and the loss of weight in the vessel from which the balloon was filled, the density follows directly. This method was used by E. W. Morley (1896) for hydrogen, and by A. Jaquerod and A. Pintza (1904) for sulphur dioxide. In a variation of this procedure, the measuring vessel is filled with the purified gas and its temperature maintained at 0°, while the pressure (approximately 760 mm.) is determined. The gas is then absorbed in a suitable apparatus previously evacuated and connected with the voluminometer by a tightly fitting joint. The weight of the absorbed gas completes the required data. This method was used by P. A. Guye and A. Pintza (1904–5) for nitrous oxide, carbon dioxide, and ammonia; by E. P. Perman and J. H. Davis (1906) for ammonia; and by R. W. Gray and E. P. Burt (1909) for hydrogen chloride.

C. Measuring the buoyancy of the gas in atmospheres at a known pressure.—A good analytical balance will indicate 0·0001 grm. when carrying a load of 100 grms.;

the balances used for assaying will indicate 0·00001 grm. with a load of 10 grms. The sensibility of instruments for detecting variations of mass has been so sharpened that the latest form of **micro-balance** will carry a maximum load of 5×10^{-3} grms., and is sensitive to $3\cdot3\times10^{-8}$ grm. The weighing of minute masses is called **micro-weighing**.[4] Probably the first micro-balance was made by E. Warburg and T. Ihmori in 1886. The beam of this balance was made of thin quartz rods to which were cemented razor knife-edges; the deflections of the beam were read from a mirror and scale without taring the weights. The sensitiveness of this balance was about the same as the assay balances. In 1906, W. Nernst and E. H. Riesenfeld devised a torsion micro-balance in which a quartz fibre was cemented to the prongs of a vertical brass fork; and a thin glass rod likewise fixed horizontally to the quartz fibre. One end of the rod is intended to serve as a pointer on a silvered scale, and the other carries a tiny pan. The load causes a slight torsion of the quartz fibre. The maximum load is 2 mgrm., and the lower limit of sensibility is 5×10^{-6} grms. In another type, the principle of Archimedes is applied, and a gas manometer takes the place of a set of weights. This apparatus was improved by B. D. Steele and K. Grant (1909), and W. Ramsay and R. W. Gray (1911), so that a weight 0·0000001 grm. can be accurately determined. In some of the improved forms a still greater sensibility has been attained. In this way, the density of less than 0·75 cubic millimetres of the emanation from radium has been determined, and the corresponding molecular weight computed from the result. This is a triumph of manipulative skill.

If air at the same temperature and pressure as the ambient atmosphere be confined in a quartz bulb, it will apparently weigh nothing, but if the outside air be reduced in density, the air inside the quartz bulb will appear to have a positive weight. Given the pressure of the ambient air, the weight of the confined air can be readily calculated as indicated in the subjoined example. The beam of the instrument is a framework of thin rods of silica arranged to swing on a central knife-edge resting on a central support. A scale-pan or bucket and a sealed air bulb of known volume are suspended from the framework by quartz threads, and counterpoised by a weight. All is enclosed in an air-tight metal case fitted with a mercury gauge. A mirror reflects a beam of light from the window to a scale a few feet away. The tube containing the gas under investigation is placed in the bucket, and the pressure noted at which the beam is in equilibrium. This is indicated by the spot of reflected light. The bulb containing the gas is broken, and all the glass splinters are placed in the bucket. The gas is removed by evacuating the metal case a few times. The pressure of the air again required to bring the spot of light to equilibrium is noted. Suppose, by way of example, that the pressure of the air required to bring a tube of xenon gas in the equilibrium position be 70 mm.; and similarly the empty tube, 52·9 mm. The difference, 17·11 mm., corresponds with a weight 608 millionths of a milligram. A correction is required for differences in the weight of the glass vessel at pressures of 70 mm. and 52·9 mm. It is 15 millionths mgrm. Again, the effect of the reduced pressure on the buoyancy of the glass bulb and the silver counterpoise is different. By substituting a counterpoise of silica the difference was found to be 91 millionths of a mgrm. Hence the weight of the gas in question is $608-91+15=532$ millionths of a milligram.

The micro-balance has been used by F. W. Aston (1914) to compare the densities of two gases. The gas to be investigated, density D, is admitted to the balance case, and the pressure p determined at which the balance beam is in a given position. The corresponding pressure p_1 for a gas of known density D_1, say, oxygen is then determined. The densities of the two gases D and D_1 are inversely proportional to the pressure p and p_1, or the density D of the required gas is p_1D_1/p.

The vapour density of solids and liquids which can be vaporized without decomposition can be obtained by the following methods:

A. Weighing a known volume of the vapour.—In **J. B. A. Dumas' process** (1826)[5] the substance is vaporized in a weighed glass bulb at atmospheric pressure. The bulb is then sealed up, and the weight of the vapour determined. The capacity of the bulb is then measured. From the resulting data, the vapour density of the gas follows directly.

EXAMPLE.—The following data were obtained by H. E. Roscoe (1878) for vanadium tetrachloride: Weight of globe filled with air (9°, 760 mm.), 24·4722 grams; weight of sealed globe (9°, 760 mm.), 25·0102 grams; temperature of bath when sealing the globe, 215°; barometer when sealing the globe, 762 mm.; and the weight of bulb full of water, 194 grams. The globe held less, 24·4722 = 169·5 grams of water at 9°. This represents very nearly 169·5 c.c. of water, or the capacity of the globe is 169·5 c.c. The apparent weight of the substance at 9° is 25·0102 − 24·4722 = 0·538 gram. The empty globe was buoyed up, during weighing, by its own bulk of air at 9° and 762 mm., and since 1 c.c. of air weighs 0·001293 grams, 169·5 c.c. of air at 9° and 762 mm. weigh at (0·001293 × 169·5 × 273 × 762) ÷ (760 × 282) = 0·213 gram. This added to 0·538 gram, gives 0·751 gram, the weight of the vapour in the globe at the time of sealing. The 0·751 gram of vapour occupied 169·5 c.c. at 215° and 762 mm. pressure, or 95·10 c.c. at 0° and 760 mm. pressure. Hence, 22,300 c.c. of vapour at normal temperature and pressure weigh 176·1 grams. This number also represents the molecular weight of vanadium chloride.

Vessels made of porcelain have enabled H. St. C. Deville and L. Troost (1858), H. E. Roscoe (1878), and others to determine vapour densities by this process at temperatures far exceeding those at which even hard glass softens. The objection to Dumas' process is the amount of material which has to be vaporized in order to drive out the air from the bulb. This waste is avoided in the two succeeding methods—Hofmann's and Meyer's processes. By using porcelain or platinum vessels, Dumas' process has been employed for bodies volatilizing at high temperatures.

B. Measuring the volume of a known weight of the vapour.—J. L. Gay Lussac (1811) showed that the vapour density of a substance can be determined by measuring the volume of a known weight of the vapour in such a way that the volatile substance is confined in a small vessel of known capacity by means of mercury or any other substance which boils at a high enough temperature—*e.g.* Wood's fusible alloy. When the vessel has been heated the bath is removed. After cooling, the volume of the vapour at the highest temperature of the bath can be calculated from the weight of, say, mercury remaining in the vessel. J. L. Gay Lussac's process was perhaps the oldest method used for measuring vapour densities. He placed a known weight of the substance under investigation in a graduated glass tube, about 40 cm. long, and filled with mercury. The tube dipped in mercury and was surrounded by a hot jacket so as to vaporize the substance. The temperature and volume of the confined vapour were measured. In **A. W. Hofmann's process** (1868) the measuring tube is over 760 mm. in length.

EXAMPLE.—The following data were obtained for carbon tetrachloride, CCl_4: Weight of liquid in bulb, 0·3380 grm.; the volume of vapour, 109·8 c.c.; the temperature of vapour, 99·5°; the barometer, 746·9 mm.; and the height of mercury in tube, 283·4 mm. The pressure of the vapour is the barometric height less the weight of the column of mercury in the Hofmann's tube, that is, 746·9 − 283·4 = 463·5 mm. Hence, 0·3380 gram of vapour at 99·5° and 463·5 mm. pressure occupy 109·8 c.c., and 49·09 c.c. at 0° and 760 mm. Hence, 22,300 c.c. of the vapour at normal temperature and pressure weigh 153·6 grams, and this number represents the molecular weight of carbon tetrachloride.

A. W. Hofmann's process is useful when only a small amount of the substance is available for a determination; and for a substance which decomposes when heated at a temperature in the vicinity of its boiling point at ordinary atmospheric pressures. In **V. and C. Meyer's process** (1877) [6] the apparatus is simplified by measuring the volume of air displaced by a given weight of the substance vaporized in a suitable vessel.

If the substance be vaporized too slowly, vapour will be carried forward with the expelled air, and be condensed, thus reducing the volume of air (or gas) measured in the gas burette. It is considered that the vaporization vessel should be at least 30° above the boiling point of the substance in order to secure rapid vaporization. If the gas be collected over water instead of over mercury and is filled with ordinary moist air instead of with dry air, *a correction for the pressure of aqueous vapour* may be applied. If air contains a per cent. of moisture; and f denotes the pressure of aqueous vapour at the room temperature; and p, the barometric pressure, the actual pressure of the confined gas is taken to be $p-(1-\frac{1}{100}a)f$. This refinement is usually ignored.

Example.—The vapour density of water was determined, and the following data were obtained. Xylene, boiling at about 138°, was used in the hot jacket *E*. It was found that the weight of the water in the stoppered tube was 0·0102 grm.; the temperature of the gas in the burette, 16·5°; the barometer, 703·8 mm.; and the volume of gas, 16·6 c.c. The 16·6 c.c. of vapour at 16·5° and 703·8 mm. becomes 14·496 c.c. at 0° and 760 mm. This is the volume of 0·0102 gram of vapour. Hence, 22,300 c.c. of the vapour will weigh 15·7 grams. This number represents the molecular weight of water vapour.

V. Meyer's apparatus has been modified in various directions without altering the fundamental principle. J. S. Lumsden (1903) proposed a modification in which the increase of pressure was measured while the volume of the apparatus was kept constant. Glass vessels are suited for this determination only at comparatively low temperatures; vessels made of hard porcelain have been used by J. Mensching and V. Meyer (1886) for temperatures up to about 1500°; platinum, platinum-iridium alloy, vitreous silica by J. Dewar and A. Scott (1879), L. F. Nilson and O. Pettersson (1886), and by J. Mensching and V. Meyer (1886); and vessels of iridium lined inside and outside with a magnesian cement, and heated in an electric furnace, enabled W. Nernst (1903) and H. von Wartenberg (1908) to measure vapour densities at temperatures as high as 1800° and even 2000°.

§ 7. The Struggle of Avogadro's Hypothesis for Recognition

The first attempt at generalization seldom succeeds; speculation anticipates experience, for the results of observation accumulate but slowly.—J. J. Berzelius (1830).

A. Avogadro's hypothesis had a long struggle for recognition in spite of the fact that his memoir was followed three years later by A. M. Ampère's note addressed to M. le Comte Berthollet and entitled, *Sur la détermination des proportions dans lesquelles les corps se combinent, d'après le nombre et la disposition respective des molécules dont leurs particles intégrantes sont composées* (1814), advocating similar views. Half a century elapsed before the hypothesis was generally accepted. Among the many reasons for its failure was the fact that comparatively few substances which could be vaporized were then known, and hence the molecular weights of but few compounds had been determined with precision. At that time, an accurate knowledge of the weights of the elements was considered to be the most pressing subject of investigation. J. Dalton's atomic theory had just been born, and accurate data were also needed before that theory could be utilized. Referring to J. Dalton's theory J. J. Berzelius said :

> I recognized that if the newly arisen light was to be spread, it would be necessary to ascertain with the utmost accuracy the atomic weights of all elementary substances. . . . Without such work, no light would follow the dawn.

Something more than the mere accumulation of experimental data was necessary to find a method for determining the number of atoms in a molecule, in order that the atomic weight of the constituent elements could be obtained. Dalton pointed out that in fixing the atomic weight of oxygen with respect to hydrogen unity, he assumed that water is a binary compound of one atom of hydrogen and one of oxygen. If water be really a ternary compound containing two atoms of hydrogen and one of oxygen, it will be necessary to double the atomic weight of oxygen determined on the former assumption ; and if water contains two atoms of oxygen and one of hydrogen, the atomic weight of the oxygen would have to be halved. Similarly with other compounds. *The uncertainties in the application of J. Dalton's atomic theory are due to the arbitrary nature of the assumption of the number of atoms in a molecule.*[1]

W. H. Wollaston (1814).—In 1810, T. Thomson gave a list of the weights of various acids and bases which neutralized one another, and showed that these numbers were independent of the hypothesis of Dalton. W. H. Wollaston, in his paper *A synoptic scale of chemical equivalents* (1814), proposed to substitute the term *equivalent* in place of Dalton's *atom*. He claimed that his numbers were not warped by the uncertainties of the atomic theory, and that for practical purposes it is not necessary to know hypothetical atomic weights when equivalent weights are known. Wollaston thus proposed to do for the elements what J. B. Richter (1791–1802) had done for the acids and bases, and he accordingly used the term equivalent proposed by H. Cavendish in 1788. Starting with oxygen 10 as the unit of reference, he found the equivalent of hydrogen to be 1·3—meaning that 1·3 parts of hydrogen unite with 10 parts of oxygen to form water. In this sense, equivalent weights are identical with combining weights. Wollaston, however, got into difficulties in dealing with substances like carbon with two combining weights, for he was obliged to assume that in carbon dioxide two equivalents of oxygen were united with one of carbon so that equivalents and combining weights were no longer the same. Since 7·5 parts of carbon unite with 20 parts of oxygen by weight to form carbon dioxide, W. H. Wollaston said the formula of the compound is CO_2 ; and because 7·5 parts of carbon unite with 10 parts of oxygen by weight to form carbon monoxide the formula is CO. W. H. Wollaston might just as arbitrarily have said 3·75 of carbon unite with 10 parts by weight of oxygen to form carbon dioxide, and the formula is accordingly CO ; and in carbon monoxide 7·5 parts of carbon unite with 10 parts of oxygen by weight, and therefore the formula is C_2O. Hence, W. H. Wollaston's equivalents leave the difficulty with J. Dalton's atoms just as it was. Ignoring this uncertainty, the former computed the equivalents of 12 elements, and 45 compounds from various analyses. A. Ladenburg (1869) [2] is severe on W. H. Wollaston, for he says that Wollaston's views involved a retrograde step, for W. H. Wollaston believed that he was dealing with unambiguous conceptions free from all hypothesis ; and in introducing the term equivalent, he confused the conceptions of the equivalent and the atom, and rendered a vigorous struggle necessary before the two concepts could be clarified.

J. J. Berzelius (1810–26).—J. J. Berzelius seems to have regarded the investigation of the laws of combining proportions to be one of the most important objects of his life's work, and in a memorable work, *Essai sur la théorie des proportions chimiques et sur l'influence chimique de l'électricité*, published in Sweden in 1814, and at Paris in 1819, he developed his conceptions of the atomic theory, and collected together the results of his arduous work on the combining proportions of the elements which he had published between 1810 and 1812. In his *Lehrbuch der Chemie* (Dresden, 1825), J. J. Berzelius remarked that it did not matter much whether the particles which combine chemically be called atoms, molecules, chemical equivalents, or any other terms, but he preferred to use the term atom. In spite of Dalton's demonstration that Gay Lussac's law does not mean that equal volumes of elemental gases contain the same number of atoms, J. J. Berzelius used this erroneous *Volumtheorie* as a guide in determining the numerical values of the atomic weights of the elements which were gaseous at ordinary temperatures. He said, one volume of an elementary substance in the gaseous state corresponds with one atom, and he called the smallest particles *Volumatome*. This erroneous theory gave him satisfactory results in deducing the composition of water, and of the two carbon oxides; and consequently also of the atomic weights of oxygen, hydrogen, and carbon. J. J. Berzelius (1818) was not so fortunate with some of the metallic oxides, particularly the sesqui-oxides. It is illogical, said he, to express the composition of a series of oxides of an element A by the formulæ A_2O_2, A_2O_4, A_2O_6 . . ., and declared that in a series of compounds of the two elements one compound must always be represented as containing a single atom of one of the elements, and accordingly he wrote the formulæ AO, AO_2, AO_3 . . . If the simplest oxide were A_2O_2 Berzelius said that the atoms of the elements A would be divisible mechanically. J. Dalton saw the fallacy in this argument for fixing the number of atoms in a molecule of the solid oxides, but, led on by the erroneous argument, Berzelius (1818) wrote the formulæ for ferrous oxide FeO_2 instead of FeO ; and ferric oxide, FeO_3 instead of Fe_2O_3, and thus obtained numbers for the atomic weights of iron, chromium, etc., double the values of those now accepted. The chemical similarities of iron with chromium led him to symbolize chromic oxide CrO_3 by analogy with FeO_3 ; similarly he formulated the metal oxides ZnO_2, MnO_2 . . . by analogy with FeO_2. In 1826, however, he wrote—

> Assuming that chromic oxide contains three atoms of oxygen ; and that chromic anhydride contains six atoms, in forming neutral salts, chromic anhydride neutralizes an amount of base containing one-third as much oxygen as it itself contains. By analogy with sulphuric anhydride, and other anhydrides with three atoms of oxygen, it is most probable that chromic anhydride contains three atoms of oxygen to one of chromium, consequently chromic oxide will contain three atoms of oxygen to two of chromium, and the formulæ for chromic oxide will be Cr_2O_3, and for chromic anhydride, CrO_3. The isomorphic law will then make ferric oxide, Fe_2O_3, instead of FeO_3 ; and aluminium oxide, Al_2O_3, instead of AlO_3.

These considerations led J. J. Berzelius in 1826 to halve the atomic weights of the metals published in his 1818 Table of Atomic Weights. The following table represents atomic weights of a few elements selected from Berzelius' 1818 and 1828 Tables, and recalculated for the standard oxygen 16 instead of 100 used by Berzelius. The modern values also are given by way of comparison.

TABLE III.—BERZELIUS' ATOMIC WEIGHTS.

Elements	1818.	1828.	1919.
Carbon . . .	12·12	12·25	12·0
Oxygen . . .	16·0	16·0	16·0
Sulphur . . .	32·3	32·24	32·06
Mercury . . .	406	202·86	200·6
Iron . . .	109·1	54·36	55·84
Sodium . . .	93·5	46·62	23·00
Silver . . .	433·7	216·61	107·88

Berzelius never succeeded in deciding whether the binary compounds he analyzed contained two or more atoms per molecule. Without any rules to guide him, said J B. A. Dumas (1832), but guided mainly by analogies, he fixed by intuition the atomic weights of a number of elements which subsequent experience has only tended to confirm. When all is said, however, this method is unsatisfactory, because it is arbitrary, and liable to be capriciously modified by each worker. In addition to his volume law, Berzelius also used Dulong and Petit's rule of specific heats, and Mitscherlich's isomorphic law to assist him in fixing the atomic weights of the elements.

J. B. A. Dumas (1826–37).—In 1826, J. B. A. Dumas[3] published an important memoir *Sur quelques points de la théorie atomistique :*

> The object of these researches is to replace by definite conceptions, the arbitrary data on which nearly the whole of the atomic theory is based.

Dumas accepted the hypothesis of Avogadro as propounded by Ampère, namely, that equal volumes of gases contain an equal number of particles, and in the case of the simple gases, that these particles are subdivided during chemical reactions. J. B. A. Dumas thus recognized the importance of measuring the relative densities of gases and vapours, and he devised his well-known method for determining these constants. In 1832, he had determined the relative vapour densities of mercury, iodine, phosphorus, sulphur, arsenic, etc., and noted some irregularities with sulphur, mercury, phosphorus, and arsenic. He spoke of *un demi-atome* in the same way that Avogadro spoke of *une demi-molécule.* J. J. Berzelius appears to have been obsessed by his dualistic theory (*q.v.*), in which he assumed that the ultimate particles (molecules) of elementary substances cannot be split when they form a binary compound ; so that he wrote the formula of hydrogen chloride H_2Cl_2 ; or else he misunderstood J. B. A. Dumas, owing to the confusion of the words atom and molecule, and was led to say (1826) :[4] "It is usually supposed that an hypothesis ought to be abandoned as soon as it leads to an absurd conclusion ;" and if Avogadro's hypothesis involves the subdivision of an atom, it must be condemned.

In his *Leçons sur les philosophie chimique* (Paris, 1837), J. B. A. Dumas applied Avogadro's volume law—equal volumes, an equal number of atoms—to explain the formation of hydrogen chloride, HCl, and nitric oxide, NO, from the elementary gases, and he showed that the physical atoms must be split during the reaction. Hence, said J. B. A. Dumas, *la chimie coupait les atomes que la physique ne pouvait pas couper,* so that Avogadro's molecules are Dumas' physical atoms. Here again there was some confusion owing to the unfortunate use of the word atom in place of Avogadro's molecule. J. B. A. Dumas then went on to show that while Avogadro's volume law gives satisfactory values for the atomic weights of oxygen, nitrogen, chlorine, bromine, and iodine, difficulties are encountered with phosphorus, arsenic, mercury, and sulphur. For instance, ammonia is formed by the union of three volumes of hydrogen and one volume of nitrogen ; and phosphine, a similar gas, is presumably formed in a similar manner so that phosphine should be produced by replacing the nitrogen of ammonia by an equal volume of phosphorus gas. Consequently, it was argued that the density of phosphorus vapour ought to be 31·4 (hydrogen unity—in the original, oxygen 100 is the standard of reference) ; experiment gives a number twice as great ! A similar discrepancy was found with arsenic. This can only mean that equal volumes of the vapours of nitrogen, phosphorus, and arsenic do not contain the same number of atoms. Again, J. B. A. Dumas showed that about 200 parts of mercury unite with 16 parts of oxygen to form mercuric oxide, and therefore the atomic weight of mercury must be nearly 200 ; but judging from the density of mercury vapour, the atomic weight of this element is nearly 100. Consequently, *le chaleur diviserait les particles du corps plus que l'action chimique.* Equal volumes of gases sometimes contain an equal and sometimes an unequal number of atoms, and therefore the determination of the densities of vapours cannot be a trustworthy guide in evaluating the atomic weights of the elements. The facts seemed to be against Avogadro's hypothesis and J. B. A. Dumas accordingly gave it up in despair. He then tried an application of Dulong and Petit's rule, but here again he was disappointed with the exceptions; and finally, after trying Mitscherlich's isomorphic rule, he said, *tout considéré, la théorie atomique serait une science purement conjecturale, si elle ne s'appuyait pas sur l'isomorphisme.*

W. Prout (1833) and A. Gaudin (1835).—W. Prout, in his work *Chemistry . . . considered with reference to Natural Theology* (London, 122, 1833), adopted the hypothesis of Avogadro's, *viz.* " under the same pressure and temperature, all bodies in a perfectly gaseous state contain an equal number of self-repulsive molecules," to explain the volume relations of hydrogen, oxygen and water, and of hydrogen, chlorine, and hydrochloric acid. W. Prout's explanation is almost as clear as if it had been written to-day. From the observed results, said he,

> It follows irresistibly that every self-repulsive molecule of oxygen has been divided into two, and consequently must have originally consisted of at least two elementary molecules, somehow or other associated, so as to have formed one self-repulsive molecule.

M. A. Gaudin, in his papers *Recherches sur la structure intime des corps inorganiques*, published in 1833, had previously pointed out that J. B. A. Dumas' difficulty with mercury and phosphorus could be explained by assuming that the mercury molecule is monatomic, and that of phosphorus tetratomic; evidently J. J. Berzelius did not like this mode of evading the discrepancy observed by J. B. A. Dumas, and considered it to be *nur ein Spiel der Phantasie*, although M. A. Gaudin's suggestion is now generally accepted; so also is Gaudin's happy use of the terms mono-, di-, tri-, . . . atomic for indicating the number of atoms in a molecule.

Failures with Avogadro's hypothesis.—Towards the middle of the nineteenth century, as a result of these failures to apply Avogadro's hypothesis, the atom was abandoned by the majority of chemists as a discredited theory. In illustration, J. B. A. Dumas said in 1837: *Si j'en étais le maître, j'effacerais le mot atome de la science.* Wollaston's equivalents were used, notably by L. Gmelin in his popular *Handbuch der theoretischen Chemie* (Frankfurt-am-Main, 1817–9). In the early editions of this book Gmelin used the term *Mischungsgewichte*—mixing weights—and in a later edition (1843), the term *stoichiometric numbers* in place of equivalents. Gmelin said, if an atom is the smallest quantity of a body which enters into combination, the equivalents must represent atoms; the atomic notation of Dalton is based on hypothesis, equivalents are a reality. The inconsistencies involved in W. H. Wollaston's equivalents were thus ignored. The whole subject at this time (1840–50) was in a very confused state. In addition to the muddling of the terms atom, molecule, and equivalent, there were tables of atomic weights, equivalents, H. V. Regnault's *équivalents thermiques* (1849) based upon Dulong and Petit's rule; H. Rose's (1857) and J. C. G. de Marignac's *équivalents isomorphiques* (1855) based upon Mitscherlich's rule; and M. Faraday's *electrochemical equivalents* (1834).[5] Different chemists used different standards for their equivalent and atomic weights. The same chemical formula was used for different compounds, and different formulæ for the same compound—for instance, F. A. Kekulé in his *Lehrbuch der organischen Chemie* (Stuttgart, 1861) indicated nineteen different formulæ which had been proposed for acetic acid. Inorganic chemists thus failed to establish the conception of an atom, but fortunately organic chemists had begun to see more clearly.

C. F. Gerhardt and A. Laurent (1842–56).—In 1842, in a memoir entitled *Recherches sur la classification chimique des substances organiques*, C. F. Gerhardt was groping for a method of distinguishing between equivalent and atomic weights, and he put forward some important views respecting the equivalents of certain elements taking part in organic reactions. He showed that when an organic reaction gave rise to water, carbon dioxide, carbon monoxide, or ammonia, the smallest amounts produced are those represented by the formulæ H_4O_2, C_2O_4, C_2O_2, S_2O_4, NH_3

respectively, on the assumption that the equivalent or atomic weights are H=1, O=8, C=6, S=16, N=14. Hence, the quantities indicated by the formulæ must represent an equal number of equivalents. It seems strange, said he, that no reaction in organic chemistry can give rise to less than a single molecule of water, H_4O_2, or carbon dioxide, C_2O_4; and that these quantities of gases occupy equal volumes. Consequently, H_4O_2 and C_2O_4 represent either one or two equivalents; the former hypothesis fits the facts best, and therefore he argued that the equivalents of the elements O=8, C=6, and S=16 should be doubled so that the preceding formulæ can be written H_2O, CO_2, CO, SO_2, and NH_3 respectively. C. F. Gerhardt thus obtained numbers for the equivalents of the elements, hydrogen, oxygen, carbon, sulphur, and nitrogen in agreement with the atomic weights used by Berzelius in 1826.

C. F. Gerhardt also advocated the adoption of a common standard for comparing chemical formulæ with one another, and he recommended the use of what is known as the *two-volume standard*: those quantities by weight which occupy two volumes when in the gaseous state and when the volume of atomic hydrogen is taken as unity. Hence, Avogadro's hypothesis is sometimes called the *Avogadro-Gerhardt law*. In a later part of his paper, Gerhardt showed that his notions of atomic weights, the volume theory, and equivalents were not clear, because he stated that all these concepts coincide. A. Laurent (1846), however, obtained a clear grasp of the meanings to be attached to these terms, and he adopted Gerhardt's happy idea that chemical formulæ should represent comparable quantities; he also adopted the two-volume standard, but in doing so he was obliged to admit that there are some exceptions—*e.g.* the vapour of ammonium chloride, and sulphuric acid—which seemed to correspond with a four-volume standard. The names of Laurent and Gerhardt are usually linked together; it is, indeed, difficult to isolate the particular contributions made by each because they published a great deal jointly, and, being intimate friends, they probably discussed the whole subject together. A. Laurent's posthumous *Méthode de chimie* (Paris, 1854) and C. F. Gerhardt's *Traité de chimie organique* (Paris, 1856),[6] did much to clear the conceptions of equivalents, atoms, and molecules; and their definitions of these entities, and most of their formulæ for organic and inorganic compounds are virtually in use to-day. Laurent represented the union of hydrogen and chlorine by the equation (HH)+(ClCl) =(HCl)+(HCl); to-day we write, $H_2+Cl_2=2HCl$; similarly the synthesis of water was symbolized, (HH)+(HH)+(OO)=(HH)O+(HH)O; to-day we write, $2H_2+O_2=2H_2O$. A. Gaudin (1832) employed special diagrams to symbolize these reactions.

Several other systems of symbolizing chemical operations have been proposed. A. C. Brown (1867), for example, used Greek letters to represent different chemical actions, thus ϕ represented the replacement of hydrogen in a molecule by the radicle CH_3, and if a denotes a molecule of ammonia, NH_3, the symbol ϕa represented the substitution of one hydrogen atom in ammonia to form CH_3NH_2. In view of the great variety of chemical processes and compounds, such a system would be more cumbrous and throw greater strains on the memory than the present system. B. C. Brodie proposed a new notation in his *Calculus of Chemical Operations* (1867), which he regarded as "a rigid expression of fact," independent of the atomic hypothesis. B. C. Brodie's system, however, involved assumptions even more drastic than the atomic theory, and the notation was so confusing that it died as soon as it was born.

S. Cannizzaro (1857–8).—In 1857, S. Cannizzaro stated his belief:

> There are no exceptions to the universal law that equal volumes of gases contain equal numbers of molecules, and that the apparent exceptions will disappear when more searching experiments are made.

He showed that the apparent exceptions to C. F. Gerhardt's two-volume law, pointed out by A. Laurent, are not real, for the work of H. St. C. Deville (1857) has shown that ammonium chloride and sulphuric acid are decomposed by heat, and therefore the observed vapour densities are the densities of mixtures of the decomposition products and not of homogeneous compounds to which Avogadro's hypothesis alone refers. Similar conclusions were deduced independently and almost simultaneously by H. Kopp (1858)[7] and F. A. Kekulé (1858). Immediately afterwards, S. Cannizzaro published his celebrated *Sunto di un corso di filosofia chimica fatto nella Reale Universita di Genova* (1858), which placed Avogadro's hypothesis at the foundation of the system of chemistry which obtains to-day—witness, among other works, W. Nernst's popular *Theoretische Chemie vom Standpunkte der Avogadroschen Regel und der Thermodynamik* (Stuttgart, 1916). The atomic theory of the present-day chemistry is the work of many minds. In the words of G. Chrystal (1885):

> Few scientific ideas spring up suddenly without previous trace or history; a close examination always shows that the sprite was in the air before the Prospero came to catch him. . . . There are long periods in science in which great improvements were effected which cannot be traced to any individual, but seem to have been due merely to the working of the minds of scientific men generally upon the matter, one giving it this little turn, another that, in the main, always for the better.

§ 8. Deviations from Avogadro's Law

> When a fact appears to be opposed to a whole train of deductions, it invariably proves to be capable of bearing some other interpretation.—SHERLOCK HOLMES.

It is sometimes said that a phenomenon "ought to take place," but it does not; the phenomenon is then said to be abnormal or anomalous. These terms are not very happily chosen, and they are sometimes used rather carelessly; they are not intended to imply that nature is erratic, arbitrary, and lawless. The words simply mean that in groping for the truth, an unexpected result has been obtained, which once stood, or now stands, challenging investigators to show how the unexpected should have been expected. In this sense it has been said that abnormal phenomena do not occur in nature. Some of the most treasured generalizations in science have been won by investigating the abnormal. This applies both in the laboratory and in the study.

Abnormal vapour densities.—According to Avogadro's hypothesis, if the relative density of hydrogen be taken as unity, the quotient $M/D=2$, where M denoted the molecular weight, and D the relative density of the gas. Some puzzling exceptions to this rule were encountered during the early application of the hypothesis, for several substances do not conform to the ratio when molecular weights deduced by the ordinary chemical methods are employed, and, in consequence, these substances were said to possess abnormal vapour densities. This led chemists to look upon Avogadro's rule with suspicion, and there were some controversies as to whether (i) substances with abnormal vapour densities really follow Avogadro's rule;

or whether (ii) substances with an abnormally low vapour density are dissociated into simpler molecules, and substances with an abnormally high vapour density are associated into more complex molecules. J. B. A. Dumas (1836)[1] thought that the abnormal vapour densities invalidated the hypothesis, while M. A. Gaudin (1833) considered that the alleged failure was due to a peculiarity in the molecules of the gas, which, when taken into account, left the hypothesis quite valid. Independent proofs of the validity of M. A. Gaudin's inference are discussed later on when the particular substances are treated. As soon as M. A. Gaudin's interpretation had been demonstrated experimentally, Avogadro's hypothesis won its way into the heart of chemical science.

There are two possible deviations with compounds; the ratio

$$\frac{\text{Molecular weight}}{\text{Density}} \text{ may be greater or less than 2}$$

when the density of hydrogen is taken unity. In the case of elementary gases, S. Cannizzaro (1858) showed that the atomic weight A is equal to half the vapour density of the gas, if hydrogen 2 be the unit, or to the vapour density itself, $A/D=1$, if hydrogen be unity. Here, again, there are two possible deviations:

$$\frac{\text{Atomic weight}}{\text{Density}} \text{ may be greater or less than unity}$$

when hydrogen unity is the standard of reference. The interpretation of the results in the two cases are similar.

The molecules of the substance are decomposed or dissociated; the molecules are actually less complex than corresponds with the simple chemical formulæ, and the ratio M/D is greater than 2, or the ratio A/D is greater than unity. For example, the vapour density of steam is 9 ($H=1$), the molecular weight 18, and the ratio $M/D=2$; at a very high temperature, there are reasons for supposing that the vapour density would be 6, and the ratio M/D would appear to be 3. This corresponds with the value of M/D on the assumption that the steam is dissociated into its elementary molecules: two volumes of hydrogen, and one volume of oxygen, so that the density of a mixture is involved and not that of a homogeneous substance as is required if Avogadro's rule is to be applied. The density of such a mixture will be $(2+16)\div3=6$; the assumed dissociation thus gives a number in agreement with observation. If the observed density were 8, this would represent a mixture with $33\frac{1}{3}$ per cent. of dissociated, and $66\frac{2}{3}$ per cent. of undissociated steam. The cases with phosphorus pentachloride, PCl_5; ammonium chloride, NH_4Cl; sulphuric acid, H_2SO_4; mercurous chloride, $HgCl$; nitrogen peroxide, N_2O_4; and hydrogen iodide, HI, are discussed later. With elementary gases, J. B. A. Dumas (1832) found that mercury vapour has a density of 100 corresponding with an atomic weight of 100, but the atomic weight deduced by chemical methods is 200, consequently $A/D=2$ instead of 1. It is therefore assumed that the molecule of mercury vapour is monatomic and $M/D=2$, while $A/D=1$. The cases with iodine, the metal vapours, etc., are discussed later.

The molecules of the substance are associated or condensed; the molecules are more complex than corresponds with the simple chemical formulæ; and the ratio M/D is less than 2, or the ratio A/D less than unity. The molecular weight of acetylene, C_2H_2, is 26, the vapour density is 13, and the ratio M/D is normal. Benzene has exactly the same chemical composition, and its vapour density is 39 (H unity); if the molecular weights of the two gases be the same, the ratio M/D for benzene would be 0·67, but if benzene be more complex than acetylene, say $(C_2H_2)_3$ or C_6H_6, the molecular weight of the complex molecule will be 78, and the ratio M/D becomes normal. Hence, for this and other reasons, benzene is regarded as if it were a product formed by the condensation of three molecules of acetylene. Phosphorus trioxide and pentoxide, and other examples, are discussed later. With elemental gases, J. B. A. Dumas (1832) found that the density of phosphorus vapour is 62·8, and the atomic weight deduced by chemical methods, by analogy with nitrogen, is 31·4, so that the ratio A/D is one-half. This is taken to mean that the molecular weight of phosphorus is not that equivalent to P_2, but is rather equivalent to P_4. Sulphur and arsenic are discussed later.

The effect of changes in the molecular weight of a gas on the laws of Boyle and Charles.—The gas equation,

$$\frac{pv}{T}=\frac{p_1v_1}{T_1}$$

must now be revised in order to allow for changes in the molecular weight of the gas when it changes from one state to another. Remembering that the density D of a gas is equal to the molecular weight M divided by the volume v, or $M=Dv$, the gas equation can be written,

$$\frac{p}{TD}=\frac{p_1}{T_1D_1}$$

provided $M=M_1$. Let M, D, and v respectively denote the molecular weight, density, and volume of the gas by one condition of temperature and pressure; and M_1, D_1, and v_1, the same constants for another condition of temperature and pressure, then, by substitution in a preceding equation, $pv/MT=p_1v_1/M_1T_1$. If the volume v_1 at some standard temperature T_1 and pressure p_1 be taken, the numbers p_1, v_1, and T_1 will always have one fixed value. Let R denote this constant value of p_1v_1/T_1. The gas equation then assumes one of the forms :

$$\frac{pv}{MT}=\frac{p_1v_1}{M_1T_1}\text{; or, }pv=\frac{M}{M_1}RT\text{; or, }pv=iRT$$

where i stands in place of the ratio of the molecular weights of the gas in the two conditions, M/M_1. If the molecules of the gas neither dissociate nor polymerize when the conditions change, $M=M_1$; or $pv=RT$ because $i=1$. Again, if the gas molecules polymerize or condense so that, say, two molecules combine together to form one molecule, there will be only half as many molecules in a given space as before : $M=\frac{1}{2}M_1$, and $pv=\frac{1}{2}RT$. If, however, the gas dissociates or decomposes so that each molecule of the gas forms two molecules of another gas or gases, then $M=2M_1$, and $pv=2RT$. Hence, **the ordinary gas equation, $pv=RT$, is a special case of the more general relation, $pv=iRT$, where the numerical value of i indicates whether or not the gas keeps the same molecular concentration during the change. If $i=1$, there is neither dissociation nor polymerization ; if i be less than unity, the gas polymerizes ; and if i be greater than unity, the gas dissociates when the conditions are changed.**

The effect of deviations from Avogadro's hypothesis on Gay Lussac's law of volumes.—The molecular volumes of many gases are not all the same, and they thus exhibit small deviations from the law $M/D=2$ (hydrogen unity). This is shown for a few gases at 0° and 760 mm. in the following table :

TABLE IV.—A COMPARISON OF THE MOLECULAR VOLUMES OF SOME GASES.

Gases.	Molecular weight M.	Observed density (O=16).	Molecular volumes M/D.
Oxygen, O_2	32	16	2·000
Nitrogen, N_2	28·02	14·00	2·001
Carbon monoxide, CO	28·00	14·01	2·000
Carbon dioxide, CO_2	44·00	22·15	1·988
Methane, CH_4	16·03	8·03	1·998
Ethane, C_2H_6	30·05	15·20	1·980
Ethylene, C_2H_4	28·03	14·28	1·966
Acetylene, C_2H_2	26·02	13·12	1·984

In calculations involving gaseous volumes, the errors due to the deviations of the molecular volumes from the theoretical may be greater than the experimental errors. Instead of writing the reaction, $2CO+O_2=2CO_2$, in the form, 2 Vols. CO+1 Vol. O_2=2 Vols. CO_2: it becomes necessary to write $2\times0{\cdot}994=1{\cdot}988$ volumes of carbon dioxide, and the equation becomes 2 Vols. CO+1 Vol. O_2=1·988 Vols. CO_2. Similarly, with equations involving other discrepant gases. If the partial pressure of the deviating gas be less about 25 per cent., the discrepancy may be disregarded since **the lower the partial pressure of the gas, the more nearly does it behave like an ideal gas.** Thus, the lower the pressure confining carbon dioxide, CO_2, at 20°, and of ethane, C_2H_6, at 0°, the more nearly do the molecular volumes approach the value 2 for ideal gases.

Pressure	100	300	500	600	700	760 mm.
Carbon dioxide	1·998	1·996	1·994	1·992	1·990	1·988
Ethane	1·998	1·992	1·988	1·984	1·982	1·980

Correction of the ratio M/D for gases which deviate from Boyle's law.—It follows from Avogadro's hypothesis: (i) The molecular volumes—*i.e.* the quotients of the molecular weights M by the respective densities D—of all gases are the same, so that $M_1:D_1=M_2:D_2$, and (ii) the molecular weights of all gases are proportional to their densities, so that $M_1:M_2=D_1:D_2$. These deductions can be true only for gases in which the pressure is not affected by intermolecular attractions as is the case with gases which follow the simple gas laws. Densities calculated for gases which do not conform with Boyle's law do not agree satisfactorily with observations unless the gases are attenuated or rarefied, thus showing that Avogadro's hypothesis is not strictly accurate with gases under normal pressure. Similarly, the experiments of H. V. Regnault [2] (1847) and others have shown that Boyle's and Charles' laws approach exactitude only when the pressures are very small. Gases approach the so-called ideal state when their pressures are reduced; and, at the limit, when the pressures are indefinitely small, Avogadro's hypothesis is strictly valid. Otherwise expressed, **the molecular volumes of all gases are exactly the same only when the gases are extremely rarefied**; and the limiting value of the ratio of the densities D_1 and D_2 of two gases will be equal to the ratio of their molecular weights M_1 and M_2 only when the pressures of the respective gases approach zero. The deviation of a gas from Boyle's relation $p_0v_0/pv=1$, or $1-p_0v_0/pv=0$, can be symbolized:

$$A=1-\frac{p_0v_0}{pv} \qquad (1)$$

where p_0 and v_0 respectively denote the atmospheric pressure and volume of the gas at 0°; and p and v the corresponding values at some small pressure. For the so-called permanent gases, Regnault's experiments show that the coefficient A is very nearly constant between one and six atmospheres pressure. Consider two gases under a very small pressure p; let each be subjected to atmospheric pressure p_0 when the volumes become respectively v_1 and v_2; then, $v_1=vp(1-A_1)/p_0$; and $v_2=vp(1-A_2)/p_0$; and by division,

$$\frac{v_1}{v_2}=\frac{1-A_1}{1-A_2} \qquad (2)$$

This means that the molecular volumes of the two gases under atmospheric pressures have the proportional values $1-A_1$ and $1-A_2$. Let D_1 and D_2 denote the respective densities of the gases under atmospheric pressures—temperature constant—then, the ratio of the molecular weights $M_1:M_2$ is equal to the ratio of the products of their molecular volumes by the corresponding densities; that is, to the ratio $D_1(1-A_1):D_2(1-A_2)$; or,

$$\frac{M_1}{M_2}=\frac{D_1(1-A_1)}{D_2(1-A_2)} \qquad (3)$$

If A for the two gases be zero the expression reduces to that required by Avogadro's rule. The densities employed in calculations with formula (3) are the weights in grams of a normal litre of the respective gases; the evaluation of the coefficients A is a problem for the physicists. A number of values have been determined, but the task is a difficult one, and is subject to some uncertainty since it involves an extrapolation of the pv and p-curve. The following values for A_0^1 between atmospheric and zero pressures are compiled from data by A. Leduc (1898), R. W. Gray and F. P. Burt (1909), and A. Jaquerod and O. Scheuer (1908)[3]:

TABLE V.—NUMERICAL VALUES OF THE COEFFICENT A.

Gas.	A_0^1	Gas.	A_0^1
Hydrogen	$-0·00056$.	Nitrous oxide . . .	$+0·00750$
Oxygen	$+0·00096$	Hydrogen chloride . .	$+0·00786$
Nitrogen	$+0·00044$	Sulphur dioxide . .	$+0·02314$
Carbon monoxide . .	$+0·00060$	Methane	$+0·00175$
Nitric oxide	$+0·00114$	Ethane	$+0·01194$
Carbon dioxide	$+0·00678$	Methyl chloride . .	$+0·02468$
Ammonia	$+0·01504$	Ether	$+0·02587$

If oxygen be the standard gas with $M_2=32$, $D_2=1·4290$, and $A_2=0·00096$, it follows that if the numerical values of the density D and the deviation a be known, the

$$\text{Molecular weight}=22·5739D(1-A)$$

The results computed by this method are in fair agreement with the values obtained by chemical processes. For example, with oxygen, 32, as standard

	Hydrogen.	Nitrogen.	Carbon monoxide.	Nitric oxide.	Methane.
M (Chemical) . .	2·015	28·019	28·009	30·006	16·039
M (Physical) . .	2·016	28·020	28·000	30·010	16·032

These results are in close agreement. This physical method thus rivals in accuracy the molecular weights of the permanent gases determined by chemical processes. There are not so many complications with physical methods as are involved in conducting a series of chemical operations with pure substances. This physical method is known as **D. Berthelot's limiting density method of determining molecular weights.**[4] The data required for the application of Berthelot's method are (i) the densities, and (ii) the compressibility of the gas under investigation; and also (iii) the compressibility of the standard gas.

With the more easily liquefiable gases, the coefficient A changes rapidly with changes of pressure, and consequently A cannot be assumed constant without sensible error. It is therefore necessary to use values for the coefficients A determined for the variations of pressure near to those under which the density has to be determined. The available data are not sufficiently exact to enable the method to be used for accurate molecular weights of such gases, the coefficients A are usually too high, and the molecular weights correspondingly low. For instance:

	Carbon dioxide.	Nitrous oxide.	Ethylene.	Ammonia.	Sulphur dioxide.
M (Chemical .	44·000	44·020	30·048	30·034	64·070
M (Physical) .	44·013	44·003	30·037	30·018	64·063

where the comparison is not so favourable.

According to D. Berthelot,[4] the molecular weight M of a normal liquid is related with its critical density D_c, critical pressure p_c, and critical temperature T_c by the formula

$$M=22·4\frac{D_c}{3·6}\cdot\frac{T_c}{273}\cdot\frac{1}{p_c}$$

where 3·6 represents the mean value of the actual to the theoretical density at the critical temperature for normal or non-associated liquids. E. Mathias has also shown that in accord with the law of rectilinear diameters, the critical density of a substance is related to the densities of the liquid D_l and of the saturated vapour D_v at a temperature T by the expression

$$D_c = \frac{D_l - D_v}{2\left(2 - \frac{T}{T_c}\right)}\text{; or, } D_c = \frac{D_l}{2\left(2 - \frac{T}{T_c}\right)}$$

when the temperature does not exceed the boiling point of the liquid under atmospheric pressure. Consequently, by substitution of the second of these equations in that of Berthelot,[5]

$$\text{Molecular weight} = 11{\cdot}4\,\frac{D_l T_c}{p_c\left(2 - \frac{T}{T_c}\right)}$$

The molecular weights of substances which are liquid at ordinary temperatures, calculated by this expression, are often a little too high. For example—

	Cy_2	SO_2	CCl_4	CS_2	NH_3	H_2O	$SnCl_4$
Calculated . .	50	65·1	152·3	73·4	19·2	25·1	252·4
Formula weight . .	52	64	153·8	76	17	18	260

§ 9. Radicals or Radicles

For the chemist, each molecular compound is proximately made up of less compound atoms which are indivisible by forces which can divide their product, and these in turn can be separated by chemical agents into simple atoms.—S. Brown.

In 1815, J. L. Gay Lussac,[1] after studying the properties of hydrocyanic acid, reported cyanogen $(CN)_2$, to be "a remarkable example, and at present, a unique example, of a body which, although a compound, plays the part of a single body in its combinations with hydrogen and the metals." Indeed, if chemists did not know how to resolve cyanogen into its constituent elements, this compound would very probably be classed as an element, and further, it would probably be assigned a place in the halogen family of elements to be studied later. Since Gay Lussac's discovery a great number of similar groups of what might be called *pseudo-elements* have been found. For convenience, they are commonly called *radicals* or, following the custom of the London Chemical Society, *radicles*. There have been periodic discussions on the spelling of the term—radicle or radical. The latter is taken to be historically correct, and the former etymologically correct.[2] The word *radical* was previously employed by G. de Morveau (1787) and by A. L. Lavoisier[3] with a different meaning, for with A. L. Lavoisier a radicle could be a simple or compound body; he says, *le carbone est le radical de l'acide carbonique*, and added that vegetable acids contain *le radical oxalique, tartarique*, etc. The definition: **a radicle is a group of atoms which can enter into and be expelled from combination without itself undergoing decomposition,** is virtually that given by J. von Liebig in 1838. Each radicle acts as an unchanging constant in a series of compounds; and each can be replaced by an equivalent element or elements. In very few cases has it been possible to isolate the radicle, but the definition has nothing to say about the independent existence of radicles. " Radicles," said A. Kekulé (1858), " are not firmly closed atomic groups, but they are merely aggregates of atoms placed near together which do not separate in certain reactions, but fall apart in other reactions." For convenience, the term radicle is sometimes applied to an atom in a compound which can be replaced by another atom or radicle without a further change in the nature of the compound; in that case, the radicle is said to be a *simple radicle*, in contrast with *compound radicles*, which are groups of atoms.

§ 10. The Atomic Weights of the Elements

> Every chemical element is regarded as having a distinct and definite nature of its own, which nature, moreover, determines all its activities.—B. P. BROWNE.
>
> The ratio between the atomic weights of oxygen and hydrogen is the base-line upon which our entire system of atomic weights depends. —F. W. CLARKE (1896).

What are the best representative values for the atomic weights of the elements? —The best available determinations of the value of the oxygen-hydrogen ratio give numbers ranging between 1·005 and 1·008 when the standard reference is oxygen 16. **All measurements made by man are affected by unavoidable errors of experiment; and measurements of the numerical value of all constants differ within certain limits amongst themselves.** It is convenient to select one representative value from the set of different observations ranging between the limits 1·005 and 1·008. The majority of chemists have agreed to let the *International Committee of Atomic Weights* decide what are the best representative values for the atomic weights of all the elements year by year. Hence, the generally accepted ratio for the atomic weights of hydrogen and oxygen is **1·008 : 16.** Every time new and more refined methods of measurement are employed, a change—generally insignificantly small—may be necessary. It must be recognized that the **true atomic weights** cannot be altered by the votes of the majority of the members of the International Committee of Atomic Weights.[1] There is an uncertain factor in the accepted values of the atomic weights, as there is in all our judgments. Aristotle was no doubt right, " Nothing can be positively known, and even this cannot be positively asserted." This doctrine, however, if rigorously applied, would paralyze all action. Accordingly, sound-minded people are accustomed to balance the evidence and then act. A careful consideration of all the available evidence considerably reduces the risk of error, and this method adopted by the Committee appears to be the most satisfactory solution of the problem.

The atomic weights of the elements are indicated in the following table. The numbers are those recommended by the International Committee on Atomic

Weights (1920). The atomic number, indicated in the same Table, will be discussed later.

TABLE VI.—INTERNATIONAL ATOMIC WEIGHTS (1921). O=16.

	Atomic number.	Symbol.	Atomic weight.
Aluminium	13	Al	27·1
Antimony	51	Sb	120·2
Argon	18	A	39·9
Arsenic	33	As	74·96
Barium	56	Ba	137·37
Beryllium (Glucinum)	4	Be	9·1
Bismuth	83	Bi	208·0
Boron	5	B	10·9
Bromine	35	Br	79·92
Cadmium	48	Cd	112·40
Cæsium	55	Cs	132·81
Calcium	20	Ca	40·07
Carbon	6	C	12·005
Cerium	58	Ce	140·25
Chlorine	17	Cl	35·46
Chromium	24	Cr	52·0
Cobalt	27	Co	58·97
Columbium (Niobium)	41	Cb	93·1
Copper	29	Cu	63·57
Dysprosium	66	Dy	162·5
Erbium	68	Er	167·7
Europium	63	Eu	152·0
Fluorine	9	F	19·0
Gadolinium	64	Gd	157·3
Gallium	31	Ga	70·1
Germanium	32	Ge	72·5
Glucinum (Beryllium)	4	Gl	9·1
Gold	79	Au	197·2
Helium	2	He	4·00
Holmium	67	Ho	163·5
Hydrogen	0·95	H	1·008
Indium	49	In	114·8
Iodine	53	I	126·92
Iridium	77	Ir	193·1

Krypton	36	Kr	82·92
Lanthanum	57	La	139·0
Lead	82	Pb	207·20
Lithium	3	Li	6·94
Lutecium	71	Lu	175·0
Magnesium	12	Mg	24·32
Manganese	25	Mn	54·93
Mercury	80	Hg	200·6
Molybdenum	42	Mo	96·0
Neodymium	60	Nd	144·3
Neon	10	Ne	20·2
Nickel	28	Ni	58·68
Niobium (Columbium)	41	Nb	93·1
Niton (radium emanation)	86	Nt	222·4
Nitrogen	7	N	14·08
Osmium	76	Os	190·9
Oxygen	8	O	16·00
Palladium	46	Pd	106·7
Phosphorus	15	P	31·04
Platinum	78	Pt	195·2
Potassium	19	K	39·10
Praseodymium	59	Pr	140·9
Radium	88	Ra	226·0
Rhodium	45	Rh	102·9
Rubidium	37	Rb	85·45
Ruthenium	44	Ru	101·7
Samarium	62	Sa	150·4
Scandium	21	Sc	44·1
Selenium	34	Se	79·2
Silicon	14	Si	28·3
Silver	47	Ag	107·88
Sodium	11	Na	23·00
Strontium	38	Sr	87·63
Sulphur	16	S	32·06
Tantalum	73	Ta	181·5
Tellurium	52	Te	127·5
Terbium	65	Tb	159·2
Thallium	81	Tl	204·0
Thorium	90	Th	232·15
Thulium	69	Tm	168·5
Tin	50	Sn	118·7
Titanium	22	Ti	48·1
Tungsten	74	W	184·0
Uranium	92	U	238·2
Vanadium	23	V	51·0
Xenon	54	Xe	130·2
Ytterbium (Neoytterbium)	70	Yb	173·5
Yttrium	39	Yt	89·33
Zinc	30	Zn	65·37
Zirconium	40	Zr	90·6

For ordinary calculations involving the use of atomic weights, most of these constants, excepting chlorine (35·5), copper (63·5), and zinc (65·5), are rounded off to the nearest whole numbers. The elements just named are then assigned the constants indicated in the brackets. The atomic weight table made by J. J. Berzelius in 1826 has excited admiration on account of its accuracy. With the standard O=16, most of J. J. Berzelius' numbers are remarkably close to those we are using to-day. For instance, with the common elements :

	O.	H.	N.	Cl.	S.	P.	Pb.	Cu.
Berzelius' atomic weights	16	1	14·15	35·47	32·2	31·4	207·4	63·4
To-day's numbers	16	1·008	14	35·46	32·07	31·0	207·1	63·5

This is a testimony to the accuracy of J. J. Berzelius' work and particularly so when the state of the knowledge of analytical chemistry in Berzelius' time is borne in mind.

Are atomic weights whole numbers ?—It must be added that although we are compelled to take the numbers as we find them, yet, the experimental errors involved in a complex operation are great, and these errors are sometimes so obscured by a cloud of auxiliary calculations that they are not always easy to detect. Consequently, G. D. Hinrichs (1893) suggests that **the true atomic weight of an element must be regarded as a limit to which the observed values approach as the disturbing factors are eliminated.**[2] It required a century of measurements on the density of atmospheric nitrogen before the presence of 1 per cent. of argon was detected therein. Accordingly, many chemists firmly believe that the rounded numbers are the best representative values of the atomic weights, and that the small deviations from the rounded numbers indicated in the International Table represent real, if unrecognized, errors of experiment; M. Rudolphi (1901) also attributed the deviations of the atomic weights from whole numbers to the presence of small quantities of unknown elements whose properties are closely allied to the elements with which they are mixed.

Why is oxygen 16 taken as the standard in preference to hydrogen unity ?—During the latter part of the nineteenth century, J. Dalton's (1803) standard hydrogen unity, was used for the atomic weights instead of oxygen 16. Hydrogen was selected as a standard for gas densities and atomic weights because it is the lightest element known. In determining atomic weights, it will be observed that one of them, say A, is arbitrarily fixed as a standard, and the atomic weights of the other elements are fixed through the relations $B=k_1A$; $C=k_2B$; $D=k_3C$; . . . where k_1, k_2, k_3, . . . k_n are numerical ratios. Here, obviously, the numerical ratios referred to the element A as standard are :

$$\frac{B}{A}=k_1\,;\ \frac{C}{A}=k_1k_2\,;\ \ldots\ \frac{N}{A}=k_1k_2\ \ldots\ k_n$$

Hence, since each observed ratio k embodies unknown errors, the errors will accumulate most on that particular ratio which is least directly connected with the standard of reference, A. Consequently, J. S. Stas (1860–65) pointed out, as J. J. Berzelius (1818) did before him, that the determination of the atomic weight of an element should be connected with the standard as directly as possible. Very few compounds of the metals with hydrogen are suitable for an atomic weight determination, while nearly all the elements form stable compounds with oxygen. Hence, if hydrogen be the standard, it is necessary to find the exact relation between the given element and oxygen, and then calculate what that relation would be on the assumption that the relation between hydrogen and oxygen is known. C. W. Blomstrand expressed similar ideas in his *Die Chemie der Jetztzeit* (Heidelberg, 1869) ; he said the atomic weights of practically all the elements are compared with hydrogen through the intervention of oxygen. Hydrogen compounds—hydrides—are comparatively rare ; oxygen compounds—oxides—are common. Hence, the weight ratio between oxygen and hydrogen must be known with great accuracy since a small error becomes cumulative and it becomes serious in elements with a large atomic weight—*e.g.* with uranium, the experimental error is multiplied about 15 times. Every improved determination of the relation between hydrogen and oxygen would then be followed by an alteration in the weight of every other element whose value, with respect to hydrogen as a standard, has been determined by the indirect process just indicated, for as J. J. Berzelius said in 1816, oxygen is a kind of nucleus about which chemistry has grown. The determination of the exact relation between hydrogen and oxygen appears to be more difficult than many other determinations, and hence, the majority of chemists think it better to refer the atomic weights of the elements to oxygen 16 as the standard instead of making the atomic weights depend on the more or less uncertain relation H : O. Hydrogen is a theoretical standard, oxygen is the real basis. The standard oxygen 16 is quite arbitrary. G. D. Hinrichs (1893) proposed carbon (diamond)=12 as the standard of reference. T. Thomson (1825) used oxygen 1; W. H. Wollaston (1814), oxygen 10; J. S. Stas (1860–65), oxygen 16; and J. J. Berzelius (1830) oxygen 100 as standard. The latter number makes the atomic weights of many elements inconveniently large, and if the atomic weight of oxygen be any whole number less than 16, fractional atomic weights will be required. The use of the oxygen O=16 unit involved the least change in the number in vogue when hydrogen unity was the standard.

This question of a standard is not of mere academic interest, because, in buying and selling ores on the percentage amount of contained metal, a difference in the atomic weight selected may involve appreciable differences in the estimated value of the ore. For instance, if oxygen be taken 16, the corresponding atomic weight of antimony is 119·9, and of uranium 239·61; if hydrogen be taken as unity, these values become respectively 118·9 and 237·65—differences of one and two units.[3]

§ 11. The Relation between the Molecular Weights and the Volumes of Gases

The theory of molecules is an ideal conception placed by the mind like another Atlas underneath a measureless world of facts to give them intelligible cohesion and hold them up to view.—S. BROWN.

The molecular weight of any gas is numerically equal to the weight of any volume of the gas when the weight of an equal volume of hydrogen under the same physical conditions of temperature and pressure is 2. Two grams of hydrogen, taken as the standard, occupy **22·3** to **22·4** litres at normal temperature—0°—and normal pressure—760 mm. of mercury. Hence, it follows directly from Avogadro's hypothesis that **the molecular weight of any gas, expressed in grams, occupies approximately 22·3 litres at 0° and 760 mm. pressure.** Consequently, to find the molecular weight of a gaseous substance, weigh 22·3 litres of the gas at a convenient temperature and pressure; calculate the corresponding volume at 0° and 760 mm. pressure, and calculate by proportion the weight of 22·3 litres.

EXAMPLE.—A litre of gas at 20° and 730 mm. weighs 1·764 grams, what is the molecular weight of the gas? By the method of calculation indicated in the next chapter, one litre of a gas at 20° and 730 mm. pressure contracts to 894·5 c.c. at 760 mm. and 0°. Hence, if 894·5 c.c. weigh 1·764 grams, 22·3 litres will weigh 43·97 grams. Hence the molecular weight of the gas is nearly 44.

It must here be mentioned that the number 22·3 is not quite right for all gases. Many gaseous molecules have a slight attraction for one another, so that the molecules are slightly more closely packed than is represented by Avogadro's hypothesis. The greater the intermolecular attraction, the greater the weight of 22·3 litres, and consequently, the less the volume of a molecular weight of the gas expressed in grams. Thus, experiment shows:

Hydrogen.	Oxygen.	Nitrogen.	Chlorine.	Hydrogen chloride.	Carbon dioxide.	Steam (0°, 760 mm.).	Mercury.
22·40	22·39	22·45	22·01	22·22	22·26	22·39	22·55

The deviation from 22·3 can be neglected in ordinary chemical calculations.

The molecular weight of a compound not only tells us a weight, but it also tells us that if the molecular weight be expressed in grams, the substance when gaseous will occupy 22·3 litres at 0° and 760 mm. Further, **the molecular weight of a gas, expressed in kilograms, occupies, approximately, 22·3 cubic metres at 0° and 760 mm. pressure.** By mere chance, the number of avoirdupois ounces in a kilogram is 35·26, which is very nearly the same as the number of cubic feet in a cubic metre (35·31)—J. W. Richards.[1] The difference is only one-seventh of 1 per cent. Hence, the **molecular weight of any gas, expressed in avoirdupois ounces, occupies, approximately, 22·3 cubic feet at 0° and 760 mm. pressure.** These factors are useful in calculations involving cubic feet, cubic metres, and litres.

§ 12. Chemical Equations and Chemical Arithmetic

> In his calculations, the chemist relies on the supposed numerical relations of the invisible, intangible, immeasurable particles he calls atoms. These relations have been determined by others in whom he has confidence, and the accuracy of these relations has to be accepted on faith.—H. C. BOLTON.

The molecular weight of an element or compound is the sum of the atomic weight of each of the atoms of the constituent elements.—Let a molecule be composed of n_1 atoms of one element, n_2 atoms of another, n_3 atoms of a third, and so on; further, let A_1, A_2, A_3, . . . , denote the atomic weights of the respective elements, then the molecular weight of the compound will be $n_1A_1+n_2A_2+n_3A_3+$ . . . For example, with the approximate atomic weights, the molecular weight of hydrogen, H_2, is 2; of water, H_2O, 18; of sulphuric acid, H_2SO_4, 98; and of ferrous ammonium sulphate, $FeSO_4.(NH_4)_2SO_4.6H_2O$, 392—since the summation furnishes $56+32+4\times16+2(14+4)+32+4\times16+6(2+16)=392$.

The process or art of calculating the numerical relations of the elements and their compounds is sometimes called **stoichiometry**—from the Greek στοιχεῖα, a fundamental constituent; μετρέω, I measure. The term appears to have been devised by J. B. Richter, in his book, *Anfangsgrunde der Stöchyometrie oder Messkunst chymischer Elementes* (Breslau, 1792–3), or, *The rudiments of stoichiometry or the numerical relations of the chemical elements*, for that branch of chemistry which deals with the numerical proportions in which substances combine. To-day the term is sometimes extended to comprise molecular and atomic weight determinations and also the general measurable properties of solids, liquids, and gases; solutions and mixtures; etc.—witness, S. Young, *Stoichiometry* (London, 1908).

When the initial and final products of a chemical reaction as well as the composition and proportions of the molecules concerned in the reaction are known, the facts can usually be symbolized or abbreviated into a kind of shorthand expression which takes the form of a chemical equation. There are some limitations which will be described later.

The equation indicates the nature of the different substances concerned in the reaction; as well as the proportions of the different substances which occur in the initial and final products of the reaction.—For instance, when mercury is heated in air and mercuric oxide, HgO, is formed, the reaction can be represented in symbols: $2Hg+O_2=2HgO$. We here ignore the nitrogen of the air because, so far as we can tell, it plays no direct part in the chemical reaction. Similarly, when mercuric oxide is heated to a high temperature, it decomposes, forming metallic mercury and oxygen. In symbols, $2HgO=2Hg+O_2$. The symbol = or → is used instead of the words "produces" or "forms," and the symbol + is used for "together with" on the right side of the = sign, and for "reacts with" on the left side. The latter equation reads: "Two molecules of mercuric oxide, on decomposition, produce a molecule of oxygen and two molecules of monatomic mercury." The number and kind of the atoms of the two sides of the equation must always be the same (persistence of weight).

The equation indicates the proportions by weight of the substances concerned in the reaction.—The atomic weight of mercury is 200, and the atomic weight of oxygen is 16, hence, the molecular weight of mercuric oxide is 216, and of oxygen 32. The latter equation can therefore be read: "432 grams (ozs. or tons) of mercuric oxide in decomposing form 32 grams (ozs. or tons) of oxygen gas and 400 grams (ozs. or tons) of metallic mercury." Hence, the chemical equation can be employed in all kinds of arithmetical problems dealing with weights of substances formed or produced.

Examples.—(1) How much mercuric oxide is required to furnish 20 grams of oxygen gas? Write down the proper equation; write 432 below the mercuric oxide, and 32 below the oxygen. We are not concerned with the mercury in this problem. Since we read from the equation: 32 grams of oxygen are furnished by 432 grams of mercuric oxide, one gram of oxygen will be furnished by $432 \div 32 = 13{\cdot}5$ grams of mercuric oxide; and 20 grams of oxygen will come from $20 \times 13{\cdot}5 = 270$ grams of mercuric oxide.

(2) Show that $2\frac{2}{9}$ grams of oxygen and $27\frac{7}{9}$ grams of mercury can be obtained theoretically from 30 grams of mercuric oxide. Obviously, 432 grams of mercuric oxide will give 32 grams of oxygen, therefore 30 grams of mercuric oxide will give $2\frac{2}{9}$ grams of oxygen.

The equation indicates the proportion by volume of the gases concerned in the reaction.—We have seen in the preceding section that if we express

Molecular weight in	Volume at 0° and 760 mm. per molecular weight.
Grams	**22·3 litres**
Kilograms	**22·3 cubic metres**
Ozs. (avoir.)	**22·3 cubic feet**

Consequently, the idea conveyed by the equation, $2HgO=O_2+2Hg$, can be expressed in these words: "432 grams (kilograms or ozs.) of mercuric oxide will furnish 32 grams (kilograms or ozs.) of oxygen, or 22·3 litres (cub. metres or cub. ft.) of oxygen gas at 0° and 760 mm. and 400 grams of mercury."

Examples.—(1) What volume of oxygen will be obtained by heating 30 grams of mercuric oxide? 432 grams of mercuric oxide will furnish $30 \times 22{\cdot}3 \div 432 = 1{\cdot}55$ litres of oxygen gas at 0° and 760 mm. pressure.

(2) How much mercuric oxide will be needed for 10 cub. ft. of oxygen gas at 0° and 760 mm. pressure? Here 22·3 cub. ft. of the gas come from 432 ozs. of mercuric oxide, hence, $432 \times 10 \div 22{\cdot}3 = 193$ ozs., or 12 lbs. 1 oz. of mercuric oxide are required.

It will be observed that in these examples it has been assumed that the reactions go to an end. This is an idealized imaginary condition which rarely obtains in practice where other factors—temperature, concentration, unequal mixing, etc.—introduce disturbances. In practice, there are nearly always some losses, and the actual yield is x per cent. of that theoretically possible on the assumption that the idealized equation is the limit or goal of perfection. In order to make sure that a reaction will proceed to an end, y per cent. excess of the initial products may be required. Each reaction, in this respect, has its own specific character. For example, the formation of nitric acid, HNO_3, by heating sulphuric acid, H_2SO_4, with sodium nitrate, $NaNO_3$, is represented by the equation: $2NaNO_3+H_2SO_4=2HNO_3+Na_2SO_4$, where 170 parts of sodium nitrate apparently require 98 parts of sulphuric acid to produce 126 parts of nitric acid. The manufacturer, however, has found by a process of trial and failure that under his conditions, an excess of about 80 more parts of sulphuric acid are needed to convert the 170 parts of sodium nitrate into nitric acid. The equation would then be more correctly written: $2NaNO_3+1·817H_2SO_4=2HNO_3+Na_2SO_4+0·817H_2SO_4$, where the excess $0·817H_2SO_4$ on both sides of the equation does not cancel out when the reaction is applied under industrial conditions. This, however, makes no difference to the general principles of chemical arithmetic here discussed. If the limitations of the stoichiometrical rules be not appreciated by the industrial chemist, his work will be considerably hampered. In general, the rigid application of fixed (scientific) principles, without a due appreciation of their limitations, is disastrous in the application of scientific methods in industrial work where success is estimated, not by the profoundness of a theory, but by the results achieved, or dividends secured.

§ 13. The Relation between Atomic and Combining Weights—Valency

Die Valenz nur ein Ausdruck des Gesetzes der multiplen Proportionen ist.—C. W. Blomstrand (1869).

Each atom carries into its combinations two things: first, its own proper energy; and second, the faculty of expending this energy in its own way, in attaching other atoms to itself, not indiscriminately, but definite atoms and in definite numbers.—C. A. Wurtz (1869).

Observation shows that the relative combining weights of oxygen and hydrogen are very nearly as O : H=8 : 1; and that the atomic weights of oxygen and hydrogen, deduced from the atomic theory and Avogadro's hypothesis, are very nearly as O : H=16 : 1. In fine, the atomic weight of oxygen is twice its combining weight. For carbon in carbon dioxide, the combining weight is 3, while the atomic weight of carbon is 12, that is, the atomic weight of carbon is four times the combining weight. In the case of hydrogen and chlorine, the atomic and combining weights are the same. In A. W. Hofmann's *Introduction to Modern Chemistry* (London, 1865), it is emphasized that the *atomic weight* of an element represents the minimum quantity of an element which can take part in forming a molecule of a compound; the equivalent, or combining weight of an element, represents the minimum quantity of an element which is required to fix one atom of hydrogen taken as a standard; and the *valency* or *valence* (*valens*, worth), or the atom-fixing power of an element, represents the number of times the combining or equivalent weight is contained in the atomic weight. In illustration,

	Hydrogen.	Chlorine.	Oxygen.	Nitrogen.	Carbon.
Atomic weight .	1	35·5	16	14	12
Combining weight .	1	35·5	8	4·67	3
Valency . . .	1	1	2	3	4

Consequently, as a first approximation,

$$\frac{\text{Atomic weight}}{\text{Combining weight}}=\text{Valency.}$$

Elements, however, may have more than one equivalent or combining weight, and since the atomic weight remains constant, an element may have more than one valency. Consequently, an atom not only has the power of fixing an atom of another element, but, under definite conditions, it has a definite number of such powers.

Although valency is primarily a number or a numerical ratio, the term is also used to express a general characteristic of the elements. **The valency of an element (or radicle) represents the general property of an atom (or radicle) to combine with a certain definite number of other atoms (or radicles).** In order to avoid confusing valency a number with valency a property, some restrict the use of the term so that *valency is reserved for the property, and valence for the number*; thus, mercury is an element with a valency of one or two, and in mercuric chloride, $HgCl_2$, mercury has a valence of 2, and in mercurous chloride, HgCl, a valence of one. This suggestion is good when there is any risk of confusion.

The meaning of valency can be represented another way. Numerous observations indicate that there is generally a limit to the number of atoms which can unite with a given atom, so that the atoms of an element appear to differ from one another with respect to the number of other atoms with which they habitually combine; valency may then be regarded as representing a *habit* of an element for combination; it has nothing to do with the force holding the atoms together. The valence of an element is obtained by finding—directly or indirectly—how many atoms of hydrogen can combine with or be replaced by an atom of the given element. The valence of hydrogen is always taken as unity. Hence the definition: **The valence of an element is a number which expresses how many atoms of hydrogen, or of other atoms equivalent to hydrogen, can unite with one atom of the element in question.** Strictly speaking, *valency is only applicable to those gases and liquids whose molecular weights have been determined;* and it is extended to solids by analogy with gases. We do not know the molecular weights of solids, and we therefore do not know if the valency concept can be extended to solids; it may possibly require modification.

Chemical affinity and valency are both peculiar but essentially different properties of the atom, and they must not be confounded. The terms, however, are sometimes used synonymously, since valency could not be manifested between two elements which have no affinity for one another. **Affinity refers to the act of chemical combination; valency governs the form of chemical combination.** The intensity of the chemical energy displayed by hydrogen, oxygen, nitrogen, and carbon, in the act of combining with chlorine, is very different—chlorine unites with hydrogen with great avidity; with carbon the action is so sluggish that it requires a powerful stimulant: while, the union of chlorine with oxygen and nitrogen is so difficult that it can only be effected indirectly, not directly. On the other hand, however vigorous the act of combination, the hydrogen atom is so constituted that it can unite with only one atom of chlorine, while carbon can unite with four, nitrogen with three, and oxygen with two. If the energy of the combination of chlorine with these four elements be represented by the amount of heat, evolved (+) or absorbed (—) during the combination, the chemical affinity is approximately:

	HCl.	OCl_2.	NCl_3.	CCl_4.
Chemical affinity .	+22·0	−8·9	−12·8	+5·2 units
Valency . .	1	2	2	4
	Stable.	Unstable.	Very unstable.	Stable.

A. S. Couper (1858), one of the pioneers in clarifying our ideas about valency, distinguished the two concepts by calling the former *affinity of kind*, and the latter *affinity of degree*. Affinity of kind, said he, is the specific affinities manifested by the elements the one for the other; affinity of degree is the grades or limits of combination which the elements display.

According to the law of multiple proportions, the states of saturation of the elements change *per saltum;* so also according to the doctrine of valency the affinities of the elements are exhausted by stages. The two conceptions are not identical. According to the latter, each element has a capacity for saturation which is definite for a given combination, but which varies from element to element. In 1858, S. Cannizzaro explained the difference by comparing the two series of chlorides: $HgCl$ and $HgCl_2$; $CuCl$ and $CuCl_2$; etc., and he added that the law of multiple proportions asserts that the quantities of an element contained in different molecules must be whole multiples of one and the same quantity; but this law cannot foresee that one atom of the element is equivalent in one case to one atom of hydrogen and in the second case to two atoms of hydrogen.

Nomenclature.—With hydrogen and chlorine, the atomic and combining weights are the same, and the valency is unity. These elements are accordingly said to be univalent, or monads; for similar reasons, oxygen is bivalent, or a dyad; nitrogen is tervalent, or a triad; carbon is quadrivalent, or a tetrad; and so on to octovalent elements or octads. The valency of an element is frequently represented by attaching the necessary numbers, in dashes or Roman numerals, to the top right-hand corner of the symbol for the element, as suggested by W. Odling in 1855. Thus, the symbols H^{I} and Cl^{I} respectively mean that hydrogen and chlorine are univalent; O^{II} means that oxygen is bivalent; N^{III} means that nitrogen is tervalent; and C^{IV} that carbon is quadrivalent. By collecting together a few compounds with their symbols the idea can be made clearer.

Univalent.	Bivalent.	Tervalent.	Quadrivalent.	Quinquevalent.	Sexivalent.
$H^{I}Cl^{I}$	$Ba^{II}O^{II}$	$H_3{}^{I}N^{III}$	$H_4{}^{I}C^{IV}$	$P^{V}F_5{}^{I}$	$S^{VI}F_6{}^{I}$
$Na^{I}Cl^{I}$	$Mo^{II}Cl_2{}^{I}$	$Fe^{III}Cl_3{}^{I}$	$C^{IV}Cl_4{}^{I}$	$W^{V}Br_5{}^{I}$	$U^{VI}F_6{}^{I}$
$K^{I}I^{I}$	$Zn^{II}Cl_2{}^{I}$	$Mo^{III}Cl_3{}^{I}$	$Mo^{IV}Cl_4{}^{I}$	$Mo^{V}Cl_5{}^{I}$	$Mo^{VI}F_6{}^{I}$

Some heptads and octads are known. Hence, the valency of all known atoms can be represented by an integer ranging from 0, 1, 2, . . . to 8. The elements generally combine in such a way that an equal number of valencies are opposed to one another.

No chemical compound is known to be formed by the union of the elements of the argon family, the so-called inert or noble gases. So far as our knowledge goes, these gases have therefore a **zero-valency**, and the elements appear to be **non-valent.** Any element existing free in a monatomic condition is non-valent in the sense that its atoms are not united with others by means of valency bonds; but the two cases differ in that the maximum valency of the latter is n units, while that of the inert gases is zero.

A few examples of radicles of different valency may be quoted: *Monad radicles*—OH, CN (generally written "Cy"), NO_3, NH_4 (sometimes written "Am"), COOH, etc. *Dyad radicles*—SO_4, SO_3, CO_3, SiO_3, etc. *Triad radicles*—PO_4, $FeCy_6$, etc. *Tetrad radicles*—$FeCy_6$, SiO_4, etc. There are some important hydrocarbon radicles—CH_3, called *methyl*; C_2H_5, *ethyl*; C_3H_7, *propyl;* C_4H_9, *butyl;* C_5H_{11}, *amyl;* etc. The members of the group of hydrocarbon radicles with the general formula C_nH_{2n+1}, are called the *alkyl radicles.* The members of the group, C_nH_{n-1} radicles—C_6H_5, *phenyl;* $C_6H_4.CH_2$, *benzyl,* etc.—are called the *aryl radicles.* There are also many other uni- and poly-valent hydrocarbon radicles.

Structural, graphic, or constitutional formulæ.—The valency of an element is sometimes represented by attaching the necessary number of hyphens to the symbol for the element. This enables the molecules of a substance to be represented by a kind of graphic formula. The symbol for hydrogen will have one hyphen; oxygen, two; nitrogen, three; carbon, four; etc.; a bivalent oxygen atom may be represented O^{II}, $-O-$, $O=$, $O<$, etc. The hyphens are usually attached so that the graphic formula occupies as little space as possible; they are drawn in the most convenient direction. The atoms of a molecule are then supposed to be joined together by their valencies; and this is represented diagrammatically by hyphens. The symbol for hydrogen chloride then becomes $H-Cl$; potassium iodide, $K-I$; water, $H-O-H$; mercuric oxide, $Hg=O$; a molecule of hydrogen, $H-H$; a molecule of oxygen, $O=O$; carbon dioxide, $O=C=O$; and

$$H-N{<}^{H}_{H}$$

Ammonia.

$$O{<}^{Fe=O}_{Fe=O}$$

Ferric oxide.

$$^{H}_{H}{>}C{<}^{H}_{H}$$

Methane.

Accordingly, the terms *bonds* or *links* are sometimes employed as well as *valencies.*

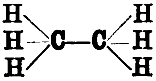
Graphic formulæ are also called structural or constitutional formulæ. *Structural formulæ primarily assume that the chemical properties of a substance are determined by the arrangement of the atoms in the molecules; and if the molecules of two compounds of the same chemical composition have their atoms differently arranged, the properties of the two compounds will be different.* Graphic formulæ are sometimes very convenient for representing the composition of compounds, but the student would err rather seriously if he supposed that the symbol given above for, say, methane represents the way the atoms are actually grouped in the molecule of methane. This would involve a leap far beyond our real knowledge, although the available evidence is in favour of the view that the atoms have a definite arrangement in the molecule, and, in some cases, the little knowledge we do possess can be better summarized by a graphic formula than in any other way. The graphic formula furnishes a clearer mental image of the curious way certain groups of atoms remain clustered together through a complex series of chemical changes than if the reaction were represented by ordinary symbols. The structural formula has a real and important signification ; it should symbolize the chemical character of the molecule. A graphic formula is thus a kind of dummy model illustrating the way a compound is formed, how it decomposes, and the relations between one compound and another. Indeed, chemists now investigate the position of a particular atom in a chain or ring of atoms, and find it to be at the side, in the middle, or in some other position relative to the remaining atoms. Without accepting C. F. Gerhardt's contention (1856) that *les formules chimiques ne sont pas destinées à représenter l'arrangement des atomes*,[1] it must not be believed for one moment that the model simulates reality since, for one thing, the formulæ are built on a plane two-dimensional surface, whereas the molecule probably extends into three dimensions ; again, graphic formulæ make the molecule appear as a fixed rigid structure, whereas there is some evidence indicating that the atoms within the molecule are in ceaseless rhythmic motion. The remarkable work which has been done by the aid of structural formulæ will always justify their use in the past and present, whatever future generations may think of them. The wonderful development of organic chemistry, said J. U. Nef (1904), is a consequence of the simple valency concept.

The doctrine of valency has furnished the chemist with a basis for calculation, and enabled him to deduce algebraically the existence of series of compounds previously unknown. It has been said that the theory of valency has enabled the chemist to predict reactions of unknown compounds with other known compounds, and enabled him to found a mechanics of the atoms which in another direction is as wonderful as the mechanics of the astronomer which has enabled him to fix the position and path of an invisible planet from its effect on the movements of one visible and known. Although the theoretical limitation seems valid in the majority of cases, yet there are several compounds whose existence appears contrary to the valency hypothesis—*e.g.* nitric oxide. However, where investigation is guided by a wrong theory, only those things which are sought are likely to be found, and the theoretical limitation may not have any real counterpart in nature. Hence, A. G. V. Harcourt [2] could say :

> A chemist who should depart from the general course, and set himself to prepare substances whose existence is not indicated by theory, would perhaps obtain results of more than usual interest.

Maximum and active valency.—Most elements have more than one valency. Stannous oxide has a composition corresponding with SnO ; and stannic oxide, with SnO_2. In the former case, the tin is said to be bivalent ; and in the latter, quadrivalent. There are thus two series of tin compounds—stannous and stannic. Similarly with copper, iron, etc. There are also two carbon oxides, carbon monoxide, CO, and carbon dioxide, CO_2. If carbon monoxide could be written $O{=}C{=}C{=}O$, and there is nothing in the analysis by weight which prevents this, all might be well ; but writing the formula in this manner would involve a contradiction of Avogadro's hypothesis, since the vapour density of carbon monoxide corresponds with the molecule CO, not C_2O_2. We cannot see the way clear to admit carbon monoxide as an exception to Avogadro's hypothesis, for that would introduce confusion into our system, and there would be no immediate prospect of restoring order. Some get over the difficulty by assuming that two of the free valencies in carbon monoxide mutually saturate one another, and write the graphic formula

$O{=}C\colon$; others assume that oxygen is quadrivalent, and write the graphic formula for carbon monoxide $C{\equiv}O$; and for carbon dioxide, $C{\lessdot}^{O}_{O}$, the two oxygen atoms are supposed to be doubly linked to one another and to the carbon atom. The question is therefore somewhat involved. The case of sulphur bivalent in hydrogen sulphide, $H{-}S{-}H$; quadrivalent in sulphur dioxide $O{=}S{=}O$; and sexivalent in sulphur trioxide $O_2{\equiv}S{=}O$, fits very well into this scheme. So do the series of compounds represented by ethane, C_2H_6 ; ethylene, C_2H_4 ; and acetylene. C_2H_2, which can be respectively represented by the graphic formulæ :



Ethane (with single bonds)

$$\begin{matrix}H\\H\end{matrix}{>}C{=}C{<}\begin{matrix}H\\H\end{matrix}$$

Ethylene (with double bonds)

$$H{-}C{\equiv}C{-}H$$

Acetylene (with triple bonds)

provided it be assumed that the respective carbon atoms are joined by single, double, and triple bonds. It may be added that the circumstantial evidence advanced by organic chemistry strongly favours this assumption.

Since chlorine or fluorine forms combinations with the metals far more generally than does hydrogen, it has been proposed to use chlorine or fluorine in place of hydrogen as the standard of valency. The hydrogen and fluorine valencies, however, are not always the same. For instance :

Hydrides . .	LiH	CaH_2	$(BH_3)_2$	CH_4	PH_3	SH_2	IH	—
Fluorides . .	LiF	CaF_2	BF_3	CF_4	PF_5	SF_6	IF	OsF_8

The maximum valency of the hydrides is thus attained with the tetrads ; but with fluorides, the maximum valency is reached with the octads. The preceding definition of valency is troublesome if applied to azomide, HN_3, although it works all right with ammonia, NH_3.

F. A. Kekulé (1866)[3] argued that valency is a fundamental property of the atom which is just as constant and invariable as the atomic weight ; the equivalent weight of an element may vary, the valency cannot. E. Frankland (1852) showed that the elements of the nitrogen family are sometimes ter- and sometimes quinquevalent. A controversy whether valency is fixed or variable was carried on about 1864 by F. A. Kekulé, C. A. Wurtz, A. Naquet, H. Kolbe, and A. W. Williamson. The controversy, after all, turned out to be nothing more than *ein Streit um ein Wort*. If valency means maximum saturation capacity, this property is unchangeable, but if valency means that this maximum power is always exerted, and that every atom exerts a constant invariable valency, the doctrine *est en désaccord flagrant avec les faits*. The discussion was then diverted to atomic and molecular compounds (*q.v.*). **Each element has a maximum valency towards certain other elements.** When an element appears to have a lower valency than its maximum valency, the compound is said to be an **unsaturated compound,** in contrast with a **saturated compound** in which the atoms are exercising their maximum valency. In many unsaturated compounds, the valencies appear to diminish in pairs. The pairs of *dormant* or *sleeping valencies*, *crypto-valencies* (κρυπτός, hidden), or *latent* or *passive valencies* are supposed to be self-saturated. Hence W. Odling (1855) proposed to call elements with an odd number of bonds *perissads* (περισσός, odd), and those with an even number of bonds *artiads* (ἄρτιος, even). It was also assumed that the sum of the valencies of the atoms forming a molecule is always an even number.

As a matter of fact, the hypothesis of the self-saturation of the bonds in pairs breaks down completely. The idea probably arose from the application of an inaccurate hypothesis—started in 1864 by E. Erlenmeyer[4]—which is stated in some of the older books on chemistry in words like these : " All chemical evidence shows that a body with unsatisfied bonds cannot exist by itself." All chemical evidence, as we shall see, shows nothing of the kind. Mercury and many other elements, when vaporized, give gases with one-atom molecules. The principle of self-saturation breaks down when applied to the nitrogen oxides, say nitric oxide, $N^{III}O^{II}$. The relative density (Avogadro's hypothesis) will not let us write N_2O_2, that is, $O{=}N{-}N{=}O$. We are therefore confronted with what appears to be an odd unsaturated valency in the molecule $-N{=}O$. Again, chlorine forms chlorine monoxide, Cl_2O, and chlorine peroxide, ClO_2; indium forms the three chlorides, InCl, $InCl_2$, $InCl_3$. The original form of the doctrine of valency is not tenable; elements cannot be classed as invariably uni-, bi-, ter-, quadri-, . . . valent, nor as artiads and perissads, since some elements can have any of these valencies according to circumstances. Chlorine, nitrogen, ruthenium, and manganese can be cited as examples; again, molybdenum forms a series of compounds with univalent chlorine or fluorine—$MoCl_2$, $MoCl_3$, $MoCl_4$, $MoCl_5$, and MoF_6; and vanadium forms VCl_2, VCl_3, VCl_4, and VCl_5. In view of facts like these, it is difficult to maintain the thesis that the apparent inconstancy of the valency of an element is due to the mutual saturation of pairs of valencies. Either a molecule can exist with free valencies, or Kekulé's maximum valency hypothesis breaks down when confronted with facts.

A great many ingenious hypotheses, more or less satisfactory, have been suggested to explain the difficulties. At present we are compelled to frankly admit with W. Lossen (1880) and A. Claus (1881) that **the active valency of an element is a variable habit of combination.** An explanation of the meaning of valency is thus left open. C. A. Wurtz (1864) distinguished between what he called *atomicité actuelle* and *atomicité virtuelle*, and in order to distinguish between the greatest valency an element is known to exhibit, and the valency which actually prevails in a particular compound, the terms **maximum or absolute valency** and **active or actual or free valency** may be respectively employed. So far as we can see, **the active valency of an element is dependent upon the properties of the atoms of the other elements with which it is combined as well as on the prevailing physical and chemical conditions to which the element is exposed.** Thus sulphur is bivalent towards hydrogen, but it can be sexivalent with fluorine; antimony, arsenic, and phosphorus are tervalent towards hydrogen, while phosphorus and antimony may be quinquevalent towards chlorine; arsenic is tervalent towards chlorine—and there is some doubt if the pentachloride, $AsCl_5$, has been made.

Werner's Nomenclature.—With a complex series of salts, instead of representing the number of times the acidic radicle is contained in the molecule—*e.g.* CuCl, copper monochloride; $CuCl_2$, copper dichloride; CuO, copper monoxide; $PtCl_4$, platinum tetrachloride, etc.—it is simpler, according to A. Werner.[5] to represent compounds with the same valency by names ending in the same suffix or letter. Thus, if M represents an atom of a basic element, and X an atom of acidic univalent element,

TABLE VII.—A. WERNER'S NOMENCLATURE OF SALTS.

Compound.	Valency.	Termination.	Examples.	
			Werner's name.	Old name.
MX	uni-	a	CuCl—cupr**a**chloride	copper monochloride
MX_2	bi-	o	$CuCl_2$—cupr**o**chloride	copper dichloride
MX_3	ter-	i	$MoCl_3$—molybden**i**chloride	molybdenum trichloride
MX_4	quadri-	e	$MoCl_4$—molybden**e**chloride	molybdenum tetrachloride
MX_5	quinque-	an	$MoCl_5$—molybd**an**chloride	molybdenum pentafluoride
MX_6	sexi-	on	MoF_6—molybd**on**fluoride	molybdenum hexafluoride
MX_7	septi-	in	Cl_2O_7—chlor**in**oxide	chlorine heptoxide
MX_8	octi-	en	OsO_4—osmium**en**oxide	osmium tetroxide

The suffixes have been chosen to make them differ as little as possible from those already in existence. The only serious objection appears to arise with salts like univalent and bivalent copper, mercury, etc., of the type $CuCl$, $CuCl_2$; and $HgCl$, $HgCl_2$, where cuprous becomes cupra-, and cupric, cupro-; and mercurous becomes mercura-, and mercuric, mercuro-.

The effect of external conditions on the valency of an element.—Active valency has been compared with friction in so far as it appears to be called into play by external causes which may vary from zero upwards, because the valency of an element is determined by the physical and chemical conditions under which the element is placed. For instance,

(1) *Temperature.*—The valency of an element generally diminishes with rise of temperature, *e.g.* sulphur trioxide, SO_3, when heated dissociates into sulphur dioxide, SO_2, and oxygen; and carbon dioxide, CO_2, into carbon monoxide, CO, and oxygen. Copper oxide, CuO, at 1110° becomes cuprous oxide, Cu_2O; and lead dioxide, PbO_2, at 615° yields lead monoxide, PbO.

(2) *Pressure.*—The valency of an element is often diminished with a decrease of pressure. Pressure usually facilitates chemical action. By heating bismuth with water at 280° under a pressure of 10,000 atm. the monoxide, BiO, is formed, but at higher temperatures and less pressure the sesquioxide, Bi_2O_3, is produced; similarly antimony is said to form the monoxide, SbO, and aluminium the monoxide, AlO, under conditions where the sesquioxides would normally be produced. Carbon monoxide, CO, under a pressure of 600 atm. at 320° is partially converted into the dioxide, CO_2, and free carbon.

(3) *Light or radiant energy.*—Numerous physical and chemical changes are induced by exposure to light, and the reactions may be accompanied by changes in the valency of some of the elements concerned. Thus, by exposure to light ferric oxalate, $Fe_2{}^{III}(C_2O_4)_3{}^{II}$, is reduced to ferrous oxalate, $Fe^{II}C_2O_4$—in symbols: $Fe_2(C_2O_4)_3=2FeC_2O_4+2CO_2$; and an aqueous solution of mercuric chloride, $HgCl_2$, is reduced to mercurous chloride, $HgCl$, under similar conditions: $4HgCl_2+2H_2O=4HCl+O_2+4HgCl$. Similar remarks, *mutatis mutandis,* apply to the effect of other forms of radiant energy.

(4) *Chemical reagents.*—Changes in the valency of an element are usually induced by oxidizing or reducing agents. Thus, ferrous chloride, $FeCl_2$, is oxidized to ferric chloride, $FeCl_3$, by the action of hypochlorous acid, $HClO$; the reaction is symbolized: $2Fe^{II}Cl_2+HCl+HClO=2Fe^{III}Cl_3+H_2O$; and ferric chloride is reduced to ferrous chloride by the action of sulphur dioxide, $2Fe^{III}Cl_3+SO_2+H_2O=2Fe^{II}Cl_2+2HCl+SO_3$. At the same time, it will be noticed, the sulphur dioxide, $O=S=O$, is oxidized to sulphur trioxide, $O=S\ll\begin{smallmatrix}O\\O\end{smallmatrix}$, where quadrivalent sulphur probably becomes sexivalent. Hence, **oxidation usually involves an increase in the valency of an element, and reduction a decrease.**

§ 14. The Polarity of Valency

> The doctrine that the chemical forces by which the elements of bodies are held together or separated, are identical with the polar forces of electricity is now entirely established in the minds of the most profound and philosophical chemists of our time.—W. WHEWELL.

An agent exhibits polarity when it is characterized not only by a numerical value, but also by a sign indicating the direction in which it will act. For example, during the electrolysis of binary compounds some elements always accumulate at one particular electrode; the hydrogen, for instance, goes to the cathode, never to the anode; and conversely, the oxygen goes to the anode, not to the cathode. It is therefore assumed that hydrogen carries a positive electrical charge, oxygen a negative charge; otherwise expressed, oxygen has a negative polarity, hydrogen a positive polarity.

In 1881, in a paper *On the modern development of Faraday's conception of electricity*, H. von Helmholtz deduced from Faraday's work that during electrolysis the same quantity of either positive or negative electricity (96,540 coulombs) always accompanies each univalent atom, or each valency of a multivalent element, so that the same quantity of electricity passing through an electrolyte always sets free or transfers the same number of units of affinity (or valency) at each electrode. Otherwise expressed, an n-valent atom or radicle carries n unit charges of electricity. Electricity thus behaves as if it were divisible into definite elementary portions—positive or negative—which behave as if there were atoms of electricity. Following G. J. Stoney's proposal (1881), these unit or atomic changes of electricity are called *electrons*.[1] It may therefore be said that valency is a polar phenomenon, each valency being associated with a positive or negative electron. The valency of a univalent hydrogen atom carrying a positive charge can therefore be called a **positive valency,** and each valency of a bivalent oxygen atom carrying two negative charges a **negative valency.** Each positive valency can be represented by a + or · sign attached to the symbol of the element, say H^+ or $H^{\cdot}$; and, in a similar manner, each negative valency represented by a — or ′ sign, say O^{--} or O''. These symbols properly interpreted represent observed facts.

Again, during the electrolysis of certain compounds, some elements—arsenic, antimony, boron, bromine, carbon, iodine, nitrogen, phosphorus, selenium, silicon, sulphur, tellurium, etc.—act sometimes like hydrogen and sometimes like oxygen in that with some compounds a given element may accumulate at the positive pole and with other compounds at the negative pole. Otherwise expressed, the atoms of these elements sometimes carry positive and sometimes negative charges, so that in some compounds the atoms of these elements have positive valencies, and at other times negative valencies. R. Abegg (1904) called these elements with a dual nature *amphoteric elements* (ἀμφί, both). Hence, a description of the valency of an element in a particular compound should indicate whether the active valency is positive or negative. In further illustration, the sulphur in hydrogen sulphide, H_2S, has two negative valencies; and in sulphur trioxide, SO_3, the same element has six positive valencies, so that a change from sulphur with -2 valencies to sulphur with $+6$ valencies involves a change of eight units of electricity—the algebraic difference 8, not the numerical difference 4 units. Similarly, in methane, CH_4, the carbon atom has four negative valencies; in carbon tetrafluoride, CF_4, the carbon atom has four positive valencies; so that the passage from the former to the latter again involves a change of eight valency units. To avoid confusion with valency as a number, the term **polar number** has been employed to represent the algebraic number of negative charges which are lost, or positive charges gained by an atom of an element in the formation of a given compound. The valency and polar number of nitrogen in ammonia are 3 and -3 respectively; the valency of nitrogen in ammonium chloride is 5 and the polar number -3 (*i.e.* $-4+1$), as illustrated in the diagram, Fig. 4. In nitrous acid, HO.N : O, with oxygen negative, the polar number is $+3$, and the valency 3; whereas in $H-N\equiv O_2$, the polar number is still $+3$, but the valency is 5. In potassium permanganate, $KO.MnO_3$, the polar number of manganese is +7, and the valency 7.[2]

D. I. Mendeléeff (1871) assumed that the highest oxide (omitting the peroxide) gives the maximum valency of an element, and R. Abegg (1904) adopted practically the same suggestion for finding the maximum positive valency of an element; J. N. Friend (1908) suggested that the fluoride be employed for the same purpose. The hydrides usually give the numerical values of the negative valency of the non-metals. J. N. Friend (1908) has compiled the following Table VIII showing the positive and negative values of some amphoteric elements with respect to their hydrides and fluorides:

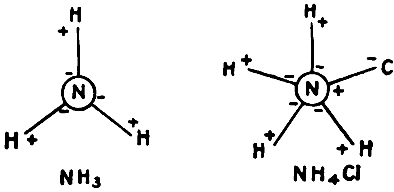

FIG. 2.—Polar Numbers of Nitrogen (−3).

TABLE VIII.—HYDRIDES AND FLUORIDES OF SOME AMPHOTERIC ELEMENTS.

Element.	Negative valency.		Positive valency.		Total valency.
	Hydride.	Active valency.	Fluoride.	Active valency.	
Antimony	SbH_3	3	SbF_5	5	8
Arsenic	AsH_3	3	AsF_5	5	8
Boron	BH_3	3	BF_3	3	6
Bromine	BrH	1	BrF_3	3	4
Carbon	CH_4	4	CF_4	4	8
Iodine	IH	1	IF_5	5	6
Nitrogen	NH_3	3	NOF	3	6
Phosphorus	PH_3	3	PF_5	5	8
Selenium	SeH_2	2	SeF_6	6	8
Silicon	SiH_4	4	SiF_4	4	8
Sulphur	SH_2	2	SF_6	6	8
Tellurium	TeH_2	2	TeF_6	6	8

It is interesting to note that the majority of the known amphoteric elements give 8 as the sum of the positive and negative valencies. R. Abegg (1904), indeed, assumed that all elements are amphoteric and possess 8 positive and negative valencies, but the observed facts with hydrogen, the alkali metals, and the inert gases do not favour this generalization. The positive valencies of the alkali metals appear to be so strong that they show little or no sign of their supposed negative valencies; and the negative valencies of fluorine are so strong that they show little or no sign of positive valencies. R. Abegg and G. Bodländer (1899) developed the hypothesis that elements have a different valency according as they are united with electropositive or electronegative elements; and that each element possesses the two kinds of valency—positive and negative. The usually accepted valencies of the non-metals are negative, and of the metals, positive; R. Abegg and G. Bodländer called these the **normal valencies** of the elements; and the secondary valencies of opposite polarity, active only under special conditions, were called **contra-valencies.** The normal valencies are supposed to be the stronger. The sum of the normal and contra-valencies, as indicated, is assumed to be 8, ranging over the different families of elements:

	Metals.			Non-metals.			
	Na	Mg	Al	Si	P	S	Cl
Normal valencies	+1	+2	+3	+4	−3	−2	−1
Contravalencies	−7	−6	−5	−4	+5	+6	+7
Polar number	−6	−4	−2	0	+2	+4	+6

Thus chlorine is univalent, polar number −1 in hydrogen chloride, HCl, where it is coupled with electropositive hydrogen; but it has its maximum heptavalency, polar number +7, when it is united with electronegative oxygen in chlorine heptoxide, Cl_2O_7. In particular cases, neither all the normal nor all the contra-valencies may be active. The contra-valencies in a particular family of elements increase in activity as the atomic weights of the elements increase; thus, in the halogen family, fluorine (atomic weight 19) does not form a compound with oxygen, while iodine (atomic weight 127) gives a stable oxide. All the normal valencies of an element are supposed to be equivalent, but if one be saturated, the remainder are weakened. Consequently, the active valency of an element depends upon the electrochemical character of the associated atoms—arsenic pentafluoride, AsF_5, for instance, is fairly stable (O. Ruff and H. Graf, 1906), while arsenic pentachloride, $AsCl_5$, is so very unstable that it is doubtful if it really has been prepared (C. Baskerville and H. H. Bennett, 1902). The formation of the so-called molecular compounds by the union of two or more molecules is attributed to the presence of *unsaturated*, *contra*, *or secondary valencies* in at least one of the constituent atoms.

There are some modifications of this theory of valency. Most are agreed about this interpretation of positive and negative valencies; and the formation of double and associated compounds is supposed to be due to the exercise of residual, contra or secondary valencies. L. Spiegel (1902) assumed that elements possess secondary valencies which can be called forth only in pairs of equal and opposite sign, so that when not externally saturated they neutralize one another and impart no electro-chemical characters to the element. Spiegel called these extra-valencies, *neutral affinities*. S. Arrhenius (1904) made a similar assumption and called them *electrical double valencies*, and J. N. Friend (1908) used a similar hypothesis and called the sleeping valencies, *residual or latent valencies*. I. Langmuir (1916) assumed that the aggregation of molecules into liquid and solid masses is due to the exercise of the secondary valencies, and thus the *cohesion* of solids and liquids is due to the exercise of an attraction similar in kind to chemical affinity. The electron hypothesis will be described later.

§ 15. The Association of Atoms in Three Dimensions

The arrangement of the atoms of a molecule in one plane is equally convenient in diagrams, and improbable as a natural fact.—A. G. Vernon Harcourt (1875).

When our views are sufficiently extended as to enable us to reason with precision concerning the proportions of elemental atoms, we shall find the arithmetical relation will not be sufficient to explain their mutual action and we shall be obliged to acquire a geometrical conception of their relative arrangement in all three dimensions of solid extension. . . . When the number of particles (combined with one particle) exists in the proportion of 4 : 1, stable equilibrium may take place if the four particles are situated at the angles of the four equilateral triangles composing a regular tetrahedron. . . . It is perhaps too much to hope that the geometrical arrangement of primary particles will ever be perfectly known.—W. H. Wollaston (1808).

In order to explain why the atoms of diatomic molecules travel about in pairs, it seems to be necessary to assume that the atoms exert an attraction on one another, and that the position of the atoms in space must be conditioned by the attractive forces. As Isaac Newton said in his *Opticks* (London, 1704):

> How the particles which touch only in a few points can stick together and that so firmly as they do, without the assistance of something which causes them to be attracted or pressed towards one another, is very difficult to conceive.

When two univalent atoms unite with one bivalent atom, it is natural to imagine two points of contact, and two directions in which the bivalent atom exerts its power of combination. This conception of direction appears to be almost necessary in the case of carbon with its four valencies, and organic chemists have founded upon this what is known as **stereochemistry** (στερεός, solid), or *chemistry in three dimensions*, or *chemistry in space*, on lines dimly foreshadowed by W. H. Wollaston in 1808, and A. M. Ampère in 1814. Since then, many chemists have thrown out hints of a tridimensional arrangement of the atoms in a molecule—L. Pasteur (1861), F. A. Kekulé (1861), A. M. Butleroff (1863), E. Paternó (1869), A. Gaudin (1873), etc. Thus, in his celebrated lecture, *Recherches sur la dissymétrie moléculaire des produits organiques* (Paris, 1861), L. Pasteur asked: Are the atoms of *d*-tartaric acid grouped on the spiral of a helix winding to the right, or placed at the summits of an irregular tetrahedron, or disposed according to some other asymmetric grouping? and replied: We cannot answer these questions. It was not until the appearance of J. H. van't Hoff's paper, *On a system of atomic formulæ in three dimensions*, in Holland, September, 1874; [1] and J. A. le Bel's *Sur la relations qui existent entre les formules atomiques*, in France, November, 1874, that this idea was systematically developed as a working hypothesis in organic chemistry. After demonstrating the probability of the hypothesis that the carbon atom exerts its valencies in definite directions in tridimensional space, it appeared highly probable that other elements would be found to exhibit the same phenomenon, and thus arose a stereochemistry of nitrogen, sulphur, silicon, selenium, tin, etc. The relative directions of the four valencies of the carbon atom have been studied, and the attempt has been made to find the effect of the displacement of these directions upon the properties of the resulting compounds. It appears to be necessary to assume that the carbon atom is a material body with a certain shape and size, because K. Auwers (1890) has shown that in the case of two carbon atoms united by a double-bond, the linking forces probably act in such a way as to make an angle with each other and not a straight line joining the two points, because the existence of such forces acting from mere point-centres is highly improbable. Without making any suggestion as to the actual form of the tetrahedral arrangement of the valencies of the carbon atom—whether the attractive forces are concentrated at the apices (J. Wislicenus, 1888), or at the centres of the faces (A. Wunderlich, 1886)—organic chemists, following Wollaston's suggestion, find it convenient to represent graphically the four valencies of the carbon as acting in the direction of the line joining the centre with the apices of a regular tetrahedron. According to this hypothesis, the constitution of methane, CH_4, will be that represented in the diagram, Fig. 5, where the circles represent the relative positions of the hydrogen atoms with respect to the central carbon atom; similarly, for ethane, C_2H_6, with a pair of single-linked carbon atoms, Fig. 5, acetylene, C_2H_2, with a pair of triple-linked carbon atoms, Fig. 5; and benzene, C_6H_6, with a chain of six carbon atoms alternately single- and double-linked so as to form a closed chain or ring.

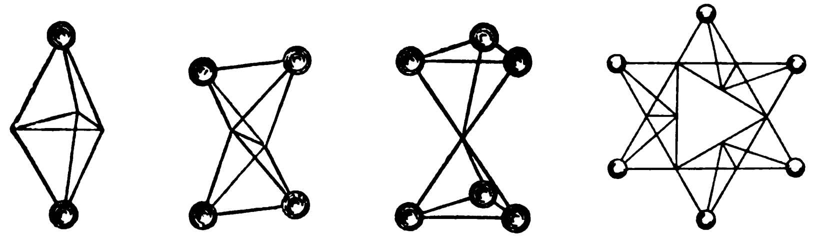

FIG. 3.—Diagrammatic representation of the Tetrahedron Theory of Quadrivalent Carbon with Single-, Double-, and Triple-linked Carbon Atoms.

In the case of double- or triple-linked carbon atoms, are the lines assumed to be normally directed from the centre of the tetrahedron, bent with or without straining, or do the forces act rigidly in one fixed direction so that their components alone act in a direction parallel with the line joining the centres of the two tetrahedra? If it be assumed, with A. Naumann (1890), that the two valencies joining a pair of double-linked carbon atoms in, say, ethylene, C_2H_4, are directed from the centre of a tetrahedron towards the apices, and if each of these forces be resolved in two directions according to the parallelogram of forces, the sum of the components of each of these forces acting in the direction of the line joining the centres of the two tetrahedra, is effective in holding the two carbon atoms together. If the force with two single-linked carbon atoms be taken as unity, the force holding a pair of double-linked atoms will be $0{\cdot}577 \times 2$, and between a pair of triple-linked carbon atoms, $0{\cdot}33 \times 3$. This is not in agreement with J. Thomsen's thermal data.

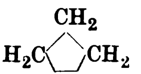
A. von Baeyer, in a paper *Ueber Polyacetyleneverbindungen* (1885), showed that if the four valencies of carbon are directed from a centre towards the four corners of a regular tetrahedron, the lines must make an angle of 109° 28′ with one another; and he made the assumption that if the direction of the attraction be diverted, there will be a corresponding strain; the greater the divergence, the greater the strain; and the greater the strain, the less the stability of the resulting molecule. The negative heat of formation of acetylene with its two carbon atoms connected by a triple bond, and the great instability of the acetylene compounds, show that the three linking bonds of the two acetylene carbons may be under some such strain; otherwise it might be anticipated that a pair of triple-linked atoms would be more stable than a pair of double-linked atoms, and the latter in turn more stable than a pair of single-linked carbon atoms. J. Thomsen's study of the heats of formation of the hydrocarbons (1882) shows that the breaking up of a double-bond requires 15·46 Cals. less thermal energy than a pair of single-bonds, and the breaking of a triple-bond requires 43·92 Cals. less thermal energy than is needed for three single-bonds.

Consequently, **A. von Baeyer's strain theory** of valency—*Spannungstheorie*—assumes that the four valencies of the carbon atom normally act in the direction of the lines joining the centre with the apices of a regular tetrahedron making angles 109° 28′ with one another; and if these directions be bent or diverted, the lines are strained as if they were elastic wires, so that the greater the divergence the greater the strain, and the less the stability of the molecule. It follows that if the carbon atoms all lie in one plane, the angles of divergence with ethylene and with tri-, tetra-, penta-, and hexamethylene, C_nH_{2n}, will be

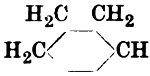
(C_2H_4), 54° 44′
Ethylene

(C_3H_6) 24° 44′
Trimethylene

(C_4H_8), 9° 44′
Tetramethylene



(C_5H_{10}), 0° 44′,
Pentamethylene



(C_6H_{12}), —5° 16′
Hexamethylene

and generally, for a ring compound of this type containing n carbon atoms in the ring, the angle of divergence will be 54° 44′ less $(n-2)\ 90° \div n$. H. Sachse introduced further developments.

This hypothesis explains how the members of the closed ring series increase in stability up to a maximum with pentamethylene, which should be more stable than all the other members of the series, for the higher members decrease in stability with increasing complexity; the theory also explains how organic compounds with open chains have a greater tendency to form closed rings with five and six members than closed rings of greater or less complexity. F. Stohmann and C. Kleber's measurements (1892) of the energy required to break such rings and add two hydrogen atoms are in approximate agreement with this deduction; so also is I. Traube's work (1899) on atomic volumes. There are, however, several series of compounds whose behaviour does not fit in quite so well with the hypothesis. For instance, it will be obvious that the strain theory itself cannot be a sufficient explanation of ring formation because it does not take the influence of chemical affinity into account —*e.g.* the influence of side-chains in facilitating the closing of the ring. H. N. Stokes (1900) applied a similar hypothesis to the phosphimic acids in which the phosphorus atoms form closed rings and the results were in general agreement with the hypothesis.

§ 16. The Evolution of the Valency Concept

> The doctrine of valency is no mere speculation or hypothesis evolved by the brilliant fancy or imagination of one man; it is the logical outcome of knowledge acquired step by step. The conception has been one of slow growth, for it gradually incorporated itself into science as the necessity arose for devising a suitable explanation for accumulated observations.—E. P. Venable (1899).

While the mists which enveloped the concepts, molecule, atom, and equivalent, were being dispelled by illuminating rays of A. Avogadro's hypothesis, many theories to explain chemical composition were struggling for existence. In the resulting controversies—chiefly among J. J. Berzelius, J. B. A. Dumas, J. von Liebig, A. Laurent, and C. F. Gerhardt—the facts were interpreted by different hypotheses; and, as A. Ladenburg (1886) has shown, this was far more favourable for progress than if a single theoretical opinion had come too prominently in front. The differences of opinion quickened interest and experiment, and gave chemistry a very intimate knowledge of many classes of compounds, because the advocate of each hypothesis tried to support his own views by evidence which could be obtained only by a close study of the chemical characteristics of the compounds in dispute. It is difficult for chemists to appreciate the labour involved in clarifying the concepts which now appear so simple. As one writer has said:

> In the glamour of recent discoveries and the attractiveness of what is new and startling, the pioneer spade work of a bygone age is forgotten or undervalued, and A. Carrel adds: Almost every step in scientific progress which appears to be due to the efforts of one individual is, in reality, the result indirectly of the unknown scientific work of many others.

The radicle or radical theories.—In his *Traité élémentaire de chimie* (Paris, 1793), A. L. Lavoisier supposed that chemical compounds were formed by the union of two bodies, and stated his belief that the composition of organic bodies depended upon the existence of complexes or radicles in union with oxygen. Adopting a suggestion of Guyton de Morveau (1787), Lavoisier called that portion of a compound which is combined with oxygen, *la base* or *le radicle*. In developing his celebrated dualistic polar hypothesis, J. J. Berzelius (1817) extended Lavoisier's idea. The dominant feature of Berzelius' hypothesis is that chemical compounds can all be resolved with two distinct parts electrically different. When J. B. A. Dumas and P. F. G. Boullay (1828)[1] announced their belief that ether, $(C_2H_5)_2O$, consisted of two parts—water, H_2O, and a basic radicle, C_2H_4, which was called at the suggestion of J. J. Berzelius *ætherine*—the radicle etherine was thought to be always present in what are now called *ethyl compounds*. For instance, alcohol, C_2H_6O, would have been regarded as a binary compound, $C_2H_4.H_2O$; and ether, $C_4H_{10}O$, as $2C_2H_4.H_2O$. J. J. Berzelius at first opposed this hypothesis, but he afterwards incorporated the idea in his dualism. J. B. A. Dumas and P. F. G. Boullay's **etherine hypothesis** was not generally accepted because it did not adapt itself to the many new organic compounds soon afterwards discovered. The interesting feature about this hypothesis is that it represents *an attempt to find a similarity in the structure of a series of chemical compounds which possess like fundamental properties by showing that they are all derived from one common primitive stock or type.*

In 1815, in his memoir *Recherches sur l'acide prussique*, J. L. Gay Lussac[2] announced the discovery of the radicle cyanogen, C_2N_2 (κύανος, blue; γεννάω, I produce); and he showed that the group CN, or Cy, persists as a radicle through a whole series of chemical compounds.

Cy.H	Cy.Cl	Cy.Br	Cy.NH_2	$CH_3CO.Cy$
Cyanogen hydride.	Cyanogen chloride.	Cyanogen bromide.	Cyanamide.	Acetylcyanide.

Again, in 1832, J. von Liebig and F. Wöhler described a series of compounds of the radicle benzoyl, C_6H_5CO, of benzoic acid, in a memoir entitled *Untersuchungen über das Radikal der Benzoësäure.* The benzoyl radicle persists in many chemical compounds—among others

$C_6H_5CO.H$	$C_6H_5CO.OH$	$C_6H_5CO.Cl$	$C_6H_5CO.NH_2$	$C_6H_5CO.OC_2H_5$
Benzoyl hydride.	Benzoic acid.	Benzoyl chloride.	Benzamide.	Ethyl benzoate

The recognition of these two radicles—cyanogen and benzoyl—led to the development of what is now called the **older radicle theory.** On this hypothesis complex groups or radicles were supposed to exist unalterable in organic compounds, and to play the same rôle as elements do in inorganic compounds. According to J. von Liebig (1837),

> Cyanogen is a radicle (1) because it is a non-varying constituent in a series of compounds; (2) because in these latter it can be replaced by other simple substances; and (3) because in its compounds with a simple substance, the latter can be turned out and replaced by equivalents of other simple substances.

Hence, while this hypothesis was in favour, organic chemistry was regarded by J. B. A. Dumas and J. von Liebig (1837) as the *Chemistry of Compound Radicles.* The purpose of organic chemistry was supposed to involve the investigation and isolation of radicles as the more intimate components of organic compounds. Cyanogen and benzoyl, said A. Ladenburg (1869), were the pillars of the radicle theory, and this hypothesis received further support from the work described in R. Bunsen's brilliant memoirs, *Untersuchungen über die Kakodylreihe* (1839–43), in which it was shown that the so-called *Cadet's fuming liquid*—obtained by A. A. F. Cadet in 1760 by distilling potassium acetate with arsenious oxide—contained the oxide of a radicle, with the empirical formula, $As(CH_3)_2$, and which he called *kakodyl* or *cacodyl* (κάκωδης, ill-smelling). R. Bunsen succeeded in isolating the radicle itself, and also in preparing various salts—the chloride, bromide, fluoride, sulphide, etc. Modifications of the theory of radicles were discussed by J. J. Berzelius (1833) and J. von Liebig (1834–38), and the principle of radicles was generally accepted although it was not so much emphasized during the reign of the so-called type theories.

The type theories.—In 1834, J. B. A. Dumas[3] found that the hydrogen of many organic compounds could be replaced or substituted by chlorine in such a way that for every volume of chlorine introduced into a compound, an equal volume of hydrogen was lost; and, shortly afterwards, J. B. Dumas found that when oxygen displaces hydrogen, half a volume of oxygen takes the place of one volume of hydrogen. Otherwise expressed, while equal volumes of hydrogen and chlorine are equivalent, these elements possess only one-half the substituting value of the same volume of oxygen. A further study of substitution or metalepsis (μετάληψις, exchange), led J. B. A. Dumas, in his memoir, *Sur le constitution de quelques corps organiques et sur la théorie des substitutions* (1839), to the so-called **substitution theory.** J. B. A. Dumas discovered two important facts in his investigation of the action of chlorine on some organic compounds: (1) When a compound containing hydrogen is exposed to the dehydrogenating action of chlorine, bromine, or iodine, for each atom of hydrogen that it loses, it takes up an equivalent volume of chlorine, bromine, etc. (2) If a compound contains water, it loses the hydrogen without an equivalent substitution or replacement. The main *assumption* of the substitution theory hangs on the doctrine that the structure and character of organic compounds are not materially altered by the substitution of chlorine in place of hydrogen.

A. Laurent in a paper *Théorie des combinaisons organiques* (1836), and later, in his posthumous work, *Méthode de chimie* (Paris, 1854), tried to reconcile the radicle theory with these new facts discovered by J. B. A. Dumas. When the substitution occurs equivalent by equivalent, the residual body exhibits certain analogies with the original substance, for the substitution occurs without disturbing the structural type—chlorine, for instance, may occupy the place left vacant by hydrogen. A. Laurent argued that all organic compounds have definite forms or nuclei—*radicaux*—and consist either of *primary nuclei—radicaux fundamentaux*—or of *secondary or derived nuclei—radicaux derivés*—in which the hydrogen atoms have been replaced by others, or in which additional atoms have been taken up. This hypothesis was called the **nucleus theory**; it included the idea of substitution, and was based on the radicle theory; but it controverted the doctrine that radicles were unchangeable, for the atoms of a radicle can be replaced by others; it gave the first hint of what is now known as "chemistry in space." The nucleus theory was specially favoured by L. Gmelin in his celebrated *Handbuch der Chemie* (Heidelberg, 1843 *et seq.*), but it was not taken up by chemists generally.

In 1839, J. B. A. Dumas prepared trichloroacetic acid, $CCl_3.COOH$, in which three of the hydrogen atoms of acetic acid, $CH_3.COOH$, are replaced by chlorine, and the resulting compound retains the chief characteristics of the parent acid. This led him, in his *Mémoire sur la loi des substitutions et la théorie des types* (1840), to extend Laurent's nucleus theory to what is now known as the **older theory of types,** in which organic substances are supposed to be formed of particles which may be replaced or displaced, so to speak, without destroying the original substance. Compounds which have similar properties and a similar structure were classed as belonging to one *chemical type*—*e.g.* acetic acid and the chloroacetic acids. The relations between the members of a series of compounds belonging to one chemical type thus recall those assumed by A. Laurent to subsist between the original and the derived nuclei. J. B. A. Dumas also found it necessary to employ what he called the *mechanical type* to classify compounds which are related in structure but which manifest different chemical characteristics. Dumas rightly classed acetic acid and alcohol under the same mechanical type, which included a number of compounds which had little or no chemical relations with one another, though they may be regarded as belonging to one natural family because they may be derived by substitution one from the other—*e.g.* methane, CH_4; formic acid, $H.CO.OH$; carbon tetrachloride, $CCl_3.Cl$. J. B. A. Dumas' mechanical type resembled what H. V. Regnault (1838) had previously called the *molecular type*. If a substance changes without losing its mechanical type, it follows the law of substitution, but if it passes into another mechanical type, the law of substitution is not maintained during the reaction. By this statement, J. B. A. Dumas admits that his original idea of substitution is not always applicable, for an equivalent of hydrogen is not always evolved when another is introduced into the compound; and a compound is not regarded as consisting of two parts. but is supposed to be a uniform whole with its component parts related in an analogous fashion to the worlds of a planetary system in which the atoms are held together by affinity instead of by gravitation. Just as the stability of a planetary system depends not on the intrinsic nature of the planetary units, but rather on their relative position with respect to one another and to the sun, so J. B. A. Dumas supposed that the chemical properties of a compound are primarily dependent on the arrangement and number of the constituent atoms, and in a less degree on their chemical nature. Dumas thus regarded the planetary molecule as the *type* of a series of compounds with a similar structure; and therefore, he opposed a *unitary theory of chemical composition* in place of J. J. Berzelius' dualism. Between 1838 and 1844, J. J. Berzelius vigorously fought a losing fight in his *Jahresberichten* against these encroachments on his dualistic views. C. F. Gerhardt having suggested that in compounds of an organic base with an inorganic acid, the organic portion of the compound, termed the copula, was supposed to unite by *accouplement* (copulation) with the inorganic acid. J. J. Berzelius tried to explain the substitution products obtained by J. B. A. Dumas by arbitrarily assuming that they were formed by the copulation or pairing of imaginary copulæ; he explained the formation of trichloroacetic acid, for example, by assuming it to be formed by the union of carbon chloride, C_2Cl_6, with oxalic acid, $H_2C_2O_4$; and he assigned different rational formulæ to trichloroacetic acid and its parent—acetic acid. Berzelius' explanation broke down completely when L. H. F. Meslen (1842) showed that chloroacetic acid could be reconverted to the original acid by reduction with potassium amalgam. J. J. Berzelius obstinately opposed the theory of types with his last breath, but he fought practically alone. His one-time supporter, J. von Liebig, gave up the dualistic hypothesis when it failed to explain the newer facts.

In 1839, C. F. Gerhardt, in his memoir *Sur la constitution des sels organiques à acides complexes et leur rapports avec les sels ammoniacaux*, rejected the radicle theory and stated his belief that a compound must be regarded as a complex of atoms bound each to all, and all to each; but he could not help admitting that certain groups of atoms do recur in chemical compounds. Accordingly, C. F. Gerhardt attempted to reconcile his hypothesis with observation, by what he called his **théorie des résidus**—*theory of residues*—in which a group of atoms previously called a *compound radical* was termed *le reste*—a residue; unlike radicles, C. F. Gerhardt's residues were not supposed to be present as such in a compound, for, said C. F. Gerhardt, *je prends l'expression de radical dans le sens de rapport, et non dans celui de corps isolable ou isolé.* C. F. Gerhardt's molecule was *une système unitaire*—a simple edifice and not a double building; all assumptions of a binary structure were excluded. He argued that the constitution of a compound can be deduced only from its modes of formation and decomposition, and that according to the theory of radicles several rational formulæ and several radicles could be imagined in the case of one substance formed in different ways—*e.g.* barium sulphate formed by the reactions symbolized: (i) $BaO+SO_3$; (ii) BaO_2+SO_2; and (iii) $BaS+2O_2$. Consequently, a *chemical type is nothing more than a general system of reactions.* Acetic acid, water, and alcohol were classed in the same way because they undergo analogous reactions—say, when they are deoxidized to form aldehyde, hydrogen, and ethyl hydride, C_2H_5H, respectively. Gerhardt further supposed that when two substances react with one another, an element in the one combines with an element in the other to form one stable compound, and the residues also unite to form what he called *corps copulés* and later *corps conjugés*, meaning *copulated or conjugated compounds.* Thus, the copula benzene, C_6H_6, unites with nitric acid, HNO_3, to form water, H_2O, and the copulated compound nitrobenzene, $C_6H_5.NO_2$. In modernized symbols:

$$\left.\begin{matrix}\mathrm{NO_2}\\ \dot{\mathrm{O}}\mathrm{H}\end{matrix}\right\} + \left.\begin{matrix}\mathrm{C_6H_5}\\ \dot{\mathrm{H}}\end{matrix}\right\} = \left.\begin{matrix}\mathrm{H}\\ \dot{\mathrm{O}}\mathrm{H}\end{matrix}\right\} + \left.\begin{matrix}\mathrm{C_6H_5}\\ \dot{\mathrm{N}}\mathrm{O_2}\end{matrix}\right\}$$

Consequently, in a reaction between two substances, each molecule is split into two parts, and the resulting residues unite in such a manner that a *double exchange* takes place, and Gerhardt said: *J'appelle radicaux ou résidus les éléments de tout* *corps qui peuvent être ainsi transportés dans un autre corps par l'effet d'une double décomposition, ou qui y ont été introduits par une semblable réaction.* It is not very obvious why C. F. Gerhardt emphasized the distinction between his own type formulæ and those of J. B. A. Dumas. The former clearly supposes substitution to be effected by replacing an element in a compound by an equivalent of another element, or by the residues (radicles) of the reacting substances, and this is but a restatement of the views of J. B. A. Dumas and A. Laurent. C. F. Gerhardt's conception of radicles, said C. Schorlemmer (1879), soon supplanted the older views, and its introduction into the theory of types led to the fusion of both theories.

The discovery of the organic ammonias by C. A. Wurtz (1849) and A. W. von Hofmann (1850)[4] revealed the close relationship between the organic ammonia bases and ammonia itself, and the hypothesis that the former were derivatives of ammonia, NH_3, produced by the substitution of hydrocarbon radicles in place of hydrogen atoms:

$$NH_3 \qquad (C_2H_5)NH_2 \qquad (C_2H_5)_2NH \qquad (C_2H_5)_3N$$

furnished the only satisfactory explanation of the constitution of these compounds. In this way, said C. A. Wurtz, the ammonia type was founded. Similarly, A. W. Williamson's *Theory of Ætherification* (1850), dealing with the substitution of hydrocarbon radicles in place of the hydrogen atoms of water, established the water type. A. W. Williamson demonstrated the close relationship between

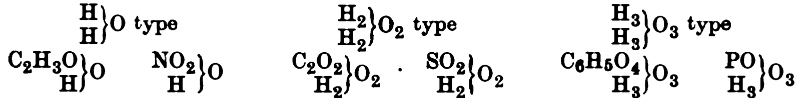
$$\underset{\text{Water.}}{\left.\begin{matrix}H\\H\end{matrix}\right\}O} \qquad \underset{\text{Alcohol.}}{\left.\begin{matrix}C_2H_5\\H\end{matrix}\right\}O} \qquad \underset{\text{Ether.}}{\left.\begin{matrix}C_2H_5\\C_2H_5\end{matrix}\right\}O}$$

In harmony with a prior suggestion made by A. Laurent in 1846, A. W. Williamson wrote: "I believe that throughout inorganic chemistry and for the best known organic compounds, one single type will be sufficient—it is that of water represented as containing two atoms of hydrogen to one of oxygen." Numerous nitrogen compounds were then referred to C. A. Wurtz and A. W. von Hofmann's ammonia type, and many oxygen compounds were likewise referred to A. W. Williamson's water type as *termes de comparaison*. C. F. Gerhardt in his *Traité de chimie organique* (Paris, 1853–6) added hydrogen and hydrogen chloride to the ammonia and water types, and he attempted to classify all organic compounds by reference to the four types: hydrogen, H_2; hydrogen chloride, HCl; water, H_2O; and ammonia, NH_3. In 1857, F. A. Kekulé, in an important memoir *Ueber die sogenannten gepaarten Verbindungen und die Theorie der mehratomigen Radicle*, proposed to add methane, CH_4, to the list of primitive or **simple types**, and to remove hydrogen chloride from the list because it is merely a special case of the hydrogen type. Thus arose the **newer theory of types** which now assumed the forms

$$\underset{\text{Hydrogen type.}}{\left.\begin{matrix}H\\H\end{matrix}\right\}} \qquad \underset{\text{Water type.}}{\left.\begin{matrix}H\\H\end{matrix}\right\}O} \qquad \underset{\text{Ammonia type.}}{\left.\begin{matrix}H\\H\\H\end{matrix}\right\}N} \qquad \underset{\text{Methane type.}}{\left.\begin{matrix}H\\H\\H\\H\end{matrix}\right\}C}$$

A. Laurent had suggested in 1846 that alcohol and ether as well as inorganic acids and oxides could be regarded as derivatives of water. In 1848–9, T. S. Hunt published several papers in which he showed that the composition of many oxygenated compounds might be derived from water as a type, and he also referred the formulæ of hydrocarbons to hydrogen as a type; but T. S. Hunt's work had little or no influence on the development of the theory of types since it was unknown to those who were working in Europe on this subject.

A. W. Williamson introduced the idea of **condensed types** in 1850; dibasic acids like sulphuric acids and oxalic were regarded as derived from two molecules of water, and the acid radicle was supposed to replace one atom of hydrogen in each of the two molecules of water. W. Odling, in his paper *On the Constitution of Acids* *and Salts* (1855), developed the idea still further, and formulæ like these were obtained:



$$\left.\begin{matrix}H\\H\end{matrix}\right\}O\ \text{type} \qquad \left.\begin{matrix}H_2\\H_2\end{matrix}\right\}O_2\ \text{type} \qquad \left.\begin{matrix}H_3\\H_3\end{matrix}\right\}O_3\ \text{type}$$

$$\left.\begin{matrix}C_2H_3O\\H\end{matrix}\right\}O \quad \left.\begin{matrix}NO_2\\H\end{matrix}\right\}O \quad \left.\begin{matrix}C_2O_2\\H_2\end{matrix}\right\}O_2 \ \cdot\ \left.\begin{matrix}SO_2\\H_2\end{matrix}\right\}O_2 \quad \left.\begin{matrix}C_6H_5O_4\\H_3\end{matrix}\right\}O_3 \quad \left.\begin{matrix}PO\\H_3\end{matrix}\right\}O_3$$

Acetic acid. Nitric acid. Oxalic acid. Sulphuric acid. Citric acid. Phosphoric acid.

F. A. Kekulé (1857) also extended the type theory to include **mixed types** supposed to be formed by the union of two simple or condensed types. For example, chlorosulphuric acid, $(HO)ClSO_2$, can be referred to a mixed hydrogen and water type; and carbamic acid, $H_2N.COOH$, was referred to the mixed ammonia and water types:

$$\begin{matrix}\left.\begin{matrix}H\\H\end{matrix}\right\}\\\left.\begin{matrix}H\\H\end{matrix}\right\}O\end{matrix} \qquad \begin{matrix}\left.\begin{matrix}Cl\\SO_2\end{matrix}\right\}\\\left.\begin{matrix}SO_2\\H\end{matrix}\right\}O\end{matrix} \qquad \begin{matrix}\left.\begin{matrix}H_2\\H\end{matrix}\right\}N\\\left.\begin{matrix}H\\H\end{matrix}\right\}O\end{matrix} \qquad \begin{matrix}\left.\begin{matrix}H_2\\CO\end{matrix}\right\}N\\\left.\begin{matrix}CO\\H\end{matrix}\right\}O\end{matrix}$$

Mixed type. Chlorosulphuric acid. Mixed type. Carbamic acid.

The need for the introduction of condensed and mixed types showed the insufficiency of the type theory, for as the number and complexity of organic compounds increase, an indefinite number of types may be required. C. F. Gerhardt's type theory is now considered but an interesting phase in the evolution of systematic chemistry. The attempts to refer a large number of compounds to a limited number of types, and the consequent need for viewing individual compounds from many different *points de vue*, enabled chemists to see many analogies and contrasts previously hidden, and to realize dimly the remarkable relations the atoms of a compound bear each to each. It soon became evident that the theory of types represented an artificial arbitrary system of classification; even C. F. Gerhardt (1856) admitted *mes radicaux et mes types ne sont que des symboles, destinés à concréter en quelque sorte certains rapports de composition et de transformation*, and H. W. Kolbe (1843 *et seq.*) seemed to get at the root of the matter when asked: "Why are we to suppose that nature has restricted herself to forming all bodies on the models of these four types? Why on these models rather than on others? The four types are nothing but a vain artifice." He answered that "the grouping of organic compounds into types verges on empty formalism, and is merely playing with formulæ." He sought to replace the purely formal types by others which he considered to be related naturally with their derivatives. In a paper *Ueber die chemische Konstitution und Natur der organischen Radikale* (1851), H. W. Kolbe built up a **newer radicle theory** in which he eliminated those tenets which were not in harmony with fact; he showed, as J. J. Berzelius supposed, that in organic compounds there are definite radicles which behave like the elements in inorganic compounds. The discovery of the organometallic compounds—typified by zinc ethyl, $Zn(C_2H_5)_2$—by E. Frankland (1849), seems to exclude every doubt of the actual existence of compound radicles; and H. W. Kolbe (1850) electrolyzed aqueous solutions of the salts of the fatty acids, and believed that he separated the constituent hydrocarbon radicles—as a matter of fact, he obtained products of the union of two radicles. Thus, with potassium acetate, $CH_3.CO.OK$, he obtained gaseous carbon dioxide and ethane, $(CH_3)_2$ or C_2H_6; the potassium, simultaneously obtained, undergoes a secondary reaction with the solvent: The primary reaction in modern symbols is represented:

$$\begin{matrix}CH_3\cdot CO.O\,K\\CH_3\cdot CO.O\,K\end{matrix} \rightarrow \begin{matrix}CO_2\\CO_2\end{matrix} + \begin{matrix}CH_3\\\dot{C}H_3\end{matrix} + 2K$$

In conjunction with E. Frankland, H. W. Kolbe published a paper entitled *Ueber den naturlichen Zusammenhang der organischen mit den anorganischen Verbindungen, die wissenschaftliche Grundlage zu einer naturgemassen Klassifikation der organischen chemischen Körper* (1859), in which it was shown by numerous examples that organic compounds can be regarded as derivatives of inorganic compounds, and result from the latter—in some cases directly—by wonderfully simple substitution processes. Consequently, organic acids can be regarded as substitution derivatives of carbonic acid, and consequently, H. Kolbe argued that carbonic acid is a natural standard of reference for organic bodies because they are formed from this gas in the vegetable kingdom. He said: The carbonic acid type must therefore exist in the very nature of things, and it seems logical to refer all organic compounds to this type, since they are all in fact derived from it.

For example—translating Kolbe's symbols into modern practice, and starting from carbonic acid, $(HO)_2CO$—when a hydroxyl group, HO, is replaced by a hydrogen, H, atom, formic acid, H.CO.OH, is formed; replacing OH by CH_3 furnishes acetic acid, $CH_3.CO.OH$; replacing two OH-groups by two H-atoms yields formaldehyde, H CO.H. If an OH-group be replaced by an H-atom, and an O-atom by two H-atoms, methyl alcohol, $CH_3.OH$, results; and if an OH-group is replaced by CH_3, and an O-atom by two H-atoms, ethyl alcohol, $CH_3.CH_2.OH$, is formed.

H. Kolbe is here perhaps a little inconsistent, for C. A. Wurtz, in his *Histoire des doctrines chimiques depuis Lavoisier jusqu'à nos jours* (Paris, 1869), has pointed out that water and ammonia are agents as indispensable as carbonic acid in the processes of vegetable life. Kolbe's objections to C. F. Gerhardt's or F. A. Kekulé's types also apply to his own carbonic acid type.

The doctrine of valency.—In conformity with the general views of chemists early in the nineteenth century, J. L. Gay Lussac,[5] in his *Recherches sur l'acide prussique* (1815), regarded salts as products of the union of an equivalent of an acid with an equivalent of the base, but T. Graham's important *Researches on the Arseniates, Phosphates, and Modifications of Phosphoric Acid*, published in 1833, showed that phosphorus pentoxide can unite with one, two, and three equivalents of water to form definite acids which can respectively unite with but one, two, and three equivalents of the base to form definite salts with characteristic properties. Five years later, J. von Liebig, in his memoir *Ueber die Constitution der organischen Säuren* (1838), found other acids to behave in a similar manner, and he employed the terms *mono-, di-, tri-, and poly-basic acids* to indicate the saturation capacity of the acids for the bases. The idea of basicity was further extended to organic radicles; and, in 1834, J. B. A. Dumas showed that an atom of hydrogen could be replaced by an atom of chlorine, but only by the equivalent of half an atom of oxygen, so that these quantities of chlorine and oxygen are equivalent to an atom of hydrogen.

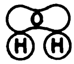
In his memorable paper *On a New Series of Organic Compounds containing Metals*, published in 1852, E. Frankland applied the idea of equivalency or saturation capacity to the elements. He showed that the power of the metals to combine with oxygen is reduced when the metal is copulated with compound radicles in such a way that, say, stannic ethyl oxide, $(C_2H_5)_2SnO$, is to be regarded as stannic oxide, SnO_2, in which one oxygen atom is replaced by two ethyl radicles; and stannic ethide, $Sn(C_2H_5)_4$, as stannic oxide with the two oxygen atoms replaced by four ethyl radicles. E. Frankland then remarked:

> When the formulæ of inorganic chemical compounds are considered, even a superficial observer is impressed with the general symmetry of their construction. The compounds of nitrogen, phosphorus, antimony, and arsenic especially exhibit *the tendency of these elements to form compounds containing three or five atoms of other elements*; and it is in these proportions that their affinities are best satisfied. . . . Without offering any hypothesis regarding the cause of this symmetrical grouping of atoms, it is sufficiently evident, from the examples just given, that such a tendency or law prevails, and that, **no matter what the character of the uniting atoms may be, the combining power of the attracting element is always satisfied by the same number of these atoms.**

Thus Frankland led chemists to see that within certain limits the atoms of the elements possess definite saturation capacities; and he proved that copulation is a consequence of the saturation capacity of the elements. In 1877, Frankland added that the hypothesis just outlined "constitutes the basis of what has since been called the *doctrine of atomicity* or the equivalence of the elements." The far-reaching importance of the above quotation from Frankland was not realized until some years afterwards. A vague inkling of the operation of some such law among organic compounds was probably at the back of the minds of the founders of the different theories of types, for in representing chemical transformations as the result of substitutions of atoms or groups of atoms, the equivalency of the substituents must have been tacitly assumed; but they were prevented from realizing the importance of the principle by laying too much stress on the *position* rather than on the *nature* of the atoms concerned.

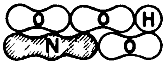
F. A. Kekulé seems to have considered himself to have been the originator of the doctrine of the valency, or, as he termed it, the *atomicity* of the elements. As a matter of fact, in 1854, two years after the publication of E. Frankland's paper, F. A. Kekulé did obtain a clearer vision of the doctrine, and, in 1857, he explained the existence of primitive types—simple and mixed—by means of the valency of the constituent elements. Soon afterwards, A. S. Couper, independently of F. A. Kekulé, published a paper, *Sur une nouvelle théorie chimique* (1858), in which he deduced constitutional formulæ for many compounds from the valency of the elements, or rather, what he called *affinity of degree* of the elements as contrasted with the ordinary manifestations of chemical affinity, or, as he called it, *elective affinity*. A. S. Couper, for the first time, also represented the composition of compounds by joining the symbols of the elements or compound radicles by means of hyphens or linking bonds. In his *Lehrbuch der organischen Chemie, oder der Kohlenstoff-Verbindungen* (Stuttgart, 1859), F. A. Kekulé symbolized the valency of an atom in graphic formulæ by means of a diagram whose size represented the valency as illustrated in the following examples:

Hydrogen chloride, HCl



Water, H_2O.

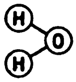
Sulphur dioxide SO_2.



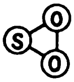
Nitric acid, HNO_3.

There was no intention, of course, to convey any idea of the relative dimensions of the atoms. In 1865, A. C. Brown suggested a system in which the symbol of the element was surrounded by a circle, with a number of radiating lines corresponding with the valency of the element. For instance,

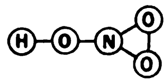
Hydrogen chloride, HCl.



Water, H_2O.



Sulphur dioxide, SO_2.



Nitric acid, HNO_3.

The grouping was not meant to indicate the physical but rather the chemical position of the atoms. E. Frankland adopted practically the same system in 1866, except that he omitted the circles round the symbols of the elements, and this method of pictorially representing the linking of the atoms of a molecule in definite order is virtually that employed by A. S. Couper, and it has persisted up to the present day. A. M. Butleroff (1861) followed up A. S. Couper's idea, and defined *the structure of a chemical compound* to be the mode in which the atoms are mutually linked together in the molecule. This does not afford any information of the position of the individual atoms in space. The chemical characteristics of a compound, said Butleroff, depend first upon the nature and relative quantity of its elementary constituents, and then on its chemical structure.

F. A. Kekulé (1857) classified the elements according to the replacing values of their atoms. Hydrogen, chlorine, potassium, etc., were called monobasic or monatomic elements; oxygen and sulphur were dibasic or diatomic; nitrogen, phosphorus, and arsenic were tribasic or triatomic; and carbon was classed as a tetrabasic or tetratomic element. There is an incongruity in the use of the terms *mono-*, *di-*, . . . *atomic*, since similar terms are employed to represent the number of atoms in a molecule; and the confusion in the use of the terms *mono-*, *bi-*, . . . *basic atoms* with J. von Liebig's polybasic acids, led E. Erlenmeyer (1860) to propose the terms *ein-*, *zwei-*, *drei-*, *and vier-werthig* which have come into use in Germany; the equivalent *uni-*, *bi-*, *ter-*, and *quadri-valent*, used by L. Meyer, or *mono-*, *di-*, *tri-*, *and tetra-valent*, with W. Odling's alternative terms (1864): *monad, dyad, triad, and tetrad* are now in use. J. Wislicenus used the terms *monaffin, diaffin, triaffin, and tetraffin*. In 1855, W. Odling placed dashes beside the symbol of the atom or radicle to express what he called the replaceable, or representative, or substitution value of the atoms, and he recognized, as E. Frankland did in 1852, that an atom can have more than one replaceable value. Various terms were used in place of valency during the clarification of the concept—e.g. *saturation capacity, combining capacity, atom-fixing power, affinity units, affinity of degree, basicity, and atomicity.* The two latter terms are objectionable. A. W. Hofmann (1865) considered that *atomicity* is a barbarous term; and is best reserved to express the number of atoms in a molecule of an element; the term *basicity* is also best retained to express the number of stages in which the replaceable hydrogen of an acid can be substituted by a metal. A. W. Hofmann did much to spread a knowledge of the doctrine of valency. He employed the term *quantivalence* "to designate the particular atom-compensating power inherent in each of the elements," and added "this power must by no means be confounded with the specific intensity of the respective activities of the atoms." H. Wichelhaus[6] shortened A. W. Hofmann's quantivalence to *valency* (or *valence*) in 1868; and H. Wichelhaus' term is now in general use.

The doctrine of valency introduced by E. Frankland and amplified by F. A. Kekulé soon stilled the controversies which had been waged between the advocates of the radicle and type theories. The nature of the problem was changed. Chemical formulæ were no longer employed to represent types of double decomposition, but rather to show the relations which subsisted between the constituent atoms of a molecule. The doctrine of valency enabled chemists to see, as in a glass darkly, the intimate structure of the molecules by establishing the way in which the atoms are bound together. Consequently, neither the type nor the radicle theory could claim a victory, for the theory of composition based upon valency absorbed and assimilated them both; it showed that chemists had really admitted a water type because there is a bivalent element oxygen; an ammonia type because there is a tervalent element nitrogen; and a methane type because there is a quadrivalent element carbon. As F. A. Kekulé's mixed metaphor expressed it: "Both sides had been striving towards the same goal by different paths; each side thereupon profited by the experience of the other, and with united forces sailed onward on the reunited stream."

§ 17. Attempts to explain Valency

The general test of truth is evidence.—J. M. C. DUHAMEL.

The composition of all chemical compounds, says H. von Euler (1903), can be regarded as a function of a valency force—*Valenzkraft*—which is probably of an electric nature, and dependent on the temperature, pressure, and the nature of the solvent. Numerous attempts have been made to invent some peculiarities in the structure of the atoms which will explain that strange power manifesting itself as valency. Even Lucretius attributed the differences in the behaviour of his atoms to differences in their shape, size, and mode of motion. The subject has rather lent itself to hypotheses established by the absence of a knowledge of contradictory facts. A brief *résumé* of the more striking forms of these hypotheses may act as a danger beacon.

I. Differences in the valency of different elements have been explained by supposing that *an atom of an n-valent element is compounded of n units, each of which is capable of attracting one other unit.* A constant quantity of one element, said E. Erlenmeyer (1862),[1] never binds itself to more or to less than a constant quantity of another element—this he called *the law of constant affinivalencies.* W. Odling (1855) called these attracting units *sub-atoms;* G. Ensrud (1907), *Kernen* or *nuclei;* L. Knorr (1894), *Valenzkörper* or *valency bodies;* E. Erlenmeyer (1867), *affinivalencies;* A. W. von Hofmann (1865), *minimum atom-binding quantities* of an element; and J. Wislicenus (1888), *primitive atoms*, which are located in certain parts of the atom and from which they exert their influence. W. Lossen, in an important paper *Ueber die Vertheilung der Atome in der Molekul* (1880), pointed out that this hypothesis cannot be sound, for if a constant mass of, say, carbon binds itself to a constant mass of oxygen in the molecule of carbon dioxide, CO_2, the same mass of carbon is bound to half the same constant mass of oxygen in carbon monoxide, CO. Hence, the assumed constant mass must be variable. G. Ensrud (1907) supposed an atom to be compounded of an enveloping shell of a substance of small density with a nucleus of great density and eccentric shape. The envelopes of different atoms repel one another, the nuclei attract one another in the direction along which valency acts. An atom of an *n*-valent element has *n* nuclei. This hypothesis recalls J. F. Redtenbacher's *Das Dynamidensystem* (Mannheim, 1857). Some of these hypotheses appear to have arisen by confusing the fractional parts of an atom with fractional parts of its weight, and assuming that the former are equal to the latter. There is nothing to show that if the atom were divided up into a number of attracting portions, each would be the same fractional part of the weight of the atom. The modern electron hypothesis of valency is one form of this hypothesis—*vide* Vol. III.

II. Other hypotheses assume that *valency is an attracting force localized at certain parts of the atom.* The atoms are supposed to be joined together at these attracting points; in other words, some parts of the atom are less active than others. This hypothesis has taken various forms. E. Erlenmeyer (1867) and A. Michaelis (1872) suggested that the attractive forces are not exerted uniformly in all directions as is the case with gravitation, but are specially strong in certain definite directions so that a straight line joining two atoms directly bound together expresses the direction of the mutually exerted force. A. Michaelis supposed an n-valent atom to have n such directions, and, if it is bound by $n-x$ bonds, to have these mutual actions exerted in $n-x$ such directions. A. C. Brown (1861–79) assumed that each atom possesses two kinds of attractive forces—positive and negative—and the point towards which these forces act was called a *pole* or active point. He made no assumption as to the nature of the attractive or repellent forces. An n-valent element has n such positive and negative poles. When two atoms unite, the positive pole of the one attracts the negative pole of the other, and *vice versâ*. When a bivalent atom combines with two univalent atoms, the forces emanating from the bivalent atoms will be divided between its two poles in some proportion depending on the forces of the two univalent atoms. In order to support the assumption that valency is due to centres of attraction localized on the atom, subsidiary hypotheses have to be invented. For instance, it has been assumed (i) that the atoms are bound to one another through the attraction of electric or magnetic charges localized on the atoms; and also (ii) that the intensity of the attractive force is modified by the shape of the atom.

(i) *Electric charges localized on the atom.*—The idea that the reacting units are polarized, and carry definite electric charges, each charge representing one valency, naturally grew from Davy's and Berzelius' electrochemical hypothesis, and Faraday's work. There are many modified forms of the hypothesis. For example, V. Meyer and E. Riecke (1888) assumed that the carbon atom is surrounded by an æthereal envelope which, in the case of isolated atoms, has a spherical shape like that supposed to be possessed by the atoms themselves. The atom in the core carries the specific affinities; the æthereal envelope is the seat of the valencies. Each valency is determined by the presence of two opposite electrical poles—called double or *di-poles*—situated at the ends of a straight line which is small in comparison with the diameter of the æthereal shell. The four valencies of carbon are represented by four such di-poles each of which is able to move freely within the æthereal shell, and to turn freely about its middle point. The carbon atom attaches other atoms to its surface by the attractions of the di-poles. The modern form of the electric charge hypothesis will be discussed later.

(ii) *The shape of the atom.*—J. H. van't Hoff, in his *Ansichten über die organische Chemie* (Braunschweig, 1881), showed that the attractive forces emanating from an atom will be uniform in all directions if the atom is spherical, but if the shape be not spherical the intensity of the force, at short distances, will be more concentrated in certain spots than in others. Thus, if the atom were shaped like a regular tetrahedron, it would behave as if it were quadrivalent, for the centres of the four bounding faces would represent maximal attractions. Given the number of maximal points on the atom, it would be possible to deduce the valency, and conversely. There will be as many maximal points as the figure has sides. If the faces are unequally distant from the centre, the maximal points may not all have the same value, so that, when the nature of the united atoms also determines the attracting power, the number of effective valencies of the attracting atom will be affected, and a change of valency will be observed on comparing combinations of an element with other different elements. J. Wislicenus (1888) has expressed a similar idea; he said:

> It is not impossible that the carbon atom more or less resembles—perhaps very closely—the form of a regular tetrahedron; and further, that the causes of those attractions which are exhibited by the so-called units of affinity or bonds are concentrated at the apices of this tetrahedral structure, so that where there is least matter there is most force. These attractions are possibly analogous to the electrical state of a metal tetrahedron charged with electricity.

If the atoms be also in rapid vibratory motion, only the parts where the greatest attractions are exerted can retain their contacts, and therefore valency will be reduced by a rise of temperature, for a rise of temperature probably augments the vibratory motions of the atoms.

III. Another set of hypotheses has assumed that *valency is due to the need for harmonizing the motions of the combining atoms so as to form complexes whose parts move in stable equilibrium.* One form of this hypothesis is indicated later on. According to L. Meyer (1884), the atoms in a molecule are not in a state of rest, but they move rotationally about a centre of equilibrium; the orbits of similar atoms in the molecules of the same substance are the same so that equivalent atoms have the same paths, but the orbits of different atoms are greater, the greater the valency of the atom. E. Molinari (1893) suggested a modification of this hypothesis in a paper entitled *Motochemistry* (*móto*, motion). The valency of an atom in a molecule is determined by the nature or energy of its oscillatory motion; and he claims that the constitution of compounds is dependent upon the intramolecular movements rather than on the relative positions of the atoms in space. F. A. Kekulé (1872) considered that valency is determined by the relative number of impacts which an atom receives from other atoms in unit time; each of the univalent atoms in a diatomic molecule impinges once, while the bivalent atoms impinge twice in unit time. It is not very clear how this explains valency, and in 1878, F. A. Kekulé said that " the nature of the motion of atoms, unknown at present, may be imagined as an oscillatory one in such a way that the number of oscillations executed in unit time exactly represents the valency of the atoms." F. M. Flavitzky (1896), following N. N. Beketoff (1880),[2] supposed that the atoms move in curves which lie in planes parallel to one another; the atoms of different elements move in planes which are inclined at definite angles to one another; the motion of the atoms of one element can be completely counteracted by the motions of the atoms of another element only when the two planes of motion are parallel; otherwise, according to the size of the angle between the planes of motion, an atom of one element may require two, three, or more atoms of another element to balance it; and only those components come into action which are parallel to the plane of motion of another atom. Accordingly, F. M. Flavitzky refers the valency of an element to the difference in the angles between the planes of the orbits of the different rotating atoms. J. H. van't Hoff, in his *Die Lagerung der Atome im Raume* (Braunschweig, 1894), argued against the hypothesis which ascribed isomeric phenomena to the varied motions of the atoms because temperature presumably favours atomic motions, and yet the phenomena become less and less complex as the temperature rises, and constantly more complex as the temperature falls.

§ 18. Atomic, Molecular, and Specific Volumes

> Modern developments in crystallography indicate with ever increasing distinctness that the chemical atom even when its individuality is shrouded by combination with other different atoms, exhibits characteristics which are essentially its own, and which are discernible in the compounds into which it enters.—W. J. POPE and W. BARLOW (1907).

So far as the balance can indicate, the weight, and by inference the mass, of an atom remains uniformly constant during all chemical changes; but the evidence is less clear with respect to the volume or space occupied by the atoms of an element when it enters into chemical combination. A. le Royer and J. B. A. Dumas [1] opened up the subject in 1821 with an attempt to determine the equivalent volumes of the elements by dividing their atomic weights by their respective specific gravities; the quotients were called *atomic volumes*.

The atomic volume of an element is obtained by dividing the atomic weight by its specific gravity; similarly the molecular volume represents the molecular weight divided by the specific gravity. Consequently, the atomic volume represents the space occupied by the aggregates of atoms, including the interstitial spaces, whose weights are proportional to the atomic weight; otherwise expressed, the volume occupied by a quantity of the element proportional to the atomic weight. The term *equivalent volume* was used before the concept of the atom had been clarified by Avogadro's hypothesis. At the suggestion of J. J. Berzelius, H. Schröder employed the term *molecular volume* in place of equivalent volume; and H. Kopp's term *specific volume* had the same connotation. It has been urged that the term specific volume is objectionable because the specific gravity of a body is the weight of unit volume, and the term specific volume by analogy suggests the volume of unit weight. The terms atomic volume and molecular volume here employed are defined by the ratio

$$\frac{\text{Atomic weight}}{\text{Specific gravity}}=\text{Atomic volume}\,;\quad \frac{\text{Molecular weight}}{\text{Specific gravity}}=\text{Molecular volume.}$$

Consequently, if the atomic or molecular weight be expressed in grams, the atomic or molecular volume respectively denotes the number of cubic centimetres occupied by a gram-atom or gram-molecule.

It follows from Avogadro's hypothesis that all gases have the same molecular volume. If the centres of gravity of the molecules of liquids were situated at the same average distance apart—as they probably are with gases—a given volume of different liquid would contain the same number of molecules; and the molecular weights of different liquids would be proportional to the specific gravities—as is also probably the case with gases. Similar remarks apply to solids. With liquids and solids, however, the molecules must be located at different distances apart because the molecular weights of different liquids and solids are not proportional to their specific gravities. The molecular volumes of liquids and solids do not exhibit the same uniformity as those of gases. This might have been predicted from the fact that while the coefficients of thermal expansion and the compressibilities of the different gases are approximately the same, each solid and each liquid has its own characteristic constant.

The molecular volume of gases can be compared at an arbitrarily defined standard temperature and pressure; but since liquids are obviously not in the same molecular condition, they are therefore not under comparable conditions at any one arbitrarily defined temperature. Consequently, H. Schröder[2] suggested that liquids would be more nearly in the same comparable state at the temperatures at which their vapour pressures are the same—*e.g.* at their boiling points under a standard pressure. In the case of solids, the effect of temperature is not so marked as with liquids, and in the first approximation, the specific gravity is taken at a convenient atmosphere temperature—say 0°, 4°, 15°, etc. A. Horstmann, W. Lossen, and A. Bartoli contend that (i) while the so-called atomic volume refers not only to the space filled by the atom, but also to the space in which the atom oscillates, it is not likely, *a priori*, that the molecules will be in the same state at 1°, the boiling point of butane, as they are at 317°, the boiling point of octadecane; (ii) relations similar to those established at the boiling temperature are likewise manifest at, say, the arbitrary temperature 0°; and (iii) the boiling point cannot be a strictly comparable state because it is affected by pressure to a different extent in the case of different liquids. G. Tschermak, F. Krafft, and G. le Bas take the melting point as a comparable state. In a valid corresponding state, the pressure, temperature, and volume should be expressed in terms of their critical values, and T. E. Thorpe has emphasized the fact that C. M. Guldberg has shown that the ratio of the critical temperature T_c to the absolute boiling point T_b approximates to a constant. Consequently, the boiling temperatures are approximately equal fractions of the critical temperatures. Consequently, properties like the molecular volume which change but slowly with temperature, are comparable at the ordinary boiling points. The results by the different methods do not show any very decisive evidence in favour of any one method, since relations which are revealed by the one may be obscured by the other. I. Traube emphasized the disturbing effects of molecular association and claimed that this can be eliminated by determining the molecular volume in dilute solution. The idea was applied many years previously by L. Playfair and J. P. Joule, who argued that "solution in water is the obvious means of destroying the cohesion of a body without at the same time altering its chemical properties."

From their observations on atomic volumes A. le Royer and J. B. A. Dumas tried to show that the atomic volumes are multiples of one and the same number and thus form an arithmetical series, but more extended investigations proved this tentative hypothesis was not in accordance with fact. At this period, the chemical combination of gases in volumetric proportions was attracting much attention, and attempts were made to show that solids likewise unite in definite volumetric proportions. For example, W. Herapath [3] tried to prove that the atomic volume of oxygen in a metal oxide bears a simple numerical relation to that of the metal with which it is combined. The same problem was attacked by C. J. B. Karsten (1832) and by P. F. G. Boullay (1840). Here again, more accurate observations falsified the hypothesis. F. Ammermüller (1840) concluded from his observations that the molecular volumes of compounds containing the same elements in different proportions are either the same, or else stand to one another in rational proportions. J. F. Persoz (1839) showed that equivalent amounts of many compounds of analogous composition have the same molecular volume, and he tried unsuccessfully to establish A. le Royer and J. B. A. Dumas' arithmetical rule.

H. Kopp's first publication, *Ueber die Vorausbestimmung des specifischen Gewichts einiger Klassen chemischer Verbindungen*, appeared in 1839 and his last publication on the subject was made in 1889. The earlier papers are mainly occupied in collecting material and in finding the best conditions for comparing the data. In 1844 H. Kopp tentatively concluded:

> (1) Equal differences in composition correspond with equal differences in specific volume. (2) Equivalent amounts of oxygen and hydrogen in liquid compounds occupy nearly the same volume. (3) The specific volume of a compound is equal to the sum of the specific volumes of its components. The same element almost invariably preserves the same specific volume. Isomeric compounds have the same specific volumes which stand to one another in the same relation as the molecular weights of the compounds. Variations in the chemical constitution of isomeric compounds are without effect on their specific volume. (4) Comparisons of specific volumes of liquids are only valid at temperatures at which the vapour pressures of the liquids are equal.

H. Kopp considered that these conclusions did not rest on a very firm experimental basis, and he therefore made accurate determinations of the physical constants required for testing them rigorously. The results of this work enabled him to take a general survey of the subject in his memoir, *Beiträge zur Stöchiometrie* *der physikalischen Eigenschaften chemischer Verbindungen*, 1855. His main conclusions were :

> (1) The selection of the temperature of equal vapour pressure as a basis of comparison seems to be warranted by the fact that regularities are thereby made evident which otherwise are not apparent. (2) Differences of specific volume are proportional to differences in chemical composition. (3) Isomeric liquids of the same chemical type have equal specific volumes. (4) The substitution of hydrogen for an equivalent amount of oxygen only slightly affects the specific volume. (5) One atom of carbon can replace two atoms of hydrogen without altering the specific volume.

The molecular volumes of the members of a homologous series of liquids which differ in composition by CH_2 increase nearly 22 units for each increment of CH_2. Thus, the molecular volume of formic acid, H.COOH, is 41·3 ; of acetic acid, CH_3.COOH, 63·6 ; and of propionic acid, C_2H_5.COOH, 85·6. Hence, the molecular volume of the group CH_2 is 22. Further, the replacement of one atom of carbon by 2 atoms of hydrogen in a compound usually makes no marked change in the molecular volume, and hence it is inferred that the atomic volume of carbon is nearly equal to the molecular volume of H_2. Since the molecular volume of CH_2 is 22, it follows that *the atomic volume of carbon is* 11. The difference, $22-11=11$, thus represents the molecular volume of H_2, and *the atomic volume of hydrogen is* 5·5. Again, the molecular volume of water is 18·8 ; deduct 11, the value of H_2, and *the atomic volume of oxygen* 7·8 remains. The molecular volumes of a large number of compounds can be calculated from the data so obtained, and compared with those obtained by actual experiment. The results for many carbon compounds are quite satisfactory. Thus, with alcohol, C_2H_5OH, the molecular volume will be $(2\times11)+(6\times5·5)+7·8=62·8$. The observed value is 62·2. Hence, if a compound contains n_1 atoms of atomic volume A_1 ; n_2 atoms of atomic volume A_2 ; . . . , the

$$\text{Molecular volume, } v=n_1A_1+n_2A_2+\ \ldots$$

H. Kopp here over-emphasized the additive character of this property, but he did point out that the specific volume of a liquid is determined not only by its composition but also by its constitution, for he found that the relative position of the oxygen atom in a molecule affected the specific volume. The atomic volumes of the oxygen atoms in carbonylic and hydroxylic oxygen are respectively 12·2 and 7·8. The idea will be clear by comparing methyl alcohol, CH_3OH, with formaldehyde, H.COH, and with formic acid, H.COOH—

$$\begin{matrix}H\\H\end{matrix}\!>C<\!\begin{matrix}H\\OH\end{matrix}$$

Methyl alcohol
(Hydroxylic oxygen).

$$O=C<\!\begin{matrix}H\\H\end{matrix}$$

Formaldehyde
(Carbonylic oxygen).

$$O=C<\!\begin{matrix}H\\OH\end{matrix}$$

Formic acid
(Hydroxylic and carbonylic oxygen).

By applying similar methods to those described above, it is found that the atomic volume of carbonylic oxygen is 12·2. The molecular volume of methyl alcohol is accordingly $4\times5·5+11+7·8=40·8$; of formaldehyde, $2\times5·5+11+12·2=34·2$; and of formic acid, $12·2+7·8+2\times5·5+11=42·0$. Consequently, it is inferred that **one and the same atom may have different atomic volumes according to the conditions under which it is placed.** In further illustration, sexivalent sulphur has an atomic volume 12·0 ; quadrivalent sulphur, 22·6 ; and bivalent sulphur, 28·3. Nitrogen in ammonia and related compounds has an atomic volume 23 ; in cyanogen compounds, 28 ; and in nitroxyl compounds, 33. Hence, *the molecular volume can sometimes be used* (1) *for estimating the molecular weight of a liquid from its specific gravity and composition ; and* (2) *it may reveal peculiarities in the constitution of the molecule.* For instance, it may be used to show whether carbonylic or hydroxylic oxygen is present.

EXAMPLES.—(1) The observed molecular volume of acetic acid, $C_2H_4O_2$, is 63·7. The only molecular volume compatible with this is 64, deduced on the assumption that the compound contains one hydroxylic oxygen atom (7·8), and one carbonylic oxygen (12·2).

The formula for acetic acid is therefore written $CH_3-CO-OH$. (2) The density of phosgene, $COCl_2$, at its boiling point, is 1·415. What is the atomic volume of chlorine, on the assumption that the atomic volume of oxygen is 12·2; and of carbon 11·0 ? Ansr. $99/1{\cdot}415=12{\cdot}2+11{\cdot}0+2x$; x, the required atomic volume, is therefore 23·4.

A large number of solid and liquid compounds—over a thousand—have been examined. The pioneer work was done by H. Kopp and extended by many other workers.[4] With solids the data which have been accumulated are even more difficult to deal with, since the disturbing factors seem to be even more perplexing than is the case with liquids. Although many additive regularities have been detected ranging over a limited number of compounds, yet, almost every investigation has emphasized the constitutive nature of this property, and narrowed the range of the simple additive rule. Even the increment CH_2 in a homologous series, when determined at the boiling points, is not additive, for its effect becomes greater as the series is ascended, but, as A. Horstmann showed, the effect is not so marked when the comparison is made at equal temperatures, or, as F. Krafft has shown, at the melting points. H. Kopp thought that isomerides of similar structure had the same molecular volume, but P. Dobriner and R. Gartenmeister have shown that the effect is related with the boiling points, for the lower boiling isomer has the larger molecular volume; J. C. Brown, A. Zander, T. E. Thorpe, and W. Städel showed that isomers with an *iso*-structure also have the larger molecular volume. F. Neubeck showed that the molecular volume of the benzene derivatives is modified according as the groups occupy the ortho-, para-, or meta-position. P. Walden and T. Liebisch found that the racemic isomer of stereo-isomerides has the smaller molecular volume, and I. Traube that the trans-isomer has the greater molecular volume. H. L. Buff also showed that the atomic volume of an element varies according to its degree of saturation, and that an unsaturated carbon atom has a larger atomic volume than a saturated one. Hence, argued H. L. Buff, the atomic volume of an element decreases as saturation proceeds. This was confirmed by R. Schiff and W. Lossen, who found that on passing from a saturated carbon atom to one with the double ethylene linkage, the molecular volume decreases about 8·5 units, and on passing from the double ethylene to the triple acetylene linkage, the molecular volume decreases about 6·5 units. In a homologous series of ethylene linkages, the effect produced by each is rather less than the preceding one. A. Horstmann found that "unsaturated compounds with closed chain formulæ have considerably smaller molecular volumes than those with open chain formulæ and multiple linkages of the atoms." R. Willstätter showed that the contraction in the molecular volume which accompanies the conversion of a normal chain hydrocarbon to the ring or cycloid structure is larger than is caused in passing from a saturated to an unsaturated compound. Consequently, **molecular volumes are dependent upon differences in the structure of the compound as well as on the nature of the atoms in the molecule.**

The difference between the molecular volumes of the MO oxides and the atomic volume of M gives fairly constant values for the atomic volume of oxygen, but in other cases very different values are obtained. Thus, the oxygen in cupric oxide has an atomic volume 5·1, and in cuprous oxide 10·5. B. Brauner and J. I. Watts have investigated the atomic volumes of the oxides, and found the results are in accord with the periodic law, and conclude:

(1) In strong bases the oxygen has a negative value. (2) In the oxides of heavy metals and metalloids the volume of the oxygen is positive. (3) The earth metals unite with oxygen without any appreciable change of volume, and thus form a connecting link between acids and bases. (4) The higher the specific volume of the element in the oxide, the less positive or more negative is the specific volume of the oxygen. (5) The more negative the value of the oxygen, the greater is the affinity of the metal for the oxygen.

L. Playfair and J. P. Joule[5] noted that the molecular volumes of certain highly hydrated salts—*e.g.* sodium decaquocarbonate, and the alkali dodecaquophosphates and dodecaquoarsenates—are exactly equal to that of the water, considered as ice, which they respectively contain, so that the molecules of the salt proper seem to exist in the interstitial spaces of the water since they exert no apparent influence on the bulk. The relation does not hold with salts less highly hydrated—*e.g.* borax, sodium pyrophosphate, and aluminium sulphate—where the molecular volume is the joint effect of the water considered as ice, and of the salt. R. Schiff also showed that the members of certain classes of hydrated salts have practically the same molecular volume—*e.g.* the alums have a molecular volume of about 277; the double sulphates of the type $M_2'M''(SO_4)_2.6H_2O$ have a common molecular volume of about 207; and the vitriols of the type $M''SO_4.7H_2O$, isomorphous or not, have the same molecular volume 146. T. E. Thorpe and J. I. Watts have further shown that the volumes occupied by the several molecules of water in polyhydrates vary with the degree of hydration, for the molecular volumes of hydrated salts are not usually equal to the sum of the molecular volumes of the anhydrous salt and of the water (18·8). With the magnesium sulphates, for example,

$MgSO_4$ plus . . .	0	1	2	5	6	7 H_2O
Molecular volume .	45·3	55·6	67·0	112·4	130·8	146·4

The first molecule of water, the constitutional water or the water of halhydration of T. Graham, here occupies a less volume than the remaining molecules. The second molecule of water raised the molecular volume 11·4; the next three molecules of water raise the molecular volume an average of 11·8; the sixth molecule raises the constant 18·4, and the seventh, 15·6. T. E. Thorpe and J. I. Watts obtained analogous results with the series of sulphates $MSO_4.nH_2O$, when n varied from 0 to 6. This is in harmony with H. Kopp's general conclusion that the water molecules of a hydrated salt contribute in different degrees to the total molecular volume, for in salts containing a small number of water molecules (1 to 3), he found the average molecular volume of the water is 12·4; in others containing a larger proportion (2 to 7), the average molecular volume is 13·4; and in a third class, with the largest proportion of water molecules (3 to 10), the average molecular volume is 15·3. F. W. Clarke compared similarly the molecular volumes of a series of chlorides $MCl_2.nH_2O$, when n varied from 2 to 6; and for a series of hydrated oxides—$B_2O_3.3H_2O$; $I_2O_5.H_2O$; $K_2O.H_2O$; $CuO.H_2O$; $SrO.H_2O$; $BaO.H_2O$; $Al_2O_3.3H_2O$; $Mn_2O_3.H_2O$; $Fe_2O_3.H_2O$. In the former, the molecular volume of the water varied from 12·5 to 15·0, and in the latter from 7·4 to 19·4. F. W. Clarke's results emphasize the difference between water of crystallization and water of constitution in that the chemical differences implied by these expressions are connected with the relative magnitudes of the spaces occupied by chemically comparable quantities of the hydrated salts. The contraction which occurs in the dilution of sulphuric acid with water is indicated in Fig. 27, Cap. X.

The atomic volume of an element obtained by dividing atomic weight by its specific gravity is not the same as the atomic volume deduced by H. Kopp from the molecular volumes when the element is in combination. The two values are not usually the same. For instance,

	H.	C.	Cl.	Br.	I.	O.
H. Kopp, atomic volume .	3·5	11	22·8	27·8	37·5	7·8–12·2
Calculated from element .	11	3·4	22·2	25·1	25·6	14·3

In 1831, T. Thomson compiled a table of atomic volumes of the metals, and noted a correspondence in the atomic volume of the elements most nearly related with one another. When the atomic volumes are plotted against the atomic weights, L. Meyer[6] showed in 1869 that a periodic curve is obtained like Fig. 4 in Cap. VI, where (1) the waves increase in amplitude as the atomic weights increase; (2) the elements of similar chemical properties occupy corresponding positions on the waves; (3) the more volatile and easily fusible elements occur on the crests or rising portions of the curve, and the elements which fuse with difficulty are in the troughs or on the descending portions of the curve. The curve was found by W. Borchers to be more regular and the relations between the elements clearer if the equivalent volume—atomic weight÷maximum valency—be employed in place of the atomic volumes.

The molecular volume of an element varies with the conditions under which the molecules are placed. The atom is presumably always in oscillatory periodic motion, and this motion gives rise to volume; consequently, the molecular volume is a relative measure of the space inhabited by the molecule; it represents the smallest space which the molecule requires for itself under the existing conditions. Similar remarks apply to the atomic volume so that **each atom can be regarded as a material nucleus surrounded by an envelope, shell, or space—called the sphere of action or sphere of influence into which no other atom or molecule can penetrate.** The sphere of influence is thus regarded as the effective boundary surface of an atom. This is what is sometimes called the *vibratory or oscillatory volume of an atom*, that is, the space within which the material nucleus performs its oscillations. Such a space would have the quasi-rigidity characteristic of a material nucleus rapidly revolving about a mean position. There is, however, no need to make any assumptions as to the nature of the internal character of the atomic nucleus with its encircling shell; it is not even necessary to assume that the complex is spherical. Under ordinary circumstances the complex can be regarded as the atom itself, since the so-called sphere of influence is the actual boundary by which we know and measure the behaviour of the atom. This is the concept of the atomic volume as pictured by D. I. Mendeléeff (1889), O. E. Meyer (1899), T. W. Richards (1901), etc.

In J. D. van der Waals' equation $(p+av^{-2})(v-b)=RT$, the term b represents the volume occupied by the substance, *i.e.* the molecular volume at absolute zero, since at this temperature v becomes equal to b and represents the volume occupied by the substance of the atoms—the atom nucleus as it may be called—but it is said to be four times the actual volume of the molecule. It is not practicable to compare the values of b for different substances because of the lack of data; but from the theory of corresponding states, it may be shown that the critical volume v_c is three times the value of b, or $v_c=3b$; and the so-called critical coefficient, T_c/p_c, or, the ratio of the critical temperature and critical pressure, is related to b by the expression $T_c/p_c=8b/R$, where R is the gas constant $pv/273$.

F. Exner[7] showed that, according to R. Clausius and O. F. Mossotti, $(\mu^2-1)/(\mu^2+2)$ is equal to the ratio of the volume actually occupied by matter to the apparent volume of the substance, when μ represents the refractive index for waves of infinite wave length, and it is found that μ^2 is equal to the dielectric constant. Consequently, as P. A. Guye has shown, the product of $(\mu^2-1)/(\mu^2+2)$ with the molecular volume will be a measure of the space filled by matter in a gram-molecule of a substance. Consequently, the magnitude b of J. D. van der Waals' equation, the critical volume, and the critical coefficient may be represented as functions of the molecular refraction. I. Traube has shown that b is between 3·5 and 4 times as large as the molecular refraction, MR, and P. A. Guye found the relation $MR=18T_c/p_c$. From I. Traube's result, it follows that atomic refraction can be employed as a measure of the material nucleus of an atom composed of a material nucleus and an encircling shell or sphere of influence. The sphere of influence represents a kind of shell about the atom nucleus, and it is presumably that portion of the atom which is permeable to light, and constitutes a dielectric medium which enables electromagnetic radiations to be transmitted through a body at a speed which is characteristic of the particular substance.

T. W. Richards[8] has shown that while it is assumed that the molecules of a gas are particles moving independently at some distance apart, it is doubtful if there are such interstitial spaces in liquids and solids. The impermeability of glass to oxygen, nitrogen, and water for long periods does not lend support to the view that there are empty spaces between the molecules; and he limits the permeability which has been observed in rigid compact solids, to such substances as can enter into the chemical structure of the solids themselves. It is therefore inferred that in solids and liquids the atoms formed of material nuclei with enveloping shell are in close contact with one another at the boundary of their envelopes. Such atoms are considered to be compressible and elastic; they can contract and expand, or vibrate among themselves even when their surfaces are closely packed together; and they are quite capable of sustaining and transmitting the vibratory motions called heat. E. Grüneisen's observations show that the compressibility of a number of metals—copper, silver, aluminium, iron, and platinum—loses only 7 per cent. in cooling from the ordinary temperature down to that of liquid air, and by extrapolation very little more diminution will occur in passing down to the temperature of absolute zero, so that it is probable that metals are as compressible at absolute zero as they are at ordinary temperatures. The value of b in J. D. van der Waals' equation is fairly constant over a wide range of pressure, but it suddenly begins to diminish when very high pressures have been attained. Again, for carbon dioxide, the value of b increases as the temperature rises, thus, if $a=0{\cdot}00874$, and $v=$unity at 0° and 760 mm., then $b=51$ c.c. per gram-molecule at 0°, and 64 c.c. at 100°. For hydrogen likewise, b is 13·8 c.c. at 0° and 15·1 c.c. at 100°. On the other hand, H. K. Onnes has shown that the apparent volume b of helium atoms is smaller at high than at low temperatures; at 0°, b is 12 c.c., and at 100°, 10·4 c.c. per 4 grms. of helium. This is not what would be anticipated, and T. W. Richards makes the tentative suggestion that "the greater velocity of the colliding atoms at the higher temperature has a greater compressing effect so that at high temperatures the atoms seem to occupy less space than at lower temperatures."

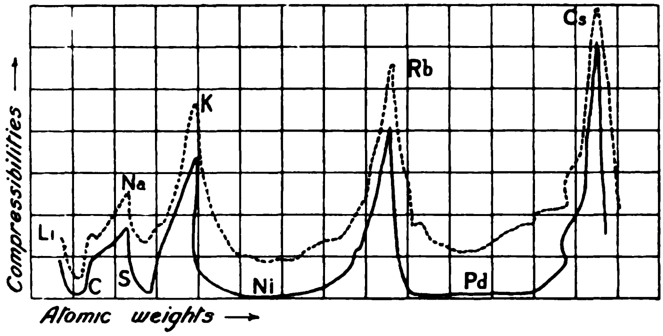

FIG. 4.—Compressibility and Atomic Volume Curves of the Elements.

T. W. Richards has shown that the compressibilities of the elements—*i.e.* the relative contractions in volume per megabar (0·987 atm.) per sq. cm.—are closely related to their atomic volumes, for the structure of the two curves is very similar as indicated in Fig. 4, where the atomic volume curve is dotted, and the compressibility curve is continuous. **The greater the densities of the elements the less their compressibility.** The elements with the larger atomic volumes are the more compressible and the more easily melted and volatilized. Consequently, the compressibilities of different substances are not only dependent on the magnitude of the applied pressure, but also on the internal pressure produced by the mutual cohesive attraction between the particles. In gases, the cohesive pressure is small, and accordingly the compressibility is large; in solids and liquids the cohesive pressure is large, and the compressibility is small. T. W. Richards' theory of compressible atoms thus reveals the existence of internal cohesive and affinity pressures holding the atoms and molecules together.

Cohesive pressure exerted by the cohesive forces which bind the molecules together.—Cohesion manifests itself in various ways; the most obvious is the mechanical resistance which a body offers to the separation of one part of a substance from another, and it appears more or less modified in such properties as ductility, malleability, tenacity, hardness, surface tension, volatility, etc. The density of a given substance is a manifestation of an internal pressure—the greater the density, the greater the internal pressure. When a rise of temperature produces a marked effect on the volume, it may be assumed that the internal pressure is less than when a rise of temperature produces only a slight effect on the volume. Substances in which the particles are held together by a high cohesive attraction are usually difficult to volatilize ; they have a small atomic volume ; a relatively large density ; a high surface tension ; high latent heat of evaporation ; and are least compressible. Conversely, if the atomic volume be relatively large owing to a small cohesive attraction, these substances will be most volatile and have the greatest compressibility. In illustration, T. W. Richards found that the three isomeric xylenes agree well with these deductions :

	o-Xylene.	*m*-Xylene.	*p*-Xylene.
Density (20°)	0·8811	0·8658	0·8611
Boiling point	144·0°	139·0°	136·2°
Compressibility (20°) . .	60×10^{-6}	$63{\cdot}5\times10^{-6}$	$66{\cdot}2\times10^{-6}$
Surface tension (20°) . .	3·09	2·96	2·92 mgrm. per mm.

T. W. Richards also compared some properties of two isomeric butyric esters, and found in each case :

	Specific gravity.	Compressibility.	Decrease in compressibility per 222 atm.	Coefficient of expansion.	Boiling point.	Surface tension.	Heat of vaporization.
Ethyl butyrate	0·8785	$76{\cdot}9\times10^{-6}$	$13{\cdot}6\times10^{-6}$	0·001247	120·8°	24·58	34·7
Ethyl isobutyrate	0·8710	$90{\cdot}8\times10^{-6}$	$15{\cdot}0\times10^{-6}$	0·001294	109·8°	23·30	33·9

The denser substance has the less compressibility, the less decrease in compressibility with an increase of pressure, the less coefficient of thermal expansion, the higher boiling point, the greater surface tension, and the greater heat of vaporization. All this is in accord with the assumption that a great cohesion produces an internal pressure which is effective in reducing the molecular volume. Hence it follows that not only is the atomic volume dependent upon the nature and location of the different atoms in the molecule, but also on the cohesive attraction of one molecule for another.

If the atomic volume be related with the cohesive pressure, and if the valency of an element in a compound be related with the atomic volume, it might be anticipated that the cohesion will be a function of the valencies of the combined elements. W. Sutherland found that the valencies of the elements in simple substances like sodium chloride influenced the cohesion, but he was unable to establish a relationship for more complex bodies. A. P. Mathews found empirically that the cohesion factor a of J. D. van der Waals' equation is related with Σv, the number of valencies, and the molecular weight M by the expression $a=0{\cdot}3125\times10^{-5}M\Sigma v$; and from the known relations of a to the critical constants T_c, v_c, and p_c, it follows that $Mp_c^{\frac{1}{2}}\Sigma v=0{\cdot}0043T_c^{3}$; and also that $M\Sigma v=4{\cdot}3\times10^{-5}(v_cT_c)^{\frac{3}{2}}$. A. P. Mathews uses these expressions for computing the valencies of chlorine, oxygen, sulphur, nitrogen, phosphorus, and the elements of the argon family.

Affinity pressure, produced by the chemical affinity or mutual attraction of adjacent atoms.—The atomic volume of an element depends on the nature of the associated atoms. In the middle of the eighteenth century, R. Kirwan sought to measure the force of the attraction between the atoms in a chemical compound from the diminution in volume which attended the union of two substances ; while H. Davy and others have alluded to the increase in density of the product of the union of two substances with a powerful affinity for one another. Thus, W. Müller-Erzbach (1881) said that in similarly constituted solids, those are the most stable which are formed with the greatest contraction—*e.g.* when lead replaces silver ; potassium, sodium ; or, when chlorine replaces bromine or iodine, contraction occurs, and the products of the replacement are the more stable. According to F. Ephraim and P. Wagner, the molecular volume of a stable compound is smaller than the sum of the volumes of its decomposition products, as shown by the schönites studied by A. E. H. Tutton. The double alkali magnesium sulphates have smaller molecular volumes than the copper or manganese salts, although the atomic volume of the metal is greater with the first than with the other two. The stability of the salts is more strictly parallel to their molecular volumes than to the atomic volumes of the free metals. The percentage contraction on the atomic volume rather than the actual contraction suffered by any particular atom is thus the important criterion of the stability of a compound.

D. I. Mendeléeff has shown that the greater the affinity of the elements for one another, the less the atomic volume of the resulting compound. Thus the contraction which occurs during the formation of potassium or sodium oxide is greater than in the formation of stannic oxide. As V. Braun expressed it, the specific gravity of solid chemical compounds is high in proportion to the intensity of the affinity which unites their components, and G. S. Johnson inferred that the affinity of iodine in potassium tri-iodide is small because combination occurs without contraction. W. Müller-Erzbach and I. Traube have emphasized the same idea. Other things being equal, **elements with the greatest densities have the least chemical affinity and suffer least change in their atomic volumes when they enter into combination**—these elements will be found distributed about the troughs of the curve, Fig. 4. Conversely, **elements with the smallest densities are usually most energetic chemically and suffer the greatest contraction in their atomic volumes when they form chemical compounds**—these elements will be found distributed about the peaks or crests of the curve, Fig. 4.

The fact that the less the density, or the greater the compressibility of an element, the greater its contraction on combination, is best illustrated by comparing the contractions occurring during the formation of similar compounds of the elements having widely different compressibilities but similar affinities. Strontium and lead are not very different in cohesive pressure as shown by the closeness of their boiling points. When a gram-atom of strontium unites with a gram-molecule of chlorine, there is a contraction of 32·6 c.c., and lead gives under similar conditions a contraction of 20·1 c.c. If affinity causes contraction this is just what would be anticipated because the affinity of strontium for chlorine is greater than that of lead; this is confirmed by the respective heats of formation 772 and 346 kilojoules per gram-molecule. The compressibilities of the elements of the alkali metals and the contractions which occur, in c.c. per gram-molecule, when the corresponding chloride is formed, are as follows:

TABLE IX.

Element.	Compressibility.	Contraction (c.c. per gram-molecule).
Lithium	$9{\cdot}0 \times 10^{-6}$	17·6
Sodium	15·6	21·5
Potassium	31·7	33·1
Rubidium	40·0	36·8
Cæsium	61·0	53·6

Not all examples will give such unequivocal evidence of the effect of chemical affinity in determining the atomic volumes of liquids and solids, because the effects of chemical affinity will be modified or even overshadowed by the effects of cohesion. Both must always be present, and it may be difficult to discriminate between the two effects. Similarly, the heat of formation Q of a compound runs parallel with the free energy, and may be regarded as proportional to the work done by the affinity pressure between two elements. Similarly, when two elements unite, the contraction Δ is evidence of the affinity uniting the elements. The contraction Δ

is the difference between the molecular volume of the compound, and the sum of the atomic volumes of the component elements in a free state. The quotient of the volume contraction, Δ, by the heat of formation, Q, will give a measure of the average compressibility. In Table X, T. W. Richards showed that the compressibility effect with the alkali halides must be the same in each member of the series, and the values of Δ/Q for the different salts should fall in the same order of magnitude as the compressibilities of the free alkali metals if the hypothesis relating affinity pressure to compressibility be correct. This is actually the case.

Table X.—Compressibilities and Affinity Pressures of the Alkali Halides.

Salt.	Compressibility of metal.	Sum of atomic volumes.	Molecular volume.	Contraction Δ.	Heat of formation Q.	$\frac{\Delta}{Q}$
LiCl . .	$8{\cdot}8\times10^{6}$	37·7	20·9	16·8	383	4·4
NaCl . .	13·4	48·7	27·2	21·5	399	5·4
KCl . .	31·5	70·0	37·8	32·2	427	7·6
LiBr . .	8·8	38·8	25·2	13·0	334	3·9
NaBr . .	13·4	49·2	34·2	15·0	359	4·2
KBr . .	31·5	70·5	44·2	26·3	398	6·6
LiI . .	8·8	38·4	33·1	5·3	257	2·1
NaI . .	13·4	49·4	41·4	8·0	289	2·8
KI . .	31·5	70·7	53·8	16·9	335	5·1

In the light of T. W. Richards' hypothesis, we can also see that for H. Kopp's rule to be valid the internal pressures of all compounds at their boiling points should be the same—subject to small variations due to differences in molecular complexity. The intense intermolecular pressures under which the molecules exist modify the boiling points, the surface tensions, the viscosities, etc. The effects produced by cohesive and affinity pressures on atoms with an elastic compressible envelope, as postulated by T. W. Richards, show that the volume occupied by an atom in the free state cannot be the same as in the combined state, and that the volume of an atom in combination will vary with the nature and orientation of the other atoms with which it is combined.

H. Schröder[9] worked on the subject of atomic volumes simultaneously with H. Kopp; he accepted F. Ammermüller's conclusion that equal volumes of the two oxides of copper contain the same amounts of copper, and multiple amounts of oxygen, and assumed that in the two compounds with the atomic volumes: $Cu_2O=24{\cdot}36$; and $CuO=12{\cdot}35$ or $Cu_2O_2=24{\cdot}70$, the quantities of copper are the same, and that the volume of the copper is in each case the same. The volume occupied by the oxygen in cuprous oxide then stands to that in cupric oxide as 1 : 2. H. Schröder concluded with H. Kopp that the molecular volume of a compound is the sum of the volumes of the component atoms. The former considered that the atomic volume of a given element under similar structural conditions throughout all its compounds is variable—the latter assumed that under these conditions the atomic volume of an element is constant. The different atomic volumes which an element can assume in different compounds were regarded by H. Schröder to be simple multiples of a certain unit volume which he called the *stere*. The stere is not the same for all elements, but it varies within comparatively narrow limits. When two elements are combined, one of them assumes the unit volume of the other, so that the stere of one element dominates the volume of the compound, and the molecular volume of the compound may be represented as a simple multiple of the stere of one of the contained elements. For example, the stere of silver is 5·14, and the atomic value is twice this, namely, 10·28, so that metallic silver occupies 2 steres.

	Stere value.	Molecular volume. Calculated.	Molecular volume. Observed.
Silver oxide	$5·14 \times 6 =$	30·8	30·8
Silver chloride	$5·14 \times 5 =$	25·7	25·8
Silver bromide	$5·14 \times 6 =$	30·8	30·8
Silver iodide	$5·14 \times 8 =$	41·1	41·8

Hence, the atomic volume of oxygen is $\frac{1}{2}(6-2)=2$ silver steres; of chlorine, $5-2=3$ silver steres; of bromine, $6-2=4$ silver steres; and of iodine, $8-2=6$ silver steres. The general conclusion is that the volumes of equivalents of different elements are approximately equal, or stand in some simple relation with one another. This naturally raises the question whether there is any connection between the valency of the atoms and its effect on the molecular volume. In a general way, an increase in the valency of an atom is attended by an increase in the molecular volume, although, as W. Städel has shown, the molecular volume is influenced by all the atoms in the molecule. G. le Bas [10] compared the molecular volumes of eighteen hydrocarbons of the paraffin series at their melting points, and found that the quotient, obtained by dividing the molecular volume by the total number of valencies of the carbon and hydrogen atoms present, is a constant—very nearly 2·97. In illustration, the molecular volume of dodecane, $C_{12}H_{26}$, is 219·9; there are 12×4 carbon valencies, and 26 hydrogen valencies, or a total of 74 valencies; consequently $219·9 \div 74 = 2·971$. The constant 2·97 thus represents one unit of valency in these compounds.

I. Traube [11] has investigated molecular volumes from a novel point of view. He takes the specific gravity at ordinary temperatures—usually about 15°—and he also allows for the association of the substance. I. Traube defines the *molecular solution volume*, V_m, of a substance in water by the relation

$$\text{Molecular solution volume, } V_m = \frac{M+A}{D_s} - \frac{A}{D_w}$$

where M denotes the molecular weight of the dissolved substance, D_s and D_w are the specific gravities respectively of the solution and of water, and A denotes the number of grams of water in which a gram-molecule of the substance is dissolved. If v denotes the ordinary molecular volume, defined by M/D, the difference $v-V_m$ denotes the contraction which occurs in the process of solution, and is called the *molecular contraction*, and it is found that if ionization and association effects are eliminated, the molecular contraction has the constant value $v-V_m=13·5$ c.c. per gram-molecule.

If ionization occurs, the number of ions which in their action are equivalent to non-ionized molecules must be taken into consideration. If α denotes the degree of ionization of a solute decomposed into n ions, then, in place of 13·5 c.c., the molecular contraction $=13·5\{1+(n-1)\alpha\}$. If association occurs, the association factor must be considered. The association factor is a number which represents how many times the molecular weight of a substance is greater than corresponds with the simple gaseous molecule. In place of 13·5 c.c. the molecular contraction is $13·5/\beta$ c.c. per gram-molecule.

The molecular solution volume can be calculated from the volume constants of the constituent elements according to H. Kopp's additive rule, and the introduction of a correction factor. I. Traube found that this correction factor is a constant 12·4 c.c., so that if $n_1, n_2, \ldots$ denotes the respective number of atoms of atomic volume $A_1, A_2, \ldots$; and $\Sigma nA = n_1A_1 + n_2A_2 + \ldots$

$$\text{Molecular solution volume, } V_m = \Sigma nA + 12·4$$

The term ΣnA also includes a correction term for multiple bonds, etc.

By empirical calculation from the observed molecular volumes, I. Traube has computed the solution volume constants in c.c. per gram-atom for different radicles. He obtains: C, 9·9; H, 3·1; F, 5·5; Cl, 13·2; Br, 17·7; I, 21·4; CN, 13·2; Na, 3·1; N^{III}, 1·5;

N^{V}, 10·7; P^{III}, 17; P^{V}, 28·5; double bonds, −1·7; triple bonds, −3·4; Hydroxylic oxygen (OH), 2·3; Hydrosulphylic sulphur (HS), 15·5. Oxygen atoms united to carbon by a double bond, 5·5; sulphur atoms united to carbon by a double bond, 15·5; oxygen atoms in a carbonyl group, or united to a carbon atom with a hydroxyl group attached to it, 0·4. The observed density of ether, $(C_2H_5)_2O$, is 0·7201 at 15°; the molecular weight is 74. Compare the observed and calculated molecular volume. The observed value is $74/0{\cdot}7201=102{\cdot}7$; the calculated value is $(4\times9{\cdot}9)+(10\times3{\cdot}1)+5{\cdot}5+25{\cdot}9=102{\cdot}0$.

If as before v denotes the molecular volume, and if there is no ionization, $v-V_m=13{\cdot}5/A$, then $v=\Sigma nV+12{\cdot}4+13{\cdot}5/\beta$, where the association factor β is usually nearly unity—*e.g.* with phosphorus trichloride, and carbon and silicon tetrachlorides, β=unity; for benzene, $\beta=1{\cdot}18$; for toluene, 1·08, etc.—but with water $\beta=3{\cdot}06$; formic acid, 1·8; acetic acid, 1·56; methyl alcohol, 1·79; ethyl alcohol, 1·67, etc. When β is unity $V_m=\Sigma nA+12{\cdot}4$; and

$$\text{Molecular volume, } v=\Sigma nA+25{\cdot}9$$

meaning, according to I. Traube, that "in the formation of any molecule from its atoms there is always a dilation; the molecular dilation is the same or nearly the same for all substances; it is independent of the chemical nature of the substance and can be only slightly modified by constitution; and at 15°, the molecular solution volume in aqueous solution is 12·4 c.c. per gram-molecule, and the molecular volume 25·9 c.c. per gram-molecule." Given the molecular volume it is possible to calculate the association factor which may or may not agree with that deduced by other methods.

I. Traube regards ΣnA as the sum of the spaces occupied by the matter of the atoms of a molecule. While the internal or nuclear volume of a molecule is the space actually filled by the mass of the atom, the external volume is the nuclear volume increased by the volume of a shell of combined æther. The external atomic volume corresponds with the magnitude b of J. D. van der Waals' equation, and is 3·5 to 4 times as large as the internal or nuclear volume. The difference $V_m-\Sigma nA$ gives what I. Traube calls the **molecular co-volume**—symbolized Co_v. The co-volume is a magnitude dependent on the temperature; for 15°, the molecular co-volume is 25·9 c.c., and at θ°, the molecular co-volume is $Co_{v_0}(1+0{\cdot}00367\theta)$, or the

$$\text{Molecular co-volume, } Co_v=24{\cdot}5(1+0{\cdot}00367\theta)$$

very nearly. There is a close formal analogy between the temperature effect of the co-volume and the volume of gas. Since, for every newly formed gram-molecule there is an expansion equal to the co-volume, and for every molecule which disappears there is a corresponding contraction, I. Traube concluded: "In a reaction between homogeneous liquids, the co-volumes of the initial and final products of the reaction stand in a simple rational ratio"—this is J. A. C. Charles' law applied to liquids. Since also I. Traube assumed that the molecular volume is the sum of the true molecular volume and the co-volume, Avogadro's rule applied to liquids becomes "with the same conditions of temperature and pressure, the co-volumes, or the volumes in which the molecules move, are all equally great."

I. Traube's method can be employed for calculating the molecular volume, and also the molecular weight M of an unknown substance of known specific gravity D. In this case, since $v=M/D$, the chemical formula which gives the closest value to

$$\frac{M}{D}-\Sigma nA=25{\cdot}9$$

is the desired chemical formula. Many examples will be found in H. Biltz's *Die Praxis der Molekulargewichtsbestimmung* (Berlin, 1898; Easton, Pa., 1899).

The observed specific gravity of tetrachloroethane is 1·6258 (15°), the empirical formula by analysis is $CHCl_2$. Hence, if the formula $CHCl_2$ obtains, the ratio $M/D=51{\cdot}6$ and $\Sigma nA=39{\cdot}4$, or $M/D-\Sigma nA=12{\cdot}2$; if the formula be $C_2H_2Cl_4$, $M/D-\Sigma nA=103{\cdot}2-78{\cdot}8$

$=24{\cdot}4$; and if the formula be $C_3H_3Cl_6$, $M/D-\Sigma nA=154{\cdot}8-118{\cdot}2=36{\cdot}6$. Here then 24·4 approximates closest to the theoretical co-volume 25·9, and the formula is accordingly $C_2H_2Cl_4$.

According to I. Traube, the **atomic co-volume** is the difference between the internal and external atomic volumes; and it represents the volume of the combined æther. I. Traube further postulates that the atomic co-volume is occupied by the valency electrons, *i.e.* the electrons which endow the atom with valency; for, unlike the molecular co-volume, the atomic co-volume varies in size and is proportional to the nuclear volume and the valency of the atom. I. Traube employed molecular refraction as a measure of the nuclear volumes of the atoms in a compound and found that the molecular refractive power, MR, of a saturated compound is proportional to the total number of valencies, n, of the component atoms. The value of the quotient MR/n for a large number of compounds deviates but little from the mean 0·787. I. Traube calls 0·787 the *refraction stere*—in illustration, the molecular refraction of alcohol, C_2H_5OH, is 12·71, and n is $8+5+2+1=16$; and $12{\cdot}71\div16=0{\cdot}794$. The nuclear volumes of the atoms in a molecule are therefore proportional to the valencies of the atoms.

W. C. Roberts-Austen[12] suggested that the remarkable influence of traces of elements on masses of metals is proportional to the atomic volumes of the contaminant. He showed that the metals or metalloids near the troughs of L. Meyer's periodic curve, Fig. 4, Cap. VI, do not diminish the tensile strength of gold; and that the metals which render gold fragile occupy high positions on the curve. Hence he argues:

> There is some relation between the influence exerted by the metallic and other impurities and either their atomic weights or their atomic volumes. It seems hardly probable that it is due to atomic weight, because copper, with an atomic weight of 63·2, has nearly the same influence on the tenacity of pure gold as rhodium, with an atomic weight of 104, or as aluminium, the atomic weight of which is 27·0. It will be evident from the following table, which embodies the results of the author's experiments, that metals which diminish the tenacity and extensibility of gold have high atomic volumes, while those which increase those properties have either the same atomic volume as gold, or a lower one. Further, silver has the same atomic volume as gold, 10·2, and its presence in small quantities has very little influence, one way or the other, on the tenacity or extensibility of gold.

It is suggested that the atoms with a small atomic volume can fill up interstitial spaces which would otherwise remain void and this without disturbing the disposition of the other atoms, while atoms with a large atomic volume act prejudicially by driving the atoms further asunder. The following experiment by E. Warburg and F. Tegetmeier illustrates a porosity in solids which will permit the passage of elements with a small atomic volume, but strain off those with a larger atomic volume.

> A cell with a glass partition with sodium amalgam about the anode and mercury about the cathode was heated to between 100° and 200°—when the glass became slightly conducting. In about 30 hrs. an appreciable quantity of sodium had passed from the glass into the mercury. The glass remained transparent, for the sodium lost by the glass was replaced by that from the mercury amalgam. W. C. Roberts-Austen showed that in the electrolysis of the glass, the passage of the sodium follows the ordinary law of electrolysis. If lithium amalgam be used, the glass becomes opaque, and then lithium accumulates in the mercury. The glass loses no potassium, but 7·8 per cent. of sodium, and gains 4·3 per cent. of lithium. With potassium amalgam, the potassium does not replace the sodium lost by the glass. It is suggested that the lithium atoms with an atomic volume 15·98 can replace sodium atoms with an atomic volume 16·04, while potassium atoms with an atomic volume 24 are too large to take the place of the smaller sodium atoms. The glass diaphragm has thus been said to act as a mechanical sifter for the potassium atoms.

The simple relation between atomic volumes and tenacity is no doubt modified when compounds are formed. F. Osmond also showed that elements with a smaller atomic volume than iron retard the transformation of β to α iron, while elements with a larger atomic volume than iron either have no influence upon the transition temperature or else raise that temperature.

Several investigators have traced the influence of the atomic volume of a metal on the mechanical properties ; for example, A. Wertheim and H. Tomlinson have shown that there is a relation between the atomic volume and elasticity ; W. Sutherland, between the atomic volume and rigidity ; R. A. Fessenden, between atomic volume and cohesion ; and H. Crompton, between the latent heat of fusion and the molecular volume of a compound. H. Crompton also showed that the molecular heat of fusion L; the absolute fusion temperatures T; and the valencies n of the elements, are so related that L/Tn is a constant; and that a similar rule holds for compounds. From I. Traube's relation between valency and atomic volume, it therefore follows that the latent heats of fusion are a function of the molecular volumes, or of the sum of the atomic volumes. Hence also the latent heat of fusion must be a function of the sum of the valencies of the atoms in a molecule.

W. Barlow and W. J. Pope [13] assume that each atom of a crystalline compound occupies a definite space or sphere of influence, so that each atom has its own polyhedral cell or domain throughout which its influence is predominant; that the space occupied by a substance is partitioned into atomic domains of definite volume; that the mode of arrangement of such atoms determines the shape of the molecule ; that the atoms are held in place in stable equilibrium by the balancing of interatomic attractive and repulsive forces ; that the atoms are incompressible but deformable; that the atoms are closely packed by the squeezing together of the spheres so that the interstices are filled, while the volumes of the polyhedral forms which the atoms assume remain constant ; and that the homogeneous structure of a crystal is obtained by a symmetrical arrangement of the atomic spheres of influence. It is further shown that any symmetrical and homogeneous aggregate of closely packed atomic spheres, can be divided into space units which represent in composition and configuration the chemical molecule ; and that the dimensions of each of these units will be in accord with the crystal form of the compound. As G. D. Liveing (1891) remarked, "The problem is then reduced to finding how to pack the greatest number of equal spherical balls into a given space." When two or more arrangements, equally closely packed, are possible, each may occur and polymorphism will result.

W. Barlow and W. J. Pope assume that the relative volumes of the atoms of a compound—the atomic domains—are proportional to their valencies, so that the valency of an atom expresses the relative atomic volume ; or *the valency of an atom is proportional to the space occupied by that atom in a crystalline compound*—**valency volume**. For example, in benzene, the volume of one carbon atom is four times that of four hydrogen atoms because the valency of carbon is four, and of hydrogen one. The atomic volume of the same element or radicle may be different in different bodies. For example, A. E. H. Tutton has shown that the potassium and cæsium sulphates

	Molecular volume,	Axial ratios, $a : b : c =$
K_2SO_4	94·91	0·5727 : 1 : 0·7418
Cs_2SO_4	84·58	0·5712 : 1 : 0·7531

so that the substitution of an atom of cæsium for potassium lowers the molecular volume while the configuration of the molecules as shown by the axial ratios $a : b : c$ remains virtually unchanged. The cæsium atom enters the molecule in a definite position, and therefore it does not seem possible for the configuration of the molecule to remain constant unless the sulphuric acid group increases in the same ratio. This shows that the absolute atomic volume of an element may vary in different chemical bodies, though the valency volume, the ratio of the volume of any constituent to the volume of the whole molecule, may remain constant.

W. Barlow and W. J. Pope build up structures representing various chemical molecules by closely packing deformable spheres in a homogeneous symmetrical arrangement, and they deduce the dimensions of the crystalline form of each substance. For example, they show that with equal spheres the dimensions of the aggregate will have holohedral cubic or hexagonal symmetry, and the axial ratio $a : c$ with the latter must be either $a : c = 1 : 0{\cdot}8165$ or $a : c = 1 : 1{\cdot}4142$. Hence, in substances built up with atomic domains of equal size—elements, and binary compounds of elements with the same valency—the crystalline forms must be either cubic or hexagonal. Of the forty elements whose crystals have been examined, half are cubic, and one-third are hexagonal with axial ratios in accord with the theoretical requirements. The remaining six are either pseudo-cubic or pseudo-hexagonal, and their exceptional behaviour is explained by assuming that the atomic spheres are packed in groups or aggregates so that some of the spheres are differently situated in a close-packed homogeneous assemblage. Again, with the binary compounds of the elements, J. W. Retgers found 88 per cent. of the known forms are either cubic or hexagonal, and nearly all of these are composed of elements of equal valency. For example :

Beryllium oxide, BeO .	$a : c = 1 : 1{\cdot}6305$	Zinc sulphide, ZnS . .	$a : c = 1 : 1{\cdot}8175$
Zinc oxide, ZnO . .	$1 : 1{\cdot}6077$	Cadmium sulphide, CdS .	$1 : 1{\cdot}8109$

In some cases in place of holohedral symmetry, these binary compounds exhibit hemihedrism or tetartohedrism, a state of things which occurs with symmetrical arrangements of two kinds of spheres of slightly different size.

The geometrical laws which govern the replacement of spheres in a closely packed assemblage by others of different size run parallel with the chemical laws which determine the relations between the valencies of the elements which can replace one another in a chemical compound. It is said that all cases of substitution can be reduced to one of two types : (i) those in which the sum of the valencies of the substituting and substituted atoms or groups is constant—*e.g.* the substitution of hydrogen by chlorine ; and (ii) those in which the sum of their valencies differ —*e.g.* the substitution of hydrogen by methyl.

In substitutions of the first type, virtually no change occurs in the configuration of the molecule. This is taken to be exemplified by B. Gossner's study of the rhombic chloro- and bromo-ethanes—Table XI. :

TABLE XI.

	Molecular volume.	Valency volume.	Axial ratios $a : b : c$.	Equivalence parameters $x : y : z$.
$Cl_3C.CCl_3$ . .	113·34	14	0·5677 : 1 : 0·3160	2·4260 : 4·2733 : 1·3503
$Cl_3C.CBr_2Cl$ . .	116·72	14	0·5612 : 1 : 0·3171	2·4047 : 4·2849 : 1·3587
$Cl_2BrC.CBrCl_2$.	120·16	14	0·5646 : 1 : 0·3192	2·4090 : 4·2669 : 1·3620
$Br_3C.CBr_3$ . .	131·83	14	0·5639 : 1 : 0·3142	2·4197 : 4·2911 : 1·3483
$HBr_2C.CBr_3$ . .	126·46	14	0·5650 : 1 : 0·3118	2·4294 : 4·2995 : 1·3406

The equivalence parameters x, y, z here represent the three dimensions of the molecular volume reduced to a volume proportional to the valency volume. The constancy of the values x, y, z is taken to mean that while the absolute volumes of the molecules vary, the configuration of the molecules undergoes no change. This means that the ratio of the volumes of substituting and substituted atoms to the volume of the whole molecule is constant. If it were not so, the configuration of the molecule would change. Hence, the relative volumes of hydrogen, bromine, and chlorine are proportional to their valencies.

With substitutions of the second type, the dimensions of the molecule do change, and the change is proportional to that of the valency of the atoms or radicles concerned. For example, with the minerals, chondrodite, humite, clinohumite, and forsterite, studied by S. L. Penfield and W. T. H. Howe—Table XII, T. V. Barker emphasized the fact that prolectite has not been analyzed, and that W. Barlow and W. J. Pope credit the mineral with the composition indicated in the table solely because its axial ratio has the value there indicated.

TABLE XII.

	Valency volume *w*.	$a:b:c.$	$x:y:z.$
Forsterite, Mg_2SiO_4 . . .	16	0·9296 : 1 : 2·4492	2·4492 : 2·2769 : 2·8691
Prolectite, $MgSiO_4.2Mg(F, OH)$.	22	1·0803 : 1 : 2·3877	2·3877 : 2·2102 : 4·1689
Chondrodite, $Mg_3(SiO_4)_2.2Mg(F, OH)$	38	1·0863 : 1 : 3·1447	2·4294 : 2·2333 : 7·0199
Humite, $Mg_5(SiO_4)_3.2Mg(F, OH)$.	54	1·0802 : 1 : 4·4033	2·4279 : 2·2475 : 9·8965
Clinohumite, $Mg_7(SiO_4)_4.2Mg(F,OH)$	70	1·0803 : 1 : 5·6588	2·4347 : 2·2769 : 12·8691

The minerals differ by the constant increment of the group Mg_2SiO_4, which corresponds with forsterite, which has the $a : b$ ratio common to the whole series, while the $c : b$ ratio closely expresses the successive increments of the c-axis. This indicates that possibly the structural units of chondrodite, humite, and clinohumite are nothing more or less than the structural unit of prolectite on which have been superposed one, two, and three structural units of forsterite. The Mg_2SiO_4 group enters the molecule in the z direction, since the values of x and y remain nearly constant. Hence, say W. Barlow and W. J. Pope, the volume of the molecule is proportional to z; but the ratio of the valency-volume $w : z$ is nearly constant, so that the volume is proportional to the valency; consequently, it follows that the axial ratios $a : b : c$, and the equivalence parameters $x : y : z$, can be predicted for some member of a series when these values for other members are known. T. V. Barker has shown that the close correspondence between fact and theory is due to the closeness with which the hypothetical valency volumes satisfy the conditions : volume of Mg_2SiO_4 : volume of $Mg(F,OH)_2 = 2 : 1$, and that the particular volumes arbitrarily selected by W. Barlow and W. J. Pope present one out of an infinite number of such solutions. Furthermore, when the minerals are arranged in accord with chemical composition, the order is not that of the accepted axial ratios, but forsterite, clinohumite, humite, chondrodite, and prolectite. There is very little difference in composition between clinohumite and forsterite, even the end-member prolectite differs from forsterite only by the amount of $Mg(F,OH)_2$. The group, indeed, is to be regarded as a series of varieties of forsterite with variable amounts of $Mg(F,OH)_2$, until further investigation has established the individuality of the mineral species.

It has been noticed that water of crystallization causes the expansion of the molecule mainly in one direction, showing that the water of crystallization probably enters the crystal structure in layers. With double salts there is usually a simple numerical relation between the valency values of the components which results geometrically from the packing. Thus, with potash alum, $K_2SO_4.Al_2(SO_4)_3.24H_2O$, the valencies of the component parts are in the ratio 14 : 36 : 96, which is nearly 1 : 3 : 8.

In a close-packed assemblage of spheres, certain groups of spheres may be situated so that they can be moved without affecting the arrangement of the others, and other spheres can be fitted into the resulting cavities so as to reproduce the original arrangement. Equivalent atoms or groups of atoms can replace others of the same volume without change of structure since, by hypothesis, valency is proportional to the relative volumes. Stable systems of related substitution products lead to likeness in crystal form—isomorphism. Equivalent atoms, though nearly equal, may differ slightly in volume, for A. E. H. Tutton, in his work on the alkali sulphates and selenates, obtained the following results, indicated in Table XIII:

TABLE XIII.

	Molecular volume.	Valency volume.	$x:y:z$.
K_2SO_4	64·91	12	2·2109 : 2·1977 : 2·8463
Rb_2SO_4	73·34	12	2·2049 : 2·1899 : 2·8648
Cs_2SO_4	84·58	12	2·2003 : 2·1826 : 2·8777
K_2SeO_4.	71·67	12	2·2207 : 2·2083 : 2·8204
Rb_2SeO_4	79·94	12	2·2147 : 2·1957 : 2·8412
Cs_2SeO_4	91·09	12	2·2112 : 2·1900 : 2·8524

The difference in the values of x, y, z indicate slight differences in the configuration of the molecules, corresponding with slight differences in the volumes of the atoms of potassium, rubidium, and cæsium. The atomic volumes of elements in the same group of the periodic classification probably increase slightly with increasing atomic weight. This principle gives an explanation of; (1) The difference in the crystal forms of the acids and many of their salts—*e.g.* H_2SO_4 and K_2SO_4—by the difference in the atomic volumes of hydrogen and potassium. (2) The isomorphism of salts of different acids—plagioclase felspars, $NaAlSi_3O_8$ and $CaAl_2Si_2O_8$. Here NaSi- and CaAl-groups have the same molecular volume and hence can replace one another. (3) The isomorphism of complex bodies not observed in simple bodies. (4) The variation in the form of the crystal when replacing atoms with the same valency-volume but different in form—*e.g.* the substitution of a NO_2-group by a methyl or CH_3-group.

If like spheres are removed homogeneously from an assemblage of molecules and replaced by larger spheres or groups of spheres the walls of the cavity will gape. Close packing can be restored by inserting new spheres in the gap so produced, and the volume of the gap will be equal to the difference in volume of replaced and replacing spheres. If v be the volume of spheres replaced, the volume of replacing spheres to produce close packing will be v; $v+1+1$ or $v+2$; $v+2+2$ or $v+4$; and generally $v+2n$; that is, the volume of replacing spheres differ by intervals of 2. Chemically this means that the valencies of multivalent elements differ constantly by intervals of 2. The change in valency by intervals of 2 involves no variation in the actual volume of the atom. Thus, cæsium can combine with iodine to form CsI, CsI_3, CsI_5, CsI_7, and CsI_9.

In general, if the volume m be replaced by a volume $n+m$, an additional volume n must be added to conserve the marshalling—thus, if a univalent hydrogen atom be replaced by a quadrivalent carbon atom, an additional three valencies are required. Again, in replacing an H-atom by an oxygen atom in ethane, the further addition of an atom of unit valency is required to produce C_2H_5OH. Again, in three molecules of benzene, three hydrogen atoms may be substituted by a nitrogen atom to form triphenylamine, $(C_6H_5)_3N$, but if a carbon atom takes the place of three hydrogen atoms an additional hydrogen atom is required to form triphenylmethane, $(C_6H_5)_3CH$. The apparent isomorphism of salts like sodium nitrate, $NaNO_3$, and calcium carbonate, $CaCO_3$, is likewise explained by the volume-valency hypothesis.

The hypothesis that each valency in a given compound has the same volume is not generally accepted. T. W. Richards, for instance, argues that the relationship between benzene and tetrabromobenzene lands its supporters in an impossible position since it requires the subsidiary assumption that all the remaining carbon and hydrogen atoms in benzene should nearly double their volume when four atoms of bromine are substituted for hydrogen. It is more in accord with H. Kopp's observations that the atomic volume of hydrogen in combination is much larger than that of free hydrogen. In the nitro-dihalogeno-benzenes, observed by E. Repossi, the introduction of chlorine causes a marked shortening of the *b*-axis; and in the rhombic chloro- and bromo-ethanes, observed by B. Gossner, the symmetrical substitution of chlorine lengthens the *a*-axis in relation to the *b*-axis, and the unsymmetrical substitution of the same element shorten the *a*-axis. In these and many other examples there are real differences in the molecular volume and crystalline form; but the greatest variation occurs with the molecular volume, probably because a change in volume produces only the cube root of its proportional effect when applied in any one axial direction. The atomic volumes of chlorine and bromine respectively at —33·5° and 63°—which are like fractions of their boiling points—are 21·8 and 25·5 respectively. Although the atomic volumes change when these elements enter into combination, under similar conditions, the chlorine would be expected to occupy less space than bromine, and this is what is actually observed. It is urged that the method of equivalence parameters employed for testing the hypothesis of valency-volume is a mathematical device which has the effect of reducing widely deviating data to apparent harmony; and of hiding differences in crystal forms. The observed data are the axial ratios $a:b:c$. According to W. Barlow and W. J. Pope, the molecular volumes of liquids of normal paraffins calculated on the basis that one volume of carbon is equal to four volumes of hydrogen ($H=2·97$ c.c.; $C=11·88$ c.c.) are in close agreement; but T. W. Richards showed that the agreement is quite as good when calculated on other hypotheses, say, when the atomic volume of carbon is twice that of hydrogen.

T. V. Barker has shown that on the volume-valency hypothesis the atomic units in potassium chloride are approximately the same, as they are likewise in potassium iodide; consequently, since the atomic volumes of these two salts are respectively 37·49 and 53·06, the atomic volumes of the potassium atoms in these salts are respectively 18·74 and 26·53. There is every reason to believe that the atomic volume of an element in the free state may be much greater than when it is combined, so that there is no inherent objection to the hypothesis that the atomic volume of an element varies a little in its different forms of combination. Again, T. V. Barker has shown that the molecular volumes of potassium and ammonium iodides are respectively 53·06 and 59·62. On the volume-valency hypothesis, "the iodine atom in potassium iodide has a volume equal to 26·53, but in the ammonium compound the iodine can only have one-eighth the volume of the molecule, since the total valency-volume is eight—that is, volume of the iodine equals 7·45. It must be assumed that when potassium is substituted by ammonium the iodine atom experiences a shrinkage equal to about five-sevenths of its volume in the potassium compound. Is it likely that this is really the case? It must be remembered that a comparison is not being made between the atomic volumes of an element in the free and combined conditions, but rather its atomic volume in two compounds which have an extraordinarily close chemical relationship." A. E. H. Tutton adds that to explain the incontrovertibly proved iso-structure of ammonium and rubidium sulphates, where there are 24 valency-volumes in the former cases and only 12 in the latter, it is necessary to assume arbitrarily that the actual spheres of atomic influence in the former are on a smaller scale—one-half indeed—than in the latter in order to afford in the total the same volume. The congruency of the monoclinic ammonium and rubidium nickel sulphates or selenates shows that the replacement of two atoms of univalent rubidium by eight atoms of univalent hydrogen and two atoms of ter- or quinque-valent nitrogen, produces no opening up of the structure. This fact, says A. E. H. Tutton, is in entire antagonism with the hypothesis of valency-volume of W. Barlow and W. J. Pope.

T. V. Barker concludes from his study of the valency-volume theory that so far "the theory has received no general crystallographic support." A. Ogg and F. L. Hopwood also concluded from the X-ray spectrometric examination of the ammonium and alkali metal sulphates, that the replacement of eight potassium atoms by forty atoms of the four NH_4-radicles produces so little difference from what the replacement by eight rubidium atoms produces on the dimensions of the elementary cell, as to furnish " conclusive evidence against the general truth of the theory of crystal structure based on the closest packing of the constituent atoms or their spheres of influence."

W. J. Sollas[14] assumed that, with the haloids of the alkali metals, the structural unit is an aggregate of four molecules. He further assumes generally that the structural units are proportional to the atomic volumes, not of the free elements, but of the elements in the compounds concerned; nor is the sum of the atomic volumes equal to the molecular volume, for an allowance is made for interstitial space. W. J. Sollas also assumed that the structural units are loosely packed; he builds up structures with his units which give results in harmony with the observed geometrical forms of the crystals and with some of their physical properties. He has applied the hypothesis to the alkali halides, silver iodide, titanium dioxide, and cassiterite. T. V. Barker adds that loose packing is equivalent to assuming that some of the atoms have a greater volume than is initially supposed, and with sufficiently loose packing, it does not seem difficult to obtain any structure whatever irrespective of the atomic volumes.

CHAPTER VI

THE CLASSIFICATION OF THE ELEMENTS

§ 1. The Classification of the Elements

> Most of our systems of classification are artificial and without distinct lines of demarcation. Being based upon limited knowledge, they have been formed upon apparent rather than upon real similarities and differences; and they are to our minds but artificial aids, like crutches to cripples.—G. GORE (1878).

THE classification of the elements has long been an attractive subject. It is only by the aid of classification that the mind of man is able to cope with the multitudinous facts presented by nature. In the words of F. Bowen (1866) [1]:

> The first necessity which is imposed upon us by the constitution of the mind itself, is to break up the infinite wealth of Nature into groups and classes of things with reference to their resemblances and affinities, and thus to enlarge the grasp of our mental faculties, even at the expense of sacrificing the minuteness of information which can be acquired only by studying objects in detail.

The primary object of classification is to arrange the facts so that we can acquire the greatest possible command over them with the least possible effort. This is accomplished by arranging the facts in a systematic way. In all systems of classification, the elements are assembled in a few groups or classes so that the members of each group possess in common the greatest possible number of important attributes; and the attempt is made to collect together in one group the elements which are alike in general properties, and to separate those which are unlike. No one has succeeded in devising an unimpeachable system of classification for the chemical elements, in which each element has only one peculiar place—when the *criterium* of the classification is chemical behaviour. It is invariably found that some elements are entitled with equal or almost equal consistency to a place in more than one group. In the ideal system of classification, each class will be clearly and sharply distinguished from every other class by some essential property or properties which can be accurately defined, and readily recognized, and which are common to the individual members of the class. In all the systems hitherto proposed the different classes are more or less affiliated one to another, and J. P. Cooke [2] has emphasized the fact that

> Nature seems to abhor abrupt transitions, and shades off her bounding lines. Many of the elements, while they manifestly belong to one series, have properties which ally them to another.

The alchemists divided the metals into two classes, the *perfect metals* and the *semi-metals*—the former included gold and silver; the latter copper, iron, lead, tin, and mercury. The former suffered no alteration when heated at the highest available temperatures; the base metals are changed under these conditions into primitive earths. The former were accordingly called *noble metals*, the latter *base metals*. At the beginning of the nineteenth century, J. J. Berzelius classified the elements into two groups, the *metals* and the *metalloids* (meaning *non-metals*). This simple division of the elements into two groups is confronted with many difficulties because some simple substances—like antimony and arsenic—have the general appearance of metals and yet behave chemically like the non-metals. These pseudo-metals exhibit characteristic properties of both classes. This simple dichotonous division leads to vagueness, ambiguity, and contradictions as soon as the attempt is made to formulate sharp clear-cut definitions of the metals and the non-metals. The attempt to group the elements by a code of definitions seems to be foredoomed to failure. There is a seductive simplicity about a definition which may be attractive, but it is artificial and often misleading. As T. Campanella (1590) expressed it: " Definition is the end and epilogue of science. It is not the beginning of our knowing, but only of our teaching."

The attempt has been made to mark the metals by a term ending in **um,** and the non-metals by a term ending in **en, ine,** or **on.** For example: *Metals*—Aluminium, barium, sodium, magnesium, calcium, ferrum (iron), hydrargyrum (mercury), etc. *Non-metals*—Boron, carbon, oxygen, silicon, chlorine, argon, neon, krypton, etc. The idea persists in many but not all the modern names of the elements. The time-honoured names, silver, gold, iron, copper, zinc, etc., have alternative Latinized equivalents—argentum, aurum, ferrum, etc.—from which their modern symbols are derived.

Philologists[3] tell us that the word *metallon* appeared in Greek literature about the time of Herodotus (*c.* 450 B.C.), and it is supposed to have been borrowed from some foreign language—possibly a Semitic word—since the Semites, represented by the Phœnicians, had mines in the island of Thasos—not of the Ægean. The Semitic meaning of the term was " to work iron like a smith," whereas the Greeks used it not for a metal but for a mine or for any kind of mineral, including salt, found in a mine. The resemblance of the Greek *μέταλλον*—a mine—to *μεταλλάω*—meaning " in quest of something "—is thought to be accidental.

With all its imperfections, J. J. Berzelius' subdivision of the elements into metals and non-metals is so convenient that it is in common use when great precision is not required. Very roughly, the properties of the metals can be contrasted with those of the non-metals as indicated in the subjoined scheme—Table I.

TABLE I.—THE PROPERTIES OF THE METALS AND NON-METALS CONTRASTED.

Metals.	Non-metals.
1. Form basic oxides.	1. Form acidic oxides.
2. Generally dissolve in mineral acids giving off hydrogen.	2. Do not usually dissolve easily in mineral acids.
3. Either form no compounds with hydrogen, or form unstable compounds—usually non-volatile.	3. Form stable compounds with hydrogen—these are usually volatile.
4. Solid at ordinary temperature (excepting mercury).	4. Gases, liquids, or solids at ordinary temperatures.
5. Usually volatilize only at high temperatures.	5. Excepting carbon, boron, and silicon, the non-metals are either gaseous or volatilize at low temperatures.
6. When in bulk the metals reflect light from polished or freshly cut surfaces.	6. Do not usually reflect light very well.
7. Specific gravity is generally high.	7. Specific gravity generally low.
8. Good conductors of heat and electricity. Electrical resistance usually increases with the rise of temperature.	8. Bad conductors of heat and electricity. Electrical resistance usually decreases with rise of temperature.
9. More or less malleable and ductile.	9. Malleability and ductility are not well defined.
10. Molecules usually monatomic in the vaporous state.	10. Molecules usually polyatomic in the vaporous or gaseous state.

If any particular property be selected as a criterion, it will be found that the different metals can be arranged in a series which passes imperceptibly into the non-metals without an abrupt change. P. P. von Weimarn,[4] indeed, has given evidence which makes it not improbable that the different metals can exist in both forms. Hence, the metallic or non-metallic nature is not an unchangeable characteristic of an element; the metallic property may predominate at a low temperature, the non-metallic at a high one. This does not mean that metals and non-metals are two distinct forms of matter like the three states of aggregation which all kinds of matter undergo when the conditions—particularly temperature—are favourable. To show how difficult it is to draw a hard-and-fast line of demarcation between metals and non-metals, the non-metals arsenic, antimony, and tellurium would be classed with the metals if we depended exclusively upon 6, 7, and 8; hence, some introduce a third division—the **metalloids**—to include the hybrids—almost analogous to the *bastard metals* of the alchemists—for elements which have properties characteristic of both the metals and the non-metals. The term metalloid is sometimes used synonymously with non-metals. The metals lithium, sodium, potassium, magnesium, and aluminium have a low specific gravity; and when potassium was discovered in 1807, some argued that it could not be a metal because it was light enough to float on water. The non-metals carbon, boron, and silicon are less volatile than most metals. The non-metal hydrogen is a good conductor of heat; and the non-metal graphitic carbon is a good conductor of heat and electricity. Hence the division of the elements into metals and non-metals is but a rough system of classification, arbitrarily adopted because it is convenient.

In A. L. Lavoisier's classification, in his *Traité élémentaire de chimie* (Paris, 1789), the elements were arranged in four classes:

> (1) Simple substances belonging to the three kingdoms which can be regarded as the elements of bodies—light, caloric, oxygen, nitrogen, hydrogen. (2) Simple non-metallic substances which are oxidizable and acidifiable—sulphur, phosphorus, carbon, muriatic radicle, fluoric radicle, boracic radicle. (3) Simple metallic substances, oxidizable and acidifiable—antimony, arsenic, bismuth, cobalt, copper, gold, iron, lead, manganese, mercury, molybdenum, nickel, platinum, silver, tin, tungsten, zinc. (4) Simple substances, salifiable and earthy—lime, magnesia, baryta, alumina, silica.

Lavoisier frequently expressed his desire to keep within the limits of experience, but that fact was not sufficient to prevent him from nursing the philosophical conception of a world made from a very small number of elements. He seems to have regarded light and heat as ponderable or material substances. Lavoisier's separation of simple substances into metals and non-metals is interesting.

A. F. de Fourcroy, in his *Système des connaissances chimiques* (Paris, 1801), divided the then known metals into five classes: The first class included brittle metals which form acids by combining with oxygen—arsenic, tungsten, molybdenum, and chromium; the second class included brittle metals which do not form acidifiable oxides—titanium, uranium, cobalt, nickel, manganese, bismuth, antimony, and tellurium. The third class included metals which showed signs of ductility and are oxidizable—zinc and mercury. The fourth class included ductile and easily oxidizable—tin, lead, iron, and copper. The fifth class included the ductile metals not oxidizable by fire—silver, gold, and platinum. The first three classes were called *demi-métaux*; the fourth class, *métaux imparfaits*; and the fifth class, *métaux parfaits*.

The elements have been classed into acidic and basic, or, what amounts to the same thing, into electro-negative and electro-positive elements—for example, J. J. Berzelius, in his *Lärbok i Kemien* (Upsala, 1818), where hydrogen with dual characteristics separated the electropositive and the electronegative groups from one another. The elements have also been classed according to their valency as A. Naquet did in his *Principes de chimie fondés sur les théories modernes* (Paris, 1864). The alchemists separated the metals into two groups—the base and the noble metals; and L. J. Thénard, in his *Traité de chimie élémentaire, théorique et pratique* (Paris, 1818), imbued with A. L. Lavoisier's views on oxidation, relegated the non-metals into one class, and classified the metals according to (i) their oxidizability when roasted in air; (ii) the stability of the oxides; and (iii) their behaviour when heated with steam. This system was modified by succeeding chemists and used by H. V. Regnault in his *Cours élémentaire de chimie* (Paris, 1853). It was soon afterwards abandoned because it failed to accommodate itself to new data and new knowledge.

J. B. A. Dumas, in his *Traité de chimie appliquée aux arts* (Paris, 1828), and later, in a *Mémoire sur les équivalents des corps simples* (1859),[5] arranged the non-metals in five groups or families. He founded his classification of the non-metallic elements on the character of the compounds which they formed with hydrogen, on the volume ratio of the two elements entering into combination, and on their mode of condensation.

I.—Hydrogène; II.—Fluor, chlore, brome, iode; III.—Oxygène, selenium, soufre, tellure; IV.—Azote, phosphore, arsenic; V.—Carbone, bore, silicium.

Hydrogen was supposed to be a metal. J. B. A. Dumas classed the metals, and in general those bodies which do not unite with hydrogen, from the character of the compounds they form with chlorine, and when possible, from the volume ratio of the two elements entering into combination, and from their mode of condensation. He further represented the atomic weights of the elements in a given family as the sum of a series $a+nd'+nd''+\ldots$ Thus, fluorine $=19$; chlorine $=19+16{\cdot}5=35{\cdot}5$; bromine$=19+2\times16{\cdot}5+28=80$; iodine$=19+2\times16{\cdot}5+2\times28+19=127$. Similarly with the other families.

J. B. A. Dumas further stated that the classification of the metals ought to be founded on the characteristic compounds which they form with chlorine; and, as a result of the further work of W. Odling,[6] L. Gmelin, etc., systems were devised in which family relationships were specially emphasized. Thus, W. Odling (1857) arranged the elements in 13 groups:

I.—Fluorine, chlorine, bromine, iodine. II.—Oxygen, sulphur, selenium, tellurium. III.—Nitrogen, phosphorus, arsenic, antimony, bismuth. IV.—Boron, silicon, titanium, tin. V.—Lithium, sodium, potassium. VI.—Calcium, strontium, barium. VII.—Magnesium, zinc, cadmium. VIII.—Beryllium, yttrium, thorium. IX.—Aluminium, zirconium, cerium, manium. X.—Chromium, manganese, iron, cobalt, nickel, copper. XI.—Molybdenum, vanadium, tungsten, tantalum. XII.—Mercury, lead, silver. XIII.—Palladium, platinum, gold.

In analytical chemistry, even to-day, the elements are conveniently classed according to their behaviour towards certain reagents which are conventionally taken as standards of reference. For instance:

Group I.—The addition of hydrochloric acid to a solution precipitates silver, mercurous, lead, and thallium chlorides; tungstic oxide; and possibly silicic acid and antimony oxychloride.

Group II.—The passage of hydrogen sulphide through the filtrate from the preceding group, acidified with hydrochloric acid, precipitates mercury(ic), lead, bismuth, copper, arsenic, antimony, tin, selenium, tellurium, gold, platinum, and molybdenum either as sulphides or as elements along with sulphur.

Group III.—The addition of ammonia, ammonium chloride, and ammonium sulphide to the filtrate from the preceding group precipitates sulphides or hydroxides of iron, nickel, cobalt, manganese, zinc, uranium, aluminium, chromium, titanium, beryllium, thallium, zirconium, and the elements of the rare earths.

Group IV.—The addition of ammonium carbonate and alcohol to the filtrate from the preceding group—after it has been evaporated to a small bulk—precipitates magnesium, barium, strontium, and calcium carbonates.

Group V.—The salts of the alkali metals—lithium, sodium, potassium, rubidium, and cæsium—remain in solution.

The groups are subdivided again and again until finally salts of individual elements remain.

In all these systems an element appears in more than one class; or elements with but few properties in common are grouped together; or elements otherwise related are separated into different classes. The properties of the elements used as the basis of classification may also vary with the conditions under which the properties are observed.

Were W. Odling's system to be revised in the light of existing knowledge, it would furnish the most convenient system of classifying the elements—*e.g.* some such system as that used in H. Moissan's *Traité de chimie minérale* (Paris, 1904); and also in L. Gmelin and K. Kraut's *Handbuch der anorganischen Chemie* (Heidelberg, 1907). It is usually supposed that the so-called periodic system (*vide infra*) is the best that can be done, but that is doubtful. Only those facts which are known can be classified; and the perfection of any system of classification must necessarily depend on the extent of our knowledge. The periodic system is usually adopted, not because it furnishes the best possible arrangement according to existing knowledge, but because it holds alluring promises for the future. According to G. Gore:

> The most perfectly philosophical classification of scientific truths can be made only when their most essential and fundamental characters are discovered, and they are probably those very characters which are the most difficult to find, and doubtless will be nearly the last to be discovered.

§ 2. Triads, and the Law of Octaves

In all things there is order, harmony, and wisdom.—H. DAVY (1811).

Les propriétés des corps sont les propriétés des nombres.—A. E. B. DE CHANCOURTOIS (1862).

In all chemical changes one property at least remains unaltered, and the more popular systems of classification have been based on this property—the atomic weights of the elements. The early efforts in this direction were seriously hampered by the uncertainty in the numerical values of the atomic weights; but after chemists had cleared up the confusion associated with the atomic theory left by J. Dalton, and obtained a consistent system of atomic weights, the results were more promising. True enough, between 1816 and 1829, J. W. Döbereiner noticed some regularities in the atomic weights of certain related elements, and, in a paper, *Versuch zu einer Gruppierung der elementären Stoffe nach ihrer Analogie* (1829),[1] he showed that most of the chemically related elements either exhibited almost the same atomic weight—*e.g.* iron, cobalt, and nickel—or else showed a constant difference when arranged in sets of three. Thus, selecting one set from Döbereiner's list, and rounding off the modern atomic weights,

	Calcium.		Strontium.		Barium.
Atomic Weight . . .	40		87		137
Difference		47		50	

Döbereiner's idea was taken up by a number of chemists—J. B. A. Dumas (1858), J. B. P. Kremers (1852), J. H. Gladstone (1853), W. Odling (1857), and E. Lennsen (1857)—and J. P. Cooke (1854) showed that the triads are probably only parts of series, similar to the homologous series of organic chemistry, in which the differences between the molecular weights are a multiple of some whole number. He struck a fatal blow at the doctrine by pointing out that the triads broke up natural groups of the elements, so that instead of co-ordinating facts it tended in the opposite direction. J. P. Cooke (1854) further arranged the elements in six groups or series in which the members of each series followed a law of progression in which the variation of the atomic weights could be expressed by a simple algebraic formula.

In 1815, W. Prout[2] had suggested that the atomic weights of the elements were probably exact multiples of the atomic weight of hydrogen, but with increasing refinements in the methods of measurement, this suggestion did not fit with observations. In 1850, M. von Pettenkofer read a paper, *Ueber die regelmässigen Abstände der Æquivalentzahlen der sogenannten einfachen Radicale* (1850), before the Bavarian Academy of Sciences, in which he tried to show that similar elements formed an arithmetical series with the atomic weight of one of the elements as a whole number, and another integer added or subtracted to obtain the series. Thus the atomic weights of the three alkali metals then known were arranged as a series $7+2n8$, where $n=0, 1, 2 \ldots$ For example, $Li=7$; $Na=7+2\times8=23$; $K=7+2\times8+2\times8=39$; and he obtained analogous results with the alkaline earths, the chromium and sulphur groups, and the halogens. Most probably in ignorance of M. von Pettenkofer's series of 1850, modifications of analogous series were advocated by both J. P. Cooke (1854) and J. B. A. Dumas (1851), although the craze in quest of groups and triads, more or less independent and distinct from one another, seemed to divert attention from the establishment of a continuous system including all the elements, and many felt intuitively that the lists of **Döbereiner's triads** or **Pettenkofer's series** were but fragments of a more general law—for instance, A. Strecker in his *Theorien und Experimente zur Bestimmung der Atomgewichte der Elemente* (Braunschweig, 1859):

> It is scarcely reasonable to suppose that all the relations between the atomic weights of chemically related elements are merely due to chance. The discovery of the hidden meaning in these numerical relations must be left to the future.

And M. Faraday (1852):

> We seem here to have the dawning of a new light, indicative of the mutual convertibility of certain groups of elements, although under conditions which as yet are hidden from our scrutiny.

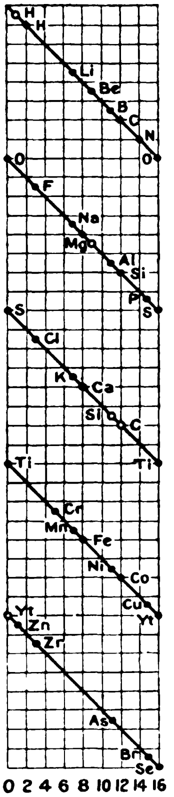

Fig. 1.—A. E. B. de Chancourtois' *Vis Tellurique.*

Some papers were published by A. E. B. de Chancourtois[3] between 1862 and 1863, in which it was proposed to classify the elements by their atomic weights. A. E. B. de Chancourtois divided the circular base of a cylinder into 16 parts, representing the atomic weight of oxygen; he then traced a helix inclined at an angle of 45°; and plotted the values of the atomic weights as *points caractéristiques* vertical to the axes of the cylinder so that one-sixteenth part of a complete rotation of the cylinder represented one unit. He called the helix so obtained the *vis tellurique*—the **telluric screw.** A portion of the telluric screw unrolled from the surface of the cylinder is illustrated in Fig. 1 as a plane surface. There is a tendency for analogous elements to fall on the same vertical line. The fundamental assumption involved in this scheme is that the atomic weights of the elements can be represented by whole numbers in accord with the formula $n+16m$, where m is an integer. Hence he assumed that the differences between the atomic weights ought to be constant. He tried to fill gaps in his list of elements by imagining new varieties of the known elements—such as actually occurs in the case of carbon—and these he called *caractères secondaires* represented in Fig. 1 by a circle. A. E. B. de Chancourtois' ideas were so much entangled with extraneous matters, and the truth was so much obscured by useless and faulty speculations, that his work lay buried for nearly thirty years, and it was only resurrected after Mendeléeff's system had become famous. There are also vague hints in N. H. Marne's *Ueber die Anzahl der Elemente* (Berlin, 1786), which, when read in the light of subsequent developments, have been taken as anticipations of the periodic law.

Again, between 1863 and 1866, J. A. R. Newlands [4] published a series of papers in which he arranged the elements in the ascending order of their atomic weights, and noticed that every succeeding eighth element was " a kind of repetition of the first." Thus, copying Newlands' first table as it appeared in his communication *On the law of octaves* (1865), where " the elements are arranged in the order of their equivalents, with a few transpositions, it will be observed that elements belonging to the same group usually appear on the same horizontal line."

TABLE II.—NEWLANDS' TABLE OF THE LAW OF OCTAVES (1865).

	No.		No.		No.		No.		No.		No.		No.		No.
H	1	F	8	Cl	15	Co, Ni	22	Br	29	Pd	36	I	42	Pt, Ir	50
Li	2	Na	9	K	16	Cu	23	Rb	30	Ag	37	Cs	44	Tl	53
Gl	3	Mg	10	Ca	17	Zn	25	Sr	31	Cd	38	Ba, V	45	Pb	54
B	4	Al	11	Cr	18	Y	24	Ce, La	33	U	40	Ta	46	Th	56
C	5	Si	12	Ti	19	In	26	Zr	32	Sn	39	W	47	Hg	52
N	6	P	13	Mn	20	As	27	Di, Mo	34	Sb	41	Nb	48	Bi	55
O	7	S	14	Fe	21	Se	28	Rh, Ru	35	Te	43	Au	49	Os	51

NOTE.—When two elements happen to have the same equivalent, both are designated by the same number.

It will be observed, said Newlands, " that the number of analogous elements generally differ by 7 or some multiple of seven ; in other words, members of the same group of elements stand to each other in the same relation as the extremities of one or more octaves in music. This peculiar relationship I propose to provisionally term **the law of octaves.**" Newlands noticed that elements belonging to the same group usually appeared in the same column, and he declared that all the numerical relations which had been observed among the atomic weights " including the well-known triads, are merely arithmetical results flowing from the existence of the law of octaves." Newlands' law of octaves did not attract much attention, probably because faulty atomic weights seriously interfered with arrangement ; and because the changes on triads and arithmetical series had been rung during the few preceding years with tiresome persistence.

§ 3. The Periodic Law—D. I. Mendeléeff and L. Meyer

The periodic series is a brilliant and adequate means of producing an easily surveyed system of facts which by gradually becoming complete will take the place of an assemblage of the known facts.—E. MACH.

D. I. Mendeléeff and L. Meyer, quite independently and, so far as we can tell, quite in ignorance of Newlands' and Chancourtois' work, obtained a far clearer vision of the law of octaves about 1869. D. I. Mendeléeff published his *On the correlation of the properties and atomic weights of the elements*, in 1869, a year before L. Meyer. Mendeléeff said: "When I arranged the elements according to the magnitude of their atomic weights, beginning with the smallest, it became evident that there exists a kind of periodicity in their properties." Otherwise expressed, if the elements be arranged in the order of increasing atomic weights, the *properties* vary from member to member in a definite way, but return more or less nearly to the same value at fixed points in the series. D. I. Mendeléeff continued: "I designate by the name 'periodic law' the mutual relations between the properties of the elements and their atomic weights. These relations are applicable to all the elements, and have the nature of a periodic function." Expressed more concisely, **Mendeléeff's periodic law reads: The properties of the elements are a periodic function of their atomic weights.** A periodic function is one whose value repeats itself at regular intervals. The interval is called a "period." The ebb and flow of the tides, and the recurrence of the seasons are periodic phenomena.

Mendeléeff's table of the atomic weights was designed to tabulate the elements in such a way as to exhibit the greatest number of relationships; the early tables were rather imperfect on account of imperfections in the atomic weight data, and the paucity of our knowledge about the chemical characteristics of some of the elements. The original tables were afterwards amended and modified owing to improved data, and the discovery of new elements. The symbols of the elements with their atomic weights have been arranged on a helix, on a spiral, and in numerous other ways. Table III, not very different in style from one of Mendeléeff's first tables, is one of the simplest modes of arrangement, perhaps the best. The so-called *atomic numbers* of the elements are indicated in brackets. These constants will be discussed later. The fundamental principle of Mendeléeff's classification is that **the atomic weight of an element determines its position in the system.** When the elements are ranged in the order of their atomic weights, they form (i) definite families or groups of elements with allied properties; and (ii) series in which the properties of allied elements recur in definite periods. The nine vertical columns of the table are usually styled **groups**; and the twelve horizontal lines, **series** or **periods.** The properties of the elements and of their compounds are consequently studied from the point of view of this system of classification. The brief reviews of the family group given in this work will suffice to emphasize the relationships of the members of any given group. The **members of a group** have (1) general family properties like specific gravity, specific volume, laws of combination which (2) gradually vary from the first to the last number, so that the members of any particular group resemble one another more closely than do any of the other elements. (3) Each family group differs from the others, but the resemblances between the individual members of a family suggest that they have been internally constructed on the same plan. The **members of a series** have properties which (1) differ much from the first to the last member; and (2) each series is more or less a repetition of that which precedes. D. I. Mendeléeff emphasized the difference between the corresponding members of what he called the **odd series** and the **even series.** The members of the odd series show comparatively greater analogies with the corresponding members of the odd series than with the even series; and likewise the members of the even series have more

TABLE III.—THE PERIODIC SERIES OF THE ELEMENTS.

	Series	Group 0	Group I R_2O	Group II RO	Group III R_2O_3	Group IV RH_4 RO_2	Group V RH_3 R_2O_5	Group VI RH_2 RO_3	Group VII RH R_2O_7	Group VIII Transition elements RO_4

analogies with corresponding members of the even series than with the odd series. For example,

Group . . .	I	II	III	IV	V	VI	VII
4th series . .	*K*	*Ca*	—	*Ti*	*V*	*Cr*	*Mn*
5th series . .	Cu	Zn	—	—	As	Se	Br
6th series . .	*Rb*	*Sr*	—	*Zr*	*Nb*	*Mo*	—
7th series . .	Ag	Cd	In	Sn	Sb	Te	I

where the 4th and 6th series resemble one another more closely than do the 4th and 5th, or the 5th and 6th. Each **short period,** it will be observed, contains eight elements; and each **long period** either contains nineteen elements of which three are the so-called **transition elements,** or else it has provision made for nineteen elements. Hyphens are inserted in the spaces where the corresponding element is unknown. The elements in the first short period are sometimes called **group elements** or **bridge elements,** since they show a notable gradation of properties from one to the other, and serve as links or bridges between the different groups. The members of the next short period or series 3, are called **typical elements** because they have the typical properties and characteristics of the group, and show a rather wide divergence from neighbouring groups. After each typical element, the different groups diverge into two **sub-groups.**

The transitional elements.—It will be noticed that there is a distinct difference between the members of the odd and the even series. The even series, say the fourth and sixth, resemble one another more closely than the members of the odd series, say the fifth and seventh. The lower oxides of the last members of the even series resemble in many ways the first members of the odd series. Thus, the basic oxides of chromium and manganese are in many ways similar to the oxides of copper and zinc. Again, there are marked differences between the last members of the odd series (halogens) and the first members of the next even series (alkali metals). Those elements which cannot be placed in short periods fall in better with last members of the even series, and the first members of the odd series. Thus, iron, cobalt, and nickel fall between manganese and copper both with respect to chemical properties and atomic weights:

	Cr	Mn	Fe	Ni	Co	Cu	Zn
Atomic weight .	52	54·9	55·8	59·0	58·7	63·6	65·4
Specific gravity .	6·9	7·4	7·8	8·7	8·8	8·9	6·9
Atomic volume .	7·5	7·4	7·1	6·8	6·7	7·1	9·5

so also Ru—Rh—Pd → Ag come just after the sixth series, and Os--Ir—Pt → Au after the tenth series. The inert gases are considered to form a kind of transition between the last members of the odd series (halogens) and the first members of the even series (alkali metals), and consequently also, they only occur in the horizontal rows where transitional elements in the eight groups are absent.

The following arrangement, Fig. 2, modified from one by T. Bayley (1882),[1] emphasizes the relationship and yet the individuality of the sub-groups, the character of the transition elements, etc. *Protyle* represents an imaginary primordial element of elements, from which the ordinary elements are made; and by *extinct elements* are understood imaginary elements of high atomic weight which may have once been made from protyle, but which proved too unstable to endure under terrestrial conditions and broke down into simpler elements of smaller atomic weight.

T. Bayley's table emphasizes the fact that while the atomic weights of the elements progressively increase, their properties recur at definite intervals. No well-known elements are omitted from the scheme, and with three exceptions the order is that of the atomic weights, and the elements usually fall into virtually the same groups as would have been obtained had they been arranged according to their chemical behaviour. Otherwise expressed, there is one element for each place in the table, and each place in the table is intended for a definite chemical individual.

The valency of the elements shows a peculiar relation, for the maximum valency rises from 1 to 8 in passing along a given series from the first to the last group. Thus,

Group	I	II	III	IV	V	VI	VII	VIII
Oxide	K_2O	CaO	Al_2O_3	CO_2	P_2O_5	SO_3	Cl_2O_7	OsO_4
Valency	1	2	3	4	5	6	7	8

The curve, Fig. 3, is obtained by plotting as abscissæ the atomic weights of the elements, and for ordinates the higher oxides of the elements which correspond

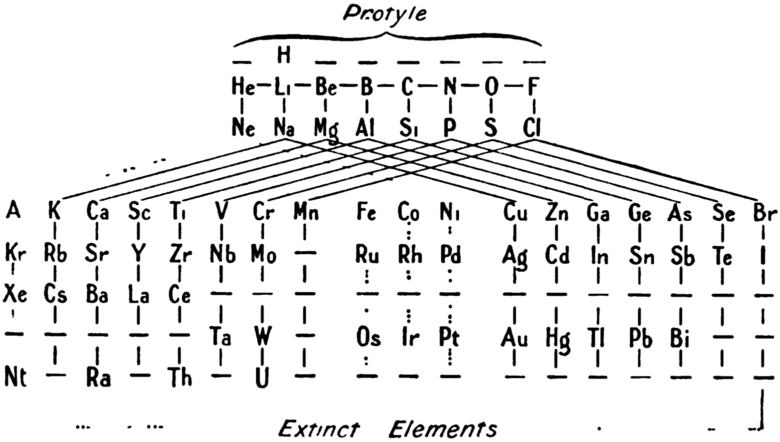

FIG 2.—T Bayley's Modification of the Periodic System.

to water and which can form hydrates with water, or unite together to form salts. There are several elements whose highest salt-forming oxide, corresponding with the family type, is not known, but, adds D. Carnegie [2]:

> Chemistry is by no means a completely worked-out science, wanting nothing, and the periodic law would be at fault did it fail to mirror forth such shortcomings and imperfections as still exist.

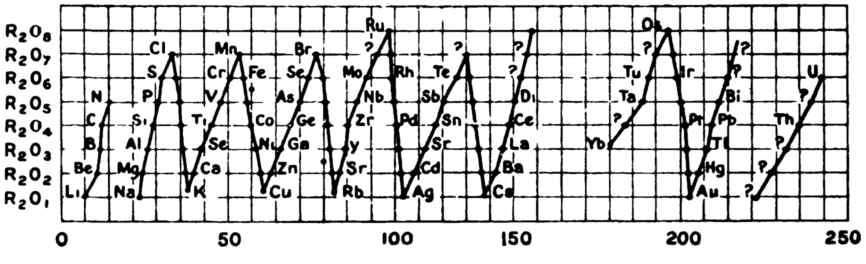

FIG. 3 —Periodic Curve of the Ideal Higher Oxides of the Elements

The periodicity of the curve, Fig. 3, is perhaps the most prominent feature. There is a blank for fluorine because it is not known to form any oxide ; there are also blanks in places supposed to correspond with unknown elements. The elements on the horizontal lines form families the members of which have many analogous properties. Elements with decided metallic characters collect towards the troughs of the wavy curve, and the non-metallic elements collect towards the crests. The basicity of the oxides decreases in passing upwards from trough to crest. Thus, lithium and sodium, and beryllium and magnesium oxides are strongly basic ; boron and aluminium oxides are but feebly basic, and they also show acidic properties ; carbon and silicon dioxides are distinctly acidic, not basic ; while the nitrogen, phosphorus, sulphur, and chlorine oxides are strongly acidic.

Again, the minimum valency rises from 1 to 4, and then falls to unity in passing through the different groups. Thus,

Group . .	I	II	III	IV	V	VI	VII
Compound . .	KH	CaH_2	(AlH_3)	CH_4	PH_3	SH_2	ClH
Valency . .	1	2	3	4	3	2	1

The maximum valencies of boron and aluminium may be quadri- not ter-valent, and if this suspicion proves well founded, these two elements will not fit the table. Note the increasing acidity of the hydrides of carbon, phosphorus, sulphur, and chlorine in passing from methane, CH_4, to hydrogen chloride, HCl. The properties of the hydrides of the elements in the first three groups are not so well known. Similar remarks apply to the halides, and in no case is a simple halide known which is higher in type than the maximum oxide indicated in the preceding scheme.

The quotient obtained by dividing the atomic weight of an element by its specific gravity in the solid condition is called the atomic volume of the element. Consequently, **the atomic volume represents the number of cubic centimetres occupied by an amount of the element equal to its atomic weight expressed in grams.** The magnitude of the atomic volume thus corresponds with the looseness of texture or porosity, so to speak, of the solid element. In 1870, in a paper, *Die Natur der chemischen Elemente als Function ihrer Atomgewichte*, Lothar Meyer[3] showed that when the atomic volumes of the elements are plotted with the atomic weights, a periodic curve showing a number of maximum and minimum points is obtained, as illustrated in Fig. 4. Certain portions of the curve are incomplete owing to the lack of data.

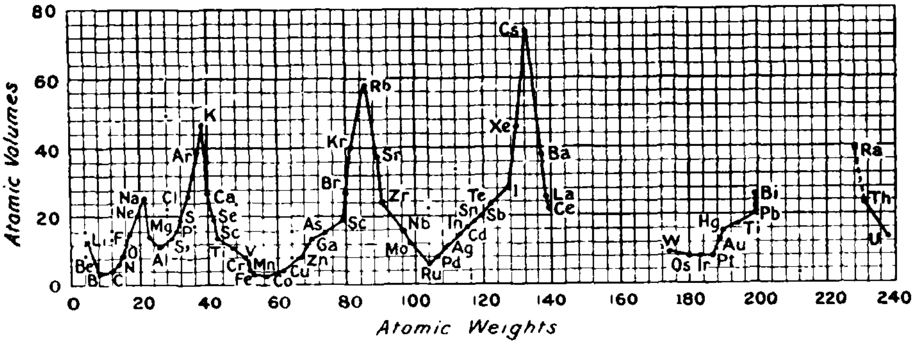

FIG. 4.—Relation between Atomic Volumes and Atomic Weights.

Most of the well-defined physical and chemical properties of the elements are periodic : for instance, specific gravity, atomic volume, melting point, hardness, malleability, ductility, compressibility, coefficient of expansion, thermal conductivity, latent heat of fusion, refraction equivalents for light, colour, electrical conductivity, magnetic power, etc. When the numerical values of these properties and the atomic weights of the elements are tabulated on squared paper, a curve is obtained which is broken up into periods as is the case with the atomic volumes —Fig. 4. The specific heats of the elements are unique in furnishing a non-periodic curve. According to Dulong and Petit's rule, if x denotes the specific heat of an element with an atomic weight y, at ordinary temperatures, we have $xy=6{\cdot}4$. This is obviously a hyperbolic curve as indicated in Fig. 5, and not a periodic curve like Fig. 4. J. Dewar's observations[4] of the specific heats of the elements at 50° K., or $-223°$, give a periodic curve running almost parallel with the atomic volume curve. Fig. 4.

There have been several attempts to represent the relation between the atomic weight of an element and the order in which it stands in the list of elements arranged in an ascending order of atomic weights, by algebraic formulæ. E. J. Mills[5] used $w=15(p-0{\cdot}9375^x)$, where the value of p ranges from 1 to 16, and x from 1 to 50. It is perhaps not surprising that the atomic weights can be represented by such a formula since the term 0·9375 approximates so closely to a whole number that any number can be expressed in decimals by this formula. J. H. Vincent represented the atomic weight of 58 elements by means of the formula $w=(n+2)^{1{\cdot}21}$, where n represents numbers rising by unity for each successive element from $n=3$ up to $n=60$. The results were good. J. B. Rydberg and F. M. Flavitzky used trigonometrical functions, and G. J. Stoney a logarithmic function to represent the magnitude as well as the periodicity of the atomic weights of the elements.

In 1870, H. Baumhauer[6] represented the relation between the elements graphically by means of a spiral; in 1876, L. Meyer used a helix after the manner of A. E. B. de Chancourtois (1862); and various other forms of periodic curve have been recommended by E. von Huth, W. Spring, J. E. Reynolds, W. Crookes, G. J. Stoney, S. Haughton, E. Loew, and others. The periodic law of D. I. Mendeléeff does not represent an uninterrupted function; it does not correspond with a continuous change of properties with a continuous variation of atomic weights. Mendeléeff therefore expressed himself against the attempt to represent the periodic relations of the elements by geometrical curves. In the Faraday lecture, 1889, D. I. Mendeléeff said:

> The periods of the elements have a character very different from those which are so simply represented by geometers. They correspond to points, to numbers, to sudden changes of the masses, and not to a continuous evolution. In these sudden changes destitute of intermediate steps or positions, in the absence of elements intermediate between, say, silver and cadmium, or aluminium and silicon, we must recognize a problem to which no direct application of the analysis of the infinitely small can be made. Therefore, neither the trigonometrical functions proposed by Rydberg and Flavitzky, nor the pendulum-oscillations suggested by Crookes, nor the cubical curves of the Rev. Mr. Haughton, which have been proposed for expressing the periodic law, from the nature of the case, can represent the periods of the chemical elements.

§ 4. The Gaps in Mendeléeff's Tables of the Elements

The periodic law has given to chemistry the prophetic power long regarded as the peculiar dignity of its sister science astronomy.—H. C. BOLTON.

Both Meyer and Mendeléeff considered it necessary to leave gaps in their tables for undiscovered elements, and more particularly in order to keep certain related elements in the same vertical column. Mendeléeff boldly prophesied that the **missing elements** would be discovered later, and in some cases even predicted their properties in considerable detail. For instance, when Mendeléeff announced the law, there were two blank spaces in group III, the missing elements were called **eka-aluminium** and **eka-boron** respectively; and another space below titanium in group IV, represented a missing element which in this case was called **eka-silicon.** The hypothetical character of these elements was considered to be an inherent weakness of the law, but the weakness was turned to strength when gallium, scandium, and germanium appeared duly clothed with those very properties which fitted closely with Mendeléeff's audacious prognostications. This fit attracted

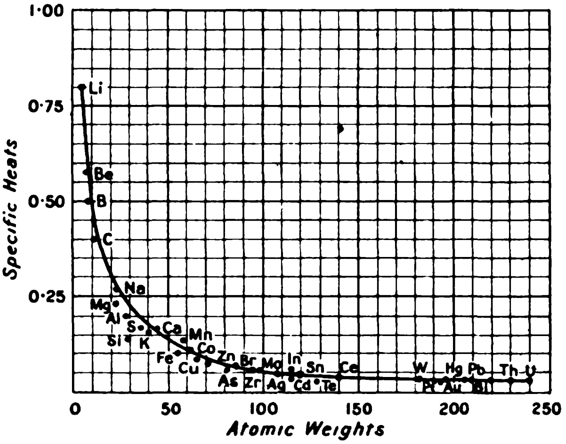

FIG. 5.—Curve showing the Relation between the Specific Heats and Atomic Weights of the Elements (0°).

TABLE IV.—COMPARISON OF PREDICTED AND OBSERVED PROPERTIES OF GERMANIUM.

Eka-silicon, Es (predicted in 1871).	Germanium, Ge (discovered in 1886).
Atomic weight, 72.	Atomic weight, 72·3.
Specific gravity, 5·5.	Specific gravity, 5·47.
Atomic volume, 13.	Atomic volume, 13·2.
Element will be dirty grey, and on calcination will give a white powder of EsO_2.	The element is greyish-white and on ignition furnishes a white oxide GeO_2.
Element will decompose steam with difficulty.	The element does not decompose water.
Acids will have a slight action, alkalies no pronounced action.	The element is not attacked by hydrochloric acid, but it is attacked by aqua regia. Solutions of KOH have no action, but it is oxidized by fused KOH.
The action of sodium on EsO_2 or on EsK_2F_6 will give the element.	Germanium is made by the reduction of GeO_2 with carbon, or of GeK_2F_6 with sodium.
The oxide EsO_2 will be refractory and have a sp.gr. 4·7. The basic properties of the oxide will be less marked than TiO_2 and SnO_2, but greater than SiO_2.	The oxide GeO_2 is refractory and has a sp.gr. 4·703. The basicity is very feeble.
Eka-silicon will form a hydroxide soluble in acids, and the solutions will readily decompose forming a metahydrate.	Acids do not precipitate the hydrate from dilute alkaline solutions, but from concentrated solutions, acids precipitate GeO_2 or a metahydrate.
The chloride $EsCl_4$ will be a liquid with a boiling point under 100° and a sp.gr. of 1·9 at 0°.	Germanium chloride, $GeCl_4$, boils at 86°, and has a sp.gr. at 18°, 1·887.
The fluoride EsF_4 will not be gaseous.	The fluoride $GeF_4.3H_2O$ is a white solid mass.
Eka-silicon will form a metallo-organic compound $Es(C_2H_5)_4$ boiling at 160°, and with a sp.gr. 0·96.	Germanium forms $Ge(C_2H_5)_4$, which boils at 160°, and has a specific gravity slightly less than water.

considerable attention, and served to strengthen the faith of chemists in the fundamental truth of the periodic law. In illustration, the predicted properties of eka-silicon and subsequently discovered properties of germanium are quoted side by side in Table IV.

The confirmations of Mendeléeff's predictions of the properties of eka-aluminium (gallium), and of eka-boron (scandium) were equally striking. This dramatic achievement focused attention on the generalization; but it is only fair to say that the predictions and their subsequent verification are not such positive proofs of the truth of the periodic law as some suppose. It is certainly wrong to say, as C. Winkler did, "it would be impossible to imagine a more striking *proof* of the doctrine of periodicity of the elements than that afforded by this embodiment of the hitherto hypothetical eka-silicon," because gaps appeared in some of the older systems of classification, and the properties of the missing members could have been predicted, and atomic weights estimated by analogy with the other members of the family, quite independently of the periodic law, and in some cases with better results.

§ 5. The Application of the Periodic Law

> A natural law only acquires scientific importance when it yields practical results, that is, when it leads to logical conclusions which elucidate phenomena hitherto unexplained, when it directs attention to occurrences till then unknown, and especially when it calls forth predictions which may be verified by experiment.—D. I. MENDELÉEFF.

D. I. Mendeléeff pointed out that the periodic law could be employed in: 1. The classification of the elements; 2. The estimation of the atomic weights of elements not fully investigated; 3. The prediction of the properties of hitherto unknown elements; and 4. The correction of atomic weights.

1. The classification of the elements.—T. H. Huxley (1864) has said: "By the classification of any series of objects, is meant the actual or ideal arrangement together of those which are like, and the separation of those which are unlike; the purpose of this arrangement being to facilitate the operations of the mind in clearly conceiving and retaining in the memory the characters of the objects in question." If a new element possesses one of the marked characteristics of a given class, it follows that it will probably possess the remaining characteristics. If a new element of the alkaline-earth family be discovered, a great many other properties could be inferred with a high degreee of probability of their being right. In fine, enthusiasts say that the periodic system is superior to all the older methods of classifying the elements, for the law makes it possible to build up a system of the greatest possible completeness free from much arbitrariness, and it furnishes strong circumstantial evidence of the correctness of the reasoning employed by Cannizzaro in deducing values for the atomic weights of the elements.

2. The estimation of the atomic weights of the elements.—On account of practical difficulties, it is not always possible to fix the atomic weight of some elements by vapour density determinations (Avogadro's rule), and by specific heat determinations (Dulong and Petit's rule), and the atomic weights of these elements were frequently assigned on somewhat uncertain grounds. According to C. L. Winkler, indium has the equivalent weight 37·8. The correct atomic weight must be some multiple of this, and for no special reason, the atomic weight was once taken to be $37{\cdot}8 \times 2 = 75{\cdot}6$. In that case, indium would fall between arsenic and selenium where it would be quite mis-matched. Mendeléeff proposed to make indium tervalent, like aluminium, so that the atomic weight became $37{\cdot}8 \times 3 = 113{\cdot}4$, and the element fell in the table between cadmium and tin where it fits very well. The subsequent determination of the specific heat of indium, 0·0577, corroborated the change made by Mendeléeff in the atomic weight from 75·6 to 113·4. Beryllium, uranium, and a number of the rare earths at one time did not fit very well into the table, but Mendeléeff's alteration of the supposed atomic weights to make these elements fit the table were subsequently justified by vapour density determinations of the volatile chlorides, or by specific heat determinations.

3. The prediction of the properties of hitherto undiscovered elements.—When an empty space occurs in Mendeléeff's table, it is assumed that an element will one day be discovered which will fill that place; and conversely, if a new element were found to correspond with a place in the table already filled, it would be suspected that the supposed element is not really elemental. In attempting to imitate Mendeléeff, and predict the properties of missing elements in the table, attention is paid to the composition and properties of the more important compounds—hydroxides, oxides, haloid salts, etc.—so as to bring out (1) the family characters of the group to which it belongs; (2) the character of the series to which it belongs; (3) its position in the series and group so that a comparison can be made with the properties of other known elements similarly situated in neighbouring groups or series; and (4) the relations of the particular group and series in which it occurs with other groups and series. In order to avoid introducing new names when speaking of unknown elements, represented by gaps in the table, Mendeléeff designated them by prefixing a Sanscrit numeral—*eka* (one), *dwi* (two), *tri* (three), etc.—to the names of the preceding analogous elements of the odd or even numbered series of the same group. Thus, the unknown elements of group I will be called eka-cæsium, and dwi-cæsium. Were strontium unknown, it would be called eka-calcium. In addition to the prediction of germanium, gallium, and scandium already discussed, Mendeléeff foretold the possible discovery of eka- and dwi-cæsium; of eka-niobium—En=146; of eka-tantalum—Et=235; of dwi-tellurium—Dt=212; and of the analogies of manganese: eka-manganese—Em=100; and tri-manganese—Tm=190.

The case of the so-called **inert gases** is of more recent date. The discovery of argon and helium could not have been predicted from Mendeléeff's periodic law, but after these elements had been discovered, and accommodated in the periodic table between the strongly acid halogen family and the strongly basic alkali metals, the probable existence of other similar inert gases was indicated. When an exhaustive search was made, krypton, neon, and xenon were discovered with properties and atomic weights which could have been predicted from the arrangement which was made for argon and helium in Mendeléeff's table.

4. The correction of the values of atomic weights.—If the atomic weight of an element does not fit with the regular course of, say, the atomic volume curve, Fig. 4, the atomic weight is probably in error. Thus, the atomic weights of platinum, iridium, and osmium at that time were probably too high, and subsequent determinations verified this inference. For example, the atomic weights of these elements were:

	Platinum.	Iridium.	Osmium.
In 1870 . . .	196·7	196·7	198·6
In 1919 . . .	195·2	193·1	190·9

§ 6. Some Defects in the Periodic Law

The scientific value of thoroughly sound hypotheses is enhanced daily both by known facts that they are continually assimilating, and new facts that they are continually revealing.—J. WARD (1899).

There are some **misfits** in the Mendeléeff's table as we have it to-day, owing to the fact that at least three pairs of elements would be mis-matched if they were simply classed according to their atomic weights: argon (39·88) and potassium (39·10); cobalt (58·97) and nickel (58·68); and tellurium (127·5) and iodine (126·92).

G. Krüss and F. W. Schmidt (1889)[1] attributed the difficulty with **cobalt and nickel** to the presence of a hitherto undiscovered element in nickel which they named *gnomium*. This explanation, however, had to be discarded. It did not survive the ordeal remorselessly applied to conjectures of this kind. No gnomium has yet been found. Again, the case of **iodine and tellurium** has been studied with relentless vigour stimulated largely by D. I. Mendeléeff's prediction: "The atomic weight of tellurium *must* be between 123 and 126, and cannot be 128." Iodine most certainly belongs to the same group as the other halogens, and tellurium undoubtedly belongs to the selenium group; these elements are accordingly placed among their own family relations in spite of the fact that if their atomic weights were alone considered tellurium would be ranked with the halogens, and iodine with selenium. B. Brauner (1889) suggested that ordinary tellurium is a complex containing α- and β-tellurium; and it was inferred that true tellurium—say α-Te—has an atomic weight 125, and that the other form of this element has a higher atomic weight, and will find a place in the periodic system in the valency below tellurium. D. I. Mendeléeff called this undiscovered element *dwi-tellurium*, Dt, and he sketched some of its physical and chemical properties; but tellurium, said G. Wyrouboff, has been tortured in every conceivable manner: it has been melted, sublimed, oxidized, hydrogenized, phenylated, dissolved, crystallized, fractioned, and precipitated; yet nothing but failure has followed all attempts to get an atomic weight lower than iodine or to fraction the element into two others. Nothing has developed which would warrant a belief in Mendeléeff's "must." Hence, in spite of the fact that "the laws of nature admit of no exception," faith in the law has led chemists to allocate these discordant elements according to their chemical properties and not according to their atomic weights. To put the matter bluntly, the procedure runs: It is necessary either to reject the periodic law or to reject the number 127·5 for tellurium; the periodic law cannot be rejected because it is the very embodiment of truth, nay, truth itself; *ergo*, in spite of all evidence to the contrary, the number 127·5 must be wrong. Bode's law of astronomy successfully *predicted* the asteroids and allocated their proper place in the solar system; but the subsequent discovery of Neptune did not agree with Bode's law. The law was accordingly abandoned and it is now regarded as a curiosity. Mendeléeff's law may have to go the same way. B. Brauner's assumption that tellurium is a mixture of true tellurium with a higher homologue, may be a good working hypothesis for stimulating experiments on this element, but to maintain the thesis against all evidence to the contrary "may afford an easier way out of the difficulty than by working steadily at the cause of the discrepancy, but it affords at best a feeble and undignified cover for one's retreat." This method must be dubbed unscientific, but the circumstantial evidence justifies the procedure in the expectation that a consistent system will ultimately grow from the truth and error engrafted into the "law." It is not very probable that the principle underlying the periodic law will be abandoned because it is founded on a vast assemblage of facts of different kinds; and because it seems to be plastic enough to fulfil subsequent requirements. The central problem in inorganic chemistry, said W Ramsay (1904), is to answer the question: **Why this incomplete concordance?**

Allocation of hydrogen.—The location of hydrogen in the table, as already indicated, is difficult, because hydrogen seems to be without companions. It is univalent, and thus falls either with the alkali metals (D. I. Mendeléeff, 1869; G. Martin, 1901) or with the halogens (O. Mason, 1896; W. Crookes, 1898; W. Ramsay, 1901). Although D. I. Mendeléeff[2] rather inclined to the belief that hydrogen occupies an "isolated independent position," he said that in virtue of "its salt-like oxide H_2O, and the salts H, it must stand in the first group;" that "the nearest analogue to hydrogen is sodium which also stands in an odd series of the first group;" and that "the more remote analogues of hydrogen are copper, silver, and gold." The attempts to displace hydrogen from its position at the head of the alkali metal group, and to place it with the halogens have not been very successful, but in either case many of the arguments appear rather strained and far-fetched; they run *pro et con.* somewhat as follows:

(1) Unlike hydrogen, the monad alkali metals appear to be monatomic, but hydrogen too is probably monatomic at a high enough temperature.

(2) If placed at the head of the halogen table, hydrogen is in close contiguity with the other gaseous elements, but the extreme mobility and lightness of the hydrogen molecules may be a powerful factor in determining its gaseity; after all gaseity is a mere accident of temperature.

(3) Hydrogen is electropositive like the alkali metals, but it is not now considered to be a metal; hydrogen does not exhibit the metallic properties characteristic of the family of alkali metals, and towards lithium it behaves like nitrogen, oxygen, and the halogens in forming a hydride. This argument is of little weight when no objection is raised to the allocation of nitrogen and bismuth; or of carbon and lead in the one family group.

(4) The difference between two consecutive elements usually ranges between 15 and 20, and this agrees better with superposing hydrogen above fluorine than above lithium (7); as G. Martin (1901) has pointed out this argument simply depends on the arbitrary selection of subtraction as a criterion; if division be selected, quite a different conclusion is obtained. Thus, progressing upwards from potassium, the ratio K : Na = 1·7; Na : Li = 3·3; and, following the same rule, Li : H = 6·9, which is near to the observed value.

(5) If hydrogen be placed above lithium, six gaps for undiscovered elements are crowded in between hydrogen and helium, or helium must come in an unnatural intermediate position, say, above carbon or nitrogen. In view of the gaps in the old periodic tables which were subsequently filled, there is, however, no particular objection to the assumption that these undiscovered elements have a real existence even if they have not yet been discovered.

(6) The mutual replacement of hydrogen and the metals which has led to the acids being regarded as salts of hydrogen, establishes a clear analogy between hydrogen and the alkali metals; against this it must be remembered that there is an equally striking analogy between hydrogen and the halogens, for these elements can mutually replace one another in many organic compounds with no more effect on the general properties of the resulting compounds than is produced by the substitution of one halogen with another. This argument loses much weight if it be remembered that the behaviour of a compound is determined by its constitution rather than by the chemical nature of the atoms themselves, and that "the most diverse radicles may displace other radicles in a compound and perform a similar function to that of the displaced radicles without materially affecting the fundamental characteristics of the body into which they have entered."

(7) If the behaviour of the halogens towards oxygen be selected as a criterion, the diminishing stability of the oxygen compounds with diminishing atomic weight culminates in fluorine. No stable oxides are known, hydrogen oxide is a very stable compound, totally unlike the halogen oxides. The halogens in their known oxides have a maximum valency of seven, while the maximum valency of hydrogen is one.

(8) Then again, there is a great contrast between the stable hydrogen compounds with the halogens, and the instability of the hydrides of the alkali metals. In a rough sort of way the former property suggests dissimilarity; the latter, similarity. Hence also B. Brauner (1901) asks: How can such a positive element as hydrogen stand at the head of such negative elements as the halogens? The elements at the head of a sub-group are always more negative and less positive than the lower members of that sub-group.

Accordingly, it will be evident that the position of hydrogen has not been definitely settled, and that *hydrogen appears to be a rogue element quite out of place in the general scheme.* Some suppose that hydrogen is a member of an extinct or yet undiscovered series of independent elements, but whether hydrogen is the *alpha* or the *omega* is indeterminate because it would be eligible for a place either in group I or group VII according to the properties selected for comparison. The supposed first member of the series is called "proto-fluorine"; so also the elements "proto-beryllium" and "proto-boron" have been invented, the former with an atomic weight 1·33, and the latter, 2. All this, however, is mere speculation.

Allocation of the rare earths.—This also presents some difficulties. Most of the rare earths can be distributed about the table according to their atomic weights, or they can be relegated to a class by themselves. B. Brauner (1902), who has made a special study of the rare earths, considers that they should all be grouped together with cerium between barium and tantalum so that "Ce, 140·25" in the table stands for: Ce, 140·25; Pr, 140·6; Nd, 144·3; Sa, 150·4; Eu, 152; Gd, 157·3; Tb, 159·2; Dy, 162·5; Er, 167·7; Tm, 168·5; Yb, 172·0 . . . This has been called the **asteroid theory of the rare earths.** The properties of the rare earths, however, are not well enough known to give us much confidence in the various proposals which have been made for dealing with them; and consequently, Mendeléeff considered that the installation of these elements should be deferred; a similar remark applies to the radioactive elements. Here F. Soddy and A. Fleck (1913)[3] assume:

> All members occupying the same place in the periodic system are chemically identical with one another, and are not separable from one another by chemical process, although their atomic weights may vary over several units.

The rare earths do not fall all in the same group in this sense because several of the members fit well enough into the table, thus, ytterbium—Yb, 172—fits into group III, series 10, etc. The so-called isotopic elements will be discussed later.

If the properties of the elements are dependent on their atomic weights the existence of two elements with different properties and approximately the same atomic weights should be impossible. Hence the difficulty with elements like cobalt and nickel; ruthenium and rhodium, etc. The peculiarities of these elements would never have been suspected from the periodic law. It might also be added that some experiments with the radioactive elements have led to the inference that "different elements not necessarily of identical atomic weight, do occupy the same place in the table, and that when this occurs, these elements possess an identical chemical nature." The evidence as to the identity of chemical properties is not very strong when it is remembered how very few chemical tests have been made owing to the small amount of available material. Not very long ago praseodymium and neodymium were considered to have identical chemical properties.

Twin elements.—R. Lorenz[4] has shown that certain elements have atomic weights which approach each other in pairs, and which differ from each other by at most 1·4 units; and he applies the term **twin elements** to pairs of elements whose atomic weights approach one another very closely—within 1·4—of one another. For example:

	Diff.		Diff.
Boron-carbon	1·009	Nickel-cobalt	0·660
Sodium-magnesium	1·322	Selenium-bromine	0·893
Aluminium-silicon	1·320	Palladium-silver	1·238
Phosphorus-sulphur	1·033	Tin-antimony	1·190
Potassium-calcium	0·864	Iodine-tellurium	0·736
Vanadium-chromium	0·940	Tantalum-tungsten	1·200
Manganese-iron	0·910	Lead-bismuth	1·099

The elements usually show many similarities in their chemical behaviour, and their separation presents some difficulties. Most of the twin-elements usually follow one another in immediate succession, so that the atomic weight of a member of one pair differs from that of the corresponding member of the next pair by approximately 4 or a multiple of 4, *e.g.* Na and Al, 4·022; Mg and Si, 4·02; Al and P, 3·95; Si and S, 3·663; etc. Lorenz shows that elements which do not form twin pairs may follow this rule if they be regarded as representing twin pairs with other unknown elements—the exceptions are H, Be, N, Zn, Ga, Rb, Y, Zr, Nb, In, Cs, Ba, Ir, Au, and some rare earths elements.

Some elements are allocated places in the table according to their atomic weights in opposition to their chemical properties. For instance, copper, silver, and gold fall into one group with the alkali metals. The tervalency of gold appears to be unconformable with the valency of its companions although in its present position the series $PtCl_4$, $AuCl_3$, $HgCl_2$, and TlCl is suggestive. Beryllium is peculiarly placed from this point of view. Thallium is very like lead, but its sulphate and some other salts are quite different from lead salts. At least three pairs of elements have been placed according to their properties irrespective of their atomic weights, as indicated by the misfits mentioned in the preceding section. Again, the so-called type-elements, Li, Be, B, C, N, O, F, which stand at the heads of the family groups—the vertical columns of Mendeléeff's table—usually have properties quite at variance with the other members of the family. In 1870, Mendeléeff attributed this to their low atomic weight, for he said :

> The elements of the first two series have the least atomic weights, and in consequence of this very circumstance, although they bear the general properties of the group, they still show many peculiar and independent properties.

The difficulty still remains, for these elements have not yet been altogether reconciled to the groups to which they should be closely analogous. The test of any given classification of the elements arises when the arguments why a given element should be included rather in one class than in another are reviewed. For instance, in spite of the unique properties of fluorine or of lithium, could the former be included in any group other than the halogens, or lithium in any group other than the alkali metals ? The answer is in the negative.

Some elements which appear to be chemically similar are separated in the table. For example, copper and mercury ; silver and thallium ; barium and lead ; etc. The position of these elements in the table gives no hint of these characteristics. Still, it might be argued that these elements exhibit many essential differences. Thus, the physical properties of the cupric and mercuric chlorides and sulphates show great contrasts. The stability of cuprous and mercurous chlorides is also very different. Lead and barium dioxides appear to have a different constitution. The unstable thallium sesquioxide, Tl_2O_3, corresponds with the other —more stable—sesquioxides in the group, but there are many important points of resemblance between thallium and the alkali metals, and between silver and lead. The extension of the periodic law to include compounds as well as elements is not always satisfactory. Many examples will appear when the different family groups are reviewed ; and J. Locke (1898) [5] inquires : Why should the relations between magnesium and zinc be emphasized and the closer relation between magnesium and manganese be ignored as if the explanation were not conditioned by an equally important law of nature ? The worship of the periodic law as a fetish may stimulate the pursuit of remote analogies in one direction, and close the door to the search for closer analogies in other directions.

Multivalent elements.—According to Mendeléeff, when an element like copper forms two series of compounds in one of which it has the same valency as its neighbour in a horizontal row, the compounds of the neighbouring elements are similar. This is confirmed by the close resemblance between the bivalent compounds of copper and zinc ; but, on the other hand, the close proximity of scandium to titanium does not seem to confer on tervalent titanium compounds any of the characteristic properties of scandium. Hence, Mendeléeff's classification does not make clear the fact that *heterologous elements*—*i.e.* elements belonging to different groups in the periodic table—may give analogous compounds when in the same form of combination below their highest valency—*e.g.* silver and thallous chlorides. The compounds of ferric iron resemble those of tervalent aluminium and chromium, while those of ferrous iron are like those of bivalent zinc and magnesium. Again, the cuprous and cupric compounds have little more in common than has hydrogen sulphide and sulphuric acid—each pair of compounds has the same element—copper in the one case, sulphur in the other. Still further, the compounds of bivalent vanadium resemble those of magnesium ; tervalent vanadium, those of aluminium ; quadrivalent vanadium, those of silicon ; and quinquivalent vanadium, those of phosphorus. Hence, J. Locke (1898) and G. A. Barbieri (1914) recommended that the compounds of an element with different valencies be regarded as belonging to so many different elements. Ferric and ferrous iron are just as distinct primary forms of matter as electricity and heat are forms of energy, and the one can be converted into the other, or into metallic iron. When a ferric salt is reduced to a ferrous salt, or into metallic iron, the form of matter analogous to tervalent iron has ceased to exist.

The higher oxides.—G. Wyrouboff represents the actual state of our knowledge of the higher oxides of the elements by a chart constructed like the ideal curve, Fig. 3. The selection of the characteristic oxides by Mendeléeff (Fig. 3) is quite arbitrary, there appears to be no guiding principle. Sometimes it is the lower oxide which is selected—*e.g.* BaO in place of BaO_2; sometimes a higher—*e.g.* Mn_2O_7 in place of MnO_2, MnO, etc. Sometimes it is the more stable oxide—*e.g.* BaO and not BaO_2; and sometimes it is the less stable one—*e.g.* Cu_2O, not CuO. The curve of the actual oxides will doubtless be modified by future researches, but it is far less regular and has more the character of a zig-zag line. No longer can the higher oxides ranged along the same horizontal line be said to have any relation with their chemical analogies; the best established of which may disappear; and harmonious order is replaced by *la plus absolue anarchie.* Against these views it has been urged that Mendeléeff purposed selecting the highest *salt-forming oxide* in his table, and that he did not regard such oxides as K_2O_2, BaO_2 as salt-forming oxides.[6] If he distinctly specified the salt-forming oxides, it is urged that the generalization cannot be impugned by the consideration of another class of oxides altogether. Mendeléeff claims that the true peroxides, BaO_2, Cr_2O_7, TiO_2, H_2O_2, cannot form corresponding salts, whereas PbO_2 and Bi_2O_5 are distinctly salt-forming oxides in that the one corresponds with the plumbates, and the other with the bismuthates. However, the existence of the persulphates, pertungstates, and permolybdates does not harmonize with D. I. Mendeléeff's views. The explanation of D. I. Mendeléeff, moreover, does not account for copper—cuprous oxide, Cu_2O, should be the maximum salt-forming oxide of this element, whereas cupric oxide, CuO, is the commoner salt-forming oxide.

G. Wyrouboff, in a paper, *Sur la classification périodique des éléments* (1896),[7] has the idea that the periodic system is a very interesting and highly ingenious table of the analogies and the dissimilarities of the simple bodies—a mere *catalogue raisonné* of the elements; and further, allowing Mendeléeff's *dictum*—the laws of nature admit of no exception—the periodic law must be accepted or rejected as a whole; there are numerous cases where the periodic law conflicts with facts; *ergo*, the law ought to be rejected. G. Wyrouboff adds that the periodic classification is a sterile combination of numbers; it is an ingenious combination of observations arbitrarily selected; and one of those vague formulæ which satisfies subjective conceptions, without corresponding with any objective reality. His proposal to reject the periodic law is somewhat precipitate, for we do not feel quite satisfied that the supposed misfits are not due to defective knowledge. Some can see a distinction between failure and incomplete success. Although a single contradictory fact is fatal to a hypothesis, the hypothesis is not to be rejected on the first *primâ facie* conflict with reality. This does not justify the relegation of inconsequent facts into obscurity, but rather indicates the need for keeping them in a conspicuous position. The law may have to be ultimately abandoned; it is only excessive zeal which could say *qu'aucun argument chimique ne pouvait prévaloir contre la loi périodique.* What M. Faraday[8] said a century ago (1819) applies to-day:

> Much as the present stage of knowledge owes to the tendency of the human mind to methodize, and therefore to facilitate its labours, still it may complain that in some directions it has been opposed and held down to error by it. All method is artificial and all arrangement arbitrary. The distinction we make between classes, both of thoughts and things, are distinctions of our own; and though we mean to found them on nature, we are never certain we have actually done so. That which appears to us a very marked distinctive character may be really of very subordinate importance, and where we can perceive nothing but analogies and resemblances, may be concealed nature's greatest distinctions.

CHAPTER VII

HYDROGEN

§ 1. The Occurrence of Hydrogen in particular and of the Elements in general

> It can be said that hydrogen is more widely distributed in the universe than any other element, since its presence has been recognized spectroscopically in all the heavenly bodies.—E. BAUR (1907).

THE element hydrogen occurs free in nature in comparatively small quantities. Free hydrogen has been detected in the gaseous exhalations from volcanoes and fumaroles. Thus R. Bunsen,[1] in 1853, found 25·14 per cent. of hydrogen, along with carbon dioxide and hydrogen sulphide, in the gases from the Reykjalidh fumaroles in Iceland; H. Moissan (1902) reported 8·12 per cent. of free hydrogen in the gases from Monte Pelée (Martinique), where the disastrous eruption of 1902 occurred; A. L. Day and E. S. Shepherd found 10·2 per cent. of hydrogen in the gases from the crater at Kilauea, Hawaii, in 1912; and F. Fouqué, 29·43 per cent. in the gases from Santorini (Ægean Sea).

TABLE I.—COMPOSITION OF SOME NATURAL GASES.

	Reykjalidh, Iceland.	Monte Pelée, Martinique.	Kilauea, Hawaii.	Santorini, Ægean Sea.	Stassfurt Mines.
Hydrogen	25·14	8·12	10·2	29·43	93·050
Oxygen	—	13·67	—	0·32	0·185
Nitrogen	0·72	54·94	11·8	32·97	5·804
Carbon dioxide	50·60	15·38	73·9	36·42	0·180
Carbon monoxide	—	1·60	4·0	—	—
Sulphur dioxide	—	—	—	—	—
Hydrogen sulphide	24·12	—	—	—	—
Ethane	—	5·46	—	0·86	0·778

Hydrogen has also been detected in natural gas. The presence of hydrogen in these gases has been denied, although many published analyses include free hydrogen [2]—for instance, S. P. Sadtler reported 4·79 to 22·50 per cent. of hydrogen in the gases from the petroleum springs of Pennsylvania; C. C. Howard found an average of 1·76 per cent. of hydrogen in natural gas from Indiana and Ohio; E. H. S. Bailey found none in the gas from Kansas, and F. C. Phillips none in the gas from Vancouver; free hydrogen has been found among the gaseous inclusions in the anhydrite or salt deposits of Stassfurt, Leopoldshall, and Wieliczka; H. Precht's analysis is given in Table I. Confirmatory observations have been made by H. Rose, H. Precht, E. Reichardt, E. Erdmann, etc.[3] Occluded gases containing free hydrogen have been obtained from granites and other rocks.[4] Thus, W. A. Tilden found:

	H_2	N_2	CO_2	CO	CH_4
Granite (Skye)	61·68	5·13	23·60	6·45	3·02
Gabbro (Cornwall)	88·42	1·90	5·50	2·16	2·03
Pyroxene, Gneiss (Ceylon)	12·49	1·16	77·72	8·06	0·56
Gneiss (Seringapatam)	61·93	0·56	31·62	5·36	0·51
Basalt (Antrim)	36·15	1·61	32·08	20·08	10·00

A. Gautier obtained 134·61 c.c. of hydrogen from 100 grams of granitic rock. A small part of the gases existing in rocks is entrapped in minute cavities and pores. Some suppose that the larger part is occluded in the mineral much as palladium can occlude hydrogen, while others assume that the gases are not free in the minerals but are liberated through chemical reactions when the mineral is heated in vacuo —*e.g.* methane comes from organic matter present; carbon oxides from carbonates; nitrogen from nitrides; and hydrogen from the decomposition of steam by iron or its oxides or salts. Free hydrogen has also been found in the occluded gases of meteorites—in quantities varying from 0·2 to nearly 50 c.c. per gram of solid. T. Graham obtained 16·53 c.c. of gas from 5·78 c.c. of the Lenarto meteoric iron, and the gas contained 85·68 per cent. of hydrogen by volume; 9·86 of nitrogen; 4·46 of carbon dioxide; and no carbon dioxide. The meteorite contained 90·88 per cent. of iron; 8·45 of nickel; 0·66 of cobalt; and 0·002 of copper. A. W. Wright's analyses of the gases occluded in iron and stoney meteorites gave

	CO_2	CO	CH_4	H_2	N_2
Iron type . .	8·6–14·4	12·5–67·7	—	18·2–76·8	1·5–5·1
Stone type . .	35·4–81·0	1·7–4·4	0·0–3·6	13·1–57·9	1·7–3·5

W. Ramsay and M. W. Travers found a gram of a sample of meteoric iron from Toluca contained 2·8 c.c. of occluded hydrogen; from Charcas (Mexico), 0·28 c.c.; and from Rancho de la Pila (Mexico), 0·57 c.c. W. E. Hidden, W. M. Flight, J. Dewar and G. Ansdall, M. W. Travers, J. W. Mallet, etc., have also found hydrogen in meteorites. Hydrogen has also been reported by J. Parry, and A. Pictet and L. Ramseyer as occluded in cast iron, steel, coke, and coal.

Although hydrogen is being constantly liberated from the earth's solid crust, the proportion actually found in the atmosphere at sea level is very small; at higher altitudes, the proportion is probably greater, but the atmosphere is there so attenuated that the actual amount is very small. J. H. Jeans estimates that the number of molecules of hydrogen per c.c. at a height h kilometres, is

	$h=0$	$h=20$	$h=80$	$h=160$	$h=800$
Hydrogen . .	10×10^{13}	8×10^{13}	43×10^{12}	182×10^{11}	3×10^{10}
Nitrogen . .	78×10^{17}	43×10^{16}	520×10^{11}	35×10^{7}	0
Oxygen . .	21×10^{17}	7×10^{16}	25×10^{11}	3×10^{6}	0

F. C. Phillips[5] could detect no hydrogen at a height of 7000 feet above sea level, but owing to exhalations from natural gas and the decay of organic matter, he believes it will be found at still higher levels; H. and E. Erdmann found it at a height of 800 metres. J. L. Gay Lussac could find none in air collected at an altitude of 6,636 metres during his balloon ascent in 1804. The estimates which have been made of the amounts of free hydrogen in the atmosphere are somewhat discrepant. J. B. A. Dumas and J. B. J. D. Boussingault's analyses of air in 1841, indicated the presence of hydrogen, but they thought the gas must be present in air in the form of methane, CH_4. In 1898, A. Gautier calculated that 100 litres of air contain from 11 to 18 c.c. of hydrogen; and, in 1900, G. D. Liveing and J. Dewar found hydrogen and helium to be always present in the more volatile portions obtained by the fractional distillation of liquid air. Lord Rayleigh's estimate, from spectroscopic observations, is about one-sixth of that of A. Gautier; and A. Leduc's observations on the density of air also indicate that A. Gautier's estimate is too high. G. Claude found air to contain less than 0·00001 part of free hydrogen.

Spectroscopic observations[6] of the sun's chromosphere show what appear to be stupendous red flames of incandescent hydrogen with calcium and a few other elements in some cases towering over 300,000 miles (M. Fenyi, 1892) into space, and 100,000 miles in width (C. A. Young, 1872)—thousands of times larger than the earth on which we live. These prominences, as they are called, have been observed to shoot nearly half a million miles within 10 minutes of time. Spectroscopic observations also show that hydrogen is present in nebulæ and certain stars.

Combined hydrogen is common. Water contains one-ninth of its weight of hydrogen. We really know nothing about the hydrogen as it is combined with oxygen in water. The fact is that when water is decomposed under certain conditions, this proportion of hydrogen is obtained. It is the *façon parler* to say that the compound *contains* the element, or that the element *occurs* in or is *present* in the compound, when the element can be obtained from the compound by suitable methods of decomposition. The occurrence of an element, refers not only to the conditions under which the free element may be found, but also to those natural compounds which contain the element united with other elements. Hydrogen occurs combined not only with oxygen as water, but also with sulphur as sulphuretted hydrogen; with chlorine as hydrochloric acid; with nitrogen as ammonia; and more rarely combined with phosphorus, iodine, bromine, and carbon. It is one of the chief constituents of animal and vegetable tissue. Hydrogen also is present in nearly all organic compounds, in all acids, and in many gases—the hydrocarbons (petroleums), hydrogen sulphide, etc.

A. Gautier (1901) attributes the formation of free hydrogen in nature, (1) to the decomposition of water at a red-heat by ferrous salts, etc.; (2) to the decomposition by heat of hydrocarbons formed from natural carbides; and (3) to the decomposition of such compounds as iron nitride by steam—$2NFe_3+6H_2O=2NH_3+6FeO+3H_2$, a reaction observed when a crystalline iron nitride from Etna lava is treated with water.

Quantitative distribution of the elements.—By comparing a large number of analyses of rocks, etc., F. W. Clarke (1916)[7] has tried to estimate the percentage composition, by weight, of the earth's crust (½ mile deep) together with the ocean and the atmosphere. His result is:

	Per cent.		Per cent.		Per cent.
Oxygen	50·02	Magnesium	2·08	Barium	0·08
Silicon	25·08	Hydrogen	0·95	Manganese	0·08
Aluminium	7·30	Titanium	0·43	Strontium	0·02
Iron	4·18	Chlorine	0·20	Nitrogen	0·03
Calcium	3·22	Carbon	0·18	Fluorine	0·10
Sodium	2·36	Phosphorus	0·11	Bromine	0·008
Potassium	2·28	Sulphur	0·11	All other elements	0·41

He also emphasizes the fact that in the solid crust, the lighter elements predominate over the heavier, so that the abundant elements all have an atomic weight less than 56. The heavier metals occur only in trivial amounts. The mean density of the earth—5·4–5·6—however, is about double that of the average of the surface rocks. This has led to the assumption that the heavier elements are concentrated in the interior—a supposition, says F. W. Clarke, which is possibly true, but unprovable.

If we try to get an estimate of the *relative* number of atoms of the different *kinds* of elements distributed in the half-mile crust, the ocean and the atmosphere, Clarke's numbers must be divided by the corresponding atomic weights of the elements. We thus obtain for **the percentage number of atoms in the half-mile crust:**

Oxygen	53·81	Sodium	1·72	Potassium	1·02
Hydrogen	16·30	Magnesium	1·61	Carbon	0·27
Silicon	15·87	Calcium	1·40	Titanium	0·16
Aluminium	4·68	Iron	1·29	Chlorine	0·11

This gives a better idea of the relative distribution of the elements from the chemical point of view than the actual weights in the preceding list.

The occurrence of the elements and the periodic law.—D. I. Mendeléeff[8] has drawn attention to the fact that *the elements which occur most abundantly on the earth's surface have small atomic weights*; the converse does not necessarily apply, for some elements with small atomic weights—*e.g.* lithium (7), beryllium (9), and boron (11) —are by no means abundant. There are some exceptions to D. I. Mendeléeff's rule; strontium, for instance, appears to be less abundant than barium. The elements in the groups of Mendeléeff's table often occur more abundantly in passing from the first to the second member, and afterwards decrease with increasing atomic weight—*e.g.* the alkali family; the tetrad group; etc. J. H. Gladstone argued that the average vapour density of the elements which are plentiful is less than that of the elements which are common; and with those which are common, it is less than with the rare elements; and with the rare elements less than with the very rare elements. Consequently, says J. H. Gladstone, as the earth cooled from the vaporous state, those elements having the least vapour density must have tended to remain near the surface, while those with a high vapour density accumulated more towards the centre, and therefore occur most rarely on the surface crust.

In a paper *On the periodic law, and the occurrence of the elements in nature* (1884), T. Carnelley has made a special study of the occurrence of the elements from the point of view of the periodic law. He shows that with the exception of carbon, nitrogen, oxygen, sodium, magnesium, aluminium, and silicon, the elements belonging to the odd series of Mendeléeff's table are, as a rule, easily reduced to the free state, while those elements belonging to the even series are usually reduced with difficulty. The exceptional elements correspond with the exceptional character of the atomic volume curve—Fig. 4, Cap. VI—where the curve instead of continuing to fall as it reaches carbon, begins to rise until it comes to sodium. The ready reducibility of the elements of the odd series corresponds with their common occurrence in the free state. Excepting carbon, nitrogen, oxygen, and group VIII, *the elements belonging to the even series do not occur in the free state, whereas elements belonging to the odd series generally, and sometimes frequently, occur free.* The following elements of the odd series, for instance, are frequently found in a free state: copper, silver, gold, mercury, arsenic, antimony, bismuth, sulphur, selenium, tellurium, lead, and tin, while gallium, indium, and thallium are so sparsely distributed that not enough is known to justify a definite statement about them. The four halogens—fluorine, chlorine, bromine, and iodine—zinc, and phosphorus are the only notable exceptions because sodium, magnesium, aluminium, and silicon have already been accounted for, and the exceptions, carbon, nitrogen, and oxygen, in the even series also belong to the peculiar part of the atomic curve. The elements of group VIII all occur native, and this tendency is the more marked the greater the atomic weight. The four halogens are the most electro-negative of the elements, and they occur in nature united with the most electro-positive elements, and excepting a few secondary products—oxychlorides and sulphochlorides—are never found in combination with oxygen or sulphur.

T. Carnelley further shows that excepting the halogens and the members of group VIII, *the elements belonging to the odd series of Mendeléeff's Table rarely occur in nature as oxides, but usually occur as sulphides (or double sulphides), selenides, tellurides, or arsenides*—*i.e.* in combination with negative elements belonging to an odd series. In illustration, the following elements of the odd series commonly occur as sulphides, selenides, tellurides, or arsenides—copper, silver, zinc, cadmium. mercury, gallium, indium, thallium, lead, antimony, sulphur, selenium, and tellurium. On the other hand, arsenic, bismuth, and tin are generally found in this form; while gold, sodium, magnesium, aluminium, silicon, and phosphorus rarely if ever occur so combined. *The tendency of the members of the odd series in any particular group to occur in nature as sulphides increases, and the tendency to occur as oxides or double oxides diminishes as the atomic weight increases.* For example, in group II, magnesium nearly always occurs as double oxide (carbonate, silicate, etc.); zinc occurs commonly as sulphide, sometimes as oxide; cadmium, found as sulphide, never as oxide; and mercury as sulphide, or metal, never as oxide. In group IV, silicon occurs always as oxide or double oxide (silicates); tin, almost always as oxide, sometimes as sulphide; and lead generally as sulphide, rarely as oxide. Similarly with the other groups.

On the other hand, *elements belonging to the even series usually occur as oxides or double oxides—silicates, carbonates, sulphates, aluminates, etc.*—*i.e.* in combination with an element belonging to an even series. In illustration, the following elements of the even series commonly occur as oxides or double oxides—lithium, potassium, rubidium, cæsium, beryllium, calcium, strontium, barium, boron, scandium, yttrium, lanthanum, ytterbium, carbon, titanium, zirconium, cerium, thallium, vanadium, niobium, didymium, tantalum, chromium, terbium, tungsten, and manganese. Molybdenum and manganese (rarely) occur as sulphides. Nitrogen (in the nitrates) and molybdenum frequently occur as oxides or double oxides.

Excepting iron, nickel, and cobalt the elements of group VIII rarely occur in a combined state. Iron usually occurs as oxide, frequently as sulphide; cobalt usually as sulphide or arsenide, and sometimes as oxide; while nickel almost always resembles the elements of the even series, cobalt the elements of the odd series. Hence the three triads of elements in group VIII show a gradual passage from the even to the odd series.

T. Carnelley summarizes the facts: *Elements standing on the falling portions of the curve of atomic volumes are reducible with difficulty, and never occur in a free state in nature or in combination as sulphides, but always in combination with oxygen, forming oxides or double oxides—e.g. silicates, sulphates, carbonates, etc. Elements on the rising portions of the curve are easily reducible, and almost always occur more or less in the free state in nature, and also in combination with sulphur, but rarely with oxygen.* It is possible that the exceptions are apparent, not real, and that with increasing knowledge the anomalies will disappear, for the coincidences are too many, and the exceptions too few, to lead to any conclusion other than that the relative abundance of the elements is somehow connected with their position in the periodic classification.

W. D. Harkins[9] has noticed that when the elements are arranged in the order of their atomic numbers, the even numbered elements are in every case more abundant in meteorites than the adjacent odd numbered elements; similar remarks apply to the earth's lithosphere. In all cases also the elements of low atomic number and low atomic weight occur much more abundantly than elements with a high atomic weight.

§ 2. The Preparation and Purification of Hydrogen

The progress of aeronautics, and the use of hydrogen for the so-called hardening or hydrogenation of oils, and the synthesis of ammonia, has incited industrial chemists to improve the existing processes and to develop new methods for preparing this gas. The use of hydrogen for the inflation of balloons was proposed by J. A. C. Charles in 1783, soon after H. Cavendish's work on inflammable air ; and the first balloon sent up from British soil on November 25, 1793, was inflated with hydrogen. The lifting power of hydrogen is about 1·2 kilograms per cubic metre, or about 68½ lbs. per 1000 c. ft.

If the molecular weight M (hydrogen=2) of a gas be expressed in ozs., a gram-molecule of the gas will occupy nearly 22·3 c. ft., at n.p.t.; an ounce of the gas will thus occupy 22·3/M c. ft., and a pound of the gas will occupy nearly 357/M. c. ft., or a cubic foot of the gas will weigh M/357, or 0·0028M lb. Again, the lifting power of a given volume, v, of any gas is equal to the difference between the weight of the gas and the weight of an equal volume of air at the same temperature and pressure. The lifting power of a gas of molecular weight M at sea level is therefore 0·0028v (28·98—M) lbs., so that the lifting power of 500,000 c. ft. of hydrogen at n.p.t. is nearly 38,000 lbs. If a gas had a lifting power greater than hydrogen its molecular weight would be less than 2, and in the extreme case, a gas with a vanishingly small atomic weight would have a lifting power about 7½ times that of hydrogen.

The gas for dirigible balloons must be free from such impurities as are liable to attack the fabric of the balloon ; and for military purposes as small a plant and as small a weight of material as is practicable must be employed. Cost is not then of prime importance. In addition hydrogen is also used as a combustible in special cases—*e.g.* the oxyhydrogen blowpipe ; for the manufacture of quartz glass ; the synthesis of gems—*e.g.* rubies and sapphires ; in the melting of platinum ; and in the autogenous welding of steel, iron, copper, and various alloys. It is also used mixed with nitrogen as an inert atmosphere in the manufacture of tungsten filaments for lamps, and in fusing tungsten powder into rods.[1]

Some processes for the preparation of hydrogen have been previously discussed. The more important methods which have been suggested for preparing hydrogen are based upon the electrolysis of water, the decomposition of water by chemical reactions, the action of metals on dilute acids, the decomposition of metal hydrides, the action of metals and alloys on alkaline lye, the decomposition of hydrocarbons, and the formation of hydrogen as a product of secondary importance—*i.e.* as a by-product—in processes pursued for other substances called the primary or main products of the reaction.

(1) *The electrolysis of aqueous solutions.*—Highly purified water is a poor conductor of electricity, but if the water be made slightly acid or alkaline it can be readily electrolyzed. Hydrogen gas is liberated at the cathode, oxygen at the anode. In addition to the work of decomposition, a certain proportion of current is expended in warming up the liquid, so that the total energy expended is the sum of that

absorbed as heat and that which does chemical work. The heating effect is proportional to the resistance, R ohms, and to the square of the current, C amps. The total electrical energy of the current—C amps. and E volts—is CE watts; the chemical work done by the current is $CE-C^2R$, and this is approximately 69 Cals. per gram-molecule of water. One coulomb of current decomposes 0·0933 mgrm of water; and gives 0·0829 mgrm. or 0·058 c.c. of oxygen; 0·01034 mgrm. or 0·1150 c.c. of hydrogen; that is, 0·0933 mgrm or 0·1725 c.c. of mixed gases. Otherwise expressed, one ampere hour of current decomposes 0·3351 grm. of water liberating 0·298 grm. or 207·2 c.c. of oxygen; 0·0373 grm. or 414·4 c.c. of hydrogen; or 0·3353 grm. or 621·6 c.c. of mixed gases. With an intensity of 1·5 volts, virtually no current passes through the electrolyte, because at least that potential is required to start the electrolysis and provide the energy for the decomposition. With a rather higher voltage, a current passes through the electrolyte, but no visible evolution of gas occurs with electrodes of the usual size until the solution is saturated with hydrogen and oxygen gases. A solution of one part of sulphuric acid with ten of water, in an electrolytic cell fitted with platinum electrodes, is readily broken down by a current with an intensity of not less than 1·7 volts; sodium hydroxide solutions have a similar minimum voltage of 1·69 volts, and potassium hydroxide, 1·67 volts. The electrolysis proceeds with a copious evolution of gas when a current with an intensity of 2 or 3 volts is used.

The strong tendency towards oxidation at the anode and towards reduction at the cathode renders the electrodes particularly liable to attack during the electrolysis. Graphite or carbon anodes suffer some oxidation; platinum and gold anodes are not attacked; and lead anodes are superficially oxidized, but the film of lead dioxide seems to protect the metal from further attack. Gold cathodes are not perceptibly attacked; platinum cathodes slowly blacken, probably owing to the absorption of hydrogen and its subsequent decomposition whereby a film of platinum-black is formed; and lead cathodes slowly blacken and disintegrate superficially so that powdered lead collects on the floor of the cell. The action is probably similar to that with platinum. Iron makes a good cathode with alkaline solutions. The electrodes, of course, must also resist the chemical action of the acid or alkaline electrolyte. If the cathode can unite with an alkali metal, or occlude or dissolve hydrogen gas, it is liable to disintegrate rapidly, presumably because of the successive formation of an alloy and its decomposition by the water of the electrolyte.

The proportion of gases liberated during the electrolysis of water is always less than the theoretical amount, and the volume of oxygen less than half that of hydrogen. Temporary losses at the beginning of the electrolysis may occur through the absorption of hydrogen at the cathode, or of oxygen by the superficial oxidation of the anode. These losses, however, cease when the cathode is saturated, and when a continuous protective coat of oxide is formed on the anode. There is a certain loss caused by the recombination of hydrogen and oxygen dissolved in the electrolyte to form water. The dissolved hydrogen unites with oxygen at the anode; and the dissolved oxygen with the hydrogen at the cathode. The diminution in the volumes of the two gases is in the same proportion as they are evolved. If the electrolysis proceeds while the system is under pressure, more amperes will be transmitted for the same applied voltage, or the same number of amperes can be passed with a smaller applied voltage. In this case, the output of gas per ampere hour decreases, and the heating effect is diminished, because, under pressure, (i) more hydrogen and oxygen dissolve in the electrolyte and this increases the amount of recombination; and (ii) the conductivity of the solution is increased while the resistance and consequently also the heating effect is decreased.

In the electrolysis of dilute sulphuric acid, oxygen may be lost owing to the formation of *persulphuric acid* or persulphates. The amount so lost depends on the temperature, current density, and the concentration of the acid. Thus, O. Schönherr[2] found that at ordinary temperatures the percentage amounts of oxygen lost in the formation of persulphuric acid with acids of different concentrations—specific gravities—and different current densities—amperes per sq. metre—are :

Sp. gr. H_2SO_4 . .		1·15	1·20	1·25	1·30	1·35	1·40
Loss of oxygen	5 amps. .	—	—	—	1·18	3·9	23·0
	50 amps. .	—	4·4	29·3	47·2	60·5	67·7
	100 amps.	7·0	20·9	43·5	51·6	71·3	75·7

In commercial work the concentration of the acid and the current density are adjusted to fall well below the minimum here indicated. The persulphuric acid in solution may pass by diffusion or circulation to the cathode where it is reduced by the hydrogen back to sulphuric acid. Under these circumstances the net result is a loss of hydrogen and oxygen in the proportions in which they are liberated—the persulphuric acid acts as an intermediate compound. The higher the temperature the less the loss of oxygen by the formation of persulphuric acid, and running the cell warm is one of the best remedies. There may be losses of oxygen from the anodic formation of *hydrogen peroxide*. The conditions which particularly favour the formation of this compound—over 60 per cent. sulphuric acid—do not usually obtain in the electrolytic cells used for the generation of hydrogen and oxygen. There is also a tendency to form a little *ozone*, which decreases the total volume of oxygen given off—but the presence of ozone is often an advantage since the oxygen gas is then a more efficient oxidizing agent. The conditions which favour the formation of ozone are high current density ; highly concentrated sulphuric acid—say up to 50 per cent. ; and low temperatures. The amount of ozone formed is small when working with a low current density, very dilute acid, and warm solutions.

When but small quantities of electrolytic hydrogen are required in the laboratory the anode is formed by immersing the platinum wire in a mass of liquid zinc amalgam (Fig. 1) which absorbs the oxygen to form zinc oxide and finally zinc sulphate ; the cathode is a platinum plate. A current from an accumulator giving between 4 and 6 volts, suffices to work the cell charged with dilute acid (1 : 10)—the gas is comparatively pure. If alkali lye and nickel electrodes be used, the hydrogen will be contaminated with hydrocarbons derived from traces of carbides, etc., in the caustic alkali ; but, according to H. B. Baker (1902),[3] an aqueous solution of purified crystalline baryta gives a gas of the highest degree of purity. H. B. Baker used a platinum plate as cathode, and a platinum wire dipping in zinc amalgam for the anode. The zinc amalgam absorbs the oxygen. According to E. W. Morley, if the alkaline solution used in the electrolysis contains carbonates, hydrocarbons may be formed.

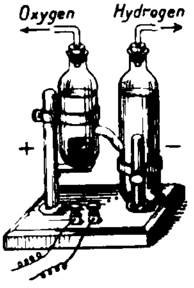

FIG. 1.—Preparation of Hydrogen on a small scale of electrolysis

On the industrial scale, a great many systems for the electrolysis of water have been designed and used ; many of these are described in V. Engelhardt's *Die Electrolyse des Wassers* (Halle a. S., 1902) and M. N. Schoop's *Die industrielle Electrolyse des Wassers* (Leipzig, 1901). In most of the arrangements, dilute sulphuric acid is electrolyzed between lead electrodes, or sodium hydroxide solutions between iron or nickel electrodes. The main practical difficulties are : (i) The slight attack of the electrodes by the electrolyte, and (ii) the necessity of preventing the admixture of the two gaseous products of the electrolysis without increasing the internal resistance of the cell too much by means of diaphragms, say asbestos. There are four leading types of cell : [4] (1) The filter-press type ; (2) the tank type : (3) the bell type ; and (4) the metal partition type.

O. Schmidt's **filter-press type** of cell is based on the fact that if a conducting material be placed between the anode and cathode of an electrolytic cell, the system behaves as if it were really two cells, because while hydrogen is liberated at the cathode and oxygen at the anode, oxygen is also liberated from the side of the diaphragm facing the original cathode and hydrogen from the side facing the original anode—provided the voltage drop between the original anode or cathode and the conducting partition is less than the minimum voltage required for electrolysis. The cell is made of recessed iron plates and they are clamped together with an intermediate partition with a rubber border and porous asbestos cloth in the centre. Hence, a series of each pair of plates forms one cell and two half cells. The iron plates are thus insulated from one another so that if the cells be filled with electrolyte, and the end plates be made respectively positive and negative poles, the current passes from pole to pole through the electrolyte and the iron plates. A series of these plates are clamped together as indicated in Fig. 2. The hydrogen and oxygen liberated at alternate sides of these plates pass through suitable passages into collecting pipes. The asbestos partitions prevent the mixing of the gas. The hydrogen is about 99 per cent. purity, the oxygen 75½ per cent.; about 5·9 c. ft. of hydrogen and 3 c. ft. of oxygen at mean temperature and pressure are collected per kilowatt hour; with a series of 40 plates, about 2·5 volts are absorbed in each cell and the current density about 2 amps. per sq. decimetre. The apparatus is compact, but the rubber joints of the diaphragm require close attention to prevent leakage.

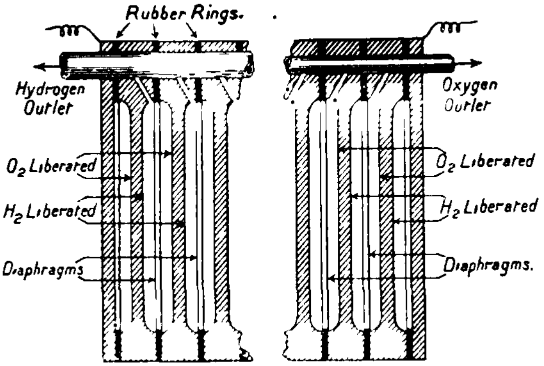

Fig. 2.—Diagrammatic Arrangement of O. Schmidt's Filter Cells.

The International Oxygen Co.'s **tank type** of cell has a mild steel tank fitted with an iron cylinder perforated with holes and hung from the cast-iron lid of the tank by means of a conducting rod. An asbestos curtain surrounds the inner cylinder. The lid of the tank is insulated from the outer walls and from the central rod. The cell is filled with a 10 per cent. solution of sodium hydroxide. The lid is also fitted with suitable outlet pipes so that during the electrolysis the hydrogen liberated from the walls of the tank and the oxygen liberated on the walls of the inner cylinder are collected in separate pipes. At 20°, and 29·92 in. pressure, 3·051 c. ft. of oxygen and 5·950 c. ft. of hydrogen were collected per kilowatt hour, and the purity of the hydrogen was 99·70 per cent., and of the oxygen, 98·34 per cent. In M. U. Schoop's **bell type** of cell, a perforated tube—made of iron if the electrolyte be alkaline, and of lead if the electrolyte be acid—is surrounded by a glass or porcelain tube as illustrated in Fig. 3. The electrodes are arranged in pairs as shown in the diagram. Two pairs are placed in each cell. One pair acts as anode, the other pair as cathode. The glass tubes collect the gases, and there is little risk of mixing the gases. In Schuckert's system, the electrodes are arranged so that the gas from each electrode collects in a separate cell. In P. Caruti's **diaphragm type** of cell, pierced metal diaphragms are employed. The electrolysis of brine solutions for caustic alkali and chlorine furnishes hydrogen as a by-product. The cost of the electrolytic process per 2000 cubic feet of hydrogen (and 1000 cubic feet of oxygen) is about 19*d.* on the assumption that the electrical energy costs ½*d.* per unit.

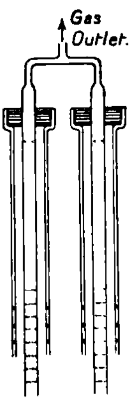

Fig 3.—Pair of M. U. Schoop's Electrodes

(2) *The decomposition of water.*—A large number of oxidizable substances can be employed for this purpose. In his *Essai de mécanique chimique fondée sur la*

thermochimie (Paris, 2. 521, 1879), M. Berthelot showed that in very many cases, the decomposition of water with the liberation of hydrogen can be effected by substances, which, in uniting with the oxygen of the water, give off more heat than occurs when hydrogen unites with the same proportion of oxygen. The results of the action of the alkali metals and the metals of the alkaline earths, previously indicated, are represented by the equations:

$$\begin{matrix}\text{Na}\\ \text{Na}\end{matrix}+\begin{matrix}\text{H}-\text{O}-\text{H}\\ \text{H}-\text{O}-\text{H}\end{matrix}=\begin{matrix}\text{Na}-\text{O}-\text{H}\\ \text{Na}-\text{O}-\text{H}\end{matrix}+\begin{matrix}\text{H}\\ \cdot\\ \text{H}\end{matrix};\ \text{and}\ \begin{matrix}\text{Ca}\\ \vdots\end{matrix}+\begin{matrix}\text{H}-\text{O}-\text{H}\\ \text{H}-\text{O}-\text{H}\end{matrix}=\begin{matrix}\text{H}\\ \cdot\\ \text{H}\end{matrix}+\text{Ca}<\begin{matrix}\text{O}-\text{H}\\ \text{O}-\text{H}\end{matrix}$$

In the former case, one atom of hydrogen in each molecule of water, H—O—H, is replaced by an atom of sodium whereby a solution of sodium hydroxide, Na—O—H, is formed; in the latter case, one atom of calcium replaces one atom of hydrogen in each of the atoms of water, and thus forms one molecule of calcium hydroxide, $Ca(OH)_2$. The reactions with the alkali metals are violent, but they are controlled by amalgamating the metals with mercury. An alloy of sodium with lead—called commercially *hydrone*—generates hydrogen when in contact with water.

According to H. Fleck and H. Basset,[5] amalgamated magnesium decomposes cold water, while the metal alone has no appreciable action on cold water. H. St. C. Deville could detect no appreciable action between aluminium and boiling water. J. B. Baille and C. Féry showed that if the aluminium be amalgamated, it is rapidly oxidized by boiling water: $2Al+6H_2O \rightarrow 2Al(OH)_3+3H_2$. In the commercial application of this process, it is not necessary to amalgamate the aluminium directly, since the metal reduces solutions of mercuric salts to the metallic state: $2Al+3HgCl_2 \rightarrow 2AlCl_3+3Hg$, and any excess of aluminium present is automatically amalgamated.

H. Wislicenus and L. Kaufmann prepare the amalgamated aluminium turnings, freed from oil by treatment with aqueous soda until a copious evolution of hydrogen has set in, by rinsing them once with water, and acting on the metal for one or two minutes with a half per cent. solution of mercuric chloride; the process is then repeated, and the metal finally well washed with water, alcohol, and ether, and kept under light petroleum ready for use. The last traces of water may, after a little while, cause a reaction vigorous enough to raise the petroleum to its boiling-point. This amalgamated aluminium decomposes water with violent evolution of hydrogen.

The aluminium should be free from copper. The alloy *duralumin* contains 94 per cent. of aluminium and 4 per cent. of copper, and it is but slightly attacked by boiling water even in the presence of a mercury salt. In M. Baupré's process an intimate mixture of aluminium powder, mercuric chloride, and potassium cyanide, which is quite stable in dry air, gives a close approximation to the theoretical yield of hydrogen when gradually added to water at about 70°. S. Uyeno's alloy of aluminium (78 to 98) with a small proportion of zinc (1·5 to 15) and tin (0·5 to 7·0 per cent.) cast into plates and then amalgamated with mercury, decomposes hot water. If a little potassium permanganate be added to boiling water, in which aluminium powder is suspended, there is a continuous evolution of hydrogen. If too much permanganate be present, the reaction is retarded. Chlorates, perchlorates, and nitrates do not act in place of the permanganate as catalytic agents. H. Fösterling and H. Philipps make a mixture of metallic sodium and aluminium silicide, Al_2Si_4, into briquettes, and preserve them in air- and water-tight boxes. In contact with water, a mixture of sodium silicate and aluminium hydroxide is formed, $Al_2Si_4+8Na+18H_2O=2Al(OH)_3+4Na_2SiO_3+15H_2$. The method has been called the *sical process*.

O. Prelinger[6] found that manganese decomposes cold water slowly, and hot water rapidly. According to J. A. Wanklyn and L. Carius, reduced iron does not decompose water at 50°, but it does decompose water at 100°, and E. Ramann obtained 12 c.c. of hydrogen by boiling water for an hour with 10 grms. of iron, reduced in hydrogen. It is not clear how much of this hydrogen was occluded in the metal. N. J. B. G. Guibourt found the reaction between iron and water is accelerated by salts of mercury, copper, and the less easily oxidizable metals. M. Lorin also found the reaction to be appreciable at 40° in the presence of ammonium salts. M. Meusnier and A. L. Lavoisier prepared hydrogen in 1784 by passing steam over red-hot iron; and the hydrogen used for inflating the first balloon sent up from French soil, in 1794, was prepared by this method. The metals chromium, nickel, and cobalt act similarly. The reaction with steam and iron is usually represented by the equation: $3Fe+4H_2O=Fe_3O_4+4H_2$. It is not clear, however, what particular mixture of iron oxides is actually formed, for the observed results would accord with the formation of ferrous oxide, FeO, on the back reaction, so that for equilibrium: $3FeO+H_2O \rightleftharpoons Fe_3O_4+H_2$. M. Gillard (1850)[7] used the iron-steam process industrially; and he reduced the spent oxide with carbon monoxide and hydrogen derived from the action of steam on heated carbon. The process was soon abandoned as commercially unsatisfactory.

Porous briquettes—made from spent pyrites, obtained as a by-product in the manufacture of sulphuric acid, and clay—have been used as a source of the iron. The oxide of iron can be reduced to the metal and used over and over again by heating the oxidized briquettes with a reducing agent—*e.g.* water gas, coal gas, or producer gas. C. Jacoby used a mixture of finely divided iron with twice its weight of a hydroxide of calcium, barium, or strontium calcined to dull redness. In the modification called A. Messerschmitt's *iron contact method*, the red-hot iron in a shaft retort, resembling a gas producer, is sprayed with a jet of steam, and the iron oxide is reduced by a stream of water gas, producer gas, or coal gas. There are two types of plant, the so-called single retort and the multiple retort processes. The process is efficient and cheap when the right kind of iron is employed. Spongy iron acts more efficiently, presumably because it presents a larger surface for a given amount of iron. J. Jacob heated iron by part of the hydrogen produced in the reaction. A great many patents have been obtained for modifications of this process. The gas employed for the reduction must be free from certain impurities which gradually reduce the activity of the iron, by forming a layer of impurities (siliceous dust, sulphides, etc.) on the surface of the metal. In practice, the iron lasts from eight to thirty days, but it may be more or less revivified by periodically heating it in a stream of air.

A. Messerschmitt[8] used natural ores of manganese, or manganese and iron with the idea of lowering the reaction temperatures; O. Dieffenbach and W. Moldenhauer used alloys of iron with manganese, chromium, tungsten, titanium, aluminium, and related elements, as well as briquetted mixtures of the oxides; the Badische Anilin und Soda Fabrik used iron oxide fused with refractory oxides—zirconia, magnesia, or silicates; C. F. Jaubert used briquettes of iron oxide with fireclay, pumice, or magnesia, together with a small amount of manganese, chromium, copper, or lead oxide. Using lime purifiers to remove hydrogen sulphide and carbon dioxide a gas of 99·75 per cent. purity can be obtained by this process. The efficiency of the process rapidly deteriorates, and the maintenance of the temperature of the reaction consumes much of the hydrogen.

F. Bergius[9] argues that liquids are more reactive than gases, and that the liquid state can be maintained from the boiling point to the critical temperature if a sufficient pressure be used, and he has patented a process for the preparation of hydrogen by the action of liquid water on iron. It was found that the gas was of 99·95 per cent. purity because liquid water does not attack the dangerous impurities —sulphur and carbides—of iron so readily as steam. The speed of the reaction is accelerated in the presence of sodium chloride, ferrous chloride, and copper—*e.g.* at 300°, 230 c.c. of hydrogen per hour were obtained with pure water and iron; 1390 c.c. per hour if ferrous chloride be present; and 1930 c.c. per hour if in addition some copper be present. The yield of hydrogen per hour in the last case was nearly doubled by raising the temperature of the reaction from 300° to 340°. The hydrogen can be charged directly into cylinders without further compression. A pressure apparatus of 10 gallons capacity produced 3000 c. ft. of hydrogen per day.

The metalloids boron, silicon, and carbon can deoxidize steam. H. Moissan[10] says amorphous boron begins to act at a red heat and the reaction then proceeds with incandescence: E. Vigouroux found amorphous silicon begins to react at a red heat, and crystalline silicon at a rather higher temperature. Steam is also decomposed in its passage over red-hot coke; hydrogen and carbon monoxide, CO, are the main products of the reaction: $C+H_2O=CO+H_2$. The mixture of gaseous products by this reaction is called *water gas*. There is also a side reaction: $C+2H_2O=CO_2+2H_2$, and according to O. Dieffenbach and W. Moldenhauer,[11] the latter reaction occurs if the coke be saturated with 10 per cent. potassium carbonate, and when the coke is also mixed with five times its weight of lime, the carbon dioxide is absorbed by the lime if the temperature of the reaction be between 550° and 750°. F. Bergius also claims that the carbon dioxide reaction alone occurs if the water be maintained in the liquid state by pressure at 340°, and if one per cent. of thallium chloride be mixed with the coke. The carbon dioxide is then removed by lime. The Badische Anilin und Soda Fabrik worked with finely-divided iron as catalyst between 400° and 500°, and from 4 to 40 atm. pressure; J. L. Buchanan and E. B. Maxted used a catalyst of finely-divided iron and copper for the same purpose.

According to J. J. Coquillion water vapour and carbon monoxide are decomposed in the presence of red-hot platinum, forming carbon dioxide and hydrogen; L. Macquenne says that the transformation is complete in 25–30 hrs. in the presence of platinum sponge. The reaction is of the balanced type: $CO+H_2O\rightleftharpoons CO_2+H_2$. O. Hahn found the equilibrium condition to be $p_{H_2}p_{CO_2}K=p_{H_2O}p_{CO}$, where the equilibrium constant K has the value 0·05 at 400°; 0·1 at 500°; 0·3 at 600°; 0·6 at 700°; and 0·9 at 800°. Hence, low temperatures favour the formation of hydrogen, but, at the same time, lead to slow reactions. Consequently, the successful production of hydrogen from water gas requires the use of catalytic agents to accelerate the reaction at as low a temperature as possible. L. Mond and C. Langer patented the use of nickel at 350°–400°, or of cobalt at 400°–450° as catalysts; C. Ellis and B. E. Eldred used iron, nickel, or manganese; W. Näher and K. Müller, rhodium or palladium asbestos; L. Vignon, iron or platinum; and H. S. Elsworthy, iron or nickel.

Another problem is to separate the hydrogen from the carbon monoxide, when the first reaction predominates. There have been several proposals; among others: (1) B. C. Sykes and S. Blamires, J. Pullmann and H. S. Elsworthy, and A. Longsdon recommend removing the hydrogen by driving the gas under pressure through porous tubes. The hydrogen and methane diffuse through the walls of the tubes faster than the carbon monoxide. A. Jouve and G. Gautier (1906)[12] reduced the percentage amount of carbon monoxide from 45 to 8 per cent. by passing water gas through a porous partition through which the hydrogen diffuses far more rapidly than the carbon monoxide. (2) C. von Linde, A. Frank, and N. Caro (1906) subject the water gas to a preliminary cooling with liquid air whereby the carbon monoxide and dioxide are liquefied, the hydrogen remains as a gas. When the liquid by-product is allowed to gasify, it can be burnt as a fuel gas. (3) A. Frank (1906) passed the dried mixture over calcium carbide, CaC_2, at a temperature exceeding 300°. The carbon monoxide and dioxide form calcium oxide and carbonate, and free carbon—any nitrogen present forms calcium cyanamide. In the former case, $CaC_2+CO\rightarrow CaO+3C$; and in the latter case, $CaC_2+N_2=CaCN_2+C$. (4) When a mixture of steam and carbon monoxide is passed over lime at about 500°, the carbon monoxide is oxidized and an equal volume of hydrogen is evolved: $CaO+H_2O+CO\rightarrow CaCO_3+H_2$. According to M. G. Levi and A. Piva the reaction occurs in two stages: $CaO+H_2O+2CO=(H.COO)_2Ca$—calcium formate; and $(HCOO)_2Ca=CaCO_3+CO+H_2$. Hence, if water gas—say, a mixture of equal volumes of hydrogen and carbon monoxide—be passed over lime under these conditions, hydrogen will be substituted in place of the carbon monoxide. (5) E. K. Rideal and H. S. Taylor[13] have shown that even in the presence of large quantities of hydrogen, carbon monoxide can be oxidized to the dioxide in the presence of suitable catalysts—a mixture of iron and chromium oxides to which small quantities of ceria and thoria have been added. This catalyst completely oxidizes carbon monoxide between 200° and 300°, but does not attack hydrogen. The problem of removing a relatively large proportion of carbon dioxide by lime is a serious one. The basal patent is by C. M. T. du Motay (1880), and the Greisheim Elektron Co. added 5 per cent. of iron powder to act as a catalyst. This action was studied by W. E. Engels.

In the so-called *auto-combustion* processes of G. F. Jaubert,[14] a combustible substance and an oxidizing agent are kindled in the presence of water. The combustion once started continues and the water is decomposed. In one case, a mixture of lime and ferrosilicon at a high temperature is exposed to steam, and a little gunpowder is used to start the reaction: $3FeSi_6+40H_2O=Fe_3O_4+18SiO_2+40H_2$. In another, a mixture of iron filings, potassium perchlorate, and hydrated lime, or a mixture of ferrosilicon, litharge, and soda lime, is used. Here the reducing agent decomposes the water in the hydrated body.

J. E. G. Lahousse (1905)[15] recommended the decomposition of steam by passing it over red-hot barium sulphide, BaS, which is thereby oxidized to barium sulphate, $BaSO_4$, thus, in symbols, $BaS+4H_2O=BaSO_4+4H_2$. The sulphate can be reduced back to the sulphide by heating it with coal or producer gas: $BaSO_4+2C=2CO_2+BaS$. In the analogous process by G. Teissier and P. Chaillaux, barium sulphate is heated with manganous oxide: $BaSO_4+4MnO\rightarrow BaS+4MnO_2$; and the product raised to a white heat: $BaS+4MnO_2\rightarrow BaS+4MnO+2O_2$. When the reactions complete, steam under pressure is passed over the mixture and hydrogen is set free: $BaS+MnO+4H_2O\rightarrow BaSO_4+MnO+4H_2$. The solid products of the reactions are then ready to be employed in a fresh cycle.

(3) *The action of metals on dilute acids.*—The usual laboratory method of preparation is to act upon zinc with dilute sulphuric acid (1 : 8) or hydrochloric acid (1 : 2) as already described. Aluminium, magnesium, or iron may be substituted for the zinc. The reaction is symbolized: $M''+H_2SO_4=MSO_4+H_2$, or $M''+2HCl=MCl_2+H_2$, where M'' represents a gram-atom of the bivalent metals. The process of chemical change results in the substitution of two atoms of hydrogen in the acid by an equivalent bivalent atom. According to E. W. Morley, the purest redistilled zinc contains a little absorbed carbon monoxide which ultimately finds it way into the hydrogen gas prepared from the zinc. The impurities in the commercial metals—carbon, sulphur, silicon, phosphorus, antimony, and arsenic—form the corresponding gaseous hydrides. Sulphuric acid may contain: (i) sulphur dioxide which is evolved as such or partly reduced to hydrogen sulphide; (ii) nitrogen compounds which form nitrogen and nitrous oxides; (iii) arsenic and selenium, which form the corresponding hydrides. Hydrochloric acid made from sulphuric acid may also contain these same impurities. If the zinc and acid are pure, the resulting hydrogen has a high degree of purity, but it is evolved so slowly as to make the process of little practical use.[16] N. A. E. Millon noticed that the speed of evolution is much accelerated if a little platinic chloride be added to the hydrochloric acid. The platinic chloride is decomposed, and platinum metal is deposited on the zinc so as to form a kind of voltaic couple. A similar result was obtained by J. C. d'Almeida with platinum wire or finely divided platinum in contact with zinc, and C. Gourdon found that in these cases the hydrogen is given off quickly at the surface of the platinum—not the zinc. A similar effect is obtained with a small quantity of a salt of copper, silver, gold, tin, antimony, bismuth, nickel, cobalt, or one of the less oxidizable metals. The reaction between zinc and sulphuric acid was reported by F. Selmi to be accelerated by the presence of sulphates of manganese, magnesium, or iron, but to be retarded by sulphates of potassium, sodium, or aluminium.

Iron is little used in the preparation of hydrogen for laboratory purposes since the gas is contaminated with hydrocarbon gases derived from the carbides in the iron. These impurities give the hydrogen an unpleasant odour. In stationary military camps, hydrogen is sometimes made in this manner, but the main objection is the enormous quantity of metal and acid needed for filling an airship or balloon of but moderate size—say, 250,000 or 500,000 cubic feet capacity. In the former case, about 18 tons of iron and 31 tons of acid are needed for an inflation. The captive balloon at the 1878 Paris Exhibition had a capacity of about 883,000 c. ft. and it is said to have required 190 tons of sulphuric acid and 80 tons of iron for an inflation. This method of making hydrogen for inflating balloons is reported to have been used in 1861 in the American Civil War. Unless specially treated, the impurities in the hydrogen produced by this process are liable to rot the fabric of balloons and airships. L. V. Pratis and P. Marengo patented a process for the purification of the gas by first scrubbing it with water; and then passing it through a solution of a lead salt. Several other methods of cleaning the gas have been patented. F. Konther patented a process for recovering the acid in the preparation of hydrogen by the action of hydrochloric acid on iron; he heated the ferrous chloride to a high temperature with steam: $3FeCl_2+4H_2O \rightarrow Fe_3O_4+6HCl+H_2$.

G. V. Barton patented the recovery of the zinc sulphate produced as a by-product when zinc is used in place of iron, by treating the solution with sodium carbonate or hydrocarbonate, and igniting the precipitated zinc carbonate to form zinc oxide —the zinc white used as a pigment by paint-makers. J. Wannschaff and J. Savelsberg [17] proposed to make hydrogen and zinc oxide by the action of zinc chloride solutions on waste zinc.

(4) *The decomposition of metal hydrides.*—The hydrides of the alkali and alkaline earth metals readily decompose water at ordinary temperatures liberating hydrogen and forming the corresponding metal hydroxide: $CaH_2+2H_2O \rightarrow Ca(OH)_2+2H_2$. The commercial powder *hydrolith*—devised by G. F. Jaubert [18]—contains 90 per cent. of calcium hydride, and it gives off hydrogen by mere contact with water. A kilogram of the solid gives about a cubic metre of hydrogen. It has been used by the French army for filling observation balloons. The process is rather expensive though very convenient. In the commercial process for making calcium hydride, CaH_2, a little nitride, Ca_3N_2, is formed at the same time, and this reacts with water producing ammonia: $Ca_3N_2+6H_2O=3Ca(OH)_2+2NH_3$. The ammonia, being very soluble in water, is readily removed by scrubbing the gas with water. The lightness—low specific gravity—of lithium hydride, Li_2H, or Li_4H_2, has led to its being suggested as a means of restoring hydrogen to an airship should there be a serious loss of this gas from any cause. 27·76 lbs. of lithium hydride and 66·6 lbs. of water give 1000 c. ft. of hydrogen at about 5° and 760 mm. This amount of hydrogen would have a buoyancy of 74·06 lbs., and if the products of the reaction were dropped overboard, every 94·36 lbs. of materials would increase the buoyancy of the airship 168·42 lbs. The cost of lithium hydride is, however, too great for the general realization of this proposal.

(5) *The action of metals and alloys on alkaline lye.*—Hydrogen gas can be obtained by warming tin, aluminium, or zinc with a dilute solution of sodium hydroxide (50 grms. of the hydroxide per 500 c.c. of water). If the metals are free from carbon, the resulting gas is fairly pure. J. P. Cooke and T. W. Richards (1888) [19] used this process in some atomic weight determinations and purified the gas by passing it over solid potassium hydroxide, calcium chloride, concentrated sulphuric acid, and phosphorus pentoxide. When aluminium is used, the method is sometimes called the *hydrik or aluminal process.* We are told that the Russians prepared hydrogen for their war balloons in Manchuria during the Russian-Japanese war, 1904–5, in this way. The reactions with aluminium and zinc are respectively represented:

$$2Al'''+\left\{\begin{matrix}NaOH\\NaOH\\NaOH\end{matrix}\right.=2Al\begin{matrix}\diagup ONa\\ -ONa\\ \diagdown ONa\end{matrix}+3H_2\text{ ; and }Zn''+\left\{\begin{matrix}NaOH\\NaOH\end{matrix}\right.=Zn<\begin{matrix}ONa\\ONa\end{matrix}+H_2$$

Here it will be observed that one hydrogen atom in each molecule of sodium hydroxide is replaced by the respective elements—three by the tervalent aluminium, and two by the bivalent zinc; sodium aluminate, $Al(ONa)_3$, is a by-product in the former process; and sodium zincate, $Zn(ONa)_2$, in the latter case. With tin, sodium stannate, $Sn(ONa)_4$, is formed. We see, therefore, that under the stated conditions, an atom of sodium or potassium can displace only *one* of the two hydrogen atoms in the water molecule—H_2O; and that tin, zinc, or aluminium can displace the other hydrogen atom.

According to H. Williams (1881),[20] zinc dust heated with water alone gives hydrogen gas. Water alone, however, does not appreciably decompose boiling water; but, as shown by W. Wilson, decomposition does occur if copper turnings are also present. L. Meyer and T. Leykauf observed the evolution of hydrogen during the action of zinc and water on crystals of copper sulphate; the action in these cases is similar to that of the zinc-copper couple. H. Schwarz obtained hydrogen by heating a mixture of zinc dust and calcium hydroxide, and the process was patented by W. Majert and G. Richter for the generation of hydrogen in the field or the inflation of observation balloons. Hydrogen may be prepared by heating slaked lime with coal—C. M. Tessie du Motay and C. R. Marechal (1868)—$C+2Ca(OH)_2=CaO+CaCO_3+2H_2$.

Under the name of the *silicol process* the preparation of hydrogen by the action of sodium hydroxide on the element silicon has been recommended by Siemens and Schuckert (1911), and on the cheaper ferrosilicon—called *silicol*—or other silicon alloys by G. F. Jaubert (1908).[21]

An intimate mixture of powdered sodium hydroxide and ferrosilicon when moistened with water gives off hydrogen rapidly, and becomes incandescent. When ferrosilicon is added to a cold solution of sodium hydroxide, the metal is not rapidly attacked, but owing to the heat of the reaction, the temperature of the liquid gradually rises as ferrosilicon is added, and then reaches a stage—about 80°—where the ferrosilicon is instantly attacked. Consequently, if ferrosilicon is added faster than it is attacked by the caustic lye, when the temperature has risen to the critical stage the accumulated ferrosilicon may be instantly attacked causing an explosive pressure of gas in the gas generator. The reaction is not a simple oxidation of the water by the silicon: $Si+2H_2O=SiO_2+2H_2$, followed by the formation of sodium silicate: $SiO_2+2NaOH=Na_2SiO_3+H_2O$, so that the composite equation is symbolized: $Si+2NaOH+H_2O=Na_2SiO_3+2H_2$, since, instead of 2·86 parts of sodium hydroxide being required for one part of silicon, the ratio is less, 1 : 1·7. This shows that a richer silicate is simultaneously formed, possibly by the action of the simple sodium silicate on the silicon: say, $Si+Na_2SiO_3+2H_2O=Na_2Si_2O_5+2H_2$, where the composite reaction is symbolized: $2Si+2NaOH+3H_2O=Na_2Si_2O_5+4H_2$. This requires a ratio of silicon to sodium hydroxide of 1 : 1·43. The ratio 1 : 1·72 is the one usually recommended. With a 10 per cent. sodium hydroxide and 92 per cent. silicol solution P. L. Teed found at 15° and 30 in. barometric pressure:

Weight ratio, Si : NaOH	1 : 0·745	1 : 1·065	1 : 1·480	1 : 3·200
Hydrogen per lb. of silicol	13·62	14·30	15·36	16·80 c. ft.

With 30 per cent. sodium hydroxide solution with the ratio by weight Si : NaOH =1 : 0·852, 1 : 2·13 and 1 : 3·19, the respective yields of gas were 19·35, 23·90, and 23·58 c. ft.; while with 40 per cent. sodium hydroxide, and a weight ratio of Si : NaOH of 1 : 1·58 and 1 : 3·19, the respective yields of hydrogen were 24·10 and 24·50 c. ft. Hence, a 40 per cent. solution of sodium hydroxide with a ratio by weight of Si : NaOH of 1 : 1·6 would appear to be best, but if the solution be too concentrated, it becomes so viscous or even solid during the action that the plant is difficult to clean; if the solution be too dilute, the frothing is troublesome. A little mineral grease is sometimes used with the soda lye to prevent frothing. The usual solution employed contains about 25 per cent. of sodium hydroxide, and the ratio of Si : NaOH by weight nearly 1 : 1·72. With the 25 per cent. caustic lye and a wide generator there is no difficulty with frothing when no grease is used.

Plants are in use generating 1500 to 6000 c. ft. per hour by the silicol process. It furnishes 2500 c. ft. of gas per hour. The sodium hydroxide is dissolved in water in a tank, and run into a generator fitted with a stirrer run by a benzene motor.

The silicol in the container is fed into the generator by an automatic feed also operated by the benzene motor. The hydrogen then passes into the condenser or scrubber, where it is cooled and freed from steam. The heat generated during the action reaction raises the temperature in the generator above 100°, sometimes to 120°. Thermometers inserted in the generator enable the temperature to be observed and if necessary controlled. An excessive pressure due to the rapid generation of hydrogen is prevented by suitable seals. Precautions are of course taken to prevent the generation of an explosive mixture of hydrogen and air—usually before the caustic lye is run into the generator—by allowing hydrogen from the gas-holder to blow back hydrogen equivalent to four times the volume of the plant. When the generation of gas from a given charge has ceased, the sodium silicate solution and sludge are run from the generator by a trapped discharge pipe ; the generator is washed out with water and is ready for another charge. Low-grade ferrosilicon is not economical because it does not give equivalent yields of hydrogen. At least 80 per cent. ferrosilicon is needed to give satisfactory yields :

Silicol	50	70	85	90	per cent. Si
Yield	12½	27¼	91	97	per cent. of theory

An 84 per cent. ferrosilicon has iron 6·9 per cent., aluminium 5·3 per cent., and carbon 0·2 per cent. The sodium carbonate impurity in the caustic lye and the iron of the ferrosilicon are found unaltered in the sludge. The sludge contains 37 per cent. of silica ; 6 per cent. sodium carbonate ; 20 per cent. of soda calculated as Na_2O ; about 10 per cent. of matter insoluble in water and the remainder is water. The ferrosilicon gives a 90 per cent. yield of hydrogen, the loss being mainly due to the protective action of impurities, leakages, and the solubility of hydrogen in the water used in the scrubber. The gas has from 99 to 99·9 per cent. purity and is virtually free from arsine and phosphine, for less than 0·01 per cent. of these gases are present; the acetylene amounts to about 0·005 per cent. The main impurity is air. This process gives a large hydrogen production from an inexpensive plant ; but the cost of the reagents is high. The process is therefore advantageous where large quantities of hydrogen are periodically required, but not where there is a continuous demand.

Slaked lime substituted in place of sodium hydroxide gives very poor yields of hydrogen, but a mixture of the two gives better results than with sodium hydroxide alone. The sodium silicate formed in the first stage of the reaction between the silicon and sodium hydroxide is probably converted into the hydroxide again : $Na_2SiO_3+Ca(OH)_2=2NaOH+CaSiO_3$. A mixture, devised by G. F. Jaubert (1910), containing 25 parts of 90–95 per cent. ferrosilicon or manganosilicon, 60 of sodium hydroxide, and 20 slaked lime, is commercially known as *hydrogenite*. It is sold compressed in cakes contained in metal cartridges to protect the mixture from moisture, and when ignited—by forcing a hot ball or wire into the briquette—forms sodium and calcium silicates with the evolution of hydrogen. A kilogram of the powder gives from 270 to 370 litres of hydrogen.

(6) *The decomposition of hydrocarbons.*—When hydrocarbon gases are heated to about 1000°, they dissociate forming lamp-black, hydrocarbons, and hydrogen. In 1911, R. Pictet [22] patented a process for heating a mixture of water and hydrocarbon vapour—*e.g.* petroleum—whereby a mixture of hydrogen with some carbon monoxide is formed. The proportion of the latter depends on the proportion of water present in the original mixture. The Carbonium Co. at Friedrichshafen, the headquarters of the Zeppelin airships, has obtained hydrogen by decomposing acetylene, C_2H_2, prepared from water and calcium carbide, by electric sparks or by explosion; preferably, according to J. Machtoff, under a pressure of 4 to 6 atmospheres, $C_2H_2=2C+H_2$. The carbon wins a high price as a high-grade lamp-black. In F. G. L. Rincker and L. Wolter's process the gas produced by the distillation of crude tar, oil, or other hydrocarbon is passed through hot coke or charcoal. The 6 to 8 per cent. of carbon monoxide and hydrogen sulphide in the washed gas is partly removed by hot soda lime. The Badische Anilin und Soda Fabrik suggest

reducing the temperature of decomposition by the use of a refractory oxide like magnesia impregnated with nickel oxide for reducing the temperature of decomposition; O. Dieffenbach and W. Moldenhauer, the use of wire gauze of nickel, cobalt, platinum, etc., with short contact and sudden cooling of the products so as to avoid the reduction of carbon dioxide to the monoxide; and the Berlin Anhaltische Maschinenbau, and C. Ellis, the use of coke as a contact catalyst.

7. *By-product hydrogen.*—Hydrogen is a by-product in the manufacture of chlorine by the electrolysis of aqueous solutions of alkali chlorides; $2NaCl+2H_2O=2NaOH+H_2+Cl_2$. Chlorine is given off at one electrode and hydrogen at the other. The sodium chloride is broken down by the electric current into sodium and chlorine; and the sodium, in contact with water, reacts as indicated in the equation: $2Na+2H_2O=2NaOH+H_2$. Hydrogen is also a by-product in the manufacture of oxalates from formates, which in turn are made by treating caustic potash with carbon monoxide (producer gas) under pressure: $KOH+CO=H.COOK$; and $2H.COOK=K_2C_2O_4+H_2$. L. Vignon (1911) showed that if carbon monoxide be passed over powdered calcium hydroxide at 300°, there is no action; at 400°, a mixture of hydrogen and hydrocarbons—chiefly methane, CH_4, and ethylene, C_2H_4—is evolved.[23] The proportion of hydrogen increases as the temperature rises until at 600° only hydrogen is formed: $CO+Ca(OH)_2=CaCO_3+H_2$. The formation of the hydrocarbons is probably preceded by the formation of calcium formate and oxalate as intermediary products of the reaction: $4CO+2Ca(OH)_2+CaO=3CaCO_3+CH_4$; and $4CO+4Ca(OH)_2+CaO=4CaCO_3+2H_2+C_2H_4$. A mixture of sodium formate and calcium oxide yields nearly pure hydrogen. Steam, carbon monoxide, and calcium hydroxide form calcium formate at 250°–300°; at 500°–600°, there is almost a quantitative yield of hydrogen; the presence of sodium hydroxide lowers the temperature of the reaction. In 1861, M. Berthelot noticed that when either the formates or the oxalates of the alkalies are heated with the alkali hydroxide, hydrogen is formed; and R. Pictet prepared hydrogen by heating sodium formate, H.COONa, with soda lime. The reaction is symbolized $H.COONa+NaOH\rightarrow Na_2CO_3+H_2$; similarly, with sodium oxalate, $(COONa)_2$, or potassium oxalate: $Na_2C_2O_4+2NaOH=2Na_2CO_3+H_2$. The reactions are not particularly convenient when compared with other methods of preparation, but E. H. Amagat used the process in his work on the effect of pressure on the volume of gases.

There are several other reactions in which hydrogen is formed. These reactions are of greater theoretical than practical interest. For example, A. Bruno[24] found that when iron filings are shaken with water saturated with carbon dioxide for 36–48 hrs., the carbon dioxide is replaced by hydrogen: $Fe+CO_2+H_2O=FeCO_3+H_2$. According to M. Lorin, most of the ammonium salts and the salts of the amine bases develop hydrogen when treated with zinc at ordinary temperatures, or better at 40°; iron acts more slowly. Ammonium nitrate is not applicable since it gives nitrous oxide at 50°; similar remarks probably apply to the nitrates of the amine bases. W. P. Winter regards the alleged evolution of hydrogen by the action of water on sodamide as probably due to the presence of some free sodium. A. Descamps found that potassium cobaltocyanide, K_4CoCy_6, decomposes water at ordinary temperatures giving off hydrogen and forming the cobalticyanide, K_3CoCy_6. M. Berthelot found that acidified solutions of chromous salts gradually decompose with the evolution of hydrogen; and R. Peters noted that the reaction is accelerated by the presence of platinum black. Hydrogen is given off by uranyl acetate in sunlight. A. Sieverts found that in aqueous solutions platinum, silver, and copper cause hypophosphorous and phosphorous acids to split off hydrogen, respectively forming phosphorous and phosphoric acids: $H_3PO_2+H_2O=H_3PO_3+H_2$; and $H_3PO_3+H_2O=H_3PO_4+H_2$. Hydrogen is often evolved when organic compounds —*e.g.* oleic acid—are fused with alkalies. Hot soda-lime converts alcohol into acetic acid with the evolution of hydrogen: $C_2H_5OH+NaOH=CH_3COONa+2H_2$; formaldehyde, H.COH, gives off hydrogen in the presence of cuprous oxide and alkali: $H.COH+NaOH=H.COONa+H_2$; and also with sodium peroxide:

$2HCOH+Na_2O_2=2HCOONa+H_2$. M. Kernbaum found water can be decomposed by sunlight in accord with the equation: $2H_2O=H_2O_2+H_2$, and by exposure to ultra-violet light; and A. Dobierne observed a similar reaction with radium rays. W. Loeb detected hydrogen among the products obtained when the electric arc is formed under water.

According to G. Pollacci, W. Palladin, and J. Stoklasa and W. Zdobnicky, the gases obtained as exhalations from the green parts of plants contain some hydrogen,[25] and F. Selmi found that hydrogen is liberated by fungi and moulds—arsenic, antimony, and sulphur are converted by the same organisms into the corresponding hydrides. S. Kostytscheff found the gas formed in the respiratory gases of some seed plants. H. Tappeiner found that the gas is formed in the fermentation of cellulose, and in the decay of certain organic bodies. C. Oppenheimer and A. Krogh detected hydrogen among the intestinal gases of many animals.

The purification of hydrogen gas.—Most of the methods of preparing hydrogen furnish a gas contaminated with impurities which can generally be removed by treating the gas with suitable reagents. The nature of the impurities depends upon the character of the materials employed in the preparation of the gas. Air is one of the commonest of impurities, and it comes from the air dissolved in the liquids used in the preparation of the gas; from the air originally present in the apparatus; and by leakage through rubber and other joints. This impurity can be considerably reduced by using liquids previously boiled; and mercury sealed glass joints for the apparatus. Oxygen may also be derived from the potassium permanganate solution sometimes used for washing the gas. According to H. Debray,[26] traces of oxygen can be removed by passing the hydrogen gas over red-hot copper, over spongy platinum, melted sodium, or through a solution of chromous chloride, but the nitrogen from the air is not removed by this treatment. According to E. W. Morley,[27] from 0·01 to 0·001 per cent. of nitrogen in the gas can be recognized spectroscopically.

The hydrocarbon gases in hydrogen are derived from carbonaceous impurities in the metals and acid. E. W. Morley states that the electrolysis of dilute alkali hydroxides, or dilute hydrochloric acid, may furnish a gas contaminated with traces of carbon compounds. When the alkali contains carbonates, or the acid organic matter, M. Berthelot says that hydrogen prepared from the metals always contains carbon compounds. The electrolysis of water acidified with purified sulphuric acid is recommended by E. W. Morley[28] as the safest process to use for hydrogen of a high degree of purity, and M. Berthelot recommends washing the electrolytic hydrogen with potassium permanganate solution and scrubbing it with fused potassium hydroxide.

The metal used in preparing the gas may contain occluded carbon oxides, or sulphur, selenium, phosphorus, silicon, antimony, and arsenic, which contaminate the hydrogen with gaseous compounds. Sulphuric acid may also be reduced by hydrogen to sulphur dioxide or even to hydrogen sulphide.[29] The acids may also contain nitrogen, selenium, and arsenic compounds. Hydrocarbons can be removed by passing the gas through alcohol, or, according to J. W. Döbereiner and J. Stenhouse,[30] by passing the gas through a tube packed with recently ignited wood charcoal, or paraffin wax. M. Donovan recommends passing the gas through an oxidizing liquid—say fuming nitric acid followed by a solution of ferrous sulphate to absorb the nitrous fumes; E. Varenne and E. Hebre used a sulphuric acid solution of potassium dichromate followed by potassium hydroxide; and E. Schobig used potassium permanganate in a similar way. The sulphur, selenium, and silicon compounds are absorbed by passing the gas through a solution of potassium hydroxide; and the hydrides of arsenic, antimony, and phosphorus, according to A. Lionet,[31] are decomposed by passing the gas over red-hot copper turnings, but they are usually removed by passing the gas through solutions of the salts of metals—*e.g.* mercuric chloride, silver sulphate, lead nitrate—as indicated by J. B. A. Dumas in 1843; or else by passing the gas through a saturated solution of potassium permanganate, and then through a 5–10 per cent. solution of silver nitrate. According to H. Reckleben and G. Lockemann (1908), bromine, bleaching powder, and potassium hypochlorite are good absorbents for arsine ; the same gas is said to be removed by bubbling hydrogen through petroleum spirit cooled by liquid air at —110°, and H. K. Onnes recommends freezing out the various impurities from hydrogen by cooling it with liquid air. Carbon monoxide can be removed by passing the gas over heated soda lime : $2NaOH+CO \rightarrow Na_2CO_3+H_2$.

Hydrogen has been purified in special cases by passing it into a glass tube containing metallic palladium previously evacuated, and heated red-hot. The metal is allowed to cool in contact with the gas. The hydrogen is assumed to be alone absorbed by the metal ; and to be given off again when the tube containing the metal is heated. The tube containing the palladium is of course attached to the apparatus into which the hydrogen is to be introduced.

Drying gases.—In 1766, H. Cavendish dried gases by passing them through a tube containing a hygroscopic salt. Anhydrous calcium chloride and concentrated sulphuric acid are most commonly used as drying agents, and in special cases phosphorus pentoxide is employed. Several attempts have been made by R. Fresenius (1865),[32] E. W. Morley (1885), and G. P. Baxter and R. D. Warren (1911), to estimate the amount of moisture left in a gas after the desiccating agents have done their work. From these investigations it appears that the weight of residual water (grams) left in a litre of gas dried by different desiccating agents is as follows :

	Calcium chloride.	Zinc bromide.	Zinc chloride.	Calcium bromide.	Sulphuric acid (1·838).	Phosphorus pentoxide.
Moisture .	0·0021	0·0011	0·0008	0·0002	0·0000025	0·000000025 grm.

The phosphorus pentoxide should be freed from the lower oxides of phosphorus by distillation over platinized asbestos in a current of oxygen. Alumina dehydrated at a low temperature is said to be a little superior as a drying agent to sulphuric acid, and has the additional advantage that it can be revivified by reheating after it has done its work.

Storage.—The gas is compressed in steel cylinders called *bombs*—under a pressure of about 100–150 atmospheres. There has been a number of fatal accidents from the explosion of the cylinders. In most cases it is certain that an explosive mixture of hydrogen and oxygen has been introduced into the cylinder, or an oxygen cylinder still containing oxygen has been charged with hydrogen. The cylinders of hydrogen or the taps of hydrogen cylinders are often coloured red to lessen the risk of accidentally using a cylinder of hydrogen for one of oxygen. We are told that in the Boer War, the British transported hydrogen compressed in cylinders at about 200 atm. pressure, and that it required 50 horses to transport sufficient for a balloon 400 cubic metres capacity.

The cost of hydrogen per cubic metre prepared by the different processes, is, according to E. D. Ardery (1916)[33] : Steam on iron, 1·5*d.* ; distillation of crude oils and tar, 1·75*d.* ; ferrosilicon, 10*d.* ; water gas, 2·5*d.* ; iron and sulphuric acid, 12·5*d.* ; hydrogenite, 16*d.* ; hydrolith, 44*d.* to 50*d.* ; silicon and caustic soda, 53*d.*

§ 3. Chemical Affinity

There are agents in nature able to make the particles of bodies stick together by very strong attractions. And it is the business of experimental philosophy to find them out.—ISAAC NEWTON.

All things act according to their nature. The atoms of the different elements join because they possess a tendency to combine with definite other atoms, and one affinity is overpowered by another stronger affinity so that atoms far from being pushed or passively pressed into combination, are themselves actively pushing.—P. CARUS (1913).

The cause of chemical action has mystified man from the earliest ages, and there is no prospect of an immediate solution. The crucibles, pelicans, and alembics of the working alchemists of the Middle Ages must have demonstrated every day in a thousand different forms that matter seems to be endowed with properties—or to possess a kind of *vis occulta*—in virtue of which two or more dissimilar substances, when brought into contact, give rise to other forms of matter possessing properties quite distinct from the original substances. The process of change is called a **chemical reaction.** At present, *chemical action can only be referred back to the presence of a selective force, indwelling in the different kinds of matter, which leads certain substances, under certain conditions, to undergo chemical change.* This selective force is called **chemical affinity.**

Nearly five centuries before Christ, Empedocles attributed the various changes which occur in the form of matter to the operation of two motive forces which he personified by assuming *love* to be a dynamic attractive force which induces the union of substances, while an analogous repulsive force, *hate*, effects their separation. Union was regarded as a marriage of the elements, decomposition a divorce ; love unites, hate scatters :

All through hate are split to shapes diverse ;
Each through love draws near and yearns for each. . . .

Aristotle (*c.* 320 B.C.) rightly maintained that Empedocles' two forces—harmony and discord ; love and hate ; attraction and repulsion—are two different aspects of one motive force, because the formation of a new combination must involve the disruption of a previous one, and the decomposition of one system must involve the production of another system.

Not very long after the time of Empedocles, Hippocrates postulated that when two substances unite to form a compound, they must possess one common principle or bond of kinship, for, said he : " like unites only with like." In later centuries, Hippocrates' maxim seems to have given rise to the idea that substances with kindred qualities react chemically ; the greater the resemblance between two specific forms of matter, the more likely are they to enter into combination, and the more stable the resulting product. It was argued that the metals are akin to mercury, and therefore " mercury devours the metals," or " the metals lick up the mercury," *æqualitas enim amicitiæ parens est ;* and the word affinity was coined near the end of the thirteenth century—in a work *De rebus metallicis* attributed rightly or wrongly to Albertus Magnus [1]—in order to connote the idea that the *affinitas* (relationship) between combining substances is the cause of their union. Sulphur burns the metals, said Albertus Magnus, because of the affinity it has for these substances—for the metals were themselves supposed to contain the common principle sulphur. J. J. Becher [2] expressed the same idea in 1669 when he stated that one substance *attrahet* another in virtue of its *affinitas*, and a *reactio* ensues ; the stronger the attraction, the more vigorous the reaction. J. Mayow [3] used the term affinity in the same sense in 1674. He said :

> Nitro-aerial spirit and sulphur are engaged in perpetual hostilities with one another . . . and each has a great affinity and relationship with salt, for these very active elements are being married to salt as to a fitting bride, and are fixed in its embrace.

J. Mayow also used the word *combinetur* or *combinentur* in speaking of the *congressus* of different substances. The necessary similitude, relationship, kinship, or family tie between reacting substances was taken for granted by J. C. Barchausen in his *Pyrosophia* (Lugduni Batavorum, 1698), and the then chemical world generally. Heretics, however, did insist that opposite natures are best suited for chemical union, and, following Empedocles, the principle was enforced by analogies drawn from the theory of marriage. For example, in his book *Elementa chemiæ* (Lugduni Batavorum, 1732), Hermann Boerhaave maintained that dissimilar substances show the greatest tendency to combine with one another, and he metaphorically compared affinity with love: *amicitiæ si amor dicendus copulæ cupido*—if love be called the desire for marriage; and in 1837, J. B. A. Dumas said that we must allow that there is some truth in this poetic comparison. A. F. de Fourcroy (1801)[4] also emphasized the fact that the concept of affinity is a generalization largely derived from observations made on reactions between bodies of dissimilar natures, or between unlike particles; and the existence of this force is regarded as one of the first principles of dynamical chemistry. There is, however, nothing to show that the force which binds two dissimilar atoms to say chlorine and hydrogen is intrinsically different from the force which binds a pair of hydrogen or a pair of chlorine atoms together.

Although unlike elements have a greater tendency to unite than like elements, F. W. Clarke[5] has shown that there appears to be a preference for neighbouring elements in the horizontal rows of the periodic table, rather than for those more remote. Thus, silicon follows its neighbour aluminium in the magnitude of its atomic weight, and the alumino-silicates form the most extensive class of stable minerals; similarly, phosphorus is nearer than arsenic to aluminium, and the aluminium phosphates are more common than the arsenates; while with copper nearer to arsenic than to phosphorus, the arsenates are more common than the phosphates. Another striking illustration is furnished by the compounds of oxygen, sulphur, selenium, and tellurium. The oxides or oxidized salts are the most common with the elements of low atomic weight; from manganese and iron, the sulphides are the most abundant; while selenium and tellurium are more often united with the metals with the larger atomic weights.

H. Boerhaave distinguished what he called *cohesion* between the parts of the *same* substance from the *affinity* between the parts of *different* substances. Boerhaave virtually used the term affinity to connote the tendency of different kinds of matter to unite with one another; and the term is therefore applied to that peculiar selective force or form of energy which is the origin of all chemical changes. This definition has nothing to say about the similarity or dissimilarity of the reacting substances, and it makes no reference to the very real difficulty in distinguishing clearly between chemical and physical changes. This definition has been repeated with superficial variations of phraseology by most writers.

Although the law of gravitation has been styled " the most extensive generalization to which the human intellect has ever attained," Isaac Newton did not unduly speculate on the cause, but he employed the term *gravitation* to signify, in general, any force by which bodies tend towards each other, whatsoever be the cause. He said:

> To show that I do not take gravity for an essential property of bodies, I have added one question concerning its cause, choosing to propose it by way of a question because I am not yet satisfied about it for want of experiments.

Newton applied the gravitation concept to atoms, and in this sense he was the founder of molecular as well as of celestial mechanics. The propensity of two bodies to react chemically was attributed to the attraction of the particles of the one for the particles of the other, pair by pair; and conversely, when a compound of two bodies is decomposed by a third body coming into the field of action, the particles of the intruding body were supposed to attract the one and repel the other constituent. The struggle between the three kinds of particles was supposed to be decided by the resultants of two pairs of forces. Shortly after Isaac Newton had published his views on chemical attraction, St. F. Geoffroy changed Newton's term *attraction* to *affinity*, and attempted to make a table in which the powers which different bodies possess of uniting with one another are represented by numbers.[6] The same concept, if not the name, was used by J. R. Glauber (1648), F. de la Böe Sylvius (1659), A. L. Lavoisier (1783),[7] and others. For instance, R. Boyle (1664) used the terms *coalition* and *association*[8] for the concept affinity. Both T. Bergmann and G. L. L. Buffon,[9] following Newton, tried the hypothesis that the forces between the constituent particles of a body are the same in kind as those which determine the relations of the heavenly bodies ; but both abandoned the idea as impracticable, because it was believed that the atoms are so close together that their shapes must interfere with the attractive force and make the theorems to be solved inextricably complex.

The idea that the atoms were retained each to each by hooks or other mechanical means is suggested in Lucretius' poem, and was adopted by N. Lemery.[10] R. J. Haüy supposed that different particles have different polygonal solid shapes which when chemically compounded pack themselves together like so many solid bricks.

There have been many attempts to evade the use of the word affinity, and as alternatives, the terms electric attraction, atomic gravitation, chemical activity, chemical avidity, chemical energy, chemism, etc., have been variously suggested ; but the original term chemical affinity is convenient, provided it be kept in its place —*in verbis non simus faciles*. To say that " oxygen unites with hydrogen because it has an affinity for it " explains nothing, but simply restates the fact in different words. Many examples of similar pseudo-explanations might be given : " Hydrogen burns because it is combustible," " morphine induces sleep because of its soporific qualities," " arsenic causes death because it is a poison," " potassium carbonate absorbs moisture from the air because it is deliquescent." Explanations and definitions of this kind are so rife that the fault has been given a name : *circulus in definiendo*. We quite recognize with Isaac Newton (1675) that " to tell us that every species of things is endowed with an occult specific quality by which it acts and produces manifest effects is to tell us nothing," yet is it hardly fair to say that the term chemical affinity is a veil which covers our ignorance in obscure language. What H. F. Link[11] wrote at the end of the eighteenth century—1795—might almost have been written to-day :

> Although the term affinity has sprung from the dark ages of chemistry, and appears at first glance to be mystical and unprofitable, yet, it is certain that since the causes of all chemical phenomena have been referred to one single cause, chemistry has made extraordinary progress for which it has to thank the definition—affinity is the cause of chemical action.

With this understanding, chemical affinity can be conveniently regarded as " the driving force of a chemical reaction." In 1887, W. E. Ayrton and J. Perry expressed the idea that

$$\text{Reaction velocity} = \frac{\text{Driving force}}{\text{Resistance}}$$

Consequently, if we could measure the **chemical resistance** offered by substances to undergo chemical change, it would be possible to get a definite and quantitative idea of chemical affinity from measurements on the velocity of a reaction. No real advance can be made in the study of chemical affinity until a method of measurement has been devised. As W. Whewell (1840) expressed it : " In all attempts to explain the processes of nature, the proper course is first to measure the facts with precision, and then to endeavour to understand their cause."

§ 4. The Measurement of the Affinity between the Acids and the Metals

> I often say that if you can measure that of which you speak, and can express it by a number, you know something of your subject; but if you cannot measure it, your knowledge is meagre and unsatisfactory.—LORD KELVIN.

Towards the end of the eighteenth century, T. Bergmann found it necessary to issue a warning against "some chemists who consider thermometers and suchlike measuring instruments to be physical subtilties, superfluous and unnecessary in a chemical laboratory," and he further emphasized his belief in the importance of generally "so comparing an effect with its cause as to determine the exact quantitative relation between the two." At this day, the resources of the physical laboratory are commandeered by the chemist in his quest after the quantitative relations between causes and their effects.

Chemical reactions are not instantaneous processes, but are propagated with finite measurable velocities which may range from the explosion wave travelling through a mixture of hydrogen and oxygen at a speed not much less than 10,000 feet per second; or it may be so slow that years are needed to detect an appreciable change. It is assumed that every elementary atom and every molecule is charged with a definite amount of energy which is a measure and cause of its *chemical affinity*; chemical affinity is assumed to be the *driving force* of chemical reactions; and the *speed of chemical reactions*, other things being equal, is proportional to the driving force. It will be obvious that if a ball be sent rolling with a velocity of 20 cm. per second, the force applied to the ball will be twice as great as would be required to make the ball travel with a velocity of 10 cm. per second during the same time. Neglecting friction, the intensities of the two forces are proportional to the velocities which they impart to each unit of mass during the same time.

The relation between the speed of a chemical reaction and affinity.—In an important book, *Lehre von der Verwandtschaft* (Dresden, 28, 1777), C. F. Wenzel tried to determine the affinities of the metals for different acids by comparing the rates at which the metals liberate gas from acids of different concentration. He found that if an acid of a given concentration dissolves one unit of metal per hour, an acid of half that concentration will take two hours to dissolve the same amount of metal. The velocity of these reactions can be measured by finding the amount of gas liberated per minute, or the amount of acid or of metal consumed, say, every minute. Then, at any given moment:

$$\text{Velocity} = \frac{\text{Amount of gas liberated}}{\text{Time occupied}} = \frac{\text{Acid consumed}}{\text{Time occupied}}$$

The affinity of a metal for an acid depends on the concentration of the acid. In fine, **the velocity of the chemical action at any instant is proportional to the concentration of the reacting substances.** This is sometimes called **Wilhelmy's law,** because L. Wilhelmy (1850) [1] demonstrated the generalization by measurements on the speed of inversion of cane sugar. A comparison of the rate of dissolution of, say, magnesium in hydrochloric acid of different concentrations, $\frac{1}{10}N$, $\frac{1}{20}N$, and

$\frac{1}{50}N$, where N here denotes an equivalent weight of HCl per litre, brings out clearly the increase of speed with increasing concentration. The slopes of the curves in Fig. 4 are proportional to the speed of the attack..

If a solution be of such a concentration that it contains a gram-molecules of acid per unit volume, then at the end of a certain time t, x gram-molecules of the acid per unit volume will have been consumed, and the solution will contain $a-x$ gram-molecules of the acid per unit volume. Hence, the velocity of the reaction will gradually slacken down. At the beginning, the velocity V will be proportional to a; that is, $V=ka$, where k is a constant of proportion; and at the end of the time t, the velocity will be $V=k(a-x)$. Hence, in C. F. Wenzel's experiment, when $x=\frac{1}{2}a$, the reaction is only progressing half as fast as at the beginning when $x=0$. The speed of the reaction at different times is illustrated by the slope of the curve in Fig. 5, where the abscissa axis represents time, and the ordinate axis, the velocity expressed in any convenient units—say, volume of gas evolved per minute.

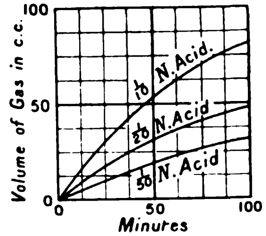

FIG. 4.—Dissolution of Magnesium in Hydrochloric Acid of Different Concentrations.

The velocity of a reaction is not always quickest at the start. When some reacting substances are brought into contact, a certain interval of time—called the **period of induction**—elapses before the reaction can proceed "full speed ahead." With zinc and dilute hydrochloric acid, for example, the dotted line, Fig. 5, shows how the speed gradually increases, reaches a maximum, and then gradually diminishes as described by Wilhelmy's law.[2] A similar period of induction has not been observed with magnesium. During the period of induction, therefore, some action takes place by which the resistance to combination is decreased, or a more favourable condition for combination is inaugurated.

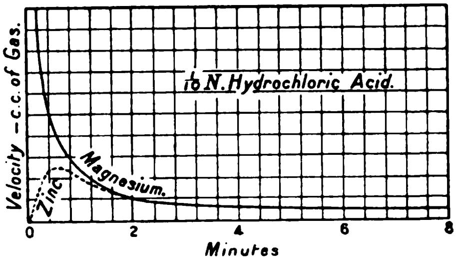

FIG. 5.—The Reduction in the Speed of Chemical Action with Time.

By measuring the rate at which hydrogen is liberated per minute per unit area of the different metals on the same sample of dilute acid, it is possible to get a rough idea of the relative affinities of the different metals for that particular acid. The comparison of the effect of dilute hydrochloric acid on zinc and magnesium—Fig. 6—shows that the dissolution of magnesium gives a steeper curve than does zinc. This means that magnesium dissolves faster than zinc. Experiments with other metals show that with dilute hydrochloric acid, starting with the most vigorous, this order is: Potassium, sodium, calcium, magnesium, zinc, and iron.

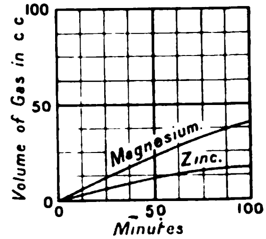

FIG. 6.—Dissolution of Zinc and Magnesium by Dilute Hydrochloric Acid.

The surface of the dissolving metal is supposed to be constant. As near as can be determined, the rate of attack, for any given concentration of acid, increases or decreases proportionately with the surface exposed to attack. Exact measurements are difficult because so many disturbing influences are at work—local rise of temperature; bubbles of gas protecting the surface of the metal from attack; variations in the surface of the metal during the action; etc. Still, the conclusion just indicated is in harmony with a great deal of work on a variety of other simple heterogeneous reactions. The generalization now under discussion is a special case of one still more general: **The speed of a heterogeneous reaction at any instant of time is directly proportional to the remoteness of the system from its equilibrium condition, and to the surface of contact of the reacting parts.** M. Wildermann (1899) has shown that this generalization is generally applicable to molecular reactions between two parts of a heterogeneous system—*e.g.* the evaporation of liquids, the condensation of vapours, the solidification and crystallization of liquids, etc. When zinc dissolves in acid, the rising bubbles of gas keep the liquid constantly agitated, bringing fresh acid to the zinc plate, but when a solid dissolves in a liquid, without disturbances of this kind, the rate of dissolution is nearly proportional to the rate at which the solid diffuses in the liquid; because the nearer the liquid is to the dissolving solid, the greater its concentration, and the layer of liquid in the immediate vicinity of the solid, is virtually a saturated solution.

By measuring the rates at which hydrogen is evolved with one metal and different acids of equivalent concentration, an idea of the relative affinity of the acids for the given metal can be obtained. For instance, acids containing 36·5 grms. of HCl (hydrochloric acid) per litre, 49 grms. of H_2SO_4 (sulphuric acid), and 60 grms. of CH_3COOH (acetic acid) per litre are chemically equivalent to one gram of hydrogen. When these three acids—in equivalent concentrations—react with magnesium ribbon (say, 0·05 grm.), the relative affinities appear to be in the order named:

Hydrochloric acid.	Sulphuric acid.	Acetic acid.
100	70	0·5

The first gives off most hydrogen in a given time, the latter least. Measurements of the volume of gas (reduced to n.p.t.) evolved by the action of normal hydrochloric and acetic acids upon magnesium gave results which furnished the curves shown in Fig. 7. The difference in the speeds of attack by the two acids is brought out clearly by the relative slopes of the two curves. The swifter the reaction the steeper the curve.

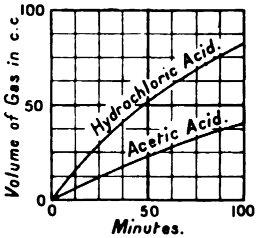

FIG. 7.—The Speed of the Dissolution of Magnesium by Hydrochloric and Acetic Acids.

The speed of the reaction of a given concentration of hydrochloric acid or sulphuric acid on iron or zinc was found by G. Lunge to be considerably reduced if the viscosity of the medium be augmented by admixture with glycerol, or gum arabic. It is assumed that the explanation is partly due to the more tardy liberation of the gas bubbles from the surface of the metal in the more viscous medium, and this prevents contact between the metal and the acid. That this is the whole explanation is regarded as improbable because a mixture of the acid with a little lamp-black (moistened with alcohol to make the acid "wet" it) also acts in an analogous manner.

Returning to the law symbolized in the equation $V=k(a-x)$, with an acid of unit concentration, it follows that the initial velocity $V=k$. And k has accordingly been called the **affinity constant** of the acid for the metal; k represents the speed of the reaction at the instant when the acid has unit concentration. The speed of a chemical reaction is usually, not always, augmented by raising the temperature. In illustration, with $\frac{1}{2}N$-sulphuric acid, a rise of temperature from 12·8° to 35° nearly doubled the speed of dissolution of zinc; and a rise from 12·8° to 55° nearly trebled the speed. The result of this discussion shows that **the velocity of a chemical reaction is proportional (1) to the "affinity constant" between the reacting substances, and (2) to the concentration of the reacting substance; while (3) the velocity of a chemical reaction is augmented by raising the temperature.**

§ 5. Opposing Reactions. Guldberg and Waage's Law

Chemical action is reciprocal, and its effect is the result of a mutual tendency to combination.—C. L. BERTHOLLET (1803).

In an aggregate of molecules of any compound, there is an exchange constantly going on between the elements which are contained in it.—A. W. WILLIAMSON (1850).

Some of the earlier chemists [1]—*e.g.* St. F. Geoffroy (1718), and Torbern Bergmann, in his *De attractionibus electiviis* (Upsala, 1775)—argued that the result of a chemical change must be in favour of that substance with the stronger affinity. Accordingly St. F. Geoffroy compiled what he called *Tables des différents rapports observés en chimie entre différentes substances;* and T. Bergmann, **affinity tables** intended to show the order in which the different substances would displace one another from a given compound. It was argued that *if A displaces B from one compound, and B displaces C from another compound, the order of the affinity of these three substances is A, B, C.* It was clearly recognized that this method of work does not give a numerical measure of affinity, but it was thought that relative results were obtained. The suggestion is certainly a good trial hypothesis. Let us compare it with the facts.

We have seen that iron can displace hydrogen from its combination with oxygen; hence iron has a stronger affinity than hydrogen for oxygen. Similarly, we have seen that hydrogen can displace iron from its combination with oxygen; consequently, hydrogen has a stronger affinity than iron for oxygen. These two conclusions are contradictory; both cannot be true. Therefore, *the affinity hypothesis must be either false, or some powerful perturbing influence must be at work.*

In 1799, C. L. Berthollet [2] clearly recognized an important disturbing factor, and described it in an heretical but prophetic work entitled *Recherches sur les lois de l'affinité* (Paris, 1801). Berthollet noticed large quantities of *trona*—sodium carbonate—on the shores of the natron lakes of Egypt. He suggested that the sodium chloride brought down by the rivers was decomposed by the calcium carbonate present on the banks of these lakes:

$$CaCO_3+2NaCl=CaCl_2+Na_2CO_3$$

Berthollet knew, quite well, that this reaction is the reverse of that which usually obtained in the laboratory, for sodium carbonate, when added to calcium chloride, precipitates calcium carbonate:

$$Na_2CO_3+CaCl_2=CaCO_3+2NaCl$$

but, added Berthollet, the large masses of calcium carbonate on the banks of these lakes is able to " strengthen " the weak affinity of carbon dioxide for sodium, or of chlorine for calcium. Here Berthollet brings the disturbing factor into bold relief: **Chemical action is conditioned not only by affinity but by the relative concentrations of the reacting bodies—Berthollet's law.** Excessive concentration can compensate for a weakness of affinity. A chemical reaction can be reversed by changing the concentrations of the reacting bodies. We must apply Berthollet's hypothesis to the reaction under consideration—the action of iron on steam.

The reaction between iron and steam.—At the outset, it will be obvious that we have to deal with two opposing reactions: steam reacts with iron to produce iron oxide and hydrogen :

$$3Fe+4H_2O=Fe_3O_4+4H_2$$

and iron oxide and hydrogen react to produce steam and metallic iron :

$$Fe_3O_4+4H_2=3Fe+4H_2O$$

J. L. Gay Lussac and H. V. Regnault[3] showed that these opposite effects are not produced merely by a difference of temperature, for, at every degree of temperature from the dullest to the brightest red heat, the action takes place sometimes in one way and sometimes in the other. All depends on the relative proportions of hydrogen and water vapour which are present. If hydrogen be in excess, iron oxide is reduced and water vapour is formed ; while if the water vapour be in excess, the iron is oxidized and hydrogen is formed. In either case a mixture of water vapour and hydrogen is obtained. Reactions of this kind were regarded by the older chemists as an example of the conflict of affinities, and they grouped such reactions as a class exhibiting what they called *reciprocal affinity—affinitates reciprocæ.* C. M. Despretz found zinc, tin, cobalt, and nickel to act in the same manner as iron, and H. V. Regnault found uranium and cadmium to do the same.

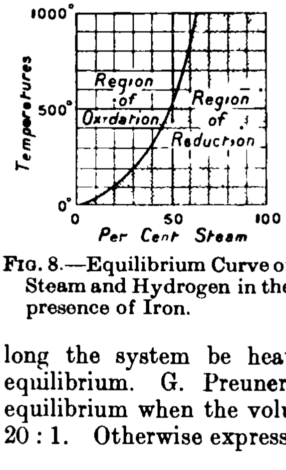

FIG. 8.—Equilibrium Curve of Steam and Hydrogen in the presence of Iron.

It is therefore clear that two antagonistic changes take place simultaneously in the system. The result of the change will be determined by the fleeter reaction. When steam is passed over red-hot iron, the hydrogen does not get much chance, it is carried away into the gas jar before it has had time to set up the reverse change. Similarly, when hydrogen is passed over red-hot iron oxide, the steam does not get a chance, for it is carried away from the reduced iron by the stream of hydrogen. In order to study the affinity relations between these different substances, they should be heated in closed vessels so that the products of the reaction are not whisked away from the seat of the reaction as soon as they are formed. The result is then very curious. It seems as if the reaction stops after a time. At any rate, if the temperature remains constant, no further change can be detected, however long the system be heated. In other words, the system assumes a state of equilibrium. G. Preuner's experiments show that at 200° the system is in equilibrium when the volume of the steam is to the volume of hydrogen nearly as 20 : 1. Otherwise expressed, for equilibrium at 200° :

$$\frac{\text{Volume of hydrogen}}{\text{Volume of steam}}=\frac{1}{20}$$

If a mixture of one volume of hydrogen and twenty volumes of steam be passed over iron filings or over iron oxide at 200°, no apparent change will occur, for the mixture, after passing through the tube at 200°, will have the same composition as when it entered, if no secondary actions occur. If more than this proportion of hydrogen be present at 200°, some iron oxide will be reduced until the equilibrium ratio is obtained. If the temperature be raised, the velocities of the two reactions are altered in such a way that at 440° the volume of steam will be to that of hydrogen nearly as 6 : 1, or as 1 : 0·17 ; and at 1500°, as 1 : 1. This means that if equal volumes of steam and hydrogen be passed over iron filings or iron oxide at 1500°, no change in the composition of the gaseous mixture will be perceptible. The results are summarized in Fig. 8. The curve showing the percentage amount of, say, steam in the system at different temperature divides the plane surface into two regions. If the state of the system be described by a point in the region of oxidation, iron will be oxidized; and conversely, if the state of the system be described by a point in the region of reduction, iron oxide will be reduced.

Chemical equilibrium is dynamic, not static.—Let us now try to picture what is taking place. Start with metallic iron and steam. At the outset when the reaction is just starting, the velocity of decomposition of the steam will be greatest because the system then contains the greatest amount of reacting substance, and because the velocity of chemical action is proportional to the concentration of the substances taking part in the reaction. From this moment, the velocity of the reaction gradually slows down as the concentration of the reacting steam becomes less and less. On the other hand, the velocity of the reverse action will be zero at the commencement, because none of the reacting hydrogen is then present. The speed of the reverse change will become faster and faster as the product of the first-named reaction—hydrogen—accumulates in the system. Ultimately, a point will be reached where the velocities of the two opposing reactions will be equal. The one will be balanced by the other. The reaction will appear to have stopped in spite of the fact that more or less of the original substance still remains untransformed. The system is then in a state of equilibrium. No further change will occur, however long the substances be heated under the same physical conditions of temperature, etc. Chemical changes of this kind are conveniently styled **opposing or balanced reactions,** according as it is wished to emphasize the fact that the one reaction is undoing the work of the other; or that the speeds of the opposing reactions are ultimately so nicely balanced that the composition of the system remains constant. The idea of a dynamic and not a static equilibrium is such reactions was emphasized by A. W. Williamson [4] about 1850, while studying the action of acids on alcohol. He said:

> An exchange is constantly going on between the elements of the molecules of a compound so that each atom of hydrogen in the molecules of HCl present in a drop of hydrochloric acid does not remain quietly in juxtaposition with the atom of chlorine with which it first united, but, on the contrary, is constantly changing places with the other atoms of hydrogen, or what is the same thing, changing its chlorine atom.

A. W. Williamson further adds that when a system appears to be *in equilibrio*, that condition "is only kept up by the number of exchanges in one direction being *absolutely* the same in each moment of time as those in the opposite direction." This is a very clear explanation of M. Lieben's contention that when substances are decomposed by heat and the products of decomposition are not removed as they are formed, the decomposition is never complete; and the small quantity of the original substance, which always remains undecomposed, produces a kind of "molecular equilibrium."

Terminology.—Reversed pointers "$\rightleftharpoons$" are conventionally used in place of the symbol "=" for opposing reactions, so as to indicate that two reactions are proceeding simultaneously "from right to left" and "from left to right." Accordingly, the reaction under consideration is symbolized: $3Fe+4H_2O\rightleftharpoons Fe_3O_4+4H_2$. Opposing reactions are also called **incomplete or reversible reactions** in contradistinction to **irreversible or complete reactions** typified by the action of zinc on sulphuric acid, where the reaction is completed in one direction and is not opposed by a counter reaction.

Concentration and active mass.—It is not difficult to see that the *absolute quantities* of steam, hydrogen, iron, and iron oxide, in the reaction under consideration, do not matter. The velocities of the two opposing reactions, and therefore **the distribution of the reacting substances, when in equilibrium, is determined by the relative concentrations of the changing substances.** This is conveniently expressed by the number of gram-molecules of each present in unit volume. Thus 18 grams of water—H_2O—per litre represents one gram-molecule; 36 grams of water per litre, two gram-molecules; etc. The concentration of a reacting substance is sometimes (inappropriately) called—after C. M. Guldberg and P. Waage (1864)—its **active mass** or—after C. L. Berthollet (1803)—its **chemical mass.** However, it is not mass but concentration which is the determining factor in chemical equilibria, and hence, C. N. Lewis (1907) proposed to substitute the term **activity** in place of active mass.

If the surface of the iron were doubled, it is true that twice as many molecules of the black oxide, Fe_3O_4, might be formed in a given time by the decomposition of the steam, but then twice as many molecules of Fe_3O_4 would be decomposed by the hydrogen in the same time. Hence, **the amount or the concentration of the solid in a gaseous reaction can have no appreciable influence on the equilibrium; although it may affect the speed at which the state of equilibrium is attained.** In studying equilibria in gases and liquids, anything which separates in the solid condition is often supposed to be thrown out of the reacting system because the state of equilibrium is independent of the concentration of the solid; and a liquid which separates when studying gaseous equilibria, is also supposed to be thrown out of the reacting system. The vapour pressure of water, for instance, in presence of its own liquid is independent of the *amount* of liquid water present. Suppose also that the back reaction between hydrogen and black oxide of iron, Fe_3O_4, at the temperature of the experiment furnishes black ferrous oxide, FeO, the reaction would then be symbolized:

$$3FeO+H_2O\rightleftharpoons Fe_3O_4+H_2$$

Determinations of the ratio $H_2O:H_2$ would not give any information as to the accuracy of the assumption. The principles of opposing reactions just outlined are summarized: **In a system of reacting bodies, the effect of each substance is proportional to its concentration, and the total effect is proportional to the product of the molecular concentrations of the reacting substances.** This is one statement of what is called **Guldberg and Waage's law of mass action,** because the ideas of Berthollet were expressed in this form by C. M. Guldberg and P. Waage in an important memoir, *Études sur les affinités chimiques* (Christiania, 1867), published first in Norwegian in 1864.[5]

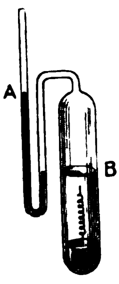

FIG. 9

L. P. Cailletet (1869) [6] has shown that when, say, sodium amalgam acts on water, the hydrogen exerts no back action because it passes away from the seat of the reaction as soon as it is formed. Suppose the reaction be conducted in a thick-walled vessel, *B*, in Fig. 9, capable of withstanding great pressure and fitted with a manometer, *A*, in order to measure the pressure of the hydrogen as it accumulates in the apparatus. The speed of the reaction gradually slackens and finally stops. With dilute sulphuric acid and zinc, this occurred when the hydrogen was exerting a pressure of nearly 20 atmospheres. The cessation of the reaction is not a mere mechanical effect because an equal pressure exerted by an indifferent gas will not do. The idea of preventing chemical action in this way is said to have been first tested by C. Babbage in 1813, for he confined concentrated hydrochloric acid in a hole 30 inches deep and 6 inches wide drilled in limestone rock (Chudley Rocks, Devon) and plugged up the hole. He thought the pressure of the developed gas would prevent the action of the acid on the limestone. No definite conclusion was drawn from the experiment.

Still further, as N. N. Beketoff (1864) has shown, if salts like zinc sulphate, copper acetate, silver sulphate, etc., be exposed to hydrogen under great pressures —over 100 atmospheres—the metal is precipitated and the acid is re-formed. Hence, the reaction $Zn+H_2SO_4=ZnSO_4+H_2$ is reversible when conducted in a closed vessel.

It might be added that in some cases the back reaction does not proceed along the same path as the forward reaction. Thus, hydrogen at 130 atmospheres pressure (70°) precipitates cuprous oxide from copper acetate, and at 150 atmospheres (120°) metallic copper. It might also be added that the work done by affinity during, say, the reaction between zinc and dilute acid, may be roughly regarded as proportional to the pressure exerted by the gas provided the reacting system suffers no change in volume. If v denotes the change in volume, and p the pressure registered by the manometer when the reaction just stops, the work W done by affinity at a constant temperature will be $W=pv$.

Chemical affinity.—To summarize the preceding discussion: chemical affinity is a convenient term for the driving force which causes certain substances to combine together and to remain united with one another. (1) Unlike gravitation, chemical affinity seems to act only when the reacting substances are in contact with one another; or, as it is sometimes expressed, "when the substance are brought within insensible distances of each other." (2) Unlike gravitation, chemical affinity is a selective force, and it seems to act more intensely the more unlike the substances are; or, as it is sometimes expressed, "Like reacts with the unlike." (3) The affinity of an element is not only definite as to the *kind*, but it is also definite as to the *quantity* of the elements which enter into combination. In this again it differs from gravitational attraction. The quantitative characteristics are described by the laws of chemical combination. (4) The strength of the affinity varies with changes in the conditions of temperature, pressure, light, etc. This has not been noticed with gravitational attraction. (5) The effects produced by chemical affinity are modified by the relative concentrations—active masses—of the reacting substances.

The ideas developed in this section were not so clear to the old workers, not even to Berthollet himself, for Berthollet appears to have confused the incompleteness of certain reactions with the law of multiple proportions. The confusion gave him some strong arguments in the celebrated Berthollet *v.* Proust Controversy. Proust did not know enough to clarify Berthollet's argument.

§ 6. The Solubility of Hydrogen

Hydrogen is slightly soluble in water. About 1803, W. Henry[1] found that 100 c.c. of water absorb 1·56 c.c. of hydrogen; J. Dalton found 2·5 c.c.; and T. de Saussure, 4·55 cc. N. Paul noted that the solubility is augmented by pressure, so that 100 c.c. of water can be made to absorb about 33 c.c. of hydrogen. According to A. T. y Marti, water can be made by degrees to absorb more and more hydrogen, so that in two years water will take up not quite its own volume of the gas. It was suggested that *hydrogen suboxide*, H_4O, is formed, and C. J. B. Karsten even supposed this oxide to be formed by saturating cold water with hydrogen sulphide, and removing the sulphur by certain metals. There are no satisfastory reasons for supposing the existence of this oxide.

R. W. Bunsen (1855) [2] thought that the solubility of hydrogen in water is not affected by variations of temperature between 0° and 24°, so that between these temperatures one volume of water absorbs the equivalent of 0·0193 vol. of hydrogen; but his method of measurement was probably not sensitive enough to detect the difference, since W. Timofejeff and others have shown that there is quite an appreciable change between these temperatures. Let β denote the *absorption coefficient* used by R. W. Bunsen; it represents the volume of gas reduced to 0° and 760 mm. which is absorbed by one volume of the solvent when the pressure of the gas itself, without the partial pressure of the solvent, amounts to 760 mm.; and let β' denote the absorption coefficient when the total pressure of the gas and water vapour is the barometric pressure, 760 mm. The solubility of a gas—symbolized S—can also be represented as the volume of gas absorbed by unit volume of the solvent at the temperature of the experiment—consequently, the solubility S of a gas at $\theta°$ is $1+0{\cdot}003670\theta$ times the coefficient of absorption β, or $S=\beta(1+0{\cdot}003670\theta)$. The solubility can also be represented as the weight ω of gas in grams dissolved by 100 grams of the solvent at the temperature of the measurement and a total pressure 760 mm., where 760 mm. represents the partial pressure of the gas plus the partial pressure of the solvent.

The solubility of hydrogen in water.—The values of the constants β and ω for the solution of hydrogen in water between 0° and 24° are:

	0°	4°	8°	12°	16°	20°	24°
β .	0·02153	0·02079	0·02010	0·01947	0·01889	0·01837	0·01791
ω .	0·03192	0·03185	0·03179	0·03173	0·03167	0·03162	0·03157

and W. Timofejeff represents the coefficient of absorption β at a temperature θ over the range 0° to 26°, by $\beta=0{\cdot}0215286-0{\cdot}03196\theta+0{\cdot}0_517228\theta^2$. For the range from 25° to 100°, the four solubility coefficients are:

	25°	30°	40°	50°	60°	80°	100°
β .	0·0175	0·0170	0·0164	0·0161	0·0160	0·0160	0·0160
β' .	0·0171	0·0163	0·0153	0·0141	0·0129	0·0085	0·0000
S .	0·0156	0·0145	0·0140	0·0131	0·0125	0·0113	0·0107
ω .	0·03156	0·03147	0·03139	0·03129	0·03119	0·0470	0·0000

Although hydrogen, like other gases, decreases in solubility as the temperature rises, no definite law has been discovered for the phenomenon. According to C. Bohr and J. Bock the solubility of hydrogen decreases gradually with rise of temperature and from $S=0{\cdot}0203$ at 0° to $S=0{\cdot}0155$ at 90°, and then rises to 0·0166 at 100°. Helium is the only other gas which gives any indication of a reversal in the direction of the solubility curve. The formulæ representing the relation between the temperature θ and the solubility S, based on the series $S=a+b\theta+c\theta^2+\ldots$—where $a, b, c, \ldots$ are constants whose numerical values are derived from the observed data—are quite empirical. L. W. Winkler (1892) sought to prove that the percentage decrease in the absorption coefficient or solubility is nearly proportional to the cube root of the molecular weight of the gas in question. A comparison between the observed and calculated results for hydrogen, nitrogen, oxygen, carbon monoxide, and nitric oxide was satisfactory; but T. E. Thorpe and J. W. Rodger (1894) showed that L. W. Winkler's rule is not generally valid, though they found that for the same gas, the decrease in the coefficient of absorption for any interval of temperature is nearly proportional to the corresponding decrease in the viscosity coefficient of the solvent.

According to K. Angström,[3] the increase in the volume of the solvent which occurs during the solution of a gas is proportional to the amount of gas absorbed; and with

	Nitrogen.	Air.	Carbon monoxide.	Oxygen.	Hydrogen.	Carbon dioxide.
Dilation .	0·04294	0·04346	0·04418	0·04474	0·04204	0·0023

The increase in volume with hydrogen is 0·0016 for chloroform; 0·0017 for benzene; 0·0017 for methyl alcohol; 0·00152 for ethyl alcohol; and 0·00184 for ether

The dilation due to absorption was found to be independent of the nature of the liquid, and not in agreement with W. Ostwald's statement that "the volume of the absorbed gas is almost exactly reduced to the volume of its molecules."

The solubility of hydrogen in aqueous solutions of acid, bases, and salts.—A great many empirical observations have been made on the solubility of hydrogen in aqueous solution of acids, bases, and salts.[4] The values of S for *hydrochloric, nitric, sulphuric, acetic, chloroacetic,* and *propionic acids* at 25° are :

	HCl	HNO_3	$\frac{1}{2}H_2SO_4$	CH_3COOH	$CH_2ClCOOH$	C_2H_5COOH
$\frac{1}{2}N$-acid .	0·0186	0·0188	0·0185	0·0192 .	0·0189	0·0017
$4N$-acid .	0·0160	0·0160	0·0141	0·0186	0·0180($2N$)	0·0016($1\frac{1}{2}N$)

A. Christoff found the solubility of hydrogen in 95·6 per cent. sulphuric acid to be 0·01097 between 17° and 20° ; in 61·62 per cent. sulphuric acid, 0·007181 ; in 35·82 per cent, acid, 0·009544 ; and in pure water, 0·02077. The solubility S of hydrogen in a $\frac{1}{2}N$-solution of *potassium hydroxide* is 0·0167 ; and in a normal solution, 0·0142 ; for a $\frac{1}{2}N$-solution of *sodium hydroxide,* 0·0165 ; for a normal solution, 0·0139 ; and for a $4N$-solution, 0·0055. W. Knopp, H. von Euler, and others have suggested formulæ for representing the effect of a salt on the solubility of hydrogen in water.

The coefficient of absorption, β, of a 1·037 per cent. solution of *ammonium nitrate* at 20° is 0·01872, and for a 11·55 per cent. solution, 0·01647 ; for a 4·73 per cent. solution of *potassium nitrate* β=0·01683 (15°). and a 21·46 per cent. solution β=0·01180 (15°) ; a 5·57 per cent. solution of *sodium nitrate* has β=0·01603 (15°), and a 37·43 per cent. solution, β=0·00578 (15°). A 3·83 per cent. solution of *potassium chloride* has β=0·01667 (15°), and for a 22·92 per cent. solution, β=0·00892 (15°) ; with a 1·25 per cent. solution of *sodium chloride,* β=0·0191 (15°), 0·0177 (20°), and for a 23·84 per cent. solution, β=0·00595 (15°) ; a 3·48 per cent. solution of *lithium chloride* has β=0·01619 (15°), and a 14·63 per cent. solution, β=0·0099 (15°). For a 3·29 per cent. solution of *barium chloride,* β=0·0185 (15°), 0·0172 (20°) ; a 7 per cent. solution has β=0·0172 (15°), 0·0159 (20°) ; with a 3·47 per cent. solution of *calcium chloride,* β= 0·01450 (15°), and a 26·34 per cent. solution, β=0·00519 (15°). For a 4·58 per cent. solution of *sodium sulphate,* β=0·01519 (15°), and a 16·69 per cent. solution, β=0·00775. For a 4·97 per cent. solution of *magnesium sulphate,* β=0·01501 (15°), and for a 23·76 per cent. solution, β=0·00499 (15°) ; for an 8·1 per cent. solution of *zinc sulphate,* β=0·001446 (15°), and a 48·4 per cent. solution, β=0·00510 (15°). A 22·82 per cent. solution of *potassium carbonate* has β=0·01628 (15°), and a 41·81 per cent. solution, β=0·0016 (15°) ; for a 2·1 per cent. solution of *sodium carbonate,* β=0·01639 (15°) ; and a 11·52 per cent. solution, β=0·00839 (15°).

The solubility of hydrogen in organic liquids.—Hydrogen is much more soluble in *ethyl alcohol* than it is in water. The solubility decreases the more the alcohol is diluted with water down to about 28 per cent. alcohol, when the coefficient of absorption increases ; there is therefore a minimum in the solubility curve. Thus, at 20° the absorption coefficient β is :

Per cent. alcohol	0	9·09	28·57	33·33	50·0	66·67	98·8	99·7
β . . .	0·0184	0·0133	0·0097	0·0108	0·0187	0·0237	0·0740	0·0740

W. Timofejeff (1890) found the absorption coefficient β of hydrogen in 9·88 per cent. alcohol increased from 0·0676 at 0° ; to 0·0693 at 6·2° ; to 0·0705 at 13·4° ; and to 0·0740 at 18·8°. L. Carius (1855) found rather lower numbers ; he represents the coefficient of absorption β of hydrogen in alcohol at $\theta°$ by the expression : $\beta=0{\cdot}06925-0{\cdot}0001487\theta-0{\cdot}000001\theta^2$, when $\theta°$ lies between 0° and 25°. The solubility S of hydrogen in some alcohols is—

	Methyl alcohol		Ethyl alcohol		Iso-butyl alcohol		Amyl alcohol	
	20°	25°	20°	25°	20°	25°	20°	25°
S .	0·0902	0·0945	0·0862	0·0894	0·0929	0·0976	0·0353	0·0301

The corresponding values for water are S=0·0200 (20°) and S=0·0199 (25°). The solubilities of hydrogen in a large number of organic compounds and in aqueous solutions of organic compounds have been measured.[5] In some cases it will be observed that the solubility of the gas is greater at the higher temperature.

The solubility S of hydrogen in a 2·29 per cent. *glycerol* solution at 14° was found by P. Drucker and E. Moles to be 0·01886, and in a 15·31 per cent. solution, 0·01765; while at 25°, a 4·0 per cent. solution has a solubility of 0·0170; a 50·5 per cent. solution, 0·0089; and a 95·0 per cent. solution, 0·0030. For a 2·63 per cent. solution of *propionic acid* at 20°, S=0·0186; and for a 9·91 per cent. solution, 0·0165, which rises to 0·0209 at 5°. For a solution of 89 grams of *amidopropionic acid*, $CH_3.CH(NH_2).COOH_2$, per litre, S=0·0145 (20°); for a solution with 75 grms. of *glycocol* per litre, S=0·0147 (20°); for a solution with 60·07 grams of *urea* per litre, S=0·0159 (20°); and for one with 59 grams of *acetamide* per litre, S=0·0167 (20°). The solubility of hydrogen in a 4·91 per cent. solution of *chloral hydrate* at 20° is 0·0171, and in a 63·9 per cent. solution, 0·0122; in 16·67 per cent. For *sugar* solutions at 15°, C. Müller found S=0·01479; and in 47·65 per cent. solutions, S=0·008456; with 41·4, 80·8, and 166·62 grams of *glucose* per litre, at 20°, S was respectively 0·0164, 0·0153, and 0·0141. The solubility S of hydrogen in *aniline* is 0·0303 (20°) and 0·0285 (25°); *nitrobenzene*, 0·0353 (20°) and 0·0371 (25°); *toluene*, 0·08384 (20°) and 0 08742 (25°); *xylene*, 0·07834 (20°) and 0·08185 (25°); *carbon disulphide*, 0·0336 (20°) and 0·0375 (25°); *acetone*, 0·0703 (20°) and 0·0764 (25°); *ethyl acetate*, 0·0788 (20°) and 0·0852 (25°); *amyl acetate*, 0·0743 (20°) and 0·0774 (25°); and *iso-butyl acetate*, 0·09287 (20°) and 0·09758 (25°). S. Gniewasz and A. Walfisz found the absorption coefficient of hydrogen in *petroleum* at 10° is 0·0652, and at 20°, 0·0582 (water at 20°, 0·0193); G. Fahr measured the solubility of hydrogen in the *blood* and *serum* of different animals.

As a rule, the absorption coefficient of hydrogen in organic solvents decreases with increasing concentrations of the solutions; it is also noteworthy, that the solubility of hydrogen in several organic solvents increases as the temperature rises—usually, the solubility decreases as the temperature increases. The work of A. Christoff, previously cited, shows that the solubility increases as the surface tension of the solvent decreases.

The permeability of the metals to hydrogen.—In 1863, H. St. C. Deville and L. Troost[6] showed that hydrogen gas can diffuse through red-hot platinum or iron, but not through the cold metals, and they suggested that the permeability was caused by the development of a kind of porosity of a greater degree of minuteness than the porosity of graphite and earthenware; they said that this new porosity is entirely due to the expansive agency of heat opening up intermolecular spaces in the heated metal—*la porosité résulte de la dilation que la chaleur fait éprouver aux espaces intermoléculaires.* It has been estimated that about four litres of hydrogen can pass through a square metre of palladium per minute; and about half a litre through a square metre of platinum in the same time. T. Graham and many other investigators have investigated the pressure obtained by the diffusion of hydrogen through platinum and palladium. According to A. Winkelmann, the quantity of hydrogen which diffuses through the metal is not proportional to the pressure, for at low pressures the quantity which diffuses is relatively larger than accords with this assumption. A. Winkelmann also investigated the diffusion of hydrogen through iron and platinum; and O. W. Richardson, J. Nicol, and T. Parnell also studied the diffusion of hydrogen through platinum. A. Sieverts and P. Beckmann found hydrogen begins to diffuse through copper at 640°; platinum at 500°; nickel at 450°; iron at 300°; and palladium at 240°. O. W. Richardson, J. Nicol, and T. Parnell found the speed of diffusion increased with a rise of temperature, while the temperature coefficient at the same time decreased. The speed of diffusion at a constant temperature is proportional to the square root of the pressure. The diffusion is probably connected with the absorption of the gas by the metal. The gas is absorbed on one side and given off on the other side where the partial pressure of the hydrogen is smaller. It is suggested by A. Winkelmann[7] that the hydrogen is dissociated and only hydrogen in the atomic condition can traverse the platinum. J. Schmidt raised objections to the atomic hypothesis, but neither O. W. Richardson nor A. Winkelmann accepted J. Schmidt's views. A. Lessing found the velocity of diffusion of electrolytic hydrogen increases with increasing potential. The diffusion of hydrogen through platinum has to be taken into consideration in chemical analysis when certain substances are heated over the gas flame in a platinum crucible. Reducing gases, from the coal gas, pass through the walls of the crucible and exert a reducing action on substances being calcined—*e.g.* manganese oxide.

According to G. Quincke (1877),[8] hydrogen, oxygen, and nitrogen do not diffuse through glass of 1·5 mm. thickness at ordinary temperatures, and under a pressure of 126 atmosphere, nor is there any sign of the permeability of glass up to its softening temperature. M. Berthelot maintained that hydrogen can diffuse through the walls of heated glass—ordinary and Jena. A. Sieverts and W. Krumbhaar (1910) also found that unglazed porcelain is impervious to hydrogen at 1650°, and that it can support a vacuum at 1400°. Glass surfaces absorb hydrogen. According to P. Chappius, 1 sq. mm. of glass at normal pressure, on heating from 0° to 180° gives off 0·00027 c.c. of hydrogen. Powdered quartz at 1100° can absorb 0·015 c.c. of hydrogen or helium per gram. Transparent quartz glass at ordinary temperatures and pressures is impervious to hydrogen, oxygen, etc.; but at 330°, the quartz is pervious to hydrogen for pressures varying from 560 to 960 mm. No leakage was observed with nitrogen or oxygen at pressure less than one atmosphere. Hydrogen leaked through the tube at about 430°. At a constant temperature, the leakage increased with increasing pressures as illustrated in Fig. 10. M. Bodenstein and F. Kranendisck found that 4·38×10⁻⁶ c.c. of hydrogen diffused through 1 sq. c.c. of quartz glass 1 mm. thick per hour when there was a difference of pressure of 1 atmosphere on the two sides and the temperature was 732°; at 880°, 8·65×10⁻⁶ c.c. of gas diffused under similar conditions.

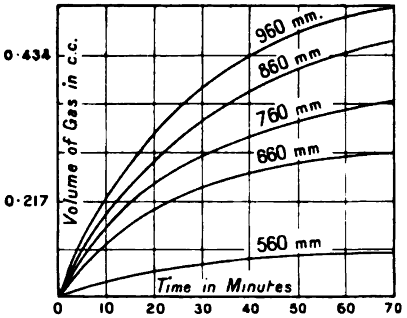

FIG. 10.—The Leakage of Hydrogen at Different Pressures from Vessels of Quartz Glass at 430°.

The solubility of hydrogen in the metals.—In 1866, the attention of T. Graham [9] seems to have been arrested by H. St. C. Deville and L. Troost's observation on the permeability of metals to gases. T. Graham could not detect any signs of the passage of oxygen, nitrogen, chlorine, steam, hydrogen chloride, carbon dioxide, carbon monoxide, methane, ethylene, hydrogen sulphide, or ammonia through a septum of platinum 1·1 mm. thick at a full red heat in an apparatus capable of detecting 0·2 c.c. per hour. He also found that when certain metals are heated in hydrogen gas, more or less of the gas is absorbed and retained as the metal cools, forming a kind of solid solution of the gas in the metal.

T. Graham heated a small piece of the metal under investigation in a porcelain tube glazed inside and out. The tube was heated to redness and exhausted. Hydrogen was then allowed to pass over the heated metal, and the metal cooled in the same gas. The tube was then evacuated, and afterwards heated, with the pump in action, until no more gas was evolved. The gas was collected over mercury and measured. The volume and weight of metal were also determined, and the results could be represented in any desired way. He expressed his results as average volumes of gas absorbed per unit volume of metal. He found:

	Vols.		Vols.
Platinum (fused) . .	4·68	Copper (wrought)	0·31
Platinum (hammered) .	3·03	Gold	0·46
Palladium (foil). . . .	495·50	Silver	0·90
Copper (sponge) . .	0·60	Iron	4·15

An osmium-iridium alloy absorbed a trace of the gas. Palladium, therefore, of all the metals, appears to possess the power of absorbing hydrogen in the highest degree. The volume of gas absorbed by a metal depends on its condition, and increases with the superficial area. The gas is retained by the metal very tenaciously, and it can be recovered from the metal only by heating to redness in vacuo. Hence, added T. Graham:

> It appears necessary to recognize in palladium a new property, a power to absorb hydrogen at a red heat, and to retain gas at a temperature under redness for an indefinite time. It may be allowable to speak of this as a power *to occlude* (to shut up) hydrogen, and the result as the **occlusion** of hydrogen by palladium.

The fixation of the gas was found to be more energetic if the metal under investigation were used as a negative electrode during electrolysis. For example, M. Thoma has shown that if palladium be employed as negative electrode during the electrolysis of acidulated water, the metal may become supersaturated with the gas and dissolve over 935 times its volume of the gas; the amount actually dissolved depends on the strength of the current. The excess is quickly evolved when the current ceases.

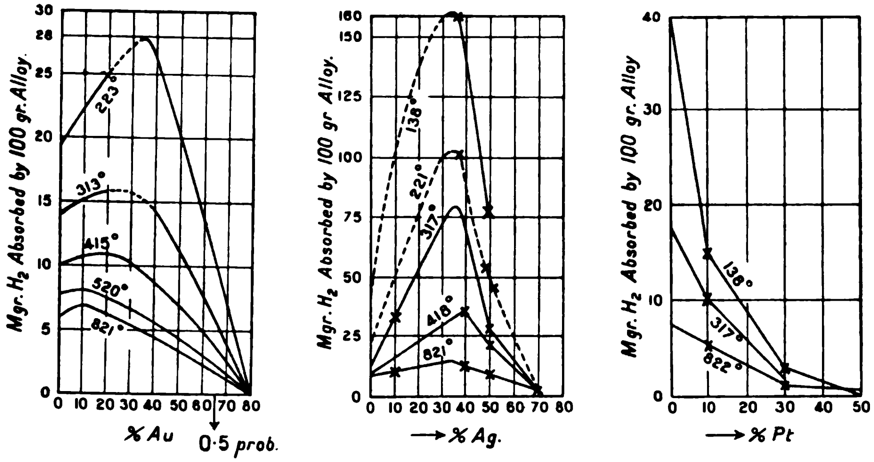
In order to prepare hydrogenized palladium, a clean piece of palladium foil about 16 sq. cm. is used as cathode in a solution of palladium nitrate—2 grams of the salt per 100 c.c. of water. The anode is also of palladium. After a current of about one ampere has passed for 20–30 minutes, the foil will be covered with a velvety-black film of palladium black. This plate is then used as cathode in the electrolysis of dilute sulphuric acid with a current of 0·8 to 1·0 amp. The plate will be saturated with hydrogen in about an hour. The foil is rapidly washed with water, and dipped in absolute alcohol and ether. It can be preserved for some weeks under air-free water.

G. Neumann and F. Streintz, like T. Graham, measured the volume of gas, reduced to standard conditions, absorbed by one volume of metal. Some of the latter's results are here included with those of the former:

	Vols. absorbed.		Vols. absorbed.
Silver (foil)	0·21	Gold (leaf)	1·4
Silver (powder)	0·9 to 0·95	Gold (precipitated)	37·0 to 46·0
Aluminium (sheet)	1·1 to 2·7	Palladium (wrought)	376·0 to 643
Cobalt (reduced)	59·0 to 153	Palladium (wire)	930·0
Copper (wire)	0·3 to 4·8	Palladium (sponge)	680·0 to 852
Copper (reduced	0·6 to 4·8	Palladium (fused)	68·0 to 200
Iron (wire)	0·46	Platinum (sponge)	1·5 to 49·0
Iron (wrought)	0·57 to 0·8	Platinum (foil)	0·8 to 1·5
Iron (reduced)	9·4 to 19·2	Lead (fused)	0·11 to 0·15
Magnesium	1·4	Zinc (electrolytic)	traces
Nickel (reduced)	17·0 to 18·0	Antimony	nil

According to G. Neumann and F. Streintz, *silver* absorbs no hydrogen—but others have reported the absorption of about one-fifth of its volume of the gas. The numbers here given are not to be taken as absolute—perhaps not even comparable. Considerable differences have been reported by other observers. Thus, according to A. Sieverts and his co-workers, hydrogen is not dissolved by *cadmium*, *thallium*, *aluminium*, *zinc*, *lead*, *bismuth*, *tin*, *antimony*, *tungsten*, *silver*, or *gold*; while *copper*, *nickel*, and *iron* do dissolve the gas. H. R. Carveth and B. E. Curry reported the occlusion of 250 vols. of hydrogen by electrically deposited *chromium*. L. Troost and P. Hautefeuille obtained evidence of the occlusion of hydrogen by *manganese*, and the presence of manganese increases the solubility of hydrogen in iron; on the other hand, E. Wedekind and T. Veit did not obtain much occlusion, but they worked with a gas containing some oxygen. C. Winkler says that *beryllium*, *manganese*, *yttrium*, and *zirconium* take up hydrogen when their oxides, intimately mixed with magnesium, are heated, but magnesium alone did not absorb the gas. The experimental conditions do not appear to be such as would furnish reliable evidence of the occlusion of gases by these elements. A. van Berghe and E. L. Lederer did not find that *molybdenum* occluded hydrogen to any marked degree; A. Sieverts and his co-workers, and G. Neumann have studied the occlusion of hydrogen by *iron*; A. Sieverts and his co-workers, W. Ipatieff, and M. Mayer and V. Altmayer have studied *nickel*; A. Sieverts, *cobalt* and *copper*. The experiments of H. E. Roscoe, and of W. Muthmann, L. Weiss, and R. Riedelbauch make it probable that hydrogen is occluded by *vanadium*; and likewise H. von Bolton,

W. Muthmann, and A. Sieverts and their co-workers suggest that hydrogen is occluded by *tantalum*. M. von Piriani says tantalum at a red heat absorbs 0·3 per cent. of gas, and more at a higher temperature. There is no evidence of the occlusion of any marked amount of hydrogen by *mercury*. T. Wilm said that *rhodium* absorbs more hydrogen than does palladium, but E. Quenessen thought this to be improbable, and A. Sieverts and E. Jurisch found rhodium absorbs very little hydrogen. F. Rother, and R. Finkener and F. Fisher show that while ordinary *iridium* does not occlude much hydrogen, under the stimulus of a prolonged cathodic bombardment it can take up 800 vols. of hydrogen. According to A. Ledeber, this, however, is doubtful evidence of occlusion. A. Gutbier and co-workers found pure iridium occludes 140 vols. of hydrogen at 20°. C. Winkler considers it unlikely that *titanium* occludes hydrogen. L. Cailletet and E. Collardeau say that *ruthenium* can take up gases during electrolysis, and T. Graham says that an *osmium-iridium* alloy absorbs no hydrogen when heated in the gas. It may therefore be said that the two elements—ruthenium and *rhodium*—as well as of *scandium*, *gallium*, and *indium*, have not been investigated. A. Sieverts and E. Bergner obtained a small occlusion of hydrogen with an impure form of *uranium*. The work of C. Winkler, C. Matignon, W. Muthmann, and H. H. Zhukoff show unmistakable evidence of the occlusion of hydrogen by *cerium* and *lanthanum*, for those metals form phases of variable composition in which the hydrogen may reach high concentrations. C. Winkler and C. Matignon found evidence of the absorption of hydrogen by *thorium*, and C. Matignon by *samarium*, *neodymium*, and *praseodymium*. Nothing definite is known of the behaviour of *europium*, *gadolinium*, *terbium*, *holmium*, *erbium*, *thulium*, and *ytterbium*.



FIGS. 11 to 13.—Absorption of Hydrogen by Palladium Alloys.

T. Graham and A. J. Berry have measured the solubility of hydrogen in *palladium-gold* alloys. A. J. Berry found that the decrease in the amount of occluded hydrogen is a simple function of the proportions of palladium in the alloy, but the occluding power of the alloy vanishes when the proportion of palladium falls below 25 per cent., roughly 0·5 gram-molecules of gold. A. Sieverts, E. Jurisch, and A. Metz extended these observations at different temperatures between 138° and 820°; they also employed *palladium-silver* and *palladium-platinum* alloys. The results with the alloys are indicated in Figs. 11–13. All proportions of platinum diminish the solubility of hydrogen; hydrogen is virtually insoluble in silver, but the addition of silver to palladium raises the solubility until a maximum is reached with 40 per cent. of silver—at 130° this alloy dissolves four times as much hydrogen as pure palladium—the solubility diminishes with increasing proportions of silver, and becomes zero with alloys containing over 70 per cent. of silver. The curves for different temperatures are illustrated in Fig. 14.

Different results are obtained with different samples of metal; this is mainly due to differences in the purity of the metal, and to the method employed in its preparation—*e.g.* cobalt in the form of ingots absorbs virtually no hydrogen, while the metal reduced from the oxide at a low temperature absorbs relatively large volumes of the gas, and if reduced at a high temperature much less gas is absorbed. In a general way, the amount of gas absorbed depends upon the *surface area* which the metal presents to the gas. Thus the colloidal palladium prepared with sodium protalbate by C. Paal and C. Amberger absorbs 300 to 400 vols. of hydrogen, and the solution prepared by C. Paal and J. Gerum absorbed 1000 to 3000 vols. The solubility of hydrogen in the metals increases proportionally with the *temperature* up to the melting point when there is an abrupt increase which again increases proportionally with the temperature. With palladium, however, the solubility does not depend on the temperature, and unlike the other metals there is an abrupt decrease in solubility (nearly one-half) as the metal melts. The dissolved gas is mainly rejected as the metal cools, and that which is retained can be recovered on heating in vacuo. If the metal is heated in an atmosphere of the gas, more and more hydrogen is retained by the cooling metal the higher the temperature to which it has been heated. The amount of hydrogen retained by iron, containing 0·04 per cent. of carbon, heated to different temperatures, is indicated in Fig. 14. The amount of gas retained by a metal also increases with the *pressure*. The relation between the amount of hydrogen absorbed by the molten metal and the pressure does not usually follow Henry's law. Thus 100 grms. of molten copper (1123°) dissolve

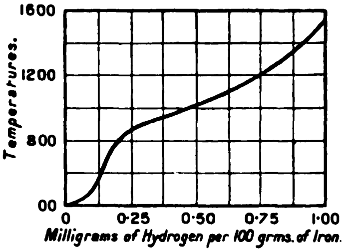


FIG. 14.—The Effect of Temperature on the Absorption of Hydrogen by Iron.

Pressure (p)	1046	883	606	281 mm.
Absorbed hydrogen (m)	0·745	0·680	0·549	0·380 mgrm.
$p^{\frac{1}{2}}/m$	43·5	43·7	45·1	44·2

showing that the quantity of hydrogen absorbed is not proportional to the pressure as it would be if it followed Henry's law—it is proportional to the square root of the pressure. Palladium increases in volume during the absorption, but its general appearance and properties—thermal and electrical conductivity, tenacity, etc.—are not much altered, although a considerable amount of heat is evolved during the absorption—4370 calories per gram of gas.

Potassium and *sodium* were found by L. Troost and P. Hautefeuille to absorb hydrogen; H. Moissan found 126 vols. of the gas were absorbed between 200° and 400°; and 237 vols. by sodium between 300° and 421°. C. Matignon found *lithium* and *thallium* absorbed no hydrogen. K. A. Hofmann, O. Ehrhart, and O. Schneider also found that *osmium tetroxide* absorbs hydrogen. F. Soddy patented the use of *calcium* as an absorbent for gases in the production of high vacua. D. P. Smith found that the elements which occlude hydrogen occupy a definite position in the periodic table—Cap. VI—and that *the capacity of a metal to occlude hydrogen is confined to those with a strong magnetic susceptibility*, for the elements which have a specific magnetic susceptibility exceeding $0·9\times10^{-6}$ at ordinary temperatures, occlude relatively large proportions of hydrogen, while those with a smaller magnetic susceptibility do not occlude hydrogen—copper, rhodium, and thorium are possible exceptions.

It was once thought that the palladium formed a chemical compound—Pd_2H—with the hydrogen, but this has not been accepted as a full explanation

T. Graham[10] thought that the gas hydrogen, during absorption, condensed to a solid metal which alloyed with the palladium. He gave the name **hydrogenium** to this hypothetical metal in order to emphasize its supposed metallic nature. It was argued that the metallic character of the occluded hydrogen is shown by the fact that if a plate of palladium be charged electrolytically with hydrogen, and subsequently immersed in a solution of copper sulphate, the metal is soon covered with a film of metallic copper: $CuSO_4+2H_{palladium}=H_2SO_4+Cu$. A similar phenomenon occurs when the plate is immersed in a solution of salts of gold, platinum, silver, or mercury, but not in solutions of salts of lead, iron, zinc, or magnesium. Solid hydrogen, however, was found by J. Dewar to have rather the properties of a non-metal than of a metal—its specific gravity, for instance, is 0·076, which is but one-eighth that (0·6 to 0·7) calculated for the absorbed hydrogen in palladium. The relation between the absorbed hydrogen and the metal is not perfectly clear.

Not only hydrogen, but several other gases are also absorbed by metals during their preparation or purification in furnaces, etc. For instance, W. Heald found that hydrogen is absorbed by many metals during their sublimation in that gas. Hence, when metals are heated to bright redness in glazed porcelain tubes exhausted by means of an air-pump, gases of various kinds are given off—*e.g.* aluminium gives off hydrogen; magnesium, hydrogen and carbon monoxide; zinc and electrolytic copper give off hydrogen, carbon dioxide and monoxide; tin and platinum give methane and nitrogen in addition to the gases just mentioned. L. Kahlenberg and H. Schlundt[11] found that when metallic sodium and mercury react with one another much heat is evolved, and 3·24 c.c. of hydrogen is evolved per gram of sodium. Allowance must always be made for the presence of occluded gases in metals, etc., which have not been heated to redness in vacuo; otherwise wrong inferences may be drawn. Indeed, at one time, H. Davy worked with the hypothesis that the elements are compounds of hydrogen with an unknown base in different proportions, and at first he seemed to succeed in getting relatively large quantities of hydrogen from sulphur, selenium, and carbon, but he got no unknown base. He soon recognized that the hydrogen he obtained was mechanically absorbed by these elements and was not a product of the decomposition of the elements, sulphur, selenium, and carbon. Alleged transmutations of one gas into another have been traced to similar phenomena in vacuum tubes. Many rocks and minerals also give off gases when heated under similar conditions, showing that they, too, have occluded gases. The meteoric iron of Lenarto containing about 91 per cent. of iron was reported by T. Graham (1867) to have yielded 2·86 times its volume of occluded gas. Since, under ordinary atmospheric pressures, iron absorbs only half its volume of gas, it was inferred that the meteorite must have come from an atmosphere containing hydrogen under a far greater pressure than our atmosphere, a deduction confirmed by spectroscopic observations on the dense hydrogen atmospheres of the sun and fixed stars.

The absorption of hydrogen or other gases in vacuum tubes has been explained as a result of the absorption of the gas by the disintegrated particles of the cathode by L. Vegard,[12] S. Brodetsky and B. Hodgson, and F. Soddy and T. D. Mackenzie; of the occlusion of the gas in the cathode by R. Riecke; of the chemical action of the gas and the cathode by K. Mey; of the chemical or mechanical action of the gas on the anode by C. A. Skinner, B. Hodgson, and V. L. Chrisler; to the chemical action of the gas on the glass by R. S. Willows, who found that the absorption was greatest with soda glass, less with lead glass, and least with Jena glass; of the occlusion of gas in the glass by A. A. C. Swinton; and by S. E. Hill, of the chemical action produced by the formation of active nitrogen.

The permeability of indiarubber to gases.—According to T. Graham, indiarubber absorbs about 0·0113 times its volume of hydrogen. In 1786, J. Priestley[13] noticed that indiarubber was permeable to gases; and J. K. Mitchell, in 1831, found that carbon dioxide diffused through a rubber membrane faster than hydrogen, and hydrogen, in turn, passed through more quickly than oxygen.

T. Graham measured the rates of diffusion of gases through rubber, and found that the rate at which the gases pass through rubber is not dependent on the densities of the gases. Equal volumes of the following gases penetrate rubber in the relative periods of time here indicated (nitrogen unity):

Carbon dioxide.	Hydrogen.	Oxygen.	Methane.	Carbon monoxide.	Nitrogen.
13·585	5·500	2·556	2·148	1·113	1·000

so that 2·556 volumes of oxygen penetrate the rubber in the same time as one volume of nitrogen. J. Dewar found with a membrane 0·01 mm. thick, and at atm. pressure, at 15°, the number of c.c. of gas which diffused per day per sq. cm.:

Air	N_2	CO	He	A	O_2	H_2	CO_2
2·0	1·38	1·88	3·5	2·56	4·0	11·2	28·0

No relation can be detected between the chemical composition or physical properties of a gas and its diffusibility through rubber. The speed increases proportionally with a rise of temperature. By plotting the logarithm of the rate against temperature, straight lines are obtained; these lines show a distinct break at 0°, suggesting that water is in some way involved; with carbon dioxide there is also a more pronounced break at $-37°$. H. Kayser found that the quantity of hydrogen which passes in unit time through a sq. cm. of surface and 1 cm. thick, when there is a difference of pressure of one atmosphere on the two faces of the rubber, can be represented by $(0·0001580\theta-0·000537\theta^2)$ c.c. per minute for temperatures θ between 9° and 33°. The effect of passing air through a vessel with rubber walls, a vacuum on the outside of the rubber, can be obtained by multiplying these numbers by the partial pressure of the gases. With air, P. Margis (1882) found that the mixture which diffused through the rubber walls contained 40 per cent. of oxygen; when this product was again passed through the apparatus a mixture containing 60 per cent. of oxygen was obtained; a third passage gave a mixture with 80 per cent. of oxygen, and after a fourth passage, the mixture contained 95 per cent. of oxygen. The phenomenon appears to depend on an absorption or occlusion of the gas by the rubber, and the subsequent evolution of the gas on the side under reduced pressure. G. Hüfner says that he found grey vulcanized rubber absorbed no measurable amount of hydrogen between $-2°$ and 13° at 760 mm. G. Austerwell and J. B. L. Juhle studied the diffusion of hydrogen through the walls of gas balloons.

According to J. Hunter,[14] cocoanut *charcoal* absorbs 4·4 times its volume of hydrogen reduced to 0° and 760 mm. The amount absorbed is proportional to the pressure (temperature constant), and inversely proportional to the temperature (pressure constant); and, according to H. Kayser, if p denotes the pressure, and v the volume of hydrogen absorbed per c.c. of charcoal, $v=6·036-1·55 \log p$ at 0°; J. Dewar found that charcoal absorbed 4 c.c. of hydrogen, and at $-185°$, 135 c.c. (reduced to n.p.t.); and J. L. Baerwald (1906) found that the volume of hydrogen absorbed at different temperatures by one volume of charcoal when the volume of gas is reduced to 0° and 760 mm.

	10°	0°	−10°	−50°	−100°	−150°	−185°
Hydrogen absorbed	3	4	4	9	24	76	135 vols.

Neither platinum nor palladium shows this remarkable increase in absorptive power at low temperatures. J. Dewar used the energetic absorption of hydrogen by wood charcoal to separate this gas from neon, helium, etc., which are absorbed to a far smaller degree, and this is in accord with the rule that the lower the boiling point, or the more volatile or less condensable the gas, the less is it absorbed by wood charcoal. J. W. McBain investigated the absorption of hydrogen by charcoal and found at the temperature of liquid air and 19 mm. pressure, the solubility is 4·1 c.c. of gas per gram. He also assumes that the absorbed gas is in the atomic condition. J. W. McBain further showed that the process of occlusion is of a dual character. If the surface of charcoal is first supersaturated by a short exposure to hydrogen at a high pressure, and a portion of the hydrogen be then removed, there is first a rise of pressure owing to the escape of the gas condensed or adsorbed on the surface, the pressure then slowly falls owing to the slow diffusion of the gas into the interior where it is absorbed or occluded to form a solid solution. He proposes to include both processes—rapid surface *adsorption*, and slow internal *absorption*—by the general term *sorption*.

§ 7. The Physical Properties of Hydrogen

Hydrogen was once used as the standard for the atomic weights because it is the lightest element known. It is so much lighter than air that it escapes very quickly from a jar with its mouth upwards, and slowly from a vessel with its mouth downwards. For the **weight of a litre** of hydrogen at 0° and 760 mm. the data by H. Cavendish correspond with 0·092 grm.; A. L. Lavoisier, 0·0769 grm.; T. Thomson, 0·0693 grm.; J. B. Biot and F. J. Arago, 0·0732 grm.; P. L. Dulong and J. J. Berzelius, 0·0688 grm.; and J. B. A. Dumas and J. B. J. D. Boussingault, 0·0695 grm. These determinations are merely of historical interest. Later and more accurate determinations by H. V. Regnault gave 0·0896 at Paris, and when this value was corrected for the difference in volume between an exhausted and full globe, J. M. Crafts found that H. V. Regnault's value should be 0·08988 at Paris. J. P. Cooke's value at 45° and sea level is 0·089864; A. Leduc's, 0·08982; Lord Rayleigh's, 0·089979; E. W. Morley's, 0·089873; and J. Thomsen's, 0·089947. The numbers [1] thus range from 0·0896 to 0·090032 for the weight of a litre of hydrogen at 0° and 760 mm. pressure, at latitude 45° and sea level—the best representative value is taken to be 0·08985 grm. For the **density** of hydrogen (air unity), H. V. Regnault gave 0·0692 grm. (air unity), and with J. M. Craft's correction, 0·06949. J. P. Cooke gave 0·06958; A. Leduc, 0 06947; Lord Rayleigh, 0·06960. The data for the density of hydrogen, air unity, thus vary from 0·06927 to 0·06960, and the best representative value is taken to be 0·0694 (air unity). Hydrogen is 14·37, say 14½, times lighter than air; 11,160 times lighter than water; and 151,700 times lighter than mercury. According to J. Dewar, the density of hydrogen at its boiling point, —252·5°, is 0·55, air unity; and according to V. Meyer, the density does not alter at high temperatures. Liquid hydrogen has a **specific gravity** about $\frac{1}{14}$th that of water—and the variation of the specific gravity with the absolute temperature T, according to J. Dewar, is such that the specific gravity at T is $0·04136–0·000247T$; it is 0·0700 at —252·5°; 0·0754 at —258·3°; and 0·0763 at —259·9°. According to H. K. Onnes and C. A. Crommelin, solid hydrogen had a specific gravity of 0·0763 at —259·9°, and 0·08077 at —262°. The contraction on freezing is about 4·8 per cent. of the liquid volume. The **atomic volume** of liquid hydrogen is therefore 14·3; and according to J. Dewar, the molecular volume of hydrogen at absolute zero is 24·18 (extrapolation).

The **weight of a hydrogen atom** was estimated by R. D. Kleeman [2] to be $1·56\times10^{-24}$ grm., and J. Perrin estimated the mass of the hydrogen atom to be $1·4\times10^{-24}$ grm. The mean **diameter of the molecule** of hydrogen is $2·68\times10^{-8}$ cm.; the **volume of the molecule,** 10^{-25} c.c.; the mean **free path** of the molecule is $18·3\times10^{-6}$ to $17·8\times10^{-6}$ cm.; the **number of molecules per c.c.** is $2·75\times10^{19}$; the **collision frequency** is $92·8\times10^{8}$, or $1·64\times10^{29}$ per c.c. per second; and the **molecular velocity** 169,400 cm. per second. The value of J. D. van der Waals' a=0·00042, and of his b=0·00088, and J. J. van Laar has discussed the variability of these magnitudes.

Published data [3] for the **viscosity** of hydrogen gas at 60°, vary from $82·2\times10^{-6}$ to $85·74\times10^{-6}$ C. G. S. units—the mean may be taken as the best representative value. According to P. Breitenbach, at 15° the viscosity is $88·9\times10^{-6}$; at 99·2°, $182·4\times10^{-6}$; and at 302°, $139·2\times10^{-6}$; K. L. Yen gives η=0·000088216 with an accuracy of 0·15 per cent. at 23° and 760 mm. The viscosity at a temperature 23° is 0·000088216 ± 0·15 per cent. According to W. Kopsch, the viscosity decreases from $83·7\times10^{-6}$ at —0·1° to $80·2\times10^{-6}$ at —17·8°; to $71·0\times10^{-6}$ at —60·2°; to $37·42\times10^{-6}$ at —194·9°. According to J. E. Verschaffelt, the viscosity of the saturated vapour of hydrogen at 20·4° K. and 769 mm. pressure is 0·000010; and of the liquid, 0·000130. The coefficient C in W. Sutherland's equation for the relation of viscosity with temperature $\eta=\eta_0\{(273+T)/(T+C)\}(T/273)^{\frac{1}{2}}$, has the value 127; Lord Rayleigh gave 128·2; H. Markowsky, 138; and F. Kleint, 136. A gas experiences frictional effects not only when two of its layers flow past one another with different speeds—internal *friction* or viscosity—but also when it streams along the surface of a fixed body or of a body which moves with it—external friction. The gas does not adhere firmly to the solid, but slips along it. If γ be the coefficient of slip, η the viscosity, and ϵ the external friction, $\gamma=\eta/\epsilon$. For hydrogen, A. Kundt and E. Warburg, and O. E. Meyer, give $\gamma=0·0000186$. Liquid hydrogen has a **surface tension** $\frac{1}{35}$th that of water, or 0·2 of that of liquid air. According to P. L. Dulong,[4] the **velocity of sound** in hydrogen gas is 1269·5 metres per second at 0°, and according to I. B. Zoch, 1286·362 metres per second at 0°.

The value of the product *pv* for hydrogen has beenstudied by S. von Wroblewsky[5] up to 70 atm.; by E. H. Amagat up to 3000 atm.; and by W. J. de Haas up to 30,000 atm. pressure. The results show that the volume of the gas at high pressures is greater than is indicated by Boyle's law. Arbitrarily assuming that the product *pv* is unity at 0° and one atm. pressure, then,

Pressure .	1	500	1000	1500	2000	2500	2800 atm.
Volume .	1·00000	0·002713	0·001725	0·001380	0·001194	0·001078	0·001024
pv . .	1·0000	1·3565	1·7250	2·0700	2·3890	2·6950	2·8686

According to H. K. Onnes and H. H. F. Hyndmann the compressibility of hydrogen at 20° is given by equation $pv=1·07258+0·000667/v+0·00000099/v^2$. A. Jaquerod and O. Scheuer give the compressibility $-(d(pv)/dp)/pv$ between 400° and 800° as −0·00052; A. Leduc gives −0·00064; D. Berthelot, −0·00060; P. Chappius, −0·00058; and Lord Rayleigh, −0·00053. S. von Wroblewsky and W. J. de Haas found the **compressibility** of hydrogen does not follow Boyle's law at high temperatures. It falls from 0·000408 at 1000 atm. to 0·000158 at 30,000 atm. pressure. According to P. A. Guye, the value of $d(pv)/pv.dv.$ is +0·00052 from 0 up to 1 atm. pressure, and 0·00069 from 40 to 70 cm. pressure—temperature 0°. According to L. Cailletet, the compressibility at 15° falls regularly between 60 and 505 atm.; while E. H. Amagat noted that it follows Boyle's law up to 250°, at 3 to 6 mm. pressure; J. A. Siljeström found its elasticity higher than is required by Boyle's law, only at pressures below one atm.; but at very low pressures, F. Fucks, E. Budde, and C. Puschl obtained negligibly small deviations. These results were confirmed by Lord Rayleigh, who found that the product *pv* at low pressures, 3 to 6 mm., is in conformity with Boyle's law for hydrogen.

The effect of variations of temperature and pressure on the **coefficient of thermal expansion** of hydrogen is, for small pressures,

Pressure . .	0·0077	0·025	0·47	0 93	11·2	76·4	100 mm.
Temperature .	16°–132°	15°–132°	12°–185°	—	—	—	0°–100°
$a\times10^2$ . .	0·3328	0·3623	0·3656	0·37002	0·36548	0·36504	0·36626

According to P. von Jolly,[6] the coefficient of thermal expansion (pressure constant) is $a=0·0036562+0·0000010001\theta$; and according to M. W. Travers, G. Senter, and A. Jaquerod, the pressure coefficient (temperature constant) is $\beta=0·00366255$, or very nearly 1/273·03 per degree. A. Leduc gives $a=0·003662$, and $\beta=0·003664$ from 0° to 100°. A. W. Witkowsky has calculated the coefficient of thermal expansion (pressure constant) from −212° up to 100°. Hydrogen has a **thermal conductivity** about seven times larger than air.[7] The great heat conductivity of hydrogen was noticed by J. Priestley as early as 1781; and F. C. Achard in 1783. According to N N. Beketoff, the conductivity expressed in terms of the number of calories transmitted per second through a layer 1 cm. thick per sq. cm. of surface when the difference of temperature at the two sides is 1°, is 0·000327 (0°), 0·0003693 (100°), and at θ°, the conductivity is $0·000327\ (1+0·00175\theta)$; S. Weber gives 0·0004165. L. Graetz's values for the heat conductivity of hydrogen at 0° and at 100° are respectively 0·0003190 and 0·0003693. The increase of the conductivity with temperature θ° is represented by $0·0003190\ (1+0·006\theta)$. According to J. Janssen, the ratio of the cooling velocity of hydrogen to that of air is 1·000 : 7·459

—the calculated value is 1 : 7 : 1. According to P. A. Eckerlein, the thermal conductivity falls from 0·0003186 at 0°, to 0·0002393 at —59°, and to 0·0001175 at —150°.

The **specific heat** of hydrogen[8] at constant volume, C_v, is 2·4 when referred to an equal weight of water, and 0·99 referred to an equal volume of air. The specific heat at constant pressure, C_p, is 0·2438 between —28° and 9° ; and the molecular heat C_p, at 16° is 3·403 ; at —76°, 3·157 ; and at —181°, 2·644 ; from 20° to 50°, 3·4212 ; and from 20° to 100°, 3·4226. The molecular heat, C_p, rises from 3·402 at atmospheric pressure to 3·788 at 30 atm. pressure. A. Eucken gives C_v=3·20 for hydrogen at a concentration of 2·67 gram-molecules per litre at 35° K., and C_v=3·14 at 45° K. ; for hydrogen at a concentration 22·3 gram-molecules per litre C_v=3·32 at 35° K., and 3·28 at 45° K. G. Vieille estimates the **molecular heat** at constant volume and ordinary temperatures as 4·8 ; at 3100°, 6·30 ; at 3600°, 7·30 ; and at 4400°, 8·10. According to W. H. Keesom and H. K. Onnes (1918), the atomic heat of liquid hydrogen at 14·82° K. is 1·75 and 2·26 at 20·11° K. ; the atomic heat of the solid at 12·55° K. is 0·64. A. Eucken gives for the molecular heat of liquid hydrogen C_p=3·95 at 17·4° K., and 4·70 at 21·3° K. For temperatures between 11° and 95°, and pressures p up to 34 atm., S. Lussana gives for the molecular heat C_p=3·4025+0·013300(p—1). W. Nernst and H. von Wartenburg give C_v=4·68+0·00026T, where T denotes the absolute temperature. M. Pier's value for C_p between 0° and 2350° is C_p=4·700+0·0004θ ; and G. N. Lewis and M. Randall's value, C_p=6·50+0·0009T, for hydrogen molecules. According to A. Eucken, the specific heat of diatomic hydrogen below 60° K. is the same as for monatomic gases, viz. 2·98. According to R. Clausius, **the ratio of the two specific heats** is 1·3852 ; O. Lummer and E. Pringsheim give 1·4084 ; K. Scheel and W. Heuse, 1·407 ; J. Jamin and F. Richard, 1·41 ; M. C. Shields gives 1·4018 at 18° ; and W. C. Röntgen, 1·3852. According to A. Eucken, the ratio of the two specific heats at —180° is 1·604 ; according to K. Scheel and W. Heuse, 1·595 ; and according to M. C. Shields, 1·592 at —191°. This makes it appear as if the hydrogen molecule entirely loses its two degrees of rotational freedom at low temperatures. According to J. Dewar, the atomic heat of liquid hydrogen is 6·4, and this is higher than that of any other known liquid. The atomic heat is therefore in conformity with Dulong and Petit's rule. N. N. Beketoff gives the atomic heat of hydrogen absorbed in palladium as 5·88. G. N. Lewis and G. E. Gibson estimate the **entropy** of hydrogen gas at 25° to be 29·4 per gram-molecule, when the increase of entropy from absolute zero to the melting point T is $\phi=\int C_p d \log T$=0·5, from the solid to the liquid at the melting point 32/15=2·13 ; from the melting point to the boiling point 1·22 ; from the liquid to the gas at the boiling point, 218/20·5=10·73 ; and of the gas from its boiling point to 298° K., 14·80.

In 1877, L. P. Cailletet noticed the formation of a mist when hydrogen at a pressure of about 280 atm. is suddenly released ; in 1884, S. von Wroblewsky obtained signs of liquefaction when hydrogen at a pressure of 190 atm. and cooled by boiling nitrogen is suddenly relieved. In 1884–5, K. Olszewsky reported that he obtained colourless drops of liquid hydrogen by a similar process. J. Dewar (1895) first obtained sufficient liquid hydrogen to show a definite meniscus by applying the regenerative process to the gas cooled to —205°. Just below the **critical temperature,** —241°, a pressure of about 15 atm. will liquefy the gas ; above the critical temperature no pressure, however great, will liquefy the gas. The **critical pressure** is 20 atm., and the **critical volume** 0·00264. Liquid hydrogen is clear and colourless, thus resembling water ; it has a sharp meniscus, and a high refractive index and dispersion. Its **boiling point** is —252·77°, or 20·5° K. ; P. G. Cath and H. K. Onnes[9] give 20·39° K., and they found for the **vapour pressure** of liquid hydrogen, at T° K., between 24·59° K. and 32·93° K., $T \log p=-56·605+3·8015T-0·10458T^2+0·003321T^3-0·00005102T^4$ atm.; while, according to M. W. Travers, G. Senter, and A. Jaquerod, the vapour pressure is, on the absolute scale of temperatures,

Temp. (abs.) .	20·41°	19·93°	19·41°	18·82°	18·15°	17·36°	19·37°	14·93°
Vapour pres. .	800	700	600	500	400	300	200	100 mm.

Hydrogen solidifies to a transparent mass like ice with a foamy surface, when the liquid is evaporated rapidly in a partial vacuum. The unique temperature, called the **triple point,** where the liquid, solid, and vapour are all in equilibrium, is near —259° and 55 mm. pressure. The white solid is crystalline and, according to J. Dewar, its **melting point** is —259·2°. The data concerning the change of state of hydrogen can be symbolized :

$$\text{Hydrogen}_{\text{solid}} \overset{-259\cdot2^\circ}{\rightleftharpoons} \text{Hydrogen}_{\text{liquid}} \overset{-252\cdot77^\circ}{\rightleftharpoons} \text{Hydrogen}_{\text{gas}}$$

W. Wahl found the velocity of crystallization of hydrogen to be very great at about 20° K. He obtained isotropic **crystals** belonging to the cubic system—either trisoctahedrons or hexoctahedrons. Needle-like branches grow at right angles to a fully developed crystal face. The **latent heat of vaporization** of liquid hydrogen is nearly 218 cals. at its boiling point. A. Eucken gives 229 cals.; W. H. Keesom, 222 cals.; and W. H. Keesom and H. K. Onnes, 212 cals. J. Dewar's value for the **latent heat of fusion** of the solid is 15 to 16 cals.[9] per gram-atom.

M. Croullebois[10] gives 1·000137 as the mean **index of refraction** of hydrogen for white light. J. Koch gives for light of wave-lengths $\lambda=230\cdot2\mu\mu$, 1·0001594 ; $\lambda=354\cdot4\mu\mu$, 1·0001449 ; $\lambda=435\cdot8\mu\mu$, 1·0001488 ; $\lambda=546\cdot1\mu\mu$, 1·0001397 ; $\lambda=670\cdot8\mu\mu$, 1·0001385 ; and for the ultra-red rays $\lambda=6709\cdot4\mu\mu$, 1·0001361 ; and $\lambda=8678\cdot4\mu\mu$, 1·00013611 at 0° and 760 mm. Analogous observations have been made by E. Ketteler, L. Lorenz, E. Mascart, E. Perreau, K. Scheel, and by C. and M. Cuthbertson. J. W. Brühl, H. Landolt, and F. Eisenlohr have calculated the **atomic refraction** by Gladstone and Dale's formula, and J. H. Gladstone gives for the *A* line 1·29 ; J. W. Brühl and J. Traube, and H. Landolt, by Lorenz and Lorentz's formula, give 1·02 for the *A*-line. The dispersive power of hydrogen from M. Croullebois' datum is 0·1814 (air unity) ; while W. Ramsay and M. W. Travers give 0·4733. K. Hermann gives for the relative dispersion $V^{-1}=(F-C)/(\mu D^{-1})$, when $V=65\cdot9$. L. Natanson, R. Ladenburg, and S. Loria have also studied the dispersion of hydrogen. J. W. Brühl gives for the atomic dispersion of hydrogen $R_\gamma-R_a=0\cdot036$. C. and M. Cuthbertson find that b of Cauchy's dispersion formula, $\mu-1=a(1+b/\lambda^2)$, rises gradually between the red and violet. Better results are obtained with $\mu-1=C/(n_0^2-n^2)$, where the constants $C=1\cdot692\times10^{27}$, and n_0 is 12409×10^{27}—and for oxygen it is $3\cdot397\times10^{27}$, and for nitrogen $5\cdot0345\times10^{27}$. Hence, these three elements agree with P. Drude's rule $C/v=\text{constant}$, when v denotes the positive valency of the atom.

The **magneto-optic rotation** of a body refers to the angle through which a ray of polarized light is rotated when the light is passed through the body in a direction parallel to the lines of magnetic force. This phenomenon with glass was discovered by M. Faraday[11] in 1845 ; it was afterwards noticed that the amount of rotation depends on the nature of the substance, on its physical condition, on the strength of the magnetic field, and on the wave-length of the polarized light. A. Kundt and W. C. Röntgen noticed the phenomenon with gases in 1879. The rotation per cm. per unit magnetic field is called **E. Verdet's constant,** for E. Verdet showed, in 1853, that with the same medium and magnet, the rotation is directly proportional to the intensity of the magnetic field. The product of E. Verdet's constant with the molecular volume—or M/D—is called the **molecular rotation.** The molecular rotations of many substances have been found to be additive, for they are the sum of constants for the constituents of the molecules. For a pressure 85 kgrms. per sq. cm., and 9·5°, and light of wave-length λ, E. Verdet's constant[12] is $0\cdot00007585\lambda^{-1}+0\cdot00002295\lambda^{-3}$ for values of λ between $0\cdot423\mu$ and $0\cdot684\mu$.

If a continuous discharge be passed through a Geissler's tube containing hydrogen at a pressure of 0·05 to 3·00 mm., there is a white glow in the capillary, and strata, alternately pale pink and pale blue, appear about the electrodes. The white glow, in the spectroscope, appears as a multitude of lines of varying intensity, and hence is called the *white spectrum* of hydrogen. If a condenser of large capacity is introduced into the circuit, the oscillatory discharge changes the colour of the glow from white to deep red. Most of the spectral lines are obliterated and the so-called *four-line spectrum* or the *red spectrum* of hydrogen is obtained which is comparable with the blue spectrum of argon. The four-line spectrum of hydrogen[13] is conveniently observed in a Geissler's tube, with the gas at about a millimetre pressure, and through which a discharge from an induction coil is passing; the four lines, shown in Fig. 15, correspond with H_α in the red with a wave-length 6564·97; H_β in the greenish-blue 4862·93; H_γ in the indigo-blue 4341·90; and H_δ in the violet 4103·10; these lines correspond respectively with Fraunhofer's dark lines, *C*, *F*. *G*, and *h*. According to L. Janicki (1906), the red line is really a double one. If the oscillatory discharge is suitably damped, the obliterated lines preceding the four-lines spectrum gradually reappear. F. Emich considers it possible to detect up to 7×10^{-14} milligram of hydrogen by means of its spectrum in a vacuum tube. H. W. Vogel and A. Paalzoff have photographed a great many other lines chiefly in the violet and ultra-violet spectrum of hydrogen, and compared them with analogous lines in the spectra of the sun and stars. A. Wüllner and J. Plücker and W. Hittorf showed that hydrogen furnishes a second and yet a third spectrum, which A. Schuster and A. V. Angström ascribed to the presence of acetylene or sulphur. G. Salet also failed to verify the observation with pure hydrogen. Several observers, however, have verified the existence of the white spectrum in which the usual four hydrogen lines are present though not specially prominent. According to J. Trowbridge and T. W. Richards, hydrogen containing a trace of water vapour readily gives the red four-line spectrum with a continuous discharge, while the perfectly dry gas gives the white spectrum, and a very great strength of current is then required to produce the red four-line spectrum.

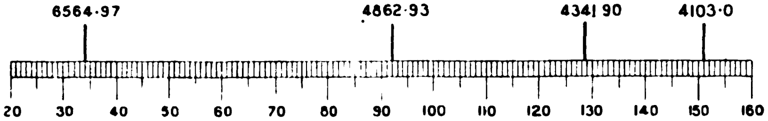

Fig. 15.—The Four-line Spectrum of Hydrogen in a Geissler's Tube.

B. Hasselberg postulates that the difference in the hydrogen spectra are due to dissociation. He says:

> As the explanation of the displacement of a spectrum by a new one with rise of temperature, and the first spectrum (of hydrogen) must be ascribed to a more complicated arrangement of molecules or to a compound of the body with itself. Since, according to the investigations of Wiedemann, in the case of hydrogen a continual rise in temperature produces first a gradual diminution of the spectrum above described, and then upon reaching a certain limit its almost sudden disappearance, these considerations lead us to the view proposed as a second alternative by Angström, according to which the spectrum belongs to a compound of hydrogen with itself. The heat-equivalent found by Wiedemann for the quantity of energy necessary to transform this spectrum into that consisting of the three characteristic bright lines, would therefore be nothing else than the thermal equivalent of the corresponding work of dissociation. This hypothesis furnishes an easy explanation of the fact that in the spectra of the sun and most stars only the characteristic lines of this gas appear as bright lines or absorption lines, as the case may be detected. The reason is to be found in the enormous temperatures existing in these bodies.

J. N. Lockyer also believes dissociation occurs in flame and spark; and A. Dufour pointed out that the gas in a Geissler's tube is under conditions specially favourable for dissociation, for the pressure is low and the temperature high.

E. Frankland and J. N. Lockyer found that with a feeble current, or by changing the pressure and temperature, the spectrum of hydrogen can be reduced to a single *F*-line. With increasing pressures the spectrum of hydrogen approaches a continuous one.

TABLE II.—BALMER'S SERIES OF LINES IN THE ARC SPECTRUM OF HYDROGEN.

H line.	n	Wave-length, λ.		Difference.
		Calculated.	Observed.	
H_α or C	3	6564·96	6564·97	+0·01
H_β or F	4	4862·93	4862·93	—
H_γ or G	5	4341·90	4342·00	−0 1
H_δ or *h*	6	4103·10	4103·11	+0·01
H_ϵ or H	7	3971·4	3971·4	—
H_ζ or *a*	8	3890·3	3890·3	—
H_η or β	9	3836·7	3836·8	+0·1
H_θ or γ	10	3899·2	3799·2	—
H_ι or δ	11	3771·9	3771·9	—
H_κ or ϵ	12	3751·4	3751·3	−0·1
H_λ or ζ	13	3735·6	3735·3	−0·3
H_μ or η	14	3723·2	3722·8	−0·4
H_ν or θ	15	3713·2	3712·9	−0·3

In 1885, J. J. Balmer discovered a remarkable relation between the vibration-periods or the wave-lengths of the spectral lines of hydrogen; if the different lines in the spark spectrum of hydrogen be numbered consecutively, starting with the H_a-line as number 3, the next 4, 5, 6 . . ., the wave-length of the nth line is given by

$$\lambda=3647{\cdot}2\frac{n^2}{n^2-4}; \text{ or } \lambda=3647{\cdot}2\frac{n^2}{n^2-2^2}$$

J. S. Ames' measurements are compared in Table II with values calculated by means of J. J. Balmer's formula. The agreement between the calculated and observed wave-lengths is very good, and hence the preceding formula may be taken to represent closely the various kinds of elastic vibration which prevail among the vibrating particles which produce **Balmer's series** of lines in the spark spectrum of hydrogen. According to R. W. Wood, the different lines of the principal Balmer's series and their accompanying channelled spectra are probably produced by different entities—either by atoms which have lost 1, 2, 3, 4, . . . electrons, or by aggregates or complexes of 1, 2, 3, 4, . . . atoms. In either case, it seems probable that the members would break up in continuously increasing numbers. W. E. Curtis' measurements led him to make a slight modification in Balmer's formula. W. Ritz and F. Paschen[14] found that there is another series of lines in the ultra-red spectrum of hydrogen—the so-called **Paschen's series**, represented by $\lambda=an^3/(n^2-3^2)$, where a is a constant; and the so-called **Lynman's series** represented by $\lambda=an^2/(n^2-1^2)$, in the ultra-violet.

F. Croze,[15] and F. Paschen and E. Back have measured the *Zeeman effect* for the primary lines of the hydrogen spectrum, *viz.* H_a, H_β, H_γ, and H_δ. J. Stark and co-workers have shown that certain hydrogen lines of the primary and secondary series are resolved into linearly polarized components under the influence of a strong electrical field of 1300 volts per cm. The longitudinal components are not polarized so that the effect of the electrical field—*Stark effect*—is in marked contrast with the Zeeman effect, for in the latter case the components are circularly polarized. With still stronger electrical fields, 104,000 volts per cm., J. Stark found a separation into further components. T. Takamine, N. Kokubu, and U. Yoshida have also investigated the Stark effect on the hydrogen lines with a field strength of 15,000 volts per cm., and found that besides the primary lines, eleven lines in the region below $\lambda=4000$ were affected. C. Fabry and H. Buisson have made estimates of the mass of the particles which emit the first and second hydrogen spectra, and found that is the same as that of an hydrogen atom. B. Reismann found hydrogen shows both its spectra at the anode and cathode of a Geissler's tube excited by a direct current discharge. H. L. P. Jolly has measured the distribution of energy in the spectrum of hydrogen.

J. Tyndall could find no absorption of invisible heat radiations by hydrogen at atm. pressure. Neither J. Janssen (1885)[16] nor V. Schumann could find an **absorption spectrum** for hydrogen gas; W. Barmeister found hydrogen gas has no infra-red absorption bands. J. Dewar (1894) did not find any in the liquefied gas. Hydrogen thus appears to be the most transparent of all known bodies; even the Schumann rays powerfully absorbed by other gases are freely transmitted by hydrogen. In 1907, A. Pflüger, and R. Ladenburg and S. Loria showed that an absorption spectrum can be obtained while the gas is in a state of luminescence during its excitation by the discharge. Several others have since studied the absorption spectrum of hydrogen.

A. L. Lavoisier and P. S. de Laplace[17] noticed that the hydrogen which is liberated by the action of sulphuric acid on iron is positively electrified; and in the case of zinc, W. Hankel showed that when the gas is positively electrified, the sulphuric or hydrochloric acid and the metal are negatively electrified. J. S. Townsend showed that the electrification is not due to the spray mechanically carried by the gas but is produced during the bubbling of the gas through the acid. J. Enright showed that this is but a special case of electrification by chemical action. J. Franck,[18] R. Pohl, and W. B. Haines have shown that free electrons exist in hydrogen gas at atmospheric pressures. Hydrogen gas, according to E. Villari, resists the passage of an electric spark less than nitrogen, oxygen, or carbon dioxide. The **discharge tension** in gases is influenced by numerous factors—temperature, pressure, form of electrodes, the character of the spark, etc.—with spherical electrodes at 0·08 cm. apart, the discharge potential is 2·4 kilovolts for hydrogen, 3·9 for air, 3·7 for carbon monoxide, 4·9 for nitrogen, and 3·4 for oxygen; with the electrodes 0·5 cm. apart, the numbers are respectively 9·7, 17·5, 15·8, 18·0, and 15·6 kilovolts. The difference between the potential of a plane and of a point placed at right angles to the plane, needed for the passage of electricity, is called the *minimum potential*. The observed minimum potentials depend on the sharpness of the point. W. C. Röntgen[19] found 1296 and 1174 volts respectively for hydrogen at 205 and 110 mm. pressure; and F. Tamm found that the decrease with high pressures is small, but more rapid with low pressures. J. Precht obtained for a + point 2135 volts and for a − point 1550 volts in hydrogen at 760 mm. E. Warburg, H. Sieveking, and F. Tamm measured the relation between the current and potential. A. L. Hughes and A. A. Dixon found the **ionizing potential** is dependent on the least energy necessary to ionize the molecules of a gas by the impact of electrons, and amounts to 10·2 volts for hydrogen; J. Franck and G. Hertz found 11 volts, F. S. Goucher, 10·25 volts; and the value calculated by K. T. Compton's formula $V=0{\cdot}194(K-1)^{-\frac{1}{2}}$ is 11·8 volts, where V denotes the ionizing potential, and K the specific inductive capacity. F. M. Bishop obtained 11 volts, and found the result independent of the pressure. W. J. Paloff obtained a similar result. F. M. Bishop also found a second type of ionization at 15·8 volts. Neither value is in accord with Bohr's theory, which requires for the ionization potential 10·2 volts for the first line of longest wave-length, and 13·6 volts for the shortest wave-lengths.

The **ionization** of hydrogen gas by Röntgen rays has been studied by R. K. McClung, A. S. Eve, J. A. Crowther, G. Shearer, H. Donaldson, N. Campbell and C. G. Barkla, and A. J. Philpot; by radium radiations by A. S. Eve, L. Wertenstein, W. Seitz and N. Campbell; by α-rays by C. G. Darwin, W. Duane and G. L. Wendt, T. S. Taylor, E. Rutherford and J. M. Nuttall, E. Marsden, and R. D. Kleeman; by β-rays, by H. W. Schmidt; by γ-rays, by T. H. Laby and G. W. C. Kaye and R. D. Kleeman; by radium bromide by H. Baker; by radiations from polonium by T. S. Taylor; by radiations from actinium by R. D. Kleeman; by light from a Geissler's tube by H. G. Cannegieter; by canal rays by R. Seeliger; by collision by E. S. Bishop and W. J. Pawloff; and by spraying by L. Block. The ionization of the hydrogen flame has been studied by M. de Broglie. The action of hydrogen on the electric discharge between various metals has been studied by A. Thiel and E. Breuning, J. N. Pring, O. W. Richardson, H. A. Wilson, A. Becker, and C. Sheard. The electric discharge in hydrogen or in hydrogen mixed with other gases has been studied by E. M. Wellisch, K. E. F. Schmidt, J. Trowbridge, K. Fredenhagen, A. P. Chattock, and A. M. Tyndall. The mean values of J. Zeleny's, J. Franck's, R. Pohl's, and A. P. Chattock's determinations of the velocities of the positive and negative hydrogen ions when the electric discharge in a field of 1 volt per cm. are respectively 6·06 and 7·69 cm. per second. J. Townsend gives for the diffusion coefficient of the positive and negative ions respectively 0·123 and 0·190 per sq. cm. per second. J. Townsend, and R. K. McClung give respectively $dn/dt=3020n^2$, and $dn/dt=-2940n^2$, where n denotes the concentration of the ions, and dn/dt the velocity of combination of the ions to form ordinary molecules. H. A. Erickson and P. Phillips have studied the effect of temperature on this reaction. F. W. Aston estimates that the minimum energy required for the ionization of the hydrogen atom in a gas is $1·7\times10^{-11}$ erg. W. B. Haines has investigated the mobilities of the positive and negative hydrogen ions. Unlike all other elements yet investigated, J. J. Thomson was never able to impart more than one charge of electricity to the hydrogen atom.

According to the ionization hypothesis, the acids are more or less ionized in aqueous solution, and they all furnish in common hydrogen ions which act as carriers of positive electricity. The characteristic properties of acids are assumed to be the characteristic properties of $H^{\cdot}$-ions; during electrolysis the positively charged hydrogen cations are discharged at the cathode, and the negatively charged anions are discharged at the anode. The electric charge carried by a gaseous ion is the same as that carried by a $H^{\cdot}$-ion during electrolysis; the charge per ion in the former case is approximately 4×10^{-10} units, although in the latter case the observed numbers vary between 1×10^{-10} and 6×10^{-10} units. Again, the value of e/m, where e denotes the charge and m the mass of the ion, is the same for all gaseous ions, and approximate to 10^7, while the value of the ratio e/m for the hydrogen ion in solution is 10^4. Consequently, the relation between the masses m of the gaseous ion and of the hydrogen ion in solution is as 1 : 1700. The gaseous ion with its negative charge was first called a corpuscle by J. J. Thomson, but the term electron is now in general use. The positively charged hydrogen ion in solution is assumed to be a hydrogen atom which has lost one of its negatively charged electrons; during the scission of the molecule in the process of ionization the electron lost by the hydrogen atom in forming the $H^{\cdot}$-ion remains attached to the other atom or radicle and so imparts a negative charge to the anion.

Solutions containing equivalent quantities of the different acids do not necessarily contain the same quantities of $H^{\cdot}$-ions, for a portion of the acid may not have suffered ionization. There is a state of equilibrium, $HA\rightleftharpoons H^{\cdot}+A'$, in which anion, cation, and un-ionized molecules are present. One or more of these three entities may be more or less hydrated in the solution. The **degree of ionization** is dependent on the concentration of the solution and on the temperature. The equivalent conductivity at infinite dilution λ_∞, when ionization is complete, is the sum of the conductivities of the $H^{\cdot}$-ion, namely, $v^{\cdot}$, and of the anion, v', so that $\lambda_\infty=v^{\cdot}+v'$, or $v^{\cdot}=\lambda_\infty-v'$. The value of the molecular conductivity μ changes with the temperature. According to F. Kohlrausch,[20] the conductivity of the hydrogen ion at $\theta°$ is $v^{\cdot}=318·1+0·0154(\theta-18)-0·000033(\theta-18)^{20}$ reciprocal ohms. W. Ostwald and R. Luther say that F. Kohlrausch's value $v^{\cdot}=352$ (25°) is too high and give $v^{\cdot}=347$ (25°); A. A. Noyes and G. V. Sammet say that F. Kohlrausch's value is too low, and give $v^{\cdot}=364·9$ (25°). V. Rothmund and K. Drucker's value is $v^{\cdot}=338$.

The **hydrogen electrode** is used in measuring the concentration of $H^{\cdot}$-ions in a solution; it is based on the definite difference of potential which exists between a platinum or palladium electrode, saturated with hydrogen gas at a given pressure, and immersed in a solution of definite acidity or alkalinity. The particular forms of the cells are indicated in laboratory manuals. The e.m.f., E, of the cell H_{2Pt} | Solution I | Electrolyte | Solution II | H_{2Pt} is given by

$$E=\frac{RT}{\epsilon}\log_e\frac{[H^{\cdot}]_1}{[H^{\cdot}]_2};\ \text{or}\ E=0{\cdot}000198T\log_{10}\frac{[H^{\cdot}]_1}{[H^{\cdot}]_2}\ \text{volts}$$

where ϵ represents the farad, 96,540 coulombs, and R the gas constant, 9·316 joules. If solution I be 0·01N-HCl, and solution II, 0·001N-HCl, and the temperature be 18°, E=0·058 volt, nearly. The hydrogen electrode with a normal solution of $H^{\cdot}$-ions may be used as a standard, and the hydrogen concentration of a given solution is determined by measuring the e.m.f. of the combination. Suppose it is 0·5 volt at 18°. Consequently, $0{\cdot}5=0{\cdot}058(\log_{10} 1-\log [H^{\cdot}]_x)$ or the required concentration of the $H^{\cdot}$-ions is $2{\cdot}4\times10^{-9}$. The total *temperature coefficient* of the hydrogen electrode is small, and is made up of a number of factors—concentration of dissolved gases, pressure of water vapour or of other gases, etc. *Pressure* raises the positive potential of the hydrogen. If the pressure of the hydrogen is p atm., the correction to be added at 18° is $E-E_p=-\frac{1}{2}$ of 0·058 log p. If the pressure be 740 mm., the correction is $\frac{1}{2}$ of 0·058 log (740/760)=0·00033 volt. The fluctuations of the barometer can usually be neglected.

The hydrogen ions often have a catalytic action accelerating the speed of some reactions, and retarding the speed of others. The catalytic action of the $H^{\cdot}$-ions on the speed of the inversion of cane sugar, the hydrolysis of methyl acetate, etc., has been used to estimate their concentration. The discharge of hydrogen ions furnishes hydrogen molecules $2H^{\cdot}=H_2$. W. Ostwald estimates the **heat of ionization** to be $H_2=2H^{\cdot}-1{\cdot}1$ Cal.; and K. Fajans, the **heat of hydration of gaseous $H^{\cdot}$-ions** to be 362 kgrm. cal. per gram-ion. The **free energy of formation of a hydrogen ion** is found by measuring the difference of potential E between hydrogen gas at a pressure p atm. and a solution of $H^{\cdot}$-ions of concentration C gram-ions per litre at the absolute temperature T, since $E=E_0+RT(\log C-\frac{1}{2}\log p)$, where R, the gas constant, is $0{\cdot}861\times10^{-4}$; and E_0 is the potential when C and p are unity. Measurements by N. T. M. Wilsmore and others give $E_0=-0{\cdot}283$ volt (25°) with the normal calomel electrode zero. The value of E_0 thus measures the tendency of hydrogen to form ions, or half the intensity of the electro-affinity. W. Nernst took the potential of the hydrogen electrode—platinum or platinized palladium saturated with hydrogen—as zero because of its position in a series of the potentials of the different elements. W. Ostwald objected to this because of the large variation which occurs with changes of pressure—one millivolt per 0·0345 atm. The relatively small electro-affinity of the hydrogen ion is correlated with its great tendency to form complex ions. Thus, with ammonia it forms $NH_4^{\cdot}$ ions, and similarly with the various amines and oxonium compounds; likewise also with the anions of the acid salts HSO_2', HSO_3', HCO_3', HC_2O_4', etc.

G. W. Osann[21] obtained a gas which he called *aktiven Wasserstoff oder Ozonwasserstoff* by the electrolysis of a mixture of distilled Nordhausen sulphuric acid and water. He claimed that the gas is a far more active reducing agent than ordinary hydrogen; but neither J. Löwenthal nor G. Magnus could confirm G. W. Osann's conclusions, and they attributed his results to the contamination of his hydrogen with some sulphur dioxide. W. Duane and G. L. Wendt exposed hydrogen, of as high a degree of purity as they could prepare, to the intense bombardment of α-radiations, and found the gas became more chemically active at ordinary temperatures, for it then combined directly with sulphur to form hydrogen sulphide; with phosphorus to form phosphine; with arsenic to form arsine; and with nitrogen to form ammonia. It reacts with mercury forming yellow crystals—possibly *mercury hydride*—which resist attack by water and weak alkali lye, but dissolve in hydrochloric and nitric acids; when gently warmed, the yellow crystals form globules of mercury. The activated hydrogen reduces potassium permanganate solutions forming manganese dioxide; it does not bleach methyl violet or indigo carmine. W. Duane and

G. L. Wendt suggest that the activated gas is related to normal hydrogen as ozone is related to oxygen—a kind of *ozonohydrogen*, H_3. They do not believe that it is monatomic hydrogen because its formation is attended by a contraction in volume. The activation of the hydrogen is not due to the formation of ions because it is not destroyed by the passage of the gas through glass wool and an intense electrostatic field; but it is removed by passing the gas through a tube immersed in liquid air. The **activated hydrogen** is not stable for its life is measured in minutes. J. J. Thomson found that in a discharge tube containing hydrogen, there are present charged atoms, charged molecules, and sometimes a constituent with three times the mass of ordinary hydrogen atoms. The potential used was of the order 20,000 volts.

A. J. Dempster found that with a potential of 800 volts hydrogen is ionized by detaching a single elementary charge from the molecule, but the gas is not dissociated; the positive molecules so formed, however, can dissociate the gas forming the complex H_3. This constituent is not stable, and is not present when there is no dissociation of the hydrogen molecule.

Liquid hydrogen is electrically non-conducting. The **dielectric constant,** K, of hydrogen[22] was found by A. Occhialini to be given by $(K-1)/(K+2)D=90154\times10^{-9}$ between 94 and 196 atm. pressure; and by extrapolation $K=1·0002705$ at ordinary pressures. Other determinations of the dielectric constant of hydrogen gas at atmospheric pressures and 0°, give 1·000264 (vacuum unity), and at 20°, 1·000273—since the dielectric constant of air at 0° is 1·000590, the dielectric constant of hydrogen at 0° is 0·999674 (air unity). At 20° and 20 atm. pressure, the dielectric constant of hydrogen is 1·00500; under 60 atm. pressure 1·01460; and under 100 atm. pressure, 1·02378. At −191°, and 760 mm., H. Riegger found 1·000928. Hydrogen is diamagnetic. The **magnetic susceptibility** of hydrogen at 1 to 40 atm. pressure and 16° is below $0·008\times10^{-16}$ volume units.[23] According to S. Henrichsen, the **atomic magnetism** of hydrogen in organic compounds is 9.

§ 8. The Chemical Properties of Hydrogen

Although **the combustibility of hydrogen** is one of its most characteristic properties, perfectly dry hydrogen ignites with difficulty, if at all, when mixed with perfectly dry oxygen. According to H. B. Baker (1902),[1] the dried mixture may be heated to the melting point of silver—960·5°—without appreciable combination. Note, however, that moisture is a product of the reaction. Many other combustible substances, if perfectly dried, do not burn when moisture is rigorously excluded. The moisture is here said to act as a **catalytic agent**—κατὰ, down; λύω, I loosen. Finely divided platinum and many other metals will cause a mixture of hydrogen and oxygen, at ordinary temperatures, to explode; and if a jet of hydrogen, in air, impinges on finely divided platinum, the metal becomes hotter and hotter, and finally ignites the gas.

"Toy" automatic cigar lighters are made so that by turning the tap of a little hydrogen generator—not unlike the Kipp's apparatus in principle—a jet of hydrogen can be directed on a piece of spongy platinum when a "light" is desired. The platinum becomes hotter and hotter, and finally ignites the jet of hydrogen. The flame is extinguished by turning the stopcock, and the apparatus is ready for another ignition when the jet of hydrogen is again turned on to the platinum. This is the principle of the self-lighting lamp designed by J. W. Döbereiner in 1822. Impurities in the hydrogen gas, however, appear to "poison" the platinum, for the apparatus soon ceases to be effective.

Hydrogen and oxygen, so far as we can tell, may remain an indefinite time in contact with one another at atmospheric temperatures without showing any sign of chemical action. Some say that the gases do react, but very, very slowly. By measuring the diminution in the speed of the reaction from, say, 600° to 500° to 400° to 300°, and assuming that the rate of diminution of the speed of the reaction follows the same law—reduction of the speed by one half per 10° reduction of temperature—it has been estimated that no appreciable amount of hydrogen and oxygen will have combined if a mixture of these gases be allowed to stand at ordinary temperatures 1,000000,000000 years. The student has the option of accepting or rejecting statements like these. They can neither be proved nor disproved. The risks which attend this mode of reasoning about natural processes have already been indicated. As P. Duhem has said (1910): " It comes to the same thing experimentally whether we say that the velocity of a reaction is absolutely null, or that it is so small that there is no way of detecting it."

Shortly after H. Cavendish's work on hydrogen gas, there were suggestions made for using hydrogen lamps for heating purposes; thus, J. Priestley stated that oxygen could be used for producing a very high temperature if fed into the hydrogen flame by means of a suitable bellows; and F. L. Ehrmann, in his *Versuch einer Schmelzkunst mit Hülfe der Feuerluft* (Strassburg, 1785), described the effect of a hydrogen flame, strengthened by admixture with oxygen, upon many substances. About 1801, R. Hare [2] devised an oxyhydrogen blowpipe, which was fully described in his *Memoir of the supply and application of the blowpipe* (Philadelphia, 1802), published by order of the Chemical Society of Philadelphia. The *oxyhydrogen flame* is one of the hottest gas flames known; by its means Robert Hare melted barytes, alumina, and silica and obtained products resembling white enamel. Magnesia and platinum were melted; and, added R. Hare, " had I sufficient confidence in my own judgment, I should declare that silver, gold, and platinum were thrown into a state of ebullition by exposure on carbon to the gaseous flame." When a stick of quicklime is placed at the tip of the flame from a mixture of hydrogen and oxygen burning from a special jet to avoid risk of explosion, the lime does not melt, but it becomes white hot and glows with an intense white light known as *Drummond's light* [3] or the *lime-light* or the *calcium light*. T. Drummond said that the lime-light is of such dazzling whiteness that it is plainly visible sixty-eight miles away. If zirconia be used in place of lime, the *zircon light* is obtained. According to T. Drummond, the light given by zirconia is less powerful than that of lime; and that by magnesia is only half as intense. C. H. Pfaff says that if the light of a wax candle be unity, the light emitted by a cylinder of lime one-fifth the diameter of the flame of a candle is 153 when heated by the oxyhydrogen flame; 76 by the ether-oxygen flame; 69 by the alcohol-oxygen flame; and 19 by the oxygen-coal gas flame. A. Pleischl and M. A. Gaudin studied the flame from oxygen and turpentine, and oxygen and oil gas. The oxyhydrogen flame is used for the autogenous welding of metals, for soldering platinum, for making vessels of fused quartz, etc.

Hydrogen unites chemically, directly or indirectly, with most of the non-metallic and with many of the metallic elements—more particularly the alkali and alkaline earth metals. The binary compounds of the metals with hydrogen are usually called **hydrides**. A. L. Lavoisier, in his *Traité élémentaire de chimie* (Paris, 1. 116, 1789), foresaw the probability of the formation of hydrides, for he said:

> As combustible substances have in general a great affinity for oxygen, they ought likewise to attract, or tend to combine with each other; *quæ sunt eadem uni tertio, sunt eadem inter se*; and the axiom is found to be true. Almost all metals, for instance, are capable of uniting with each other, and of forming what, in common language, are called alloys. Sulphur, phosphorus, and carbon readily unite with metals. Hydrogen is likewise capable of combining with many combustible substances. It is worthy of being examined whether hydrogen in its concrete state, uncombined with caloric, be susceptible of combination with sulphur, phosphorus, and the metals. There is nothing that we know of which, *a priori*, should render these suppositions impossible; for combustible bodies being in general susceptible of combination with each other, there is no evident reason for hydrogen being an exception to the rule. However, no direct experiment yet establishes either the possibility or impossibility of the union. Iron and zinc are the most likely of all metals for entering into combination with hydrogen; but, as these have the property of decomposing water, and as it is very difficult to get them entirely free from moisture in chemical experiments, it is hardly possible to determine whether the small portions of hydrogen gas obtained in certain experiments with these metals were previously combined

with the metal in the state of solid, or if they were produced by the decomposition of a minute quantity of water. The more care we take to prevent the presence of water in these experiments, the less is the quantity of hydrogen produced; and when very accurate precautions are taken, even that quantity becomes insensible.

The hydrides of the non-metals are usually, not always, more stable than the hydrides of the metals. Water can be regarded as an oxygen hydride, as well as a hydrogen oxide. Hydrogen gas reacts directly with fluorine, and this at temperatures as low as —210°, when the fluorine is liquid, or even at still lower temperatures where the fluorine is solid, and the hydrogen liquid.[4] The product of the reaction is hydrogen fluoride, HF; chlorine and bromine unite with hydrogen in light but not in darkness, forming in the one case hydrogen chloride, HCl, and in the other, hydrogen bromide, HBr. Iodine commences to unite with hydrogen at about 200° forming hydrogen iodide, HI. Aqueous solutions of the hydrides of fluorine, chlorine, bromine, and iodine are well-known acids—respectively called hydrofluoric, hydrochloric, hydrobromic, and hydriodic acid. Sulphur or selenium reacts with hydrogen at about 250°, and tellurium at 400°, forming respectively hydrogen sulphide, H_2S, hydrogen selenide, H_2Se, and hydrogen telluride, H_2Te. Hydrogen does not unite with nitrogen by direct heating, but it does so when stimulated by electric sparks or the silent electrical discharge—ammonia gas, NH_3, is the product of the action. Ammonia, NH_3, is a nitrogen trihydride; it is a well-known base. Similar compounds of phosphorus—phosphine, PH_3—arsenic—arsine, AsH_3—and antimony—stibine, SbH_3—also have basic properties; they are obtained indirectly, since direct union, if it occurs at all, is so insignificant when these elements are heated together that it is not at all certain if combination has occurred at all. Carbon and hydrogen do not react at ordinary temperatures. When an electric arc is formed between carbon electrodes in an atmosphere of hydrogen, the two elements unite forming acetylene, C_2H_2, and traces of other hydrocarbons—*e.g.* methane, CH_4. Carbon begins to react with hydrogen, forming methane CH_4, at about 1200°. Carbon forms an extensive series of hydrides usually called hydrocarbons—*e.g.* methane, CH_4; ethylene, C_2H_4; acetylene, C_2H_2; napthalene, $C_{10}H_8$; anthracene, $C_{14}H_{10}$; etc. The direct formation of the silicon or boron hydrides by heating the two elements together has not been satisfactorily demonstrated. Lithium metal burns in hydrogen gas forming lithium hydride, LiH. The alkali and alkaline earth metals unite directly with hydrogen when heated over 300° to form hydrides—*e.g.* potassium and sodium hydrides—KH and NaH respectively; calcium hydride, CaH_2, is the active agent in hydrolith. The hydrides of neodymium, praseodymium, cerium, yttrium, samarium, thorium, lanthanum, iron, cuprous and cupric copper, and silver have also been reported —the last three are said to have been formed by the reducing action of hypophosphorous acid on solutions of the salts of the respective elements. The alleged compounds are probably of the nature of the so-called palladium-hydrogen alloy—with occluded hydrogen.

The different products of the action of hydrogen on the metals may be arranged in three classes: (1) Compounds of the non-metals and metalloids—*e.g.* stibine, SbH_3—in which hydrogen seems to play the *rôle* of a positive univalent element, while the other element behaves as a negative or non-metallic element. As a rule, these compounds are gaseous at ordinary temperatures and pressures, or are very volatile. (2) Compounds of the alkali and alkaline earth metals. They are transparent and crystalline; volatile without decomposition in an atmosphere of hydrogen at comparatively low temperatures. They are probably hydrides proper, being related to the chlorides and nitrides in that the hydrogen plays the *rôle* of a non-metallic univalent element. (3) Unlike the two preceding types, these products are metallic, and form solid phases whose composition varies with external conditions. The typical example is the palladium-hydrogen alloy.

D. P. Smith[5] has shown that if A. Werner's periodic arrangement of the elements be employed, the metals which form the compounds of the first class are confined at the extreme right; and in Table III they are marked off with heavy lines. The compounds of the second class are confined to a group on the extreme left. The central part of the table is occupied by (i) metals whose relation is unknown; (ii) metals which occlude appreciable amounts of hydrogen represented by symbols in clarendon type; and (iii) metals which do not occlude anything but a relatively small amount of hydrogen—represented by symbols in brackets. The dot attached to the symbol means that the available evidence is conflicting or doubtful. The occluding elements thus appear to form a central group with subgroups on the left and right.

TABLE III.—A. WERNER'S PERIODIC TABLE MODIFIED TO SHOW THE RELATION OF THE ELEMENTS TO HYDROGEN.

The action of hydrogen on oxides and salt solutions.—Hydrogen gas reduces a great many metal oxides forming the metal and water: $MO+H_2=H_2O+M$. The oxides of silver and palladium are reduced by hydrogen gas in the cold. F. Wöhler[6] found black palladious oxide to be reduced by hydrogen with incandescence. The oxides of copper, lead, cadmium, tin, iron, cobalt, nickel, antimony, etc., must be heated before reduction occurs. If the mixture of hydrogen and metal oxide were confined in a closed vessel, the reaction would come to a standstill, but when the oxide is heated in a stream of hydrogen gas, the water vapour is whisked away from the seat of the reaction before it has time to set up the back reaction. The reduction of cupric oxide, CuO, to the extent of 1·7 per cent. can be detected after 15 minutes' exposure to a stream of hydrogen between 87° and 90°; 7 per cent., at 100°; and the reduction is complete in 15 minutes at 150°. The results differ with the physical condition of the oxide. Thus, according to F. Glaser, yellow mercuric oxide shows signs of reduction at 75°, and the red oxide at 140°. The reduction of ferric oxide was similarly detected after 15 minutes' exposure at 220°; magnetic oxide at 290°, and ferrous oxide at 305°. The reduction of manganese dioxide could be detected at about 145°, pyrolusite at about 190°; manganoso-manganic oxide, Mn_3O_4, at about 255°; and with manganous oxide no action could be detected at 600°–1300°. The temperatures at which a reduction can be detected with lead dioxide is 140°; lead monoxide, 190°–195°; cobalt sesquioxide, 110°; cobalt monoxide, 165°; nickel sesquioxide, 70°; and nickel monoxide, 225°. In view of the relatively easy reduction of, say, lead dioxide, PbO_2, at 140°, and the more difficult reduction of the monoxide, PbO, at 190°, it is highly probable that the higher oxide is first reduced to the lower oxide, and a higher temperature is then needed for the subsequent reduction of the monoxide to metal. This, for example, is the case with

$$MnO_2 \xrightarrow[145^\circ]{} Mn_3O_4 \xrightarrow[255^\circ]{} MnO \xrightarrow[1300^\circ]{} Mn\text{ ; and } Fe_2O_3 \xrightarrow[220^\circ]{} Fe_3O_4 \xrightarrow[290^\circ]{} FeO \xrightarrow[305^\circ]{} Fe$$

The oxide to be reduced may be placed in a porcelain boat which is heated in a tube through which a current of hydrogen is passing; or it may be heated in a crucible fitted with a perforated lid and tube through which a slow current of hydrogen passes. This form of crucible—called a *Rose's crucible*—is used in analytical work. For example, in certain analytical processes, cobalt is precipitated as hydroxide, and after drying, is ignited in a Rose's crucible with a stream of hydrogen, and finally weighed as metal.

According to M. Berthelot, the displacement of the oxygen from oxides, sulphur from sulphides, etc., is readily effected when the reaction generates heat, but not if the reaction absorbs heat. The greater the amount of heat developed, the more readily will the reaction occur. Contrast the heat developed during the formation of the three oxides: silver oxide, 7 Cals.; lead oxide, 51 Cals.; and zinc oxide, 85·4 Cals. The heat developed during the formation of steam is nearly 58 Cals. Hence, with silver oxide, there will be an evolution of 51 Cals. during the reduction to silver; similarly, with lead oxide there will be an evolution of 7 Cals.; but with zinc oxide, on the contrary, there is no energy to spare—rather is there a deficiency of 58—85·4 = —27·4 Cals. This is supposed to explain how silver oxide can be reduced at ordinary temperatures by hydrogen, while zinc oxide requires a high temperature:

	Silver oxide, Ag_2O.	Copper oxide, CuO.	Lead oxide, PbO.	Iron oxide, FeO.	Zinc oxide, ZnO.
Heat of reduction .	+51	+21	+7	+8·4	−27·4
Reduction begins at .	0°	90°	190°	305°	—

The rule is not rigidly exact; for one thing it takes no account of the variation in the thermal value of the reaction with temperature. According to F. Glaser, cadmium oxide shows signs of reduction at 282°, and zinc oxide at 454°.

Many metal chlorides and other salts, etc., are also reduced by hydrogen. Thus, iron, silver, and palladium chlorides are readily reduced by hydrogen gas forming hydrogen chloride and the metal; antimony sulphide is reduced to antimony; etc. According to C. Brunner, when hydrogen is passed through solutions of salts of platinum, or palladium, the metal is slowly precipitated; with silver salts, the reaction is far from complete since but a small fraction of the total silver is precipitated; iridium salts are scarcely affected; and gold and mercury salts are not reduced. B. Renault (1873) and H. Pellet (1873) claimed that silver salts are not reduced by thoroughly purified hydrogen and that the alleged reduction is a secondary effect due to the presence of arsine, silane, or other impurities; but J. W. Russell, N. N. Beketoff, and A. R. Leeds showed that reduction does take place with the pure gas. If the temperature or the pressure be augmented, the reaction may be completed. Thus, at the temperature of the water-bath, platinum, palladium, rhodium, and iridium are completely precipitated; and at 200 atm. pressure, silver is completely precipitated. E. Schobig says the reduction also occurs in darkness. Similar remarks apply to solutions of salts of nickel, cobalt, lead, bismuth, etc. The deposition of nickel is complete at 200° and 180 atm. pressure. E. Reichardt investigated the colorations produced by hydrogen on paper treated with silver nitrate; J. B. Senderens, the influence of hydrogen on hot solutions of silver nitrate; J. W. Russell, the precipitation of platinum, palladium, and gold from solutions of their salts, the reduction of cupric nitrate to nitrite, and the formation of a basic salt with mercurous nitrate; and F. C. Phillips, the influence of hydrogen on solutions of platinum, and palladium chlorides. N. N. Beketoff, J. Löwenthal, and W. Ipatjeff have studied the precipitation of silver, mercury, copper, zinc, cadmium, lead, etc. $\frac{1}{10}N$-solutions of silver and mercury salts give the metals at room temperatures and 200 atm. pressure; copper sulphate gives no metal at 600 atm.; $\frac{1}{10}N$-copper nitrate gives copper at 200° and 600 atm. Nickel salts behave similarly. Cobalt, lead, iron, and bismuth salts give the metals only at high temperatures and pressures.

Hydrogen gas is not oxidized by (*i.e.* it does not reduce) solutions of ferric chloride, potassium ferricyanide, nitric acid (specific gravity 1·42), chromic acid, or aqua regia. R. Bunsen, however, stated that in darkness ferric chloride is reduced by hydrogen to ferrous chloride. J. Milbauer studied the oxidation of hydrogen by sulphuric acid, $H_2SO_4+H_2=2H_2O+SO_2$, under the action of different catalytic agents at different temperatures. With pure hydrogen, there is no appreciable effect at ordinary temperatures, but the action is quite marked at 140°. Potassium permanganate is reported [7] to be gradually reduced in acid, neutral, or alkaline solutions at ordinary temperatures. A. C. Vournasos found that the nascent hydrogen liberated by heating dry sodium formate reacts with several elements which do not combine directly with free hydrogen. For example, phosphine is obtained when phosphorus vapour is passed over sodium formate melted at 200°; with a mixture of phosphorus and four times its weight of sodium formate, at 400°; and with a mixture of sodium formate and neutral sodium phosphite, or anhydrous disodium phosphate. Arsine is likewise obtained from sodium arsenite; stibine from sodium antimonide; hydrogen sulphide from sulphur, from sodium sulphide, or from mercury, lead, or tin sulphide; nitrides give ammonia; cyanides give hydrogen cyanide; alkali carbides give acetylene; and silicon chloride or sulphide give silicon hydride.

Hydrogen is a far more vigorous reducing agent if it acts in the presence of finely-divided metals—nickel, platinum, etc.—than when alone. Colloidal platinum or palladium is more effective than even the finely-divided platinum or palladium black. A solution of ferric chloride in the presence of platinum is reduced by hydrogen gas. There is a continuous catalytic action of the platinum on the gas and the layer of solution adhering to the metal. F. Lehmann found that osmium dioxide acts as a catalytic agent on the reduction of oleic acid and liquid oils by hydrogen. The finely-divided metals alone reduce neutral solutions of potassium permanganate, and accordingly decolorize dilute solutions, and the solution at the same time becomes alkaline, owing probably to the formation of potassium hydroxide and a brown manganic oxide—$Mn(OH)_4$, or possibly $MnO(OH)_2$—in symbols: $2KMnO_4+3H_2+2H_2O\rightarrow2KOH+2Mn(OH)_4$. Finely-divided gold, platinum, silver, arsenic, antimony, tungsten, and all the common metals reduce dilute neutral solutions of permanganate. Mercury also reduces permanganate, and D. Borar (1911) represents the reaction by the equation: $2KMnO_4+3Hg+H_2O\rightarrow2KOH+2MnO_2+3HgO$. Whatever be the mechanism of the reaction, the observed fact is that hydrogen can do its work much more quickly in the presence of platinum black; or, if the alternative statement be preferred, that the finely-divided metal can do its work more quickly in the presence of hydrogen. The point is illustrated by A. Smith's lecture experiment:

> Three test tubes are filled with dilute acidified potassium permanganate solution. Zinc dust added to the one generates hydrogen and causes decolorization; a little platinum black is added to the second, and hydrogen gas is led through this and the third solution. The contact action of the platinum enables the hydrogen quickly to reduce the permanganate, while the third portion remains unaltered.

F. Kuhlmann showed that the presence of certain metals can also induce a reaction between nitric oxide and hydrogen with the formation of ammonia; [8] and P. Sabatier and J. B. Senderens have studied the reaction between hydrogen and many organic compounds—thus, carbon monoxide is transformed into methane; ethylene or acetylene is also hydrogenized to methane; aldehyde or ketone to alcohol; benzene to hydrobenzene; etc.

In 1839, T. de Saussure [9] observed that various organic substances (peas, corn, humus) in the act of decomposition may excite the combination of hydrogen and oxygen, and that mixtures of these gases "behave with fermenting substances the same as with platinum." Several micro-organisms are also reported by A. J. Nabokich and F. A. Lebedeff, N. Bronislaff, J. Nikitinsky, and B. Niklewsky to possess the property of oxidizing hydrogen.

The nascent state—status nascens.—Hydrogen is not particularly active, chemically, at ordinary temperatures, but when the gas is exposed to an elevated temperature, or to an electrical discharge, the bonds which hold the atoms together appear to be relaxed, and hydrogen is then a potent agent, for its reactivity is great. The hydrogen which is generated by many exothermal reactions, at the moment of its birth, *in statu nascendi*, appears to be in a specially active state, for it can inaugurate many reactions which gaseous hydrogen cannot invoke. For instance, hydrogen gas can be passed into an acidified solution of ferric chloride or into water in which silver chloride is suspended without producing any appreciable change, but if metallic zinc be placed in the acidified solution, the brisk evolution of hydrogen is soon attended by the reduction of the ferric to ferrous chloride in the one case, and of the silver chloride to metallic silver in the other. Hydrogenized palladium or platinum[10] can also do chemical work which ordinary hydrogen cannot do, for instance, it can reduce a solution of ferric to ferrous chloride as illustrated by the symbols: $FeCl_3+H_{palladium}=FeCl_2+HCl$; it can reduce solutions of chlorates to chlorides; nitrates to nitrites and ammonia; mercuric to mercurous chloride; ferricyanides to ferrocyanides; sulphurous acid to sulphur and hydrogen sulphide; indigo-blue to indigo-white; nitrobenzene, $C_6H_5NO_2$, to aniline, $C_6H_5NH_2$, and it can unite with chlorine, iodine, and oxygen in the dark at ordinary temperatures. Charcoal saturated with hydrogen can also reduce chlorates to chlorides, ferricyanides to ferrocyanides, but not nitrates to nitrites. The main sources of nascent hydrogen are the amalgams of sodium, magnesium, and aluminium; the copper-zinc couple with water; or the metals zinc, tin, and iron with dilute acids, or, maybe, with alkaline solutions. Hydrogen iodide in a sealed tube at 150°–275° gives nascent hydrogen which is particularly active on account of the elevated temperature.[11] According to M. Berthelot, it reduces organic compounds to the hydrocarbon stage in which the molecule contains the maximum amount of hydrogen consistent with the quadrivalency of carbon, *e.g.* ethyl iodide and ethyl alcohol form ethane; glycerol forms propane; etc.

It has been suggested, without proof, that the hydrogen in palladium is in the atomic condition, for atoms are supposed to be more chemically active than molecules because some preliminary work has to be done in order to split the molecules into atoms before the reaction can occur, whereas atoms are ready to react immediately. This hypothesis was suggested by A. Laurent in 1846. He ascribed the greater activity of the elements in their nascent condition to their atomic condition. He reasoned that in the molecules (HH) and (BrBr) the affinity of bromine for bromine and of hydrogen for hydrogen is sufficient to prevent the one combining with the other, whereas if atomic hydrogen be in contact with atomic bromine combination sets in without the need for a preliminary rupture of the molecules of the two elements. Consequently it was inferred that the atoms of hydrogen in their nascent state do the work of reduction before they have spent part of their energy in grouping themselves into molecules. P. A. Favre and J. T. Silbermann (1846) adduced physical evidence in favour of A. Laurent's theory of the nascent state, and showed that carbon burning in an atmosphere of nitrous oxide, N_2O, develops considerably more heat than when it burns in oxygen because the energy required to decompose the molecules of ordinary oxygen is greater than the energy required to decompose the molecules of nitrous oxide. G. Bodländer also explains the greater activity of the hydrogen occluded in metals as due to its being there present in the atomic condition.

D. Tommasi (1898)[12] has emphasized the fact that this explanation does not make clear why nascent hydrogen from zinc and sulphuric acid is able to reduce chlorates or bromates to chlorides or bromides respectively, while hydrogen from sodium amalgam will not do so; nor does it explain why zinc and hydrochloric acid will reduce salts of vanadium pentoxide, V_2O_5, to the dioxide, V_2O_2, while magnesium and hydrochloric acid furnishes the trioxide, V_2O_3, under similar conditions. Nitrobenzene, $C_6H_5NO_2$, can be reduced to the base aniline, $C_6H_5NH_2$, in acidic but not in alkaline solutions—say by sodium amalgam and water. The *base* hydroxylamine is formed by the reduction of nitric acid in *acidic* solutions, and hyponitrous *acid* by reduction in *alkaline* solutions. It might be expected that if the work of reduction is really performed by nascent hydrogen, this agent should possess the same properties from whatever source it is derived; whereas the fact is that **the reducing power of nascent hydrogen varies according to the nature of the chemical reaction which gives it birth.** Hence, the greater activity of nascent hydrogen is probably caused by some influence other than the supposed atomic condition of the element *in statu nascendi*.

M. Berthelot considers that the disengagement of hydrogen in these reactions is but the result of a secondary reaction, and that the main reaction is the formation of a complex with the substance to be reduced. He calls these complexes *les systèmes reducteurs*. In reducing potassium chlorate by zinc and sulphuric acid, the system $Zn : H_2SO_4 : KClO_3$ with some water may be first formed, and this passes into the system $ZnSO_4 : H_2 : KClO_3$ or $ZnSO_4 : KCl : H_2O$, or into a system consisting of all these products. There are many reactions which are attributed to *l'hydrogène naissant*—*e.g.* reductions with sulphurous acid, ferrous hydrates, ammonium hydrosulphide, etc.—in which hydrogen is never evolved, and in which the reduction may be performed in *les systèmes reducteurs*. In the case of zinc and ferric chloride it might be then argued that the effects attributed to *l'hydrogène naissant* are really produced by the direct action of the metal; in symbols: $Zn+2FeCl_3=ZnCl_2+2FeCl_2$; and not through the consecutive reactions; $Zn+2H_2O=Zn(OH)_2+2H$; and $H+FeCl_3=HCl+FeCl_2$.

The energy which is set free during a reaction under ordinary conditions appears as heat, and this may make the gas at the seat of the reaction more reactive; or, before the energy has degraded to heat, it may be available for doing chemical work so that the difference between the so-called nascent and ordinary hydrogen lies in the greater availability of the energy of the former. D. Tommasi argues that the reducing properties of nascent hydrogen depend on the nature of the reaction from which it is derived, and that the greater affinity of hydrogen *in statu nascendi* arises from the momentary association of hydrogen with n calories of energy liberated by the reaction. Accordingly the term "nascent hydrogen" is synonymous with $H+n$ cals. The difference in the reducing properties of hydrogen produced by different reactions is determined by the amount of heat liberated in the reaction. For example:

$H_2SO_4Aq.+Cd=21{\cdot}5$ Cals.
$2HClAq.+Zn=34{\cdot}2$,,
$2HBrAq.+Zn=34{\cdot}2$,,
$H_2SO_4Aq.+Zn=37{\cdot}7$ Cals.
$H_2SO_4Aq.+Mg=112{\cdot}0$,,
$2Na$ (amalgam)$+Aq.=180{\cdot}0$,,

The greater the thermal value of the reaction, the greater is the activity of the nascent hydrogen. In some cases, the reduction is not due to $H+n$ cals., but to the metal $M+n$ cals.; for example, in the reduction of potassium chlorate by zinc and dilute sulphuric acid, the zinc unites with the oxygen of the chlorate, forming zinc oxide: $KClO_3+3Zn=KCl+3ZnO$. If a chlorate, dissolved in a dilute solution of sulphuric acid, be electrolyzed with platinum electrodes, perchloric acid is formed at the anode, and with a zinc anode, potassium chloride, but no perchlorate appears at the electrode.

When hydrogen is developed on the surface of a metal immersed in a suitable solvent, W. Ostwald[13] has pointed out that the gas in the smallest—probably submicroscopic—bubbles must be under a great pressure owing to the surface tension of the water. He calculates this pressure to be near 15,000 atm. for gas bubbles of approximately molecular dimensions, 10^{-7} cm. diameter. It has been suggested that the gas under this enormous pressure is more chemically active than when it is under ordinary atmospheric pressures.

The decomposition voltage of sulphuric acid with a platinized platinum electrode has a definite and specific value which is different from the value obtained when electrodes with other metals—*e.g.* smooth platinum, zinc, lead, etc.—are used and the difference between the voltage required to liberate hydrogen at the surface of a metal and at the surface of a platinized platinum electrode under similar conditions has been styled the overvoltage. The point where the evolution of gas begins may be taken as the point where bubbles of hydrogen begin to form, or the point where a break appears in the voltage curve. M. le Blanc (1890) takes the **overvoltage** as the excess back electromotive force generated at the given electrode over that at a platinum electrode when the charging circuit is rapidly closed and as rapidly broken making a new circuit through a commutator. The overvoltage depends on the nature of the metal, current density, temperature, etc. W. A. Caspari[14] found that with platinized platinum the overvoltage amounts to 0·005 volt; with smooth platinum, 0·08 volt; meaning that the formation of gas bubbles could be first observed on the electrode in *N*-sulphuric acid, at these voltages. With iron, sodium hydroxide was used. The overvoltages with some other metals are:

Au.	Fe.	Ag.	Ni.	Cu.	Pd.	Cd.	Sn.	Pb.	Zn.	Hg.
0·02	0·08	0·15	0·21	0·23	0·46	0·48	0·53	0·64	0·70	0·78 volt.

A. Coehn and K. Dannelberg, E. Müller, and A. Thiel and E. Breuning, obtained the same results with rather smaller voltages, but the order was the same as W. A. Caspari's. These numbers may be taken to represent the potential at which the hydrogen is liberated at the different electrodes. There is a similar overvoltage at the oxygen anode—with platinized platinum, 0·39 volt; polished platinum, 0·62; palladium, 0·39; and gold, 0·59 volt. G. Carrara found the overvoltages quite different in alcoholic and aqueous solutions. If there were no overvoltage, water could be decomposed by a current of 1·22 to 1·23 volts, but the voltage actually required is 1·23 plus the overvoltages at the two electrodes.

When hydrogen separates on a metal electrode, its chemical energy is augmented by the overvoltage beyond what it would possess if it were in the gaseous state under ordinary atmospheric pressure. The hydrogen from, say, a mercury or lead cathode is evolved at a higher potential and therefore possesses greater energy than from a platinum cathode. Lead or mercury thus possesses, in a high degree, the property of rendering difficult the escape of hydrogen from the cathode, so that many electrolytic reductions are possible with these metals—*e.g.* of caffein or uric acid—which are not produced by cathodes of other metals. While the reducing power and hydrogen overvoltage generally run parallel, E. Müller, J. Tafel and K. Neumann, C. F. Böhringer, and A. Chilesotti have shown that it does not necessarily follow that all reductions take place more readily at the cathode with the higher overvoltage. For instance, nitrites are more readily reduced than nitrates at cathodes of zinc, iron, lead, platinum, or gold, while nitrates are more readily reduced at cathodes of spongy copper or silver, and at a mercury cathode in hot solutions. Caffein is more readily reduced at a mercury than at a lead cathode, and the converse obtains in the reduction of succinimide. Obviously, therefore, factors other than hydrogen alone are involved, and these may mask the relation between the hydrogen overvoltage and high reducing power. For example, one substance may be more readily absorbed by one cathode than another, so that the effective concentrations at the cathode are different; the electrode may act as a catalytic agent on the reaction, or apparently inert substances in the solution may modify the overvoltage.

J. Tafel has shown that traces of certain metals exercise what may be called a poisonous influence on other metals in reducing the overvoltage or *super*-voltage of the hydrogen and so decreasing the effectiveness of the lead and mercury cathodes; thus, 0·004 mgrm. of platinum per 10 sq. cm. of lead cathode surface will prevent many electrolytic reductions possible in its absence. Silver, tin, copper, mercury, zinc, and iron are also enemies of electro-reduction. J. Tafel and B. Emmert found that the toxic effect cannot be attributed to the formation of a skin of the metal on the surface of the cathode.

Various hypotheses have been devised to explain what is taking place when an overvoltage occurs. F. Haber suggested that the formation of films of gas on the electrodes increases the resistance; H. G. Möller considered the overvoltage to represent the energy required to give a film of gas thick enough to generate bubbles; F. Föster suggested an oxide is formed at the anode, and a hydride or solid solution of a hydride at the cathode; while W. Nernst and J. Tafel believe that the effect is due to the slowness with which the electrode gets into equilibrium with the surrounding conditions, for metals with a slight tendency to occlude gases require energy to force the gas into the electrode and thus produce high voltages. J. Tafel, E. Müller, G. N. Lewis and R. E. Jackson and others have suggested that the discharge of the $H^{\cdot}$-ions at the cathode, $2H^{\cdot}=H_2$. takes place in two stages, $H^{\cdot}=H$ and $2H=H_2$, so that monatomic hydrogen acts as an intermediate compound, and while the reaction $H^{\cdot}=H$ takes place quickly, the reaction $2H=H_2$ which causes the polarization of the electrode is slow. The potential of the hydrogen electrode thus depends upon the concentration of monatomic hydrogen. C. W. Bennett and J. G. Thompson, and W. D. Bancroft also favour an hypothesis based on these reactions. D. Reichinstein[15] attributes the poisoning of the electrodes by the presence of certain impurities to the lowering of the overvoltage by increasing the rate of conversion of the monatomic to ordinary hydrogen. Similarly also, the effect of certain impurities—iron, cobalt, nickel, etc.—on the yield of caustic soda by the amalgam process, observed by J. W. Walker and C. S. Paterson, is attributed to the decrease in the overvoltage by the impurities acting catalytically in increasing the speed of the conversion of monatomic into ordinary hydrogen. Similar explanations have been applied to O. Aschan's observation that impurities in the sodium amalgam diminished the yield in the hydrogenation of benzoic acid; to E. Bamberger's observation of the great differences in the reducing power of different samples of zinc dust; and to G. Fernekes' observation that alcohol and many other organic substances augmented the speed of the reaction between sodium amalgam and water. The so-called nascent hydrogen is thus assumed to consist of electrically neutral monatomic hydrogen, and the difference in the nascent hydrogen derived from different sources is due to the difference in the effective concentration of the monatomic hydrogen, which in turn is determined by the rate of conversion of the monatomic into ordinary hydrogen.

Hydrogen is not a poisonous gas.[16] When small animals are placed in hydrogen, they are "drowned," suffocated for want of oxygen. The injurious action of hydrogen is therefore negative; the gas acts merely by preventing access of oxygen to the lungs. According to C. W. Scheele, F. Fontana, and H. Davy, the pure gas excites disagreeable sensations and loss of muscular power, but when mixed with air, it may be breathed a longer time. The violent symptoms described by G. Cardone as attending the respiration by hydrogen must have arisen from impurities in the gas. When hydrogen is inhaled, the voice becomes shrill—approaching falsetto. The pitch of organ pipes and other wind instruments is raised if a blast of hydrogen be used in place of air. According to F. Hatton, hydrogen has scarcely any appreciable influence on bacteria, but M. Berghaus says their power of multiplying becomes smaller in an atmosphere of hydrogen gas.

The detection and determination of hydrogen.—The determination of hydrogen in the presence of methane and other hydrocarbons is based on the contraction which occurs after complete combustion with oxygen by explosion in a eudiometer; by fractional combustion with air in contact with palladium-asbestos—methane does not oxidize at 100°, hydrogen does; by absorption by spongy palladium; by the reduction of or absorption in palladium chloride—dry or in solution—after the removal of olefine gases and carbon monoxide because these gases also reduce palladious chloride. A nearly neutral one per cent. solution of palladious chloride completely absorbs small quantities of hydrogen in a few hours; the absorption is retarded by using strongly acid solutions. According to F. C. Phillips,[17] a one per cent. solution of palladious chloride is reduced in the cold by hydrogen gas. $\frac{1}{2000}$th part of hydrogen can be detected in a gas by this reaction.

The presence of hydrogen gas can be established by spectrum analysis. In the absence of other hydrogen compounds, the gas can be passed over red-hot copper oxide whereby water is formed. A. Gautier found that one part of hydrogen in 5000 of air is completely oxidized when passed over a layer of cupric oxide about 70 cm. long at the rate of 2 or 3 litres per hour; with a tube 30 cm. long, about 70 per cent. of the hydrogen is oxidized. This reaction enables the amount of hydrogen in dry air to be determined. C. Paal and C. Amberger used a colloidal palladium solution for the absorption of hydrogen; C. Paal and W. Hartmann used a colloidal solution of palladium containing sodium picrate. A. Lidoff described a method for the volumetric determination of hydrogen by combustion with magnesium powder; T. Zerewitinoff used magnesium-methyl iodide. A. Jacquelin proposed to absorb hydrogen from a mixture of methane, CH_4, and ethylene, C_2H_4, by sodium or potassium at about 300°. C. Zengelis found that palladium or platinum absorbs hydrogen and the product colours blue a solution made by dissolving a gram of molybdenum trioxide in dilute sodium hydroxide, acidifying the solution with hydrochloric acid, and diluting the mixture to 200 c.c.

The atomic weight and valency of hydrogen.—Hydrogen was for a long time the standard unit for the atomic weights; but now oxygen =16 is the generally accepted standard. Reports of the atomic weight of hydrogen, determined through the ratio O : H lie between 16 : 0·99937 and 16 : 1·0087; and the best representative value for the atomic weight of hydrogen is taken to be **1·008.** The molecular weight of the gas is then 2·016—the molecule being therefore diatomic, H_2. According to W. Vaubel,[18] the molecular weight of hydrogen in the liquid state is nearly 5·2. The valency of hydrogen is the unit for evaluating the valencies of the other elements. R. de Forcrand [19] has favoured the assumption that hydrogen is best regarded as a bivalent element; this would entail doubling the valency of all the other elements. The doubled scheme is said to offer some advantages in dealing with the constitution of the subhalides and suboxides. There is a difficulty already discussed, in assigning a place for hydrogen in the periodic table.

The quantities of some of the metals which are equivalent to a definite quantity of oxygen have been already determined, and the results agree with the quantities of the different metals found to be chemically equivalent to one gram of hydrogen. One gram of a given metal dissolving in a suitable acid will always displace the same amount of hydrogen whatever be the reacting liquid used—*e.g.* aluminium in sodium hydroxide, in sulphuric acid, or in hydrochloric acid; but the amounts furnished by different metals are different. **The weight of a metal required to displace one gram of hydrogen is called the hydrogen equivalent of the metal.** J. D. van der Plaats [20] determined the equivalent of zinc by measuring the volume of hydrogen evolved by the dissolution of a given weight of the metal in sulphuric acid, and found that 13·8758 grms. of zinc gave 2·3767 litres of hydrogen, so that if a litre of hydrogen weighs 0·89872 grm. under standard conditions, one gram of hydrogen is equivalent to 64·89 grms. of zinc. J. W. Mallet [21] also determined the hydrogen equivalent of aluminium by dissolving it in a solution of sodium hydroxide; and E. Kohn-Abrest, by dissolving it in hydrochloric acid. J. Torrey likewise determined the hydrogen equivalent of iron. As a mean of twenty-one determinations, J. Thomsen found the ratio H : Al=0·111902 ± 0·000015; and he also found the ratio O : Al =0·88787 ± 0·000018, from which it follows that O : H=7·9345 ± 0·0022.

The dissociation of the hydrogen molecule.—According to I. Langmuir (1912),[22] the electrical energy required to maintain a tungsten wire at a given temperature in hydrogen increases at an abnormal rate with temperature, so that while the theoretical value calculated from the heat losses by hot wires agrees with observations up to 1900° K., after that, there is a rapid increase until, at 3500° K., it is four times the calculated value. No secondary electrical effects could be detected. At small pressures, the heat losses are greater than at atmospheric pressures, presumably because of dissociation. This phenomenon is not observed with the other gases tried. When a tungsten wire is heated to 1300°–2500° in hydrogen under a pressure of 0·001 to 0·02 mm., the gas slowly disappears. Hydrogen is not absorbed by the wire to any great extent, but is deposited on the glass bulb, if the latter be cooled by liquid air. When the liquid air is removed and the wire cooled, the hydrogen is liberated. Langmuir explains the phenomenon on the assumption that hydrogen is dissociated into atoms by the hot wire, and that some atoms diffuse into the tube and are condensed in the same condition on the glass walls. The hypothesis that the **hydrogen is in the atomic condition** is used to explain the greater chemical activity of the gas, for, if phosphorus is present in the bulb, the two combine, forming phosphine (phosphorus hydride), a reaction which has not been observed with ordinary hydrogen under ordinary conditions; the hydrogen also reacts with oxygen at room temperatures; tungstic oxide, WO_3, and platinic oxide, PtO_2, are chemically reduced by the dissociated gas; copper oxide is reduced almost immediately to metallic copper; ferric oxide is reduced to a lower oxide; zinc oxide is not reduced excepting over long periods of time when the colour of the dry zinc oxide gradually turns grey, although silica, close beside it, remains quite white. T. Ismardi (1915) has shown that the degree of dissociation α of hydrogen into atoms is 0·557 at 3200° K. and 25 mm. pressure; and 0·5 at the same temperature and 50 mm. pressure. Similarly, at 3100°, the degree of dissociation is 0·255 at 100 mm. pressure, and 0·230 at 200 mm. pressure. The degree of dissociation α was calculated from the expression: $\log(\alpha^2-1)^{-1}=-Q/RT-\log T+\log p-2{\cdot}95$, where Q represents the heat of dissociation which is 64,000 cals., or $2H=H_2+64{,}000$ cals.; R is the gas constant; and p the pressure. Assuming the heat of the reaction at 2500° K. to be 64,000 cals., the free energy of the reaction $2H=H_2$ at $T°$ K. is given by G. N. Lewis and M. Randall as $F=61{,}000-3{\cdot}5T\log T+0{\cdot}00045T^2+20{\cdot}2T$. E. Briner estimates the heat of formation $2H=H_2$ at 2427° as 130 Cals., and the equilibrium constant as 0·10.

§ 9. The Diffusion of Gases

Owing to the fact that air is fourteen times as heavy as an equal volume of hydrogen under the same physical conditions, if a jar of hydrogen be placed mouth upwards under a jar of air, mouth downwards, most of the hydrogen will flow upwards into the upper cylinder, and air will flow downwards into the lower cylinder. The action is analogous with what would occur if the lower cylinder contained a light oil and the upper cylinder water. The oil and water would change places. The two liquids can be left an indefinite time without mixing, for the two liquids—oil and water—are immiscible. Several of the earlier chemists used to argue that gases like those under consideration would behave like the liquids, but J. Priestley[1] noticed that this is not the case; and in 1805, J. Dalton's experiments demonstrated that two gases—hydrogen and air—when brought into contact, do not arrange themselves according to their specific gravities, but spontaneously diffuse, mutually and equally through each other, and spread throughout the two vessels so that a homogeneous mixture of air and hydrogen is obtained. This phenomenon is so marked, that it was once considered that the molecules of a gas mutually repelled one another owing to the presence of a "self-repulsive force." Gases are miscible in all proportions; had the two liquids been mutually soluble in one another in all proportions—say alcohol and water instead of oil and water—they also would diffuse one into the other so as to form a homogeneous solution of alcohol and water.

The process of diffusion in the case of liquids appears to be very much slower than with gases. The molecules of gases seem to lead a more or less independent existence. This is illustrated by the rapidity with which the molecules of, say, ammonia can travel from one end of a room to the other and affect the sense of smell. In liquids, however, the molecules are much less mobile. This can easily be proved by dropping a small grain of aniline dye into a tumbler of clear still water. The water will be uniformly coloured in a few weeks. The molecules of solid substances have practically lost their mobility—but not all. Carbon laid in contact with pure, hot, solid iron will diffuse into a mass of the metal; gold or platinum in contact with lead will diffuse into the lead.[2] J. Violle found that carbon will diffuse into the solid body of hot porcelain; and metallic silver will diffuse into hot glass, staining it yellow. According to C. E. van Orstrand and F. P. Dewey (1915), the coefficient of diffusion, of gold into solid lead at 197° is 0·0076; at 150°, 0·0043; and at 100°, 0·0002. The penetration of gold into lead at 197° can be detected at a depth of 2·5 cm. after 54 days; the penetration of the lead into gold at a depth of 0·2 mm.—but the methods of detecting lead in gold are not so sensitive as for gold in lead.

The transfer of gases in bulk from one vessel to another is an effect of gravitation, whereas diffusion is not an effect of gravitation. C. L. Berthollet (1809)[3] confirmed J. Dalton's observation that hydrogen is rather more penetrative and diffusive than any other gas tried. In 1829, T. Graham experimented on the interdiffusion or miscibility of gases with one another, and the subject was pursued further by J. Loschmidt (1870) and A. von Obermayer (1880). J. Loschmidt placed two tubes containing different gases one over the other, and, after opening a channel between them, determined the amounts of the different gases which had changed places after the lapse of a definite interval of time. The results were expressed in terms of what is called the **coefficient of diffusion,** k, which represents the quantity of gas travelling per second through a surface of one sq. cm., and along a distance one centimetre in length. Then, at 0°, the coefficient of diffusion, k_0, of hydrogen into air is $k_0=0{\cdot}64$; into steam, 0·69; into oxygen, 0·67; and into

	C_2H_6	C_2H_4	SO_2	N_2O	CO_2	CH_4
k_0 .	0·46	0·48	0·48	0·43	0·63	0·65

and likewise for carbon dioxide into

	N_2O	C_2H_4	CO	O_2	Air	H_2	CH_4
k_0 .	0·092	0·101	0·140	0·141	0·142	0·553	0·159

It is doubtful if the assumption that the coefficient of diffusion k is altogether independent of the relative proportions of the two gases, is quite valid.[4] It is assumed that the gases exert no chemical or physical attractive forces on one another. J. Loschmidt found that *the quotient obtained by dividing the coefficient of interdiffusion by the square root of the product of the molecular weights of the two interdiffusing gases is approximately constant*—1·8. This is illustrated in Table IV.

TABLE IV.—THE INTERDIFFUSION OF GASES.

Interdiffusion of gases of molecular weights M_1 and M_2.	Diffusion coefficient k.	$\frac{k}{\sqrt{M_1M_2}}$
Carbon dioxide into air	0·0512	1·825
Carbon dioxide into hydrogen	0·2001	1·877
Carbon dioxide into oxygen	0·0507	1·904
Carbon dioxide into carbon monoxide	0·0506	1·776
Carbon dioxide into methane	0·0571	1·514
Carbon dioxide into nitrous oxide	0·0354	1·557
Oxygen into hydrogen	0·2598	2·079
Sulphur dioxide into hydrogen	0·1728	1·955
Carbon monoxide into oxygen	0·0649	1·942
Carbon monoxide into hydrogen	0·2312	1·730

J. Loschmidt also found that the coefficient of diffusion k at a pressure p, and at absolute temperature T, is related with the diffusion coefficient k_0 at 273° K., and standard pressure, such that

$$k=k_0\left(\frac{T}{273}\right)^n\frac{760}{p};\quad\text{or }k=k_0(1+a\theta)^n\frac{760}{p}$$

where a denotes the coefficient of thermal expansion of the gas, and θ the temperature. J. Stefan and J. Loschmidt found that the index n is 2, but A. von

Obermayer found $n=2$ (nearly) applies only for binary mixtures of carbon dioxide with nitrous oxide, air, and oxygen; for other mixtures $n=1·5$ (nearly).

Long before J. Loschmidt, Thomas Graham[5] showed that the speed at which the molecules of a gas can diffuse or travel through thin porous membranes or septa—porous earthenware, plaster of Paris, etc.—into air or a vacuum is related to the specific gravity of the gas. For example, hydrogen diffuses nearly four times as fast as oxygen; the relative densities of oxygen and hydrogen are nearly as 1 : 16; and the relative rates of diffusion of the two gases are nearly as $\sqrt{16} : 1$; *i.e.* as 4 : 1. Hence follows **Graham's law of diffusion: the relative speeds of diffusion of gases are inversely proportional to the square roots of their relative densities.** Graham measured the speed of diffusion of gases through thin porous plates and found the numbers indicated in the last column of the subjoined table.

TABLE V.—SPEEDS OF DIFFUSION OF SOME GASES AND GRAHAM'S LAW.

Gas.	Relative density H = 1.	Speed of diffusion calculated from $\frac{1}{\sqrt{\text{Relative density}}}$	Observed speed of diffusion (Hydrogen = 1).
Hydrogen, H_2	1	1	1
Methane, CH_4	8	0·354	0·351
Ethylene, C_2H_4	14	0·267	0·266
Carbon monoxide, CO	14	0·267	0·278
Nitrogen, N_2	14	0·267	0·265
Oxygen, O_2	16	0·250	0·248
Hydrogen sulphide, H_2S	17	0·243	0·248
Nitrous oxide, N_2O	22	0·213	0·214
Carbon dioxide, CO_2	22	0·213	0·212
Sulphur dioxide, SO_2	32	0·177	0·177

The third column represents the theoretical numbers calculated on the assumption that the speeds of diffusion are inversely as the relative densities. Graham's numbers have been recalculated to H=1 instead of air=1, and whole number approximations for the relative densities have been introduced. The observed numbers for the speed of diffusion agree very closely with those obtained by calculation. There is an interesting application of the law:

To find the relative density of a gas by comparing its speed of diffusion with that of another gas of known density.—Let D_1 and D_2 represent the relative densities of two gases one of which, D_1, is known, the other, D_2, being unknown. Suppose that the relative speeds of diffusion of the two gases V_1 and V_2 are known. Then, it follows from Graham's law, $V_1\sqrt{D_1}=V_2\sqrt{D_2}$; or $V_1^2D_1=V_2^2D_2$. Given any three of these numbers, the fourth can be calculated by arithmetic.

EXAMPLES.—(1) The speeds of diffusion of carbon dioxide and of ozone were found by Soret (1868) to be as 0·29 (V_1) is to 0·271 (V_2). The relative density of carbon dioxide is 22 (D_1) when H=1. What is the relative density of ozone (D_2)? From the preceding relation, it follows that $\sqrt{D_2}=0·29\times\sqrt{22}\div0·271=0·29\times4·69\div0·271$; or $D_2=(5·02)^2=25$ nearly.

(2) A. Ladenberg (1898) found that ozonized air required 367·4 seconds to diffuse under conditions where pure oxygen required 430 seconds: what is the specific gravity of the ozonized air, assuming that the specific gravity of oxygen is unity? Ansr. 1·3698.

The slow mutual diffusion of gases makes them dissolve each other irresistibly so that there is no limit to the extensive expansion of the smallest bubble of gas which may be formed or liberated in air. It is this ceaseless interchange of gases which plays a part in preventing cities being speedily enveloped and stifled by their own noxious exhalations from the natural functions of their teeming population, and from the deadly vapours of their fires and furnaces. The ready diffusion of gas through the walls of buildings plays a part in ventilation. Most building materials are porous, and permit the passage of gases through them in both directions. The diffusion does not take place so readily when the walls are saturated with moisture —*e.g.* in new buildings, etc. The diffusion is illustrated by the following demonstration:

One leg of a U-tube is enlarged, as shown in Fig. 16, and the widened end fitted with a plug of plaster of Paris. The mercury of the other leg of the U-tube is connected with a battery and electric bell, and a wire fused in the other leg of the tube, so that when the liquid rises electric contact is made, and the bell will ring. If a beaker of hydrogen be placed over the plaster of Paris plug, hydrogen will rapidly diffuse into the enlargement, and create a pressure which depresses the mercury in the one leg, and raises it in the other so as to ring the bell. A device based on this principle has been suggested as an alarm indicator for the escape of coal gas in rooms, or fire-damp in coal mines. These gases, like hydrogen, diffuse through the walls of porous pots faster than the air can escape and produce an internal pressure. Conversely, if the enlarged bulb be bent downwards and a jar of carbon dioxide be lifted upwards so that the porous septum is bathed in this gas, air escapes from the interior faster than the heavier carbon dioxide can enter. This reduces the pressure in the interior, and causes a movement of the mercury in the opposite direction. Instead of using a plaster of Paris septum, porous pots fitted on to glass tubes can be employed, and the conditions can be so arranged that the pressure of the gas sprays a jet of liquid like a miniature fountain.

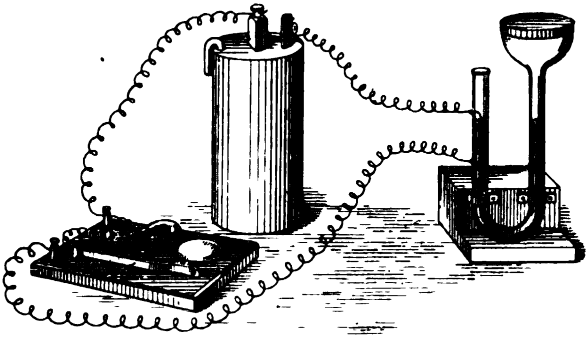

Fig. 16.—Diffusion Experiments.

In diffusing through porous walls, or through unglazed earthenware vessels, the gases actually travel through the pores of the material. The diffusion of gases through metals and indiarubber appears to follow a different procedure, for the gas probably dissolves in these substances, diffuses while in solution through the solid, and is liberated on the opposite side. The diffusion of gases through rubber is well illustrated by filling toy balloons of thin rubber with hydrogen gas; the balloons soon collapse. If the balloons be inflated with air, and then immersed in hydrogen gas, they swell out and burst. For similar reasons, a soap bubble blown with air and then made to float on carbon dioxide gas, will gradually sink in the gas owing to the diffusion of the heavy gas through the walls of the bubble.

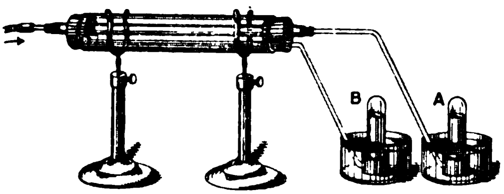

Fig. 17.—H. St. C. Deville's Experiment on Atmolysis.

The separation of a mixture of gases by diffusion.[6]—If a slow current of electrolytic gas, that is, the mixture of hydrogen and oxygen obtained by the electrolysis of water, be allowed to pass through the stem of a churchwarden clay pipe, or porous earthenware tube, and the gas issuing from the pipe be collected in a gas trough, it will no longer explode when brought in contact with a flame. On the contrary, it will rekindle a glowing chip of wood, showing that oxygen is present. In passing through the tube, hydrogen escapes by diffusion through its porous walls much more rapidly than the heavier oxygen. If the porous tube be surrounded by a glass tube, and fitted with a gas delivery tube, as shown in Fig. 17, the gas which collects in the receiver *A* will contain an excess of oxygen, and that in receiver *B* an excess of hydrogen. This phenomenon—the separation of one gas from another by diffusion—has been called, by T. Graham, **atmolysis**—ἀτμός, vapour; λύω, I loosen. If a current of steam be passed through a porous tube at a high temperature, and if the porous tube be surrounded by another tube of glazed impervious porcelain, the water vapour will be dissociated by the heat into hydrogen and oxygen; since the hydrogen diffuses much faster than the oxygen, hydrogen will pass from the inner tube into the annular space between the two tubes. The hydrogen may be collected in a suitable gas trough. Similarly, the residual oxygen can be collected from the gaseous steam passing along the inner tube. Of course, the hydrogen is contaminated with more or less oxygen, and the oxygen with more or less hydrogen. In 1906, A. Jouve and G. Gautier [7] proposed to separate carbon monoxide and hydrogen industrially by filtration through a porous partition.

Are the molecules of a gas all alike?—Experiments on atmolysis enable a conditional answer to be returned. If a gas like hydrogen or oxygen be filtered through a septum of porous earthenware, no difference can be detected in the properties of the gas on each side of the partition. If some of the molecules of, say, hydrogen have a greater density than the others, it should be possible to separate two kinds of hydrogen of different density. This cannot be done, and hence, it is inferred that within the limits of experimental observation, the molecules of hydrogen are all alike, for if there be a difference, it is too small to be detected. Similar remarks apply to oxygen and many other gases. W. Ramsay and J. N. Collie (1897) [8] showed that helium is probably a single substance because repeated diffusion did not alter its density; Lord Rayleigh and W. Ramsay (1895) showed that atmospheric nitrogen is probably a physical mixture of nitrogen with a heavier gas, because repeated diffusion altered its density; and F. W. Aston (1913) separated neon into two gases with densities 19·9 and 22·1, and hence inferred that neon is probably a mixture of two gases of different densities.

The effusion of gases.—T. Graham (1832) [9] found that the law of diffusion holds good for the passage of a gas through a very fine aperture in a metal plate. T. Graham called the phenomenon the effusion of gases to distinguish it from diffusion. The theory was indicated by D. Bernoulli [10] in 1738. The speed of effusion varies inversely as the square root of the density. If a gas of density D_1 flows out of the tube in the time t_1, then, according to the law of effusion: $D_1 : D_2 = t_1^2 : t_2^2$. In words, **the times required for the efflux of equal volumes of different gases, under like conditions of pressure, etc., are directly proportional to the square roots of the densities of the gases.** Thus T. Graham found (air unity):

TABLE VI.

Gas.	Square root of density.	Time of efflux.	
		Glass tube.	Perforated brass plate.
Hydrogen	0·263	0·277	0·276
Methane	0·745	0·756	0·753
Carbon monoxide	0·984	0·987	—
Ethylene	0·985	—	0·987
Nitrogen	0·986	0·984	0·986
Oxygen	1·051	1·053	1·053
Nitrous oxide	1·237	1·199	—
Carbon dioxide	—	1·218	1·203

The method for determining the specific gravity of coal gas based on this principle is considered one of the best. Thus, the time of effusion observed for gas was 2′25·1″ or 145·1 seconds, and for air, 3′40·8″ or 220·8 seconds. Hence, the specific gravity of the gas is $(145\cdot1/220\cdot8)^2=0\cdot432$. R. Bunsen (1857)[11] utilized this fact to determine the specific gravity of a gas when but a small quantity is available. In N. H. Schilling's effusion apparatus (1879) the gas is introduced into a glass tube, luted to a brass cover, *viâ* the cocks *b*, *c*, Fig. 18. This tube is placed in a cylinder filled with water and the temperature is indicated by the thermometer *T*. The perforated platinum plate is fixed at *b*. The time taken for the tube to sink from the level *P* to the level *O* on the cylinder is noted. The experiment is repeated with another gas of known density. A. Ladenberg (1898)[12] used this apparatus to determine the specific gravity of ozone. A. Debierne (1910) used Bunsen's effusion method for determining the density of the emanation from radium; and F. Emich (1903) modified the apparatus so that it could be used at high temperatures between 1400° and 2000°.

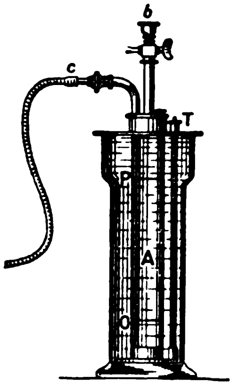

FIG. 18. — Schilling's Effusion Apparatus.

EXAMPLES.—(1) N. H. Schilling (1879) found that a given volume of air effused in 285 seconds while the same volume of coal gas effused in 209 seconds, hence the relative density of coal gas with respect to air unity is $(209)^2/(285)^2=0\cdot538$.

(2) A. Ladenberg (1898) found that a mixture containing 86·16 per cent. of ozone required 267·5 seconds under conditions where pure oxygen required 430 seconds. Hence, determine the specific gravity of ozone. From a previous example, it follows that the specific gravity of the ozonized oxygen is 1·3698, oxygen=1. The specific gravity of ozone is 1·456, if oxygen be unity; and 46·6, if oxygen O_2 be 32. Note that this does not establish the molecular weight by Avogadro's hypothesis, because, in determining the proportion of ozone in the mixture, by estimating the amount of iodine liberated by a given volume of the gas, it was assumed that the reaction proceeds as indicated in a preceding equation, which in turn assumes that the formula of ozone is O_3.

CHAPTER VIII

OXYGEN

§ 1. History of the Discovery of Oxygen

A substance is discovered only when it has been shown to differ from all other known substances.—G. W. VON LEIBNIZ.

THE history of the discovery of oxygen is intimately connected with Lavoisier's discovery of the cause of combustion. C. W. Scheele's laboratory note-books, preserved in the Royal Academy of Science at Stockholm, are said to prove that he discovered oxygen some time before 1773. C. W. Scheele exposed alkaline liver of sulphur, moist iron filings, phosphorus, etc., to the action of air confined in a jar over water; and he also burnt phosphorus, hydrogen, and a candle in air confined under similar circumstances. By measuring the volume of water which entered the vessel at the end of the process, C. W. Scheele found what fraction of the original volume had disappeared. He concluded:

> Thus much I see from the experiments mentioned, that the air consists of two fluids differing from each other, the one of which does not manifest in the least the property of attracting phlogiston, while the other, which composes between a third and a fourth part of the whole mass of air, is peculiarly disposed to such attraction.

C. W. Scheele failed to find the *lost air* in the liver of sulphur, etc. He then attempted to explain the facts by assuming that heat is a compound of fire-air (oxygen) and phlogiston, and concluded that by a double affinity, the fire-air combined with the phlogiston of the liver of sulphur, and escaped through the pores of the glass by which it had been confined. Where weight disappears, analysis is impossible, and C. W. Scheele left the composition of air to be explained by those who believed that elastic fluids cannot penetrate glass. In some further experiments, he sought an air which would behave towards liver of sulphur, phosphorus, etc., like that part of common air which had the peculiar property of attracting phlogiston from inflammable bodies. He first obtained what he called *Feuerluft*—**fire-air**—by heating a mixture of nitre and sulphuric acid, and found that a candle burned in the gas briskly and brightly. He obtained fire-air in several other ways—namely, by heating red oxide of mercury; black oxide of manganese; black oxide of manganese and sulphuric acid; nitre; etc.—and noticed that it was absorbed by those substances which caused a portion of common air to disappear. He said:

> These experiments show, therefore, that this fire-air is just that air by means of which fire burns in common air; only it is there mixed with a kind of air which seems to possess no attraction at all for the inflammable substance, and this it is which places some hindrance in the way of the otherwise rapid and violent inflammation.

C. W. Scheele's mind was probably a little misled by the phlogiston hypothesis, for he did not see that during combustion the burning body absorbs something from the air. The **vitiated air**—*verdorbene Luft*—which remained did not support combustion. C. W. Scheele also found the specific gravity of the vitiated air to be rather less, and that of fire-air rather greater, than that of common air.

C. W. Scheele did not publish an account of his work until 1777;[1] meanwhile, Joseph Priestley independently prepared the same gas which he called *dephlogisticated* *air.* He encountered the gas while examining the effect of heat upon a great variety of substances confined in a cylinder inverted over mercury, and he decomposed them by focussing the sun's rays upon them by means of "a burning lens of 12 inches diameter, and 20 inches focal distance." Joseph Priestley[2] announced his discovery of oxygen in these words:

> On the 1st of August, 1774, I endeavoured to extract air from *mercurius calcinatus per se*—that is, mercuric oxide, or red oxide of mercury—and I presently found that by means of this lens, air was expelled from it very readily. Having got about three or four times as much as the bulk of my materials, I admitted water to it and found that it was not imbibed by it. But what surprised me more than I can well express, was that a candle burned in this air with a remarkably brilliant flame.

and furthermore he said[3] that he ascertained the nature of this air very gradually during the following March, 1775. He then tried the effect of adding one measure of nitric oxide to two measures of the new air, and found that the new air behaved like common air. He added:

> I did not take notice of what I might have observed if I had not been so fully possessed by the notion of there being no air better than common air, that the redness was really deeper, and the diminution something greater than common air would have admitted. I now concluded that all the constituent parts of air were equally and in their proper proportion imbibed in the preparation of this substance, and also in the process of making red lead.

Until the first of March, J. Priestley said that he had no suspicion of the new air being fit for respiration; he then tried the mouse experiment of John Mayow, and found the new air was longer respirable than common air. His ideas, however were not so clear as those of J. Mayow, for instead of regarding air, with J. Mayow, as a constituent part of nitric acid, J. Priestley thought air to be a compound of nitric acid and earth; and added that in December, 1777,

> No doubt remained in my mind that atmospheric air, or the thing that we breathe, consists of the nitric acid and earth, with so much phlogiston as is necessary to its elasticity, and likewise so much more as is necessary to bring it from a state of perfect purity to the mean condition in which we find it.

It is therefore fairly evident that neither of the so-called discoverers of oxygen—Priestley and Scheele—had clear or accurate views of the nature of this gas, because they interpreted their results in the light of hypotheses which we now know to be wrong. This, however, does not detract from the merit of the discovery *per se.* Between August, 1774, and March, 1775, when J. Priestley had no doubt that the new air had all the properties of common air, A. L. Lavoisier, having heard an account of the new gas from J. Priestley himself, ascertained its relation to various bases and to the atmosphere; and thus, said W. V. Harcourt,[4] a property of this gas which under Priestley's observations led to nothing, in the hands of A. L. Lavoisier gave rise to one of the most important investigations in the annals of chemistry.

It must be added that J. Priestley's observation[5] in 1772 that a candle burnt with an enlarged flame in the gas obtained by heating nitre was perhaps as much a discovery of oxygen as the experiment of August 1, 1774. J. Priestley then said:

> All the kinds of factitious air on which I have yet made the experiment are highly noxious, except that which is extracted from saltpetre or alum: but in this, even a candle burned just as in common air. In one quantity which I got from saltpetre, a candle not only burned, but the flame was increased, and something was heard hissing similar to the decrepitation of nitre in an open fire; this experiment was made when the air was fresh made, and while it contained some particles of nitre which it would probably have deposited afterwards.

Joseph Priestley seems to have thought that the gas was fixed air, and he did not recognize his mistake until three years later.

For a century before this time, philosophers had suspected some kind of relationship between nitre and air, although there was no agreement as to the form of that relationship. Some, like N. Henshaw (1661),[6] maintained that the effects were due to the distribution of actual particles of nitre in the air, for " the air is everywhere full of a volatile kind of nitre." R. Boyle also, in 1664, made a similar suggestion; T. Hobbes considered that nitre consisted of "many orbs of salt filled with air"; while R. Hooke (1664) believed that the portion of air which rendered air a solvent of combustible bodies, is " like, if not the very same, with that which is fixed in saltpetre " ; and J. Mayow followed this up by demonstrating that the gas in the atmosphere which, in combining with bodies, produces the phenomenon of combustion, is identical with one of the components of nitre because (i) that salt is produced in the atmosphere; and (ii) the effects produced by both in enabling substances to burn are the same—for instance, he showed that the acid component of nitre, of nitric acid, and of the product obtained by heating antimony in the focus of a burning glass, all furnish the same substance.

There has been some discussion as to whether the alchemists were acquainted with oxygen, for there are indications in old books that this gas was known in the early centuries. Zosimus, in the fourth century, said :

> Take the soul of copper which is borne upon the water of mercury, and disengage an aeriform body.

According to F. Hoefer,[7] the *water of mercury* must here have referred to liquid mercury, and the *soul of copper* to red mercuric oxide which floats on mercury which has been heated in air. If so, the aeriform body given off when the soul of copper is heated must have been oxygen. This is an ingenious and probable interpretation of the passage, although it is easy to read into old writings a meaning which the original was not intended to express. Again, in 1742, J. H. Cohausen [8] referred to the *white dove* mentioned in the writings of Philalethes. It was said that atmospheric air is not respirable if the white dove be removed. In 1660, Robert Boyle [9] related, in a gossiping style, that Cornelius Drebell invented a kind of submarine, and that he had a chemical liquid which he accounted the chief secret of his navigation; for when the air was fouled by respiration, he could, by unstopping a vessel full of the liquid, speedily restore such vital parts as would make the air fit for use again.

Although clothed in mystical language, as was customary with the writers on alchemy of this period, it does seem as if the preparation of oxygen and its property of supporting life may have been suspected by some of the alchemists; but, their statements are so often mixed with what we know to be false, and their means of handling gases were so crude, that it requires some licence to be able to say that they discovered this gas. It has also been claimed that oxygen was discovered by E. Swedenborg,[10] half a century before Priestley, but the claims are based upon obscure and unintelligible passages which carry their own refutation.

However, P. Eck de Sultzbach [11] in 1489, did know that red oxide of mercury gave off a *spirit* when heated; about 1557, J. Cardan,[12] and about 1674, Ole Borch —the familiar term for Olaus Borrichius—obtained a *flatus* by the action of heat on saltpetre. This must have been either oxygen or nitrous oxide gas, because J. Cardan said that the gas nourished flame, and rekindled a glowing splint. A few years later, R. Boyle [13] said :

> On September 4, 1678, I exposed one ounce of minium in an open glass to the sunbeams concentrated by a burning glass, and found that it had lost three-fourths of a grain of its weight, though much of the minium had not been touched by the solar rays. . . . On May 30, the same experiment was repeated in a light glass phial sealed hermetically, but such plenty of air was produced that the glass phial broke into a hundred pieces.

Stephen Hales prepared the gas in a similar manner about 1727, and collected it over water; and in 1774, P. Bayen obtained the same gas by heating precipitated mercuric oxide in a retort. In the light of subsequent events, it appears as if these observers had really isolated oxygen gas, but one and all failed to establish its identity as a distinct individual. In some cases, the observations do not seem to have been clearly understood, probably because of the dominating influence of the idea that air was the only ponderable gaseous element. Had any one of these observers not only isolated the spirit or flatus, but also shown that it had specific properties, *sui generis*, which distinguished it from other known substances, he would have been credited with the discovery of oxygen.

The Chinese appear to have known something about oxygen in the eighth century, long before Joseph Priestley's and C. W. Scheele's experiments. Whatever be the facts of the case, the work of the Chinese played no part in the European discovery of this gas. In a paper *On the chemical knowledge of the Chinese in the eighth century*,[14] J. Klaproth, quoting from the Chinese, said :

> There are many substances which rob the atmosphere of part of its *yin*, the chief of these are the metals, sulphur and carbon. . . . The *yin* of the air is always pure, but by the aid of fire, *yin* can be extracted from nitre, or from a black mineral (black oxide of manganese) found in the marshes. It also enters into the composition of water, where the union is so close that decomposition is extremely difficult. . . . Gold never amalgamates with the *yin* of the air.

It will therefore be obvious that many erring steps have stumbled on the threshold of the discovery of oxygen. Although J. Priestley and C. W. Scheele are usually credited with the discovery of this gas, it is extremely difficult to decide whose name deserves the highest place in the discovery, for R. Hooke and J. Mayow inferred its existence in nitre and in air ; P. Eck de Sultzbach and R. Boyle disengaged the gas from red lead or minium ; S. Hales collected the gas in a jar over water ; and J. Cardan, C. W. Scheele, and J. Priestley observed that it supported combustion. Before answering the question : Who discovered oxygen ? it is necessary to answer : What is meant by the term discovery ?

§ 2. The Action of Heat on Mercuric Oxide

In the thirteenth century, the Latin Geber knew that if mercury be heated in air, it forms the red oxide ; and P. Eck de Sultzbach, as previously stated, appears to have known that if the red oxide be heated, it gives off a spirit or gas. Here then is a paradoxical result : Heating mercury in oxygen furnishes mercuric oxide ; heating mercuric oxide furnishes oxygen and mercury. Several investigations [1] have been made to determine the conditions of temperature and pressure which determine the course of this reaction—evidently one of the balanced type, symbolized $2HgO \rightleftharpoons 2Hg + O_2$. Unlike the reaction between steam and iron in closed vessels, Fig. 4, Cap. III, the reaction is here complicated by the vaporization of the mercury. If p_0 denotes the partial pressure of the oxygen at any assigned temperature, and p_m that of the mercury, Guldberg and Waage's law gives the relation $p_0p_m^2$=constant. The product $p_0p_m^2$ is least when the partial pressure of the mercury vapour is twice that of the oxygen, *i.e.* when the two elements are in the same proportion as they exist in the solid phase. When the system is in equilibrium, mercury and oxygen are uniting to form mercuric oxide, and mercuric oxide is decomposing to form mercury vapour and oxygen. When the speeds of the two reactions are perfectly balanced, the system is in equilibrium, and the gases exert a definite pressure called **the equilibrium or dissociation pressure** on the walls of the vessel as measured by the manometer. This pressure thus measures the concentration of the gases, and one-third of the pressure is due to oxygen, and two-thirds to the mercury. When the temperature of mercuric oxide in vacuo is raised the speed of decomposition of the oxide is augmented more than the rate of re-combination of the two gases, and consequently, the equilibrium pressure or the concentration of the gases increases as the temperature is raised, until finally, all the mercuric oxide is decomposed, and the mixed gases then obey the ordinary gas laws. J. B. Taylor and G. A. Hulett represent the relation between the absolute temperature, T, and the dissociation pressure, P, by the expression $\log P = -5273{\cdot}5T^{-1} + 1{\cdot}75 \log T - 0{\cdot}001033T + 5{\cdot}9461$. The following values of the total pressure P at different temperatures are selected from G. B. Taylor and G. A. Hulett's determinations :

Temperature . .	360°	390°	420°	450°	480° C.
Equilibrium pressure .	90	180	387	810	1581 mm.

The curve showing the equilibrium pressure at different temperatures is indicated in Fig. 1. When the relation between the total pressure of the oxygen plus mercury and temperature can be represented by a point on this curve, the system is in equilibrium ; if by a point to the right of the curve, mercuric oxide will be decomposing and this will continue until the pressure attains its equilibrium value ; and if by a point to the left of the curve, the gases will be recombining and mercuric oxide will be formed until the pressure is reduced to its equilibrium value. Assuming the partial pressure of oxygen in air is one-fifth of 760 mm., *i.e.* 152 mm., and that mercuric oxide is heated in air, the oxide will commence to decompose when heated above 426°, and the temperature must be kept below this limit if it is desired to form mercuric oxide by heating mercury in air.

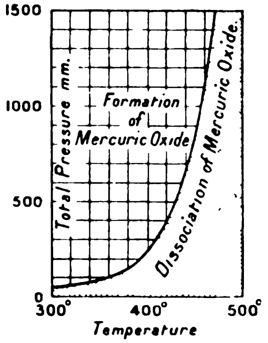

FIG. 1.—Equilibrium Pressure of Mercuric Oxide (Partial pressure of oxygen = ⅓ Total pressure).

Were it not for the cost, the preparation of oxygen by heating mercuric oxide would be very convenient. Ten grams of mercuric oxide give not quite half a litre of oxygen. The mercury is a by-product of the reaction.

Mercuric oxide decomposes more rapidly if it be previously mixed with powdered platinum or with certain metal oxides—*e.g.* ferric oxide, manganese dioxide, cadmium oxide, etc. These substances are not chemically changed during the decomposition of the mercuric oxide, and they can be used indefinitely over and over again. Hence, the oxides, which accelerate the decomposition of mercuric oxide are called catalytic agents. Stannic oxide or alumina do not exert any appreciable catalytic effect.

Many other oxides are available in place of mercuric oxide—*e.g.* gold and silver oxides decompose at temperatures even lower than mercuric oxide, while manganese peroxide (pyrolusite) decomposes at a higher temperature—over 400°. The preparation of oxygen by heating manganese dioxide was formerly one of the cheapest methods of preparing the gas on a commercial scale. The process was also used by C. W. Scheele in 1777 ; and by J. Priestley in 1779. Unlike silver, mercury, and gold oxides, the manganese oxide does not break down into the corresponding metal and oxygen, but rather into a complex oxide similar in composition to the mineral hausmannite—Mn_3O_4. The reaction is symbolized: $3MnO_2 = Mn_3O_4 + O_2$. Fairly pure manganese dioxide will furnish 88 to 89 litres of oxygen per kilogram; but pyrolusite, the native form of manganese dioxide, may give as low a yield as 34 litres of oxygen per kilogram, and the gas is contaminated with carbon dioxide and nitrogen or nitrogen oxides derived from impurities in the mineral.[2] Gold, silver, and mercuric oxides are not often used as sources of oxygen on account of the expense.

It will be observed that the alternate oxidation of mercury by roasting in air and the decomposition of the resulting oxide suggests a means of extracting oxygen from the air. Similarly, palladium sponge is directly oxidized when heated to redness in air, and the resulting oxide, Pd_2O, reforms the metal with the evolution of oxygen at a little higher temperature. When rhodium sponge is similarly treated, the oxide, RhO, is formed; and with iridium sponge, the oxide Ir_3O. These two oxides give oxygen and the metal[3] at about 1200°.

§ 3. The Action of Heat on Potassium Chlorate

Potassium chlorate is a white crystalline solid which melts to a clear liquid when heated to about 340°. According to A. Rilliet and J. M. Crafts,[1] potassium chlorate begins to give off oxygen below its melting point and the decomposition goes on several weeks before it becomes imperceptibly small; when the limit is reached, a rise of temperature starts a fresh decomposition, tending towards a new limit. At about 10° above its melting point, the melted chlorate appears to boil, because bubbles of oxygen gas are copiously evolved. The potassium chlorate is decomposing. When the bubbling ceases, the molten mass becomes very viscid or even solidifies. The potassium chlorate has decomposed into potassium perchlorate, potassium chloride, and oxygen. If the temperature be raised still further—over 600°—the mass again melts to a clear liquid and the potassium perchlorate decomposes, giving off more oxygen. The final products of decomposition are potassium chloride and oxygen, and the reaction is accordingly symbolized: $2KClO_3 = 2KCl + 3O_2$. Hence, potassium chlorate can be used in place of mercuric oxide for the preparation of oxygen gas. Ten grams of potassium chlorate will give nearly 2¾ litres of oxygen. Purified and fused potassium chlorate gives oxygen free from chlorine and ozone, O_3. The gas is of a high degree of purity, and this process was used by E. W. Morley in his work on the atomic weight of oxygen.

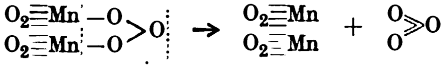
If potassium chlorate be suddenly heated to a temperature above that at which decomposition occurs, the salt may detonate in an open vessel under ordinary pressure. Some disastrous explosions have been produced by potassium chlorate. M. Berthelot's experiment (1899)[2] illustrates the explosive nature of this salt.

One end of a glass rod is drawn out into a thread, and the narrow end is dipped several times in molten potassium chlorate so that each layer of salt solidifies before the rod is dipped again. When a bead has been formed at the end of the rod, dip the rod into a test-tube heated red hot at one end so that the salt is about a centimetre from the bottom of the tube.

Take care not to touch the sides of the tube. As the chlorate melts, it slowly drops to the bottom of the test-tube; each drop of chlorate as it falls explodes with a sharp detonation.

C. L. Berthollet[3] first made oxygen by the chlorate process in 1785; and in 1832, J. W. Döbereiner noticed that the potassium chlorate decomposes completely at a much lower temperature if it be mixed with manganese dioxide; the reaction also progresses more smoothly and is more under control. Other agents can be employed—*e.g.* the oxides of copper, iron(ic), lead, cobalt, vanadium, uranium, and tungsten. With ferric oxide, the evolution of oxygen begins between 110° and 120°; with manganese dioxide, between 200° and 205°; and with platinum black, between 260° and 270°. The stimulating action of alumina and chromic oxide is less marked; and baryta, lime, magnesia, and zinc oxide have no influence. Powdered glass, sand, and china clay promote the decomposition of the chlorate to a small extent. Although oxygen can be easily obtained by heating manganese dioxide, MnO_2, to about 600° in a fireclay, porcelain, or iron retort ($3MnO_2 \rightarrow Mn_3O_4 + O_2$), and potassium chlorate, when heated *alone*, does not give off oxygen below about 240°, yet a *mixture* of the two gives off oxygen at about 205°—a temperature below the melting point of the chlorate. After the action, manganese dioxide still remains, but the potassium chlorate has decomposed into potassium chloride and oxygen. Manganese dioxide can be recovered from the residue by lixiviating the mass with water. The water dissolves the potassium chloride, and leaves the manganese dioxide as a residue. The temperature of the reaction with ferric oxide and cupric oxide is nearly the same as with manganese dioxide; with platinum black, it is 270°, and 285° with lead dioxide.[4] Cobaltic and nickelic oxides behave like manganese dioxide and accelerate the decomposition of potassium chlorate. The nitrogen is probably derived from nitrogeneous impurities in the dioxide, and is not a result of the oxidization of atmospheric nitrogen because a similar result is obtained if the dioxide be heated in a current of inert gas—say carbon dioxide.

C. F. Schönbein[5] reported that the gas obtained from lead dioxide, mercuric oxide, silver oxide, and chlorates contains traces of ozone, but A. R. Leeds showed that the ozone reactions obtained by C. F. Schönbein were produced by traces of chlorine. According to W. Spring and E. Prost, the amount of chlorine formed is insignificant if the chlorate be decomposed in a platinum vessel, but quite marked quantities are obtained when porcelain vessels are used. In the presence of carbon dioxide or phosphoric oxide, it is possible that chloric anhydride, Cl_2O_5, is disengaged from the chlorate, and that this unstable gas is instantly decomposed into chlorine and oxygen. According to O. Brunck, ozone, not chlorine, is formed in the reaction in amounts which increase with increasing proportions of manganese dioxide mixed with the chlorate. Thus, with equal parts of chlorate and the dioxide the oxygen contained 0·3 per cent. of ozone, whereas with 25 times as much of the dioxide, the oxygen contained 1·55 per cent. of ozone. If alkalies be present no ozone is formed, and with sodium carbonate, sodium peroxide is found in the residue. Nickelic and cobaltic oxides, like manganese dioxide, give oxygen contaminated with ozone; while mercuric oxide, lead dioxide, and silver oxide, give ozonized oxygen when heated with potassium chlorate. O. Brunck also claims that if these mixtures are heated in a stream of carbon dioxide no ozone is formed. It is quite certain that the gas from the mixture of potassium chlorate and manganese dioxide has usually the smell of ozone or chlorine. Traces of these two substances behave so much alike in the usual test, that one can be easily mistaken for the other. Both chlorine and ozone, for example, give a blue coloration with a solution of starch and potassium iodide. E. H. Cook[6] has reported 0·03 per cent. of chlorine in the oxygen derived from the chlorate. H. McLeod has shown that when potassium chlorate and manganese dioxide are heated, some chlorine is produced, and claims that there is no evidence of the simultaneous formation of ozone. For instance, the residue left after the reaction is over gives an alkaline solution when extracted with water. O. Brunck obtained no alkaline residue. The gas also gives a precipitate of silver chloride when it is passed through a solution of silver nitrate, suitable precautions being taken to prevent fine particles of potassium chloride being carried along with the stream of gas. O. Brunck explains the discrepancy between his own results and H. McLeod's by showing that the latter's apparatus contained traces of organic matter which would decompose the ozone, and that H. McLeod used *unnötig* high temperatures. Above 400°, O. Brunck also obtained chlorine, and he suggests that the manganese dioxide forms with the chlorate, permanganic anhydride, Mn_2O_7, and that this gives the ozone form of oxygen, O_3, in accord with the scheme : $Mn_2O_7 \rightarrow 2MnO_2 + O_3$; or graphically :



$$\begin{matrix} O_2\equiv Mn-O \\ O_2\equiv Mn-O \end{matrix}\!\!>\!O \;\rightarrow\; \begin{matrix} O_2\equiv Mn \\ O_2\equiv Mn \end{matrix} + \begin{matrix} O \\ O \end{matrix}\!\!\geqslant\! O$$

and if chromic oxide is used a chromic anhydride, Cr_2O_6, is similarly formed and decomposed. Most of the ozone is decomposed at the temperature of the reaction, $2O_3=3O_2$.

Potassium chlorate, mixed with manganese dioxide, is commonly used in the laboratory for the preparation of oxygen ; and with the idea of lessening the violence of the action still more, the addition of 10 to 30 per cent. of common salt has been recommended ;[7] but this is usually considered unnecessary. The chlorine can be removed by passing the gas through magnesia, whiting, or soda ash distributed over some inert material like glass wool or asbestos. If a highly pure gas is needed, fused potassium chlorate can be used alone. The cost of oxygen by the chlorate process is nearly double that by the pyrolusite process. By the former process, 1000 cub. ft. of oxygen are said to cost £8 to £10, and by the latter £4 to £5, against 3*s*. 6*d*. by the liquid air process.

§ 4. The Occurrence and Preparation of Oxygen

The occurrence of oxygen.—Oxygen is widely distributed on the earth in very large quantities. It is an essential constituent of air and water. About one-fourth —23·2 per cent.—of the atmosphere by weight, and about one-fifth by volume consists of free oxygen. J. H. Jeans' estimate[1] of the number of molecules of oxygen per c.c. at a height *h* kilometres is

$h=0$	$h=20$	$h=80$	$h=160$	$h=800$
21×10^{17}	7×10^{16}	25×10^{11}	3×10^{6}	0

Water contains about 88·8 per cent. of combined oxygen. Oxygen also forms a material part of rocks since a great many minerals contain a considerable proportion of oxygen. F. W. Clarke estimates that 45 to 53 per cent.—nearly one-half—the total weight of rocks, and eight-ninths of the water which make up the half-mile crust of the earth, is combined oxygen. Oxygen therefore is by far the most abundant element, being nearly equal in amount to all the others put together. Natural waters hold a small amount of oxygen in solution.

Oxygen is an essential constituent of animal and vegetable tissue and fluids. It is absorbed from the atmosphere by animals and plants during respiration; and given off by plants when they assimilate carbon dioxide from the air in sunlight. This fact was established by J. Priestley on August 17th, 1776, by showing that plants could live in fixed air in which animals perish, and that plants can restore to fixed air the properties of common air when in sunlight, but not in darkness. The explanation of J. Priestley's observation was possible only after the function of oxygen in respiration was recognized. R. Perceval, and J. Senebier showed that the amount of oxygen given off depends on the proportion of carbon dioxide in the atmosphere, and J. Ingenhousz proved that sunlight is necessary for the reaction. The oxygen contains no ozone. Some plants—*e.g. bact''rium photometricum*, can produce oxygen without the agency of light; and chlorophyllous animals give off oxygen in sunlight.[2]

H. Draper[3] showed, in 1877, that oxygen is present in the sun; J. Trowbridge (1896), however, believed that the spectral lines thought to be oxygen were due to iron; but later, from the analogy of the solar spectrum with the spark spectrum of water vapour, J. Trowbridge (1902) assumed that the sun contains dissociated water vapour and consequently also free oxygen.

The preparation of oxygen.—There are many methods available for preparing oxygen—the particular process to be employed must be determined by cost and convenience.[4] If but a few litres of gas, not specially purified, are required, cost is not very serious, and convenience is perhaps the most important factor; if pure oxygen be required, a complicated apparatus may be needed, and neither cost nor labour must be spared. An elaborate apparatus may be needed to remove traces of impurities—say, traces of ozone and chlorine from the oxygen. Pure potassium chlorate alone will give a gas of a high degree of purity. If large quantities of gas are needed, say for industrial purposes, the cost factor is of prime importance. Generally speaking, the success of industrial operations depends upon the ability of the chemist to manufacture his products cheaply. In former times, oxygen was made commercially by heating pyrolusite, and also by the chlorate method; but the cost was too great for these processes to compete successfully with the cheaper methods by barium peroxide, or the fractional distillation of liquid air. The different methods of preparing oxygen can be conveniently classed:

1. *Processes dependent on the decomposition of oxides or oxy-compounds by heat.*—The methods of preparing oxygen by heating mercuric oxide, and by heating potassium chlorate are typical. Several dioxides also yield oxygen when heated—*e.g.* manganese dioxide, lead dioxide, barium dioxide, etc. The nitrates of potassium or sodium give oxygen contaminated with nitrogen or nitrogen oxide.[5] Oxygen was probably obtained by this method by J. Priestley in 1771—some years before the date generally accepted for his discovery of this gas. The first British patent for the manufacture of oxygen was by S. White[6] in 1849, and this was effected by heating nitre.

When the vapour of sulphuric acid is passed over fragments of brick or earthenware heated to bright redness, oxygen, sulphur dioxide, SO_2, and water are formed: $2H_2SO_4=2H_2O+2SO_2+O_2$. By washing the products in water or in a solution of sodium hydroxide, the sulphur dioxide is arrested. In this way, H. St. C. Deville and H. Debray [7] obtained 140 litres of oxygen from a kilogram of concentrated sulphuric acid—between 6 and 7 per cent. of the acid escaped decomposition. W. S. Squire (1875) patented this process of making a mixture of oxygen and sulphur dioxide for the manufacture of sulphur trioxide—the water was removed by a desiccating agent. H. St. C. Deville and H. Debray also obtained 6·8 litres of oxygen by calcining zinc sulphate *au rouge blanc.* The sulphate decomposes in an analogous manner to the acid.

When potassium or sodium permanganate is heated, it also furnishes fairly pure oxygen.[8] It is well to cover the salt with a heavy layer of glass wool to retain any dust from the decomposition of the permanganate. The product of this reaction, after scrubbing by passage through a layer of solid potassium hydroxide, and drying by passage over phosphorus pentoxide, has been used in some refined determinations of the relative density of the gas. The decomposition proceeds at a lower temperature in the presence of steam forming an alkali manganite (G. Rousseau), or a mixture of manganic oxide and alkali hydroxide (C. M. T. du Motay and C. R. M. de Marechal), and a regular stream of oxygen.[9] The hypochlorites or hypobromites furnish oxygen when they are heated. Cupric metaborate, CuB_2O_4, gives off oxygen [10] at about 1000° forming the sesquiborate: $12CuB_2O_4=6Cu_2O.2B_2O_3+3O_2+10B_2O_3$.

2. *Processes dependent on the decomposition of oxides and oxy-compounds by chemical means.*—There is probably no real distinction between many of the thermal and chemical processes. Heat may be required to start the reaction in either class; and the thermal processes all involve chemical reactions. Many dioxides yield oxygen when treated with water or dilute acid, in some cases at atmospheric temperatures. Sodium peroxide, for example, is slowly decomposed by water into sodium hydroxide and oxygen: $2Na_2O_2+2H_2O=4NaOH+O_2$. If a catalytic agent, say manganese dioxide, be present, the reaction is not inconveniently slow for small quantities of gas. The trade name for a mixture of fused sodium peroxide with a small quantity of manganese dioxide is *oxone*; *oxylith* [11] is a compressed mixture of sodium peroxide with about 62 per cent. of dry chloride of lime. It slowly decomposes in contact with water, giving off oxygen: $CaOCl_2+H_2O+Na_2O_2=Ca(OH)_2+2NaCl+O_2$. Numerous other mixtures have been patented for this purpose; as well as vessels—generators or auto-generators—for producing the gas. When sodium peroxide is gently warmed with a salt containing water of crystallization—*e.g.* Glauber's salt, or sodium carbonate—a steady stream of oxygen is given off.[12] Many other methods are available for the preparation of oxygen. Heating sulphuric acid with manganese dioxide; [13] with chromic acid or potassium dichromate; [14] with potassium permanganate; etc., and this more particularly when a powerful oxidizing agent, rather than gaseous oxygen, is required. The reaction with manganese dioxide is symbolized: $2MnO_2+2H_2SO_4=2H_2O+2MnSO_4+O_2$, and with potassium dichromate: $2K_2Cr_2O_7+8H_2SO_4=2Cr_2(SO_4)_3+2K_2SO_4+8H_2O+3O_2$. Other salts rich in oxygen may be used. Hydrogen peroxide is sometimes convenient for preparing small quantities of oxygen, although the cost is rather high. For instance, a 10 per cent. solution of hydrogen peroxide mixed with a substance which provokes its catalytic decomposition—*e.g.* chloride of lime; [15] manganese dioxide; lead dioxide; [16] potassium ferricyanide in alkaline solution [17] ($2K_3FeCy_6+2KOH+H_2O_2=2H_2O+2K_4FeCy_6+O_2$); or potassium dichromate.[18] A concentrated solution of potassium permanganate gives off oxygen at ordinary temperatures when acidified with sulphuric acid.

Heat a mixture of, say, 20 grams of potassium permanganate with 80–100 c.c. of dilute sulphuric acid (one volume of the concentrated acid, with four volumes of water) in a flask with a delivery tube and safety funnel. Oxygen begins to come off when the temperature is about 50°, and continues in a steady stream. Ten grams of the permanganate with between 40–50 c.c. of the dilute sulphuric acid give just over a litre of gas.

A. Baumann (1890) [19] charges a Kipp's apparatus with lumps of pyrolusite and a mixture of commercial hydrogen peroxide with 15 per cent. by volume of sulphuric acid. A steady and continuous stream of oxygen is said to be evolved. The hydrogen peroxide can be replaced in any of the preceding mixtures by a peroxide of the alkalies or alkaline earths. L. Wolter (1908) recommends a fused mass of equal parts of sodium peroxide, and potassium nitrate with one-eighth of its weight of magnesia. Hydrochloric acid is dropped on the coarsely pulverized mass. L. Santi recommends warming a solution of ammonium chloride with barium peroxide: $2BaO_2+4NH_4Cl \rightarrow 2BaCl_2+4NH_3+2H_2O+O_2$, for a steady stream of oxygen. G. Neumann[20] similarly charges a Kipp's apparatus with cubes made from barium dioxide, pyrolusite, and gypsum in the proportions 2 : 1 : 1, together with hydrochloric acid (specific gravity 1·12).

There are numerous other reactions in which oxygen is evolved—*e.g.* a mixture of steam and chlorine[21] passed through a red-hot tube gives a mixture of hydrogen chloride, HCl, and oxygen: $2Cl_2+2H_2O=4HCl+O_2$. According to D. Muller, a temperature of 120° suffices for the reaction. Chlorine water decomposes into oxygen and hydrogen chloride when exposed to sunlight. The finely-divided metals of the platinum family decompose chlorine water even in darkness, forming oxygen and hydrogen chloride; according to C. F. Schönbein,[22] bromine and iodine water do not decompose in this way in darkness.

According to J. L. Gay Lussac, dry chlorine will displace the oxygen from certain oxides. This is the case, for instance, with the oxides of the alkaline earths, lead, or cadmium. If silver hydroxide be placed in a jar of chlorine gas, the oxygen and chlorine will change places.[23] So also if commercial "chloride of lime" which contains much calcium hypochlorite, $CaOCl_2$, be heated to redness: $2CaOCl_2=2CaCl_2+O_2$. According to H. St. C. Deville and H. Debray, a kilogram of the chloride of lime will furnish 40 to 50 litres of oxygen contaminated with a little chlorine which can be removed by washing the gas with soda lye. E. Mitscherlich[24] has also shown that a fairly steady stream of oxygen can be obtained by heating a mixture of a concentrated solution of bleaching powder, and a small quantity of a nickel or cobalt salt, at about 85°. Other hypochlorites, as well as hypobromites, can be employed. The cobalt or nickel salt forms a higher oxide which acts catalytically. The cobalt or nickel salt can be replaced by other metal oxides—*e.g.* oxides of manganese, iron, or copper. A current of chlorine or bromine passed through a boiling solution of caustic alkali or milk of lime, containing a salt of the metal, gives a 90 per cent. yield of oxygen. A hypochlorite or hypobromite is first formed, *e.g.*: $2NaOH+Br_2=NaOBr+NaBr+H_2O$; and the hypobromite, NaOBr, then decomposes: $2NaOBr=2NaBr+O_2$. According to C. F. Schönbein, an aqueous solution of iodic acid can be boiled without decomposition, but if platinum black be present, it decomposes into iodine and oxygen.

By heating a mixture of calcium sulphate and silica, N. A. Helouis[25] obtained a mixture of sulphur dioxide and oxygen, and a residue of calcium silicate. By heating a mixture of sodium nitrate with twice its weight of zinc oxide, sodium zincate, $Zn(ONa)_2$, and a mixture of nitrogen with 71·4 per cent. of oxygen is formed: $2ZnO+4NaNO_3=2Zn(ONa)_2+2N_2+5O_2$.

4. *Processes in which oxygen is obtained from the atmosphere.*—Many ingenious processes—both chemical and physical—have been devised for the continuous manufacture of oxygen, and inventors have been particularly sanguine—at first. These processes are often of much theoretical interest; but however interesting a process may be, and however enthusiastic the inventor, an installation will have a short life commercially if it cannot bring money into the pockets of the investors.

(*a*) *Chemical processes.*—These depend on the oxidation of a substance by air so as to form a compound which gives up the oxygen and re-forms the original substance. This can be again oxidized, and so the cycle can be continued indefinitely. Thus, mercury can be oxidized by heating it in air at about 400°, and the resulting mercuric oxide broken up into oxygen and mercury at about 600°. The oxidation is too slow for the process to be industrially useful. J. T. A. Mallet (1865)[26] patented a process for extracting oxygen from air by the alternate oxidation of cuprous chloride,

$4CuCl+O_2=2Cu_2OCl_2$, by exposure to moist air; and, subsequent deoxidation of the cupric oxychloride by heating to dull redness. C. M. Tessie du Motay and C. R. Maréchal (1866)[27] heated a mixture of pyrolusite and caustic alkali at a high temperature while exposed to air, oxygen from the air takes part in a reaction forming an alkali manganate—say Na_2MnO_4; the manganate then gives up its oxygen when heated in a current of steam, and the residue again forms manganite when heated in air. This process has not proved a great success although many works were erected and numerous modifications have been patented. G. Kassner (1889)[28] heated a mixture of chalk and lead oxide in contact with air whereby calcium plumbate, Ca_2PbO_4, is formed. When this is treated with potassium or sodium carbonate, caustic alkali remains in solution and calcium carbonate and lead peroxide are precipitated: $Ca_2PbO_4+2Na_2CO_3+2H_2O=4NaOH+2CaCO_3+PbO_2$. When the precipitate is dried, and heated to about 500°, oxygen is evolved, and the residue is ready for the regeneration of calcium plumbate. The caustic lye obtained as a by-product is claimed to make the process economical; but this is doubtful since the process has had no commercial success in spite of numerous modifications.

Oxygen was formerly made on a manufacturing scale by the **barium peroxide process** of L. Q. and A. Brin (1880). This depends upon a very interesting reaction discovered by J. B. J. D. Boussingault[29] in 1851. When barium oxide—BaO is heated in air to about 500°, it is rapidly oxidized to barium dioxide: $2BaO+O_2=2BaO_2$. If the barium dioxide be heated to a still higher temperature, 800°, the oxygen is given off and barium oxide remains as a residue: $2BaO_2=2BaO+O_2$. The phenomena attending the decomposition of barium peroxide in closed vessels are quite analogous with the decomposition of mercuric oxide except that non-volatile barium oxide appears in place of volatile mercury. The curve, Fig. 2, can therefore be readily interpreted. Some other oxides behave in a similar manner. For example, as found by H. Debray and A. Joannis, and by G. H. Bailey and W. B. Hopkins, cupric oxide, CuO, at a red heat forms cuprous oxide, Cu_2O; and re-forms cupric oxide when heated in air at a lower temperature. J. B. J. D. Boussingault tried to apply the barium peroxide reaction industrially, but it was found that after the baryta had been oxidized about a dozen times, it lost its power. M. Gondolo claimed to have used the barium oxide over a hundred times without deterioration, by mixing the barium oxide with a little lime or magnesia, and potassium manganate. The cause of the trouble was recognized by MM. Brin Frères in 1879. The barium oxide can be reoxidized and used over and over again, provided the air be freed from carbon dioxide, organic matter, dust, and any substance which forms a compound with barium oxide which is not decomposed under the given conditions. The regulation of the temperature offered practical difficulties which were overcome by keeping the temperature constant in the vicinity of 700°. Barium oxide is then transformed into the dioxide if the pressure be about 2 kilograms per sq. cm.—normally the atmospheric pressure is 1·033 kilograms per sq. cm. The peroxide is decomposed into the oxide and oxygen at the same temperature under a reduced pressure—about 0·05 kilogram per sq. cm. The gas pumped off under these conditions contained about 90–96 per cent. of oxygen, and 4–10 per cent. of nitrogen.

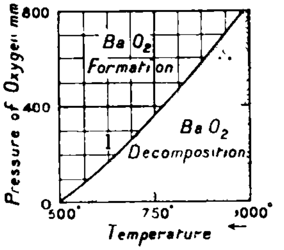

Fig. 2.—Equilibrium Pressure Curve of Barium Peroxide.

After an industrial life of nearly 20 years, Brin's process failed to compete successfully against the newer and cheaper method of preparation by the fractional distillation of liquid air. The relative costs of the two processes are said to be: 3*s*. 6*d*. per 1000 cub. ft. for the liquid air process against from 7*s*. to 12*s*. for Brin's process. The same amount of oxygen costs 16*s*. 8*d*. when manufactured by electrolysis with electrical energy at ½*d*. per unit. The oxygen obtained from liquid air is about 98 per cent. purity; that from the barium process about 94 per cent.

purity. In 1907, the British Oxygen Co. made about 30,000 cub. ft. of oxygen per day by the liquid air process, and in 1917, about 1,000,000 cub. ft. per day.

(*b*) *Mechanical and physical processes.*—Oxygen is more soluble than nitrogen in water; and J. T. A. Mallet[30] patented a process for extracting oxygen from the atmosphere by pumping off the air dissolved under pressure by water. The product was again dissolved under pressure in water; and again pumped from the liquid. By repeating the operation eight times, a gas containing 91 per cent. of oxygen was obtained. The use of liquids other than water—*e.g.* glycerol—have been patented as solvents; but these processes have not been commercially successful. Although the ratio of oxygen to nitrogen dissolved by the liquid may be greater than with water, the actual amount dissolved may be less, and, according to G. Claude,[31] *celui rend illusoire leur usage.* Similar remarks apply to the greater adsorption of oxygen from air by wood charcoal than is the case with the absorption of nitrogen.[32] Repeated absorption followed by the expulsion of the adsorbed gases by heating under a reduced pressure furnishes a product rich in oxygen. P. Margis[33] obtained a 95 per cent. oxygen by the repeated diffusion of air through indiarubber membranes—oxygen passes through the rubber much faster than nitrogen. The fractional distillation of liquid air furnishes most of the oxygen gas for commerce.

5. *Processes dependent upon the electrolysis of water.*—Nearly all the oxygen on the market is now obtained by the liquid air process. Comparatively little oxygen is obtained by the electrolytic process, since this is profitable only when the hydrogen can be readily sold at good prices.[34] As indicated in connection with the electrolytic preparation of hydrogen, one ampere of electricity decomposes 0·335 grm. of water per hour, and liberates 0·0373 grm. or 0·414 litre of hydrogen, and 0·298 grm. or 0·207 litre of oxygen. By converting the number of calories involved during the formation of water, and converting into equivalent electrical units, it follows from Kelvin's rule that 1·5 volts are needed for the decomposition of water. In practice 2·5 volts is the minimum employed; and with this voltage 12 kilowatt hours are needed to furnish a cubic metre of oxygen and two cubic metres of hydrogen; in practice 12 to 14 kilowatt hours are consumed in producing these amounts of hydrogen and oxygen. This works out at about 16*s.* 8*d.* per 1000 cub. ft., when the electrical energy costs ½*d.* per unit. A. d'Arsonval installed a plant for electrolytic preparation of oxygen about 1885. He used as electrolyte a 30 per cent. solution of sodium hydroxide with sheet-iron cylinders as electrodes. He used a current density of 2 amps. per sq. decimetre, and enclosed the anode in a woollen bag to serve as diaphragm. The hydrogen was not used. With 60 amps. about 100 or 150 litres of oxygen were obtained per diem. D. Latchinoff used an apparatus in which the gases were under pressure. Other forms are indicated in connection with the electrolytic preparation of hydrogen. There have been several explosions from the use of electrolytic oxygen, owing to the hydrogen getting mixed therewith.[35]

The oxygen obtained by any of these processes is pumped into steel cylinders under a pressure of 100-150 atmospheres, and sold as *compressed oxygen.* The gas may be obtained from the cylinders at any desired rate by regulating the valve.

§ 5. Catalysis

Materializing abstractions is a vice of thought.—H. S. R. ELLIOTT.

The action of manganese dioxide on the decomposing potassium chlorate is very curious. It acts as a **stimulant.** We do not know precisely how the manganese dioxide does its work, although we can form a rough idea of what is taking place. Many other oxides act similarly, but not quite so vigorously—*e.g.* ferric, copper, cobalt, or nickel oxide, vanadium pentoxide, V_2O_5, tungstic oxide, WO_3, uranic oxide, U_3O_8, may be used in place of manganese oxide. It is quite a common thing to find that the speed of reactions is accelerated or retarded by the presence of a foreign substance whose composition at the end of the reaction is the same as it was at the beginning. For example, in the combustion of hydrogen, platinized asbestos or moisture may act as catalytic agents; similarly metallic oxides stimulate the decomposition of mercuric oxide, potassium chlorate, etc. Indeed, there are probably few chemical reactions, if any, which are not affected by the presence of a catalytic agent. These agents are conveniently grouped together as catalytic agents, and the general phenomenon is called *catalysis;* if the catalytic agent retards the speed of the reaction, the phenomenon is conveniently called **negative catalysis.** It must be clearly understood that **catalysis is simply a term for grouping those reactions whose speed is modified, or for those reactions which can be started by the presence of a small amount of a substance which is found to possess, at the end of the reaction, the same chemical composition as it had at the beginning.** The catalytic agent may be chemically affected by interaction with the products of the reaction, etc. W. Ostwald[1] ingeniously compares the action of a catalytic agent with the action of oil on a machine, or of a whip on a sluggish horse. W. Ostwald, and his followers, believe that the reaction *must* be actually in progress before the catalytic agent can act; although if W. Ostwald's analogy be pursued it runs against his hypothesis, for we know that friction may be so great as to stop the running of a machine, when a little lubricating oil would have prevented the stoppage. Ostwald's limitation is quite arbitrary, and, so far as we can see, does not agree with all the facts.

Some have tried to evade the difficulty either by refusing to recognize it, or by reserving the term **catalytic reactions** for those reactions whose speed is merely accelerated by the catalyst; and using the term **trigger reactions** for those reactions which do not start unless their potential energy is released by contact with another substance. Of course, the introduction of a new term does not remove the difficulty. Again, different products may be obtained by a reaction with and without a catalytic agent; and further, different catalytic agents, with the same reacting materials, may furnish different end-products. So far as the evidence goes: **Catalytic agents can not only start, accelerate, or retard the speed of chemical reactions, but they can also in some cases direct or determine the course of a reaction.**

Francis Bacon long ago cautioned us against allowing words to govern thought instead of thought governing words. The word catalysis itself explains nothing. To think otherwise would lay us open to Mephistopheles' gibe:

> A pompous word will stand you instead
> For that which will not go into the head.

This means that too much trust must not be placed in words. It is just when ideas fail that a word comes in most opportunely. There is no difficulty in covering an obscure idea by a word so that the word appears to explain the idea. In passing back from the word to the idea, it becomes easy to believe that the "subjective abstraction has an objective existence," or that because there is a word, something real must lie behind the word. These remarks about the term catalysis might be applied, *mutatis mutandis,* to many of the terms in common use in chemistry—passive resistance, chemical affinity, the ions of the ionic theory, adsorption, colloids, etc.

§ 6. Consecutive Reactions

Theories are abstractions which, while they place in relief that which is important for *certain fixed* cases, neglect almost necessarily, or even disguise, what is important in other cases. A theory always puts in place of a fact something *different*, something more simple, which is qualified to represent it in some *certain* aspect, but for the very reason that it is different does not represent it in other aspects.—E. MACH (1892).

The representation of a chemical reaction by means of an equation emphasizes the character of the initial and of the end products of the reaction, but it conveys no idea of the mechanism of the reaction—*how* the different materials interact to give the final products. With the growth of knowledge, reactions represented by the older chemists by simple equations resolve themselves into reactions of greater and greater complexity. **The regular type of chemical equation shows but the beginning and end of the reaction.** Such equations are sometimes considered to represent "the essential and determining features" of the reaction, because they indicate what might be called the main products of the reaction, and they are accordingly used in the arithmetic of chemistry. However, chemists are continually striving to obtain a completer view of the real mechanism of a reaction. The truth, not simplicity, is the ultimate object of their quest. There can be no doubt that quite a number of intermediate stages temporarily subsist before the drama of the reaction closes with the final act—the formation of the end products. There is plenty of evidence leading us to infer the existence of a kaleidoscopic sequence of changing scenes during the progress of what are usually considered simple reactions. Some suppose that water has no more right to representation in the chemical equation than the glass of the vessel in which the reaction occurs. As we progress in our studies, we shall find that water profoundly modifies the properties of most substances with which it is in contact. This, said C. L. Berthollet (1803), is a striking illustration of the effect of words on the ideas we form, and even on the results of observation. We begin by considering a solvent as the liquid employed in making solutions, and that these in turn are mere mixtures of solvent and the dissolved substance; consequently, attention is rarely directed to the action of the solvent under other conditions because in them it retains the name of solvent. It must, however, never be forgotten that **all the substances present in a reacting system exercise an action,** and if there are circumstances in which the solvent may be neglected, there are others in which it contributes efficaciously to the result.

The fate of the molecules of manganese dioxide.—As a result of quite a number of experimental investigations on the decomposition of potassium chlorate [1] and a study of the available circumstantial evidence, we are able to get, in imagination, a peep behind the curtain which hides the course of the reaction. Firstly, it is not quite correct to say that the manganese dioxide is not changed in any way during the reaction because a microscopic examination of the manganese dioxide, before and after the reaction, shows that it has undergone a physical, if not a chemical, change—crystalline manganese dioxide has apparently become amorphous. The manganese dioxide does appear to take part in the reaction in spite of the fact that it has the same chemical composition at the end as it had at the beginning. Secondly, the manganese dioxide is *probably* oxidized by the decomposing chlorate to form one of the unstable higher oxides of manganese, but exactly what oxide we do not know. This uncertainty is expressed by writing the unknown oxide MnO_{n+2}, where the numerical value of n is not known with certainty. This stage of the reaction can then be represented by the equation:

$$\tfrac{1}{3}nKClO_3+MnO_2=\tfrac{1}{3}nKCl+MnO_{n+2} \quad . \; . \; . \; . \; . \quad (1)$$

Thirdly, the unstable oxide produced by the oxidizing action of the potassium chlorate probably breaks down almost as soon as it is formed, regenerating the manganese dioxide, and liberating free oxygen:

$$2MnO_{n+2}=2MnO_2+nO_2 \quad . \; . \; . \; . \; . \; . \; . \quad (2)$$

The manganese dioxide so formed is again oxidized, and the oxide again decomposed regenerating manganese dioxide anew. This cycle of changes continues until the potassium chlorate is all decomposed. The opening and closing scenes are represented:

$$2KClO_3[+MnO_2]=2KCl[+MnO_2]+3O_2$$

Equations (1) and (2), expressed in the most general form, indicate that we are dealing with a reaction in which

$$A \rightarrow \mathbf{M} \quad \text{and} \quad \mathbf{M} \rightarrow B$$

where A and B respectively denote the initial and final products of the reaction, and **M** the intermediate products. In the reaction just considered, **M** is represented by MnO_{n+2}. Under the prevailing conditions, A does not form B directly. **Consecutive reactions are those in which intermediate products are produced which do not necessarily appear as final products in the reaction.** Consecutive reactions occur in stages; one stage must be in progress before another can start. The speed of formation of B from A obviously depends on the speed of the intermediate reactions. If the reaction $A \rightarrow \mathbf{M}$ be very rapid, and $\mathbf{M} \rightarrow B$ be very slow, the intermediate product **M** will accumulate in the system, and could be recognized and probably isolated. Several examples are known. On the other hand, if $A \rightarrow \mathbf{M}$ be very slow, and $\mathbf{M} \rightarrow B$ be very fast, it would be hopeless to look for intermediate products, and the evidence in support of the assertion that the reaction involves a sequence of consecutive or intermediate reactions must be circumstantial, not direct proof. It will be obvious that the same reasoning must apply in a longer series of intermediate reactions, say, $A \rightarrow \mathbf{M}$; $\mathbf{M} \rightarrow \mathbf{N}$; $\mathbf{N} \rightarrow B$. Similarly, one or more of the intermediate reactions might be a concurrent reaction or an opposing reaction.

The favourable influence of some inert powders—powdered glass, sand, and china clay—shows that the effect may be in part due to an action similar to the effect of finely-divided particles in promoting the evolution of gases from liquids. There is evidence to show that all catalytic agents do not act in the same way; thus the acid oxides of vanadium, uranium, and tungsten, and chromic oxide, phosphoric acid, and phosphorus pentoxide favour the evolution of chlorine;[2] oxide of silver, and the dioxides of lead and barium favour the formation of perchlorate.

§ 7. Concurrent or Side Reactions

> Compounds are not marked by nature with chemical formulæ but by properties, and it is by these we have to distinguish them.—J. D. HENRICHS.

Attention must be again directed to the curious way potassium chlorate decomposes when heated. When potassium chlorate, $KClO_3$, is heated, not only is potassium chloride, KCl, formed, but, as G. S. Sérullas and N. A. E. Millon have shown, just after the development of oxygen has begun, the residue contains a considerable amount of potassium perchlorate, $KClO_4$. According to J. C. G. de Marignac, when the chlorate has lost from 4 to 5 per cent. of oxygen, there is between 64 and 65 per cent. of perchlorate, and between 12 and 13 per cent. of chlorate in the residue; and when the chlorate has lost between 8 and 9 per cent. of oxygen, the residue contains between 65 and 66 per cent. of perchlorate and no chlorate. Hence, part of the salt is transformed into perchlorate and part into oxygen and chloride. Contrary to the opinion of N. A. E. Millon, J. C. G. de Marignac could find no sign of the formation of potassium chlorite, $KClO_2$, at any stage of the process.[1] It will be observed that an indefinitely long array of possible equations could be deduced for the thermal decomposition of potassium chlorate, for, as J. Bottomley (1878) has shown, if potassium perchlorate and chloride, as well as oxygen, be the end-products of the reaction, the equation can be written:

$$2mKClO_3=2nKClO_4+2(m-n)KCl+(3m-4n)O_2$$

where m and n are any integers subject to the condition that $3m$ be not less than $4n$. For instance, if m be 11, and n be successively assigned values 1, 2, 3, . . . 8, the reaction can be symbolized by one of the following eight equations:

$$22KClO_3=2KClO_4+20KCl+29O_2$$
$$22KClO_3=4KClO_4+18KCl+25O_2$$
$$\ldots \quad \ldots \quad \ldots \quad \ldots$$
$$22KClO_3=16KClO_4+6\ KCl+O_2$$

and similarly when other values are assigned to m. It must be emphasized that most chemical equations represent unproved and simplified hypotheses as to the course of reactions. A chemical equation should, if possible, summarize ascertained facts, and symbols should not be treated as if equation-building were merely an algebraic operation.

The following illustrates one of the many possible ways [2] of building equations to satisfy the rules of chemistry *only when the initial and final products are known.* In the preparation of oxygen by the action of sulphuric acid, H_2SO_4, upon potassium dichromate, suppose the by-products are chromic sulphate, $Cr_2(SO_4)_3$, potassium sulphate, K_2SO_4, and water, and that it is desired to find their relative proportions: Write $xK_2Cr_3O_7+yH_2SO_4 \rightarrow zCr_2(SO_4)_3+uK_2SO_4+vH_2O+wO_2$. It follows that $x=u$ (K); $x=z$ (Cr); $7x=v+2w$ (O); $2y=2v$ (H); $y=3z+u$ (SO_4). There are here five algebraic equations and six unknowns; hence it is possible to solve these equations only in terms of any one of the unknowns, x, y, z, u, v, w—say u. Accordingly, $x=u$; $y=4u$; $z=u$; $v=4u$; $w=\frac{3}{2}u$. Obviously each of the unknowns must be a positive whole number, and $u=2$ is the *smallest number* which will satisfy this condition. In that case, $x=2$; $y=8$; $z=2$; $u=2$; $v=8$; $w=3$; or $2K_2Cr_2O_7+8H_2SO_4 \rightarrow 2Cr_2(SO_4)_3+2K_2SO_4+8H_2O+3O_2$.

In the numerous systems of balancing equations, there is a temptation to suppose that the result of the algebraic operation represents a real process. Chemical equations cannot be demonstrated by the manipulation of chemical symbols. J. von Liebig (1846) stigmatized this operation "a senseless form of jugglery." Practice in the art of balancing equations according to algebraic rules may have limited uses, but it is utterly bad if it conveys the impression that reactions must take place as the equation demands. Facility in the art may thus display ignorance, not learning. Accordingly, equation-building is not emphasized so much as formerly in modern works on chemistry.

The fate of the molecules of potassium perchlorate.—When potassium chlorate is heated, part of the chlorate decomposes into potassium chloride and oxygen: $2KClO_3 \rightarrow 2KCl+3O_2$, and part oxidizes another part of the chlorate into potassium perchlorate, $KClO_4$; in symbols, $KClO_3+3KClO_3 \rightarrow KCl+3KClO_4$. These two reactions proceed side by side—concurrently, yet independently. Measurements of the relative proportions of potassium perchlorate and oxygen formed at different temperatures show that the potassium perchlorate reaction proceeds nearly twice as fast as the other reaction. The lower the temperature, the greater the relative speed of the perchlorate reaction. Hence, as the potassium perchlorate accumulates in the system, the molten mass becomes more and more viscid, and if the temperature be below the melting point of potassium perchlorate (610°), the mass solidifies when enough potassium perchlorate has accumulated in the system, even though the temperature be higher than the melting point of potassium chlorate (340°). When the temperature is raised high enough, the potassium perchlorate decomposes into potassium chloride and free oxygen. Here again the opening and closing scenes are represented by the equation: $KClO_4 = KCl + 2O_2$; but the whole reaction can be perhaps better represented by the scheme:

$$6KClO_3 \begin{array}{l} \nearrow \overset{\text{Between 340–610°}}{KCl+3KClO_4} \overset{\text{Above 610°}}{\longrightarrow} 4KCl+6O_2 \\ \searrow 2KCl+3O_2 \end{array}$$

or generally remembering our ignorance of the molecular weight of the molecules of solid potassium chlorate, etc.

$$(m+n)KClO_3 \begin{array}{l} \nearrow \overset{\text{Between 340–610°}}{\tfrac{1}{4}mKCl+\tfrac{3}{4}mKClO_4} \overset{\text{Over 610°}}{\longrightarrow} mKCl+\tfrac{3}{2}mO_2 \\ \searrow nKCl \quad +\tfrac{3}{2}nO_2 \end{array}$$

The final products of both reactions are potassium chloride and oxygen, and this is the sole justification for representing the reaction by the equation $2KClO_3 \rightarrow 2KCl+3O_2$. The fact that no appreciable quantity of potassium permanganate is formed when a mixture of potassium chlorate and manganese dioxide is decomposed, shows that the catalytic agent particularly favours one of the two reactions.

This view of the mechanism of the decomposition of potassium chlorate by heat shows how the relative proportions of potassium chloride and perchlorate, and oxygen depend on the temperature, and almost an infinite number of equations are possible. This must be borne in mind when reading many text-books, for the reaction is often represented by a set of complex equations—*e.g.* P. F. Frankland and J. Dingwall[3] represented the reaction by $8KClO_3=5KClO_4+3KCl+2O_2$ at a moderate heat, followed by $2KClO_3=KClO_4+KCl+O_2$ at a higher temperature; and finally, at a still higher temperature: $KClO_4=KCl+2O_2$. It can be shown that all so far proposed are special cases of the simple equations described in the text.

The cyclic reactions between the manganese dioxide and potassium chlorate proceed rapidly at a temperature much lower than that at which the perchlorate reaction has acquired an appreciable velocity. In fine, the catalytic agent accelerates at least one of the two concurrent reactions. It must not be supposed that the above outline gives a complete representation of this remarkable reaction. The products of the reaction may interact with themselves or with the catalytic reagent. In some cases part of the oxygen comes off as ozone, and the products of the reaction may contain a little chlorine. Traces of potassium permanganate have been detected among the residual products. The chlorine and potassium permanganate are probably formed by a reaction between the potassium chloride and the manganese dioxide.

§ 8. The Physical Properties of Oxygen

Oxygen is at ordinary temperatures a colourless gas without smell. H. V. Regnault (1847)[1] found that the **weight of a litre** of oxygen at 0° and 760 mm. at Paris weighs 1·42980 grms., and this value corrected by J. M. Crafts (1888) for the difference in volume between the full and the vacuous globe gave 1·43011 grms., and corrected by J. Thomsen for 45° latitude at sea level, 1·42929. P. von Jolly's value at Paris is 1·42892 grms., when corrected by Lord Rayleigh, 1·42971. E. W. Morley found for the weight of a normal litre of oxygen $1{\cdot}42900 \pm 0{\cdot}000034$ grm. A. Leduc also found 1·42939 grms. in 1891, and 1·4293 grms. in 1896, at Paris. Lord Rayleigh (1893) gave 1·42952 grms. at n.p.t.; and J. Thomsen found 1·42904 grms. at n.p.t. when reduced to 45° latitude and sea level. E. W. Morley (1896) gave 1·42900 grms., J. Thomsen 1·42906 grms. at 45° and sea level. A. Jaquerod and A. Pintza (1904) gave 1·4292 grms.; A. Jaquerod and F. L. Perrot (1905), 1·42893 grms.; P. A. Guye's calculation of R. W. Gray's determination (1905) gave 1·42896; A. Jaquerod and M. Tourpaïan (1911), 1·4290; and A. F. O. Germann (1915), 1·42906. The best representative value for the weight of one litre of oxygen under these conditions is taken to be **1·42905** grms. A. F. de Fourcroy, L. N. Vauquelin, and B. R. Séguin found the **relative density** of oxygen to be 1·087; R. Kirwan, 1·103; H. Davy, 1·088; W. Allen and W. A. Pepys, 1·088; J. B. Biot and F. J. Arago, 1·1036; T. Thomson, 1·1056; T. de Saussure, 1·1056; P. L. Dulong and J. J. Berzelius, 1·1026; H. Buff, 1·106; J. B. A. Dumas and J. B. J. D. Boussingault, 1·1057; J. von Wrede, 1·1052. The gas in these early determinations was often saturated with moisture, and the measurements afflicted with numerous errors so that they are only of historical value. Later more accurate determinations are by H. V. Regnault, who found the **relative density** of oxygen, air unity, to be 1·10564; P. von Jolly, 1·10505; J. P. Cooke, 1·10534; A. Leduc, 1·10506 (1891) and 1·10523 (1896); J. Giesen with the microbalance, 1·1051; and Lord Rayleigh, 1·10530. The reported numbers for the relative density of oxygen are between 15·861 and 15·96 when hydrogen is unity. The best representative values are taken to be **1·10523** when air is unity, and **15·87** when hydrogen is unity. Lord Rayleigh (1908–11) found no appreciable difference in the density of oxygen prepared from different sources—the electrolysis of water heating potassium chlorate or potassium permanganate—outside the limits of experimental error. The vapour density of oxygen at −182° is normal.

According to J. Dewar, the specific gravity of liquid oxygen at 760 mm. and −182·5° is 1·1181; at −195·5°, 1·1700; and at −210·5°, 1·2386. J. Drugman and W. Ramsay[2] give 1·1321 at −183·6° and 759 mm., and 1·1310 at −183·3° at 762 mm. The **specific volume** of the liquid is then 0·8838; and the molecular volume 28·28. According to G. le Bas, the atomic volume of oxygen at the critical temperature is 26·5; the atomic volume of terminal oxygen in organic compounds is 7·2, and of ethereal oxygen, 10·8. J. Dewar estimates the molecular volume at absolute zero to be 21·21. E. C. C. Baly and F. G. Donnan give the interpolation formula $1{\cdot}248874 - 0{\cdot}00481(T-28)$ for the density of the liquid oxygen at a temperature between 69·28° K. and 88·94° K. The specific gravity of solid oxygen at −252·5° is 1·4256. J. Dewar represents these results by the expression $1{\cdot}5154 - 0{\cdot}004420T$, where T denotes the absolute temperature; otherwise expressed, liquid oxygen is about 1·13 times as heavy as an equal bulk of liquid water at 4°. J. K. H. Inglis and J. E. Coates have measured the specific gravity of mixtures of liquid oxygen and nitrogen.

The **weight of an oxygen atom** is $16 \times 1{\cdot}56 \times 10^{-24}$ grm.; the mean **diameter of the molecule** of oxygen $3{\cdot}62 \times 10^{-8}$ cm.; the mean **free path** of the molecule $6{\cdot}3 \times 10^{-6}$ cm.; the **number of molecules** per c.c. is $2{\cdot}75 \times 10^{19}$; the **collision frequency** $1{\cdot}64 \times 10^{29}$ per sec. per c.c. of gas; and the **molecular velocity** is 42,500 cm. per sec.

The value of J. D. van der Waals' $a=0·00273$, and his $b=0·00142$.[3] L. L. Grunmach calculates the molecular weight of liquid oxygen to be 41·51. The **viscosity** of oxygen at 0° is 0·001873; A. von Obermayer gives 0·000189; and K. Schmitt, 0·0001926. K. L. Yen claims $\eta=0·000204235$ at 23° and 760 mm. with an accuracy of 0·15 per cent. The viscosity increases with a rise of temperature such that at $\theta°$ A. von Obermayer found that the viscosity is $0·0001928(1+0·000283\theta)$; the observed value at 20° is 0·0002060; at 99·74°, 0·0002485; and at 185·8°, 0·0002885, or $0·0001878(1+0·003665\theta)^{0·787}$; W. Sutherland gave for the viscosity η at $\theta°$, $\eta=\eta_0\{(273+T)/(T+C)\}(T/273)^{\frac{3}{2}}$, where $C=127$; F. Kleint gives $C=136$; H. Markowsky, 138; and Lord Rayleigh, 128·2. According to O. Völker,[4] the viscosity decreases on a falling temperature, being 0·0001693 at −39·48°; 0·0001474 at −76·12°; 0·0001128 at −129·8°; and 0·0001050 at −152·5°. The **surface tension**[5] of liquid oxygen is 13·074 ± 0·066 dynes per cm., and the **specific cohesion** is 23·038. The molecular weight by R. Eötvös' formula is 41·51, so that the molecules of the liquid are rather more complex than corresponds with the formula O_2. E. C. C. Baly and F. G. Donnan, however, find the molecular surface energy $\sigma(Mv)^{\frac{2}{3}}=1·917(153·77-T)$, which gives a constant 1·917, not far from that required for a normal liquid with molecules O_2. According to P. L. Dulong,[6] the **velocity of sound** in oxygen gas at 0° is 317·17 metres per second at 0°; and S. R. Cook finds the velocity is 328·55 metres per second at 21°; 282·4 at −28·4°; 264·26 at −66·5°; 210·12 at −137·5°; and 173·92 at −183·0°.

E. H. Amagat[7] has investigated the **isothermal *pv*-curves** for Boyle's law at 0°, 15·65°, 99·50°, and 199·50° for pressures from one to 1000 atm., and for 0° and 15·6° up to 3000 atm. The values for 0° are:

Pressure	1	500	1000	1500	2000	2500	2900 atm.
Volume	1·00000	0·00231	0·00174	0·00153	0·00141	0·00133	0·00128
pv	1·0000	1·1570	1·7360	2·2890	2·8160	3·3238	3·7120

There is a minimum in the curve for $pv=0·9135$ near 150 atm. and 0°; for $pv=0·9920$ near 150 atm. and 15·65°; and the minimum was not observed at higher temperatures. According to A. Leduc, the compressibility of oxygen[8] at 11·2°, $-(d(pv)/dp)/pv$, is 0·00076. A. Jaquerod and O. Scheuer give the compressibility of oxygen between 400 and 800 mm. pressure as 0·00097; Lord Rayleigh gives 0·00094; and D. Berthelot, 0·00085. In 1886, C. Bohr measured the value of *pv* for pressures less than normal, and concluded that at a pressure of 0·70 mm., as indicated in Fig. 3, there is a break in the curve showing the relation between the pressure and the product *pv*. C. Bohr's observation was confirmed by E. C. C. Baly, W. Ramsay, A. Campetti, and A. Batelli; and it was thought to agree with the anomalous result in the radiometer repulsion of oxygen at a pressure of 0·76 mm. which was found by W. Crookes to be six to twelve times as great as that of nitrogen or of carbon monoxide or dioxide; and of H. Ebert's experiments on the dark space in vacuum tubes. It might be thought that experimental work with all this backing could be accepted with some degree of confidence. W. Sutherland[9] interprets the result as an effect of the spontaneous change of oxygen into ozone, at a certain degree of rarefaction, and with increasing rarefaction the transformation of oxygen into ozone continues so as to keep the number of molecules of ozone per unit volume constant, when all the oxygen molecules are used up, ozone alone remains, and it follows Boyle's law. No chemical test enabled R. Threlfall and F. Martin to detect ozone in suitably expanded oxygen. Neither Lord Rayleigh nor M. Thiesen could establish Bohr's

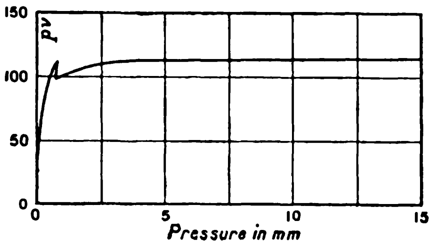

FIG. 3.—C. Bohr's Critical Value in the *pv*-curve of Oxygen at 0·7 mm. pressure.

anomaly. Lord Rayleigh found that there is no deviation from Boyle's law exceeding one part in 4000 for pressures between 0·01 and 150 mm. of mercury. M. Thiesen attributes Bohr's anomalous result to some unrecognized experimental error. Liquid oxygen is very compressible in comparison with many other liquids—*vide* water; A. Eucken found for the compressibility, β, between 10 and 20 atm., $\beta=1\cdot95\times10^{-3}$ kgrm. per sq. cm.; and calculated from the relation $C_p-C_v=Tv\alpha^2/\beta$, at 20·4° K., $\beta=2\cdot06\times10^{-3}$ kgrm. per sq. cm.

The **coefficient of thermal expansion** of oxygen gas is given by P. von Jolly[10] as $\alpha_p=0\cdot00367430$; H. K. Onnes' value for the liquid oxygen is $\alpha=00157$ at −252·6°, or 20·4° K. The **thermal conductivity** of oxygen[11] at 0° is 0·00005694, and between 7° and 8°, 0·0000563; S. Weber gives $5\cdot768\times10^{-5}$. The **specific heat** at constant pressure,[12] C_p, is 0·2175; or from 20° to 440° $C_p=0\cdot224$; and from 20° to 630°, 0·230. The specific heat at constant volume is 0·1544; or, the molecular heat at constant volume, at the absolute temperature T, is represented by W. Nernst and H. von Wartenberg by $4\cdot68+0\cdot00026T$ cals. per gram-molecule. For constant pressures the molecular specific heat may be taken as $C_p=6\cdot50+0\cdot0010T$, P. A. Müller, and O. Lummer and E. Pringsheim's measurement of the ratio of the two specific heats of oxygen is 1·398 from 5° to 14°; and 1·402 from 16° to 20°. G. N. Lewis and M. Randall give for the best representative value of the molecular heat of oxygen gas, $C_p=6\cdot50+0\cdot0010T$, which gives at 0 , 6·77; H. V. Regnault found 6·85; and M. Pier 6·89. The equation also gives 8·77 at 2000°, while M. Pier found 6·70. The higher values of L. Holborn and L. Austin, and of A. Eucken were obtained indirectly with oxygen admixed with nitrogen. The **entropy** of oxgyen gas at 25°, calculated by G. N. Lewis and G. E. Gibson, is 48·23 per gram-molecule, when the increase of entropy from absolute zero to the first transition point T is $\phi=\int C_p d\log T=2\cdot20$; $17\cdot5/23\cdot5=0\cdot74$ is the entropy of the transformation to the second form; the increase of entropy when the temperature of the solid rises from the first to the second transition temperature is 2·58; and $167\cdot4/42\cdot5=3\cdot94$ is the entropy of the second transition temperature; and the increase of entropy in rising from the second transition temperature to the melting point is 2·62; the increase of entropy in passing from the solid to the liquid state is $105\cdot5/54\cdot1=1\cdot95$; in passing from the melting to the boiling point, 6·52; in passing from the liquid to the gaseous state, $1599/90\cdot3=17\cdot72$; and in passing from the boiling point to 298° K., 7·96.

For a long time oxygen proved incoersible to all attempts to liquefy it by compression and cooling. J. Natterer, for instance, obtained no liquid at a pressure of 1354 atm. On the 16th December, 1877, L. Cailletet, and a little later R. Pictet,[13] obtained the liquid; and soon afterwards, S. von Wroblewsky, K. Olszewsky, J. Dewar, and many others prepared the liquid in quantity and investigated its properties. The **critical temperature** of oxygen is between −113° and −119°—say −118°; the **critical pressure** lies between 44·1 and 50·0 atm.—say 50 atm.; and the **critical volume** is 0·00426. If therefore the temperature is near but below or at −119°, a pressure of 50 atm. will liquefy the gas; and if the temperature exceeds −119° no pressure, however great, can liquefy the gas. Liquid oxygen has a pale blue colour. L. Grunmach found the **boiling point** of oxygen to be −182·65° at 762·22 mm. pressure; its vapour pressure[14] at −182·4° is 800 mm.; at −193°, 200 mm.; and at −211·2°, 7·5 mm. K. Scheel gives for the boiling point of oxygen at a pressure p mm. of mercury, $-183\cdot0^\circ+0\cdot01258(p-760)-0\cdot000007(p-760)^2$. The vapour pressure of liquid oxygen at T° absolute is given by $\log p=-399/T+1\cdot75\log T-0\cdot0051T+6\cdot9484$. According to W. P. Juliusberger, the **vapour pressure** between −212° and −119° is given by $\log_{10} p=3\cdot54595-313\cdot7T^{-1}+1\cdot40655\log_{10} T$ mm. The **latent heat of vaporization** of liquid oxygen is 58·0 cals. per gram, or 1856 cals. per gram-molecule. The last-named constant does not vary linearly with temperature, since at −183° the latent heat of vaporization is 52·09 cals.; at −201·5°, 59·10 cals. H. Alt's value at 760 mm. is 50·97 cals. per gram; A. Eucken's value is 1599 cals. per gram-molecule. J. Dewar (1896) cooled liquid oxygen by a spray of liquid nitrogen and obtained a hard pale blue solid with a **melting point** −227° at 0·9 mm. pressure. According to A. Eucken, the melting point is 54·1° K., or −218·9°; and the **latent heat of fusion** of oxygen is 105·5 cals. per gram-molecule.

There are signs of two transition points respectively at −249·5° and −230·5°, in the heating curve of solid oxygen. These are supposed to correspond with at least three **allotropic forms** of the solid element. A. Eucken (1916) estimates that the heat of the γ to β transformation is 17·5 cals. and of the β to α 167·4 cals. With the previous notation, therefore,

$$\alpha\text{-Oxygen}_{\text{solid}} \overset{-249{\cdot}5^\circ}{\rightleftharpoons} \beta\text{-Oxygen}_{\text{solid}} \overset{-230{\cdot}5^\circ}{\rightleftharpoons} \gamma\text{-Oxygen}_{\text{solid}} \overset{-218{\cdot}9^\circ}{\rightleftharpoons} \text{Oxygen}_{\text{liquid}} \overset{-182{\cdot}5^\circ}{\rightleftharpoons} \text{Oxygen}_{\text{gas}}$$

It is very unusual to find the heat of fusion less than the heat of transition such as is the case with solid oxygen. A. Eucken found the molecular heats of the different forms of solid oxygen to be: α-oxygen or oxygen III to be $C_p=2{\cdot}5$, $C_v=2{\cdot}48$ at 17·0° K., and $C_p=4{\cdot}42$, $C_v=4{\cdot}28$ at 21·8° K.; β-oxygen, or oxygen II, $C_p=5{\cdot}92$, $C_v=5{\cdot}62$ at 26·95° K., and $C_p \doteq 10{\cdot}52$ and $C_v=9{\cdot}12$ at 39·5° K.; γ-oxygen, or oxygen I, $C_p=11{\cdot}0$ at 44·7° K., and 10·76 at 51·3° K. The value of C_v is here calculated from the value of C_p from W. Nernst and F. A. Lindemann's relation $C_p-C_v=ATC_p^2$, where A is a constant $3{\cdot}2\times10^{-4}$. A. Eucken further gave for liquid oxygen, $C_p=12{\cdot}81$ at 57·4° K.. and 12·62, at 73° K., Debye's function=113.

W. Wahl [15] found that oxygen becomes viscid when cooled near to the point of solidification, and **crystals** grow in the viscid mass very slowly. If the cooling be rapid, a vitreous glass is formed. The crystals which grow in the cooling mass are dark between crossed nicols, but their crystalline form has not been established. If the oxygen be cooled by boiling hydrogen, a fine-grained mass of double refracting crystals belonging to the hexagonal system is formed. The transition point of α- to β- oxygen is not far below the melting point. Most of the physical constants of solid oxygen, determined at the boiling point of hydrogen, refer to the second crystalline form. J. Dewar found that when the charcoal vacuum was turned off, the vapour pressure remained near 0·46 mm. for some time and then rose rapidly to 1·11 to 1·12 mm. and then remained constant during melting. W. Wahl suggests that 0·46 mm. is the vapour pressure of the α- and β-crystals at the triple-point; and 1·12 mm. the vapour pressure of the α-crystals, liquid and vapour. The existence of two crystalline modifications of oxygen is interesting in view of the polymorphism of sulphur, and the analogies between the compounds of sulphur and oxygen. Ozone also is polymerized oxygen. The phenomena observed by I. Langmuir [16] to be associated with the formation of atomic hydrogen are largely duplicated when oxygen is substituted for hydrogen. The resulting **atomic oxygen** reacts with tungsten even at liquid air temperatures.

The mean **index of refraction** of oxygen gas is less than that of any other gas; for white light $\mu=1{\cdot}000270$; for the C-ray, 1·000255; for the G-ray, 1·000294; for the E-ray, 1·000315: and for the green mercury line, $\mu=1{\cdot}0002727$. E. Mascart (1877),[17] L. Lorenz (1880), H. C. Rentschler (1908), and C. and M. Cuthbertson (1909) have determined the **dispersion** of oxygen. The latter find for wave-lengths, from 4861 to 6563, Cauchy's formula $\mu=1+0{\cdot}00026509\lambda^{-1}+(1+7{\cdot}33\lambda^{-2}\ 10^{-11})$ holds good; but the general results with Cauchy's formula are not very good. Better results are obtained with a formula of the type used by W. Sellmayer, with the dispersion formula $\mu-1=c/(n_0{}^2-n^2)$, where n_0 is the frequency of the free vibration which has received a theoretical interpretation from the electron theory of P. Drude. The constants are $\mu-1=3{\cdot}397\times10^{27}/(12804\times10^{27}-n)$. The index of refraction of liquid oxygen for the D-ray is, according to G. D. Liveing and J. Dewar, 1·2236. According to J. Dewar, the atomic refraction of the liquid for the D-line is 3·182, and this is not far from J. H. Gladstone's value 3·0316 for gaseous oxygen. J. H. Gladstone gives for the atomic refraction of singly linked oxygen in combination 2·8; and of doubly linked oxygen 3·4; and J. W. Brühl 1·506 for hydroxylic oxygen; 1·655 for ethereal oxygen; and 2·328 for carbonylic oxygen. J. F. Homfray calculates the atomic refraction of quadrivalent oxygen to be 2·73. J. W. Brühl also gives for the atomic dispersion $R_\gamma - R_\alpha = 0{\cdot}019$ for hydroxylic oxygen; 0·012 for ethereal oxygen; and 0·086 for carbonylic oxygen. According to L. H. Siertsema, **E. Verdat's constant** for oxygen at a pressure of 10 k.grams. per sq. cm. and 7°, is $0{\cdot}0002722\lambda^{-1} + 0{\cdot}00001915\lambda^{-3}$ for wave-lengths between $0{\cdot}423\mu$ and $0{\cdot}684\mu$. For pressures between 38 and 100 atm., the constant changes proportionally with the density of the gas.

In 1864, J. Plücker and W. Hittorf[18] established the fact that one and the same element can under different conditions produce more than one spectrum. Several different spectra of oxygen have been recorded. A. Schuster distinguishes four main **spark spectra of oxygen**: (i) The *elementary line spectrum* which appears at the highest temperature to which oxygen can be subjected such as occurs when the Leyden jar and air-break are introduced into the electric circuit. This spectrum consists of a number of lines particularly in the more refrangible part of the spectrum. (ii) The *compound line spectrum* appears at a lower temperature than the elementary line spectrum, and predominates when the Leyden jar and air-break are removed and the exhaustion of the tube is not very high; if the exhaustion is high a special spectrum from the negative glow is superposed on the four-line spectrum. There are: one red line, two green lines, and one blue line as illustrated in Fig. 4. According to A. Schuster, these four lines have the wave-lengths 6156·86 (red); 5435·55 (green); 5329 41 (green); and 4367·62 (blue). With an increase of pressure, the more refrangible lines widen first while the blue line remains sharp.

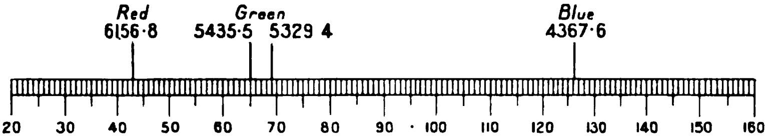

FIG. 4.—The Compound Line Spectrum of Oxygen in a Geissler's Tube.

(iii) The *continuous spectrum* appears at the lowest temperature at which oxygen becomes luminous. According to E. Becquerel, an excess of oxygen in the oxy-hydrogen flame produces a yellow colour probably due to the continuous spectrum of oxygen. (iv) The *negative-glow spectrum* was first observed by A. Wüllner in 1872, and is always seen in the glow surrounding the negative electrode in oxygen. It consists of five bands—three red, two green. The least refrangible red band is so faint that it may escape observation, and the two red bands are so close that with a small dispersion they appear as one line. With high optical powers the two green bands can be resolved into a series of lines. A. Schuster further described the appearance of a vacuum tube filled with pure oxygen as it is sparked while being gradually exhausted:

> At first the spark has a yellow colour, and the spectrum is perfectly continuous. Almost immediately, however, four lines are seen in the capillary part above the continuous spectrum. One of these lines is in the red, two are in the green, and one is in the blue. The discharge still passes as a narrow spark throughout the length of the tube. In the wide part the spectrum remains continuous, and it extends more towards the red than in the capillary part. It seems as if the four lines had taken away part of the energy of the continuous spectrum. As the pressure diminishes, these lines increase considerably in strength, the spark spreads out in the wide part of the tube, and the intensity of the continuous spectrum is, therefore, considerably diminished, while it still forms a prominent part in the spectrum of the capillary part. When the pressure is small the continuous spectrum decreases in intensity. At the same time the negative glow, with its own characteristic spectrum, gradually extends through the negative half of the tube into the capillary part. The continuous spectrum has now entirely disappeared; the bands of the negative pole and the four lines stand out on a perfectly black background. It is under these conditions that the change from the compound line spectrum to the elementary line spectrum is best studied. The mere insertion of the Leyden jar, I find, makes hardly

> any difference; the jar does not seem to be charged at all. If, in addition to the jar, we insert a movable air-break, which can be opened or closed at will, while we look through the spectroscope, we shall be able to see alternately two perfectly distinct spectra. If the air-break is closed, the four lines of the compound spectrum only are seen; if the air-break is opened, these four lines will disappear entirely, and the elementary line spectrum will come out.

The spectrum of oxygen is peculiar in that it does not show up clearly in the presence of other gases; for example, air in a vacuum tube gives the same spectrum as nitrogen. All carbonaceous impurities should be excluded from oxygen whose spark spectrum is under investigation, because the carbon is readily oxidized to carbon monoxide at the high temperature and the spectrum of the impurity may be the more brilliant, and entirely eclipse that of the oxygen. Several descriptions of the carbon monoxide spectrum have been published [19] which have been attributed to oxygen. C. Runge and F. Paschen [20] reduced the line spectrum of oxygen to two series of triplets and two series of doublets. All four series can be represented by formulæ of the type $\lambda^{-1}=a+bn^{-2}-cn^{-3}$, where a, b, and c are constants. J. J. Balmer's formula—*vide* hydrogen—is a special case of this more general expression. B. Reismann found that when a Geissler's tube of oxygen is excited by a direct current discharge the series, elementary line, and banded spectra appear at the cathode, and only the series spectrum at the anode. J. Stark and co-workers, and H. Wilsar have measured the spectrum of oxygen canal rays. The **Stark effect** with the spectrum of oxygen has been examined by U. Yoshida.

The **absorption spectrum of oxygen** has attracted some attention because certain dark lines of the solar spectrum—the so-called telluric lines—may be in part derived from the absorptive power of atmospheric oxygen. The absorption spectrum of oxygen is very feeble and it must be examined in a long tube, with the highly compressed or liquefied gas—since the two are practically identical. J. Janssen [21] used a tube 20 to 60 metres long, with the gas at 27 atm. pressure. There are two strong absorption bands in the red corresponding with the *A* and *B* Fraunhofer solar lines with wave-lengths from 6340 to 6225; a strong band in the yellow from 5820 to 5730; a feeble band in the green at 5350; and a feeble one in the blue at 4810. O. C. Lester found two series of absorption bands in the oxygen of the solar spectrum. J. Tyndall could scarcely detect any absorption of the invisible heat radiations by oxygen at atmospheric pressure. W. Burmeister found gaseous oxygen has no absorption bands in the infra-red.

The oxygen gas produced by heating potassium permanganate is positively electrified.[22] Liquid oxygen is virtually a non-conductor of electricity. For the phenomena associated with the ionization of oxygen, see hydrogen. The mean values of J. Zeleny's, A. P. Chattock's, and J. Franck's determinations of the velocity of the positive and negative oxygen ions when the electric discharge is in a field of 1 volt per cm. are respectively 1·32 and 1·83 cms. per second. The mean value of J. S. Townsend's and E. Salleo's determinations of the diffusion coefficient of the positive and negative ions per sq. cm. per sec. are respectively 0·0275 and 0·040. J. S. Townsend [23] gives $dn/dt=-3380n^2$, where n denotes the concentration of the ions, and dn/dt the velocity of combination of the ions to form ordinary molecules. A. Erickson and P. Philips have studied the effect of temperature on this reaction. The potential of the **oxygen electrode** is discussed later. The **discharge potential** has been discussed in connection with hydrogen. W. C. Röntgen found the minimum potential for a + point to be respectively 2402 and 1975 volts for pressures 205 and 110 mm., and J. Precht, 2800 volts for a + point, and 2350 volts for a − point with a pressure of 760 mm. A. L. Hughes and A. A. Dixon [24] found the **ionizing potential** is dependent on the least energy necessary to ionize the molecules of a gas by the impact of electrons, and amounts to 9·2 volts for oxygen; J. Franck and G. Hertz found 9 volts; F. M. Bishop, 9 volts; and the value calculated by K. T. Compton's formula $V=0{\cdot}194(K-1)^{-\frac{1}{2}}$ is 8·4 volts, where V denotes the ionizing potential, and K the specific inductive capacity.

The **dielectric constant** of liquid oxygen[25] lies between 1·465 and 1·491 at −182°. H. Rohmann gives the dielectric constant of oxygen gas at 0° and one atm. pressure as 1·000547; according to A. Occhialini, oxygen gas at 13·5° and compressed to a density of 35 has a dielectric constant 1·01831, and at a density 110, 1·05843. The results agree with Mossotti and Clausius' formula but not with $(K-1)/D=$constant. In 1847, M. Faraday's experiments indicated that oxygen gas is diamagnetic, but it was subsequently shown to be paramagnetic having a magnetic susceptibility of $+0{\cdot}12\times10^{-6}$ at 20° and 1 atm.; and $+6{\cdot}2\times10^{-6}$ at 16° and 40 atm. pressure (volume units). E. Becquerel noticed the magnetic qualities of oxygen—more particularly of wood charcoal saturated with adsorbed oxygen. The magnetic qualities are greatly enhanced when oxygen is condensed in the liquid state. Liquid oxygen then shares with iron, nickel, and cobalt the property of being magnetic. If the **magnetic moment** of iron be unity, that of liquid oxygen is 0·001. When a little liquid oxygen is placed in a cup between the poles of an electromagnet, the liquid leaps up to the poles, and remains attached until all has evaporated.[26] If the current is cut off while the oxygen is attached to the poles of the electromagnet, the oxygen detaches itself. A thin test tube of liquid oxygen, suspended by a long thread, will attach itself to an electromagnet, and fall away as the current is cut off. The **magnetic susceptibility** of liquid oxygen 304×10^{-6} volume units or 241×10^{-6} mass units at −182°; 280×10^{-6} at −208°. For the solid, at −253° the magnetic susceptibility is 375×10^{-6} (mass units), and at −259°, 436×10^{-6}. At its freezing point therefore the magnetic susceptibility of liquid oxygen is nearly 1·3 times as great as that of solid oxygen.

The solubility of oxygen.—The solubility of oxygen in water is small; 100 vols. of water absorb nearly 5 vols. of oxygen at 0°. The absorption coefficient was measured by R. W. Bunsen[27] in 1855. L. W. Winkler (1891) and C. Bohr and J. Bock (1891) measured the coefficient of absorption of water between 0° and 100°; L. W. Winkler's results are rather lower than C. Bohr and J. Bock's. The latter are here indicated along with ω, the weight of gas in grams taken up by 100 grams of solvent at the indicated temperature and a total pressure—gas plus the vapour of the solvent—of 760 mm.:

	0°	4°	8°	12°	16°	20°	24°
β . .	0·04961	0·04496	0·04098	0·03732	0·03425	0·03171	0·02954
ω . .	0·00704	0·00637	0·00578	0·00526	0·00481	0·00443	0·00411

L. W. Winkler represented his results for the absorption coefficient β at $\theta°$ between 0° to 30° by the empirical formula $\beta=0{\cdot}04890-0{\cdot}0013413\theta+0{\cdot}04283\theta^2-0{\cdot}0629534\theta^3$; J. J. Fox's formula (1909) is $\beta=0{\cdot}04924-0{\cdot}0013440\theta+0{\cdot}0428752\theta^2-063924\theta^3$; C. Bohr and J. Bock's values between 25° and 100° are:

	25°	30°	40°	50°	60°	80°	100°
β . .	0·02904	0·02676	0·02326	0·02070	0·01893	0·01726	0·01679
ω . .	0·00403	0·00368	0·00310	0·00263	0·00221	0·00135	0·00000

Unit volume of water increases 0·00115 unit by the absorption of one volume of oxygen. Water is easily supersaturated with oxygen, and the excess is given off with difficulty.[28] W. E. Adenby and H. G. Becker have studied the rate of solution of oxygen in water.

According to G. Geffcken,[29] the solubility λ of oxygen in acids solutions at 15° and 25°, when λ for oxygen in water is 0·0363 (15°) and 0·0308 (25°) is:

	Hydrochloric acid.		Nitric acid.		Sulphuric acid.	
	15°	25°	15°	25°	15°	25°
½*N*-acid . .	0·0344	0·0296	0·0348	0·0302	0·0338	0·0288
2*N*-acid . .	0·0299	0·0267	0·0315	0·0284	0·0335	0·0251

According to A. Christoff, the solubility λ of oxygen in 95·6 per cent. *sulphuric acid* is 0·03166 between 17° and 20°; in 0·06162 per cent. acid, 13·30; in 0·03582 per cent. acid, 15·61; and in pure water, 0·03046. The value of λ for *potassium hydroxide* in ½*N*-solutions is 0·0291 (15°) and 0·0252 (25°), and for normal solutions, 0·0234 (15°) and 0·0206 (25°); with $\frac{1}{2}N$-solutions of ***sodium hydroxide***, λ=0·0288 (15°) and 0·0250 (25°); with normal solutions of sodium hydroxide, λ=0·0231 (15°) and 0·0204 (25°). Similarly, with $\frac{1}{2}N$-solutions of ***potassium sulphate***, λ=0·0294 (15°) and 0·0253 (25°), and with normal solutions, λ=0·0237 (15°) and 0·0207 (25°). With $\frac{1}{2}N$-solutions of ***sodium chloride***, λ=0·0308 (15°) and 0·0262 (25°); and with normal solutions, λ=0·0260 (15°) and 0·0223 (25°). The solubility of oxygen in salt solutions diminishes regularly with an increase in the concentration of the salt. C. G. MacArthur measured the solubility of oxygen in solutions of lithium, sodium, potassium, rubidium, cæsium, ammonium, magnesium, calcium, and barium chlorides; sodium and potassium bromide; potassium iodide, nitrate, and sulphate; and in sodium sulphate. The density determinations also furnished data for calculating the degree of hydration of the salts. C. G. MacArthur says that allowing for the hydration of the ions, the results show that particular ions increase the solubility to a definite extent which is specific for a particular ion. ***Sea water*** was found by F. Clowes and J. W. H. Biggs to dissolve a little more than 70 per cent. of the amount of oxygen dissolved by distilled water; and the amount dissolved diminishes regularly with the salinity of the water. According to J. S. Maclaurin, the absorption coefficient of oxygen in aqueous solutions of ***potassium cyanide*** is

KCy in 100 grms. solution . .	1	10	20	30	50 grms
Absorption coefficient . . .	0·029	0·018	0·013	0·008	0·003

The solubility of oxygen in organic solvents.—Oxygen is a little less than five times as soluble in *ethyl alcohol* as in water. According to E. E. O. Libarsch, the solubility of oxygen in unit volume of water is 0·0289, and in aqueous alcohol at 20° and 760 mm.

Per cent. alcohol . .	9·09	16·67	28·57	33·33	50·00	66·67	80·0
λ	0·0278	0·0278	0·0249	0·0267	0·0350	0·0495	0·056

The solubility thus decreases with increasing concentration of the alcohol; reaches a minimum with nearly 28 per cent. solutions, and again increases with increasing concentration. The variation of the absorption coefficient with temperature for 99·7 per cent. solutions of ethyl alcohol is β=0·2337 (0°), 0·2301 (5°), 0·2266 (10°), 0·2232 (15°), 0·2201 (20°), and 0·2177 (24°); he represents the absorption coefficient β for temperatures, θ, between 0° and 23·4°, by $\beta=0{\cdot}23370-0{\cdot}0374688\theta+0{\cdot}053288\theta^2$; with methyl alcohol and acetone, the values of λ are:

	0°	5°	10°	20°	30°	40°	50°
λ (methyl alcohol) .	0·31864	0·30506	0·29005	0·25374	0·21569	0·21569	0
λ (acetone) . .	0·2997	0·2835	0·2667	0·2313	0·1935	0·1533	0

and M. G. Levi represents the values for ***methyl alcohol*** by $\lambda=0{\cdot}31864-0{\cdot}002572\theta-0{\cdot}042866\theta^2$; and for ***acetone***, $\lambda=0{\cdot}2997-0{\cdot}00318\theta-0{\cdot}0412\theta^2$. With ***petroleum***, the absorption coefficient at 10° is 0·229, and at 20°, 0·202. C. G. MacArthur measured the solubility of oxygen in solutions of ***sugar***, and he found signs of an oxidation of the sugar. C. Bohr has measured the absorption of oxygen by blood.

The solubility of oxygen in solids.—Solids adsorb, or occlude, oxygen in an analogous manner to hydrogen.[30] G. Neumann found that if the following metals be heated to 450° in oxygen,

	Silver.	Gold.	Platinum.
Volumes of oxygen occluded	4·1–5·4	32·8–48·5	63·0–77·0

per volume of metal. ***Palladium*** is oxidized[31] to Pd_2O, or a mixture of Pd_2O and PdO. According to C. Engler and L. Wöhler, ***platinum***, like palladium, forms a true compound or a mixture of compounds: PtO and PtO_2. According to E. Goldstein,[32] the platinum electrode of a Geissler's tube rapidly absorbs oxygen when red hot. R. Lucas attributes the absorption of oxygen by platinum to the presence of iridium; pure platinum, says he, absorbs no oxygen. The case of silver[33] is peculiar. Molten *silver* dissolves about ten times its volume of oxygen, and gives it up again on cooling. In cooling, a solid skin forms on the exterior surface; as the interior cools, the gas bursts through the solid crust, driving out a spurt of the still fluid metal—the phenomenon is called the *spitting* or *rockage* of silver. Molten *platinum* behaves in a somewhat similar way. A little oxygen still remains dissolved in the cold metal, and this can be recovered by heating it to redness in vacuo.

According to S. Kern,[34] *steel* dissolves from 0·025 to 0·05 vol. of oxygen. H. V. Regnault[35] said that *mercury* dissolves a little oxygen, but E. H. Amagat found no evidence of this between 0° and 100°, even at 420 atm. pressure. According to F. Leblanc, molten *litharge* dissolves oxygen which is rejected when the oxide solidifies. *Charcoal*[36] dissolves 9·25 its volume of oxygen at 12° and 724 mm. pressure, as shown by T. de Saussure in 1814 and according to L. Joulin, 26 vols. at 0° and 2·36 atm. pressure, and 230 vols. at —185°. According to J. L. Baerwald, with one volume of charcoal at 760 mm. pressure, the volume of oxygen absorbed at different temperatures is

	10°	0°	−10°	−50°	−100°	−150°
Oxygen absorbed	61·7	66·7	70·0	105·0	165·0	245·0 vols.

Neither platinum nor palladium show this remarkable increase in its own absorptive power at low temperatures. According to G. Craig, the coke from lignite which has been heated to redness and cooled with the exclusion of air, absorbs oxygen with the formation of water.

The **coefficient of diffusion** of oxygen into carbon dioxide is 0·136, and of hydrogen into the same gas, 0·538. T. Graham[37] has shown that oxygen travels through indiarubber, 2½ times as rapidly as nitrogen. Hydrogen travels 5½ times as fast as nitrogen. According to M. Berthelot, cold glass is impermeable to oxygen, but at 650° he found a glass bulb lost 8 per cent. of the gas in 2 hours, and Jena glass at 800° scarcely lost any gas in 1½ hours. Oxygen does not diffuse through cold silver, but it does if the metal be heated, say at 800°; and L. Troost showed that at this temperature about 1700 c.c. of gas will travel through a sq. metre of the metal 1 mm. thick per hour, and 3300 c.c. if the plate is ½ mm. thick. The permeability of hot silver to oxygen is connected with its power of occluding this gas. For the diffusibility of oxygen through rubber, see hydrogen.

Liquid oxygen at —190° dissolves about 380 times its volume of nitrogen and the boiling point is then changed to —188·8°. The suggested cause of the discrepancies in the boiling point determined by different investigators is probably due to the contamination of the liquid with nitrogen. Liquid oxygen indeed rapidly absorbs nitrogen from the air[38]—Fig. 25, Cap. XI. J. K. H. Inglis and J. E. Coates studied the densities and partial pressures of solutions of oxygen and nitrogen, and J. K. H. Inglis the isothermal distillation of nitrogen and oxygen. Liquid oxygen readily dissolves liquid fluorine.

§ 9. The Chemical Properties of Oxygen

Oxygen, so to speak, is the central pivot round which the whole of chemistry revolves.—J. J. Berzelius.

Oxygen is entirely unmatched among the rest of the elements both as regards the number and the varied character of its compounds.—W. A. Tilden.

The great chemical activity of oxygen is well typified by the quaint remarks which J. Priestley made about the gas. When a glowing splint of wood is plunged into oxygen it bursts into flame; the carbon of the wood is oxidized to carbon dioxide (CO_2). The inflammation of a glowing splint is often used as a test for oxygen. A mixture of nitrogen and oxygen containing less than 28·29 per cent. of the latter does not re-ignite a glowing splint, and if the mixture contains less than about 16 per cent. of oxygen the splint will be extinguished. Oxygen alone has no visible action on clear lime-water; but after a splint has burnt in the gas, the clear lime-water becomes turbid. Oxygen combines directly with most other elements, particularly at elevated temperatures, forming **oxides**.

The direct combination of oxygen with some of the elements can be illustrated by placing small dry pieces in deflagrating spoons, heating them until combustion begins, and then plunging each into a jar of oxygen. The glowing piece of *charcoal* burns very brightly and forms a gaseous oxide—carbon dioxide, CO_2. *Sulphur* burns with a lavender-blue flame, forming gaseous sulphur dioxide—SO_2—which has the peculiar odour characteristic of burning sulphur. The reaction is symbolized: $S+O_2=SO_2$; sulphur dioxide is soluble in water forming sulphurous acid—H_2SO_3—which reddens blue litmus solution—$H_2O+SO_2=H_2SO_3$. *Phosphorus* burns in oxygen vigorously and brilliantly, forming a white cloud of phosphorus pentoxide—P_2O_5. The reaction is represented: $4P+5O_2=2P_2O_5$. The phosphorus pentoxide dissolves in water, forming phosphoric acid—H_3PO_4. The reaction is written: $P_2O_5+3H_2O=2H_3PO_4$. The phosphoric acid reddens blue litmus. Metallic *sodium* treated in a similar way (spoon dry) burns with a bright yellow flame and gives a white oxide which dissolves in water, forming a solution of *caustic soda*. The solution turns red litmus blue. *Calcium* behaves similarly, but it burns with an orange-red flame. A piece of burning *magnesium* ribbon plunged in oxygen burns with an exceptionally brilliant flame. The white solid obtained is slightly soluble in water, and the solution turns red litmus blue. To show the combustion of *iron* in oxygen gas, tie a tuft of steel wool to the end of a stout iron wire by means of a piece of steel wire. Heat the end of the wool in a Bunsen's flame, until incipient combustion begins, and quickly plunge it into a jar of oxygen on the bottom of which a layer of water, sand, or asbestos paper has been placed. The wool burns with dazzling scintillations, the product of the reaction—iron oxide—falls to the bottom of the jar in fused globules. When cold, the oxide of iron resembles a blacksmith's scale. It is called black or magnetic oxide of iron—Fe_3O_4. The reaction is usually written: $3Fe+2O_2=Fe_3O_4$. Experiments showing the combustion of iron in oxygen date from G. C. Lichtenberg (1782).[1] The oxide of iron so formed is insoluble in water and has no effect on red or blue litmus.

Iodine, bromine, chlorine, fluorine, gold, platinum, and argon and its companions do not combine *directly* with oxygen. The reaction between metals and oxygen does not as a rule take place at ordinary temperatures, and heat is required. If the oxide is unstable at the temperature necessary for reaction, it will not be formed directly even though much heat be evolved in the formation of the oxide. Mercury at a high temperature does not appear to react with oxygen since the oxide, if formed, is immediately decomposed. The temperatures of formation and decomposition of the oxide are not far apart; with the oxides of silver and palladium, the temperatures of formation and decomposition are probably much nearer even than with mercury. Similar remarks apply to iodine and platinum oxides. The elements, nitrogen, fluorine, chlorine, and bromine, absorb energy when they unite with oxygen, and oxides can be formed indirectly or in some cases directly if the temperature is very high—*e.g.* nitrogen oxide.

Oxygen combines *indirectly* with all the elements excepting the argon group, fluorine, and possibly bromine. "Oxygen," said C. L. Berthollet (1803), "seems to take the lead of all substances in the extent and energy of its affinities," and, with perhaps the exception of fluorine, these words are true to-day. The energy which is degraded as heat when the different elements combine with oxygen, is a distinctive characteristic. The amount of heat liberated in combining with a gram-atom of the element is a rough indication of the avidity of the element for oxygen. Table I shows the heat developed during the formation of a gram-molecule of an oxide;[2] and also per gram-atom of the element united with oxygen. If no remark is made as to the state of aggregation—solid, liquid, gas—a solid is to be understood. If the metals be arranged in the order of their avidity or readiness to combine with oxygen, cæsium, potassium, and sodium will be found at one end of the series, while platinum and the argon family will be found at the other end. If the heats of formation of the oxides of the elements be plotted against the atomic weights, a periodic curve is obtained, corresponding approximately with the periodic curve obtained when many of the other properties of the elements are plotted against the atomic weights.

The preparation of the oxides.—The methods for preparing individual oxides are described when dealing with the respective elements. The following are common enough to merit the designation *general methods* : (1) By calcining the metal while freely exposed to air, *e.g.* tin gives stannic oxide, $Sn+O_2 \rightarrow SnO_2$; (2) By calcining the nitrate strongly, and subsequently washing the residue to remove the undecomposed nitrate, *e.g.* with copper nitrate, $Cu(NO_3)_2$, the action is represented : $2Cu(NO_3)_2 \rightarrow 2CuO+4NO_2+O_2$; with chromium nitrate : $4Cr(NO_3)_3 \rightarrow 2Cr_2O_3 +12NO_2+3O_2$; (3) By calcining the carbonate, *e.g.* with calcium carbonate : $CaCO_3 \rightarrow CaO+CO_2$. With barium and strontium carbonates it is better to mix the carbonate with powdered carbon (lampblack) before calcination. (4) By pouring a solution of alkali hydroxide or aqueous ammonia into a solution of the salt, washing the precipitated hydroxide, and afterwards calcining it to drive off the water, *e.g.* with ferric chloride and sodium hydroxide : $FeCl_3+3NaOH=Fe(OH)_3 +3NaCl$; the subsequent calcination of the ferric hydroxide, $Fe(OH)_3$, furnishes the required oxide : $2Fe(OH)_3 \rightarrow Fe_2O_3+3H_2O$.

TABLE I.—HEAT EVOLVED OR ABSORBED IN THE FORMATION OF THE OXIDES.

Oxide.	Cals. per gram molecule.	Cals. per gram atom.	Oxide.	Cals. per gram molecule.	Cals. per gram atom.	Oxide.	Cals. per gram molecule.	Cals. per gram atom.
H_2O (gas)	58·1	29·0	B_2O_3	272·6	136·3	Bi_2O_3	139·2	69·6
H_2O (liquid)	69·0	34·5	Al_2O_3	392·6	196·3	SO_2 (gas)	69·3	69·3
H_2O (solid)	70·4	35·2	Tl_2O	42·8	21·4	SO_2 (liquid)	91·9	91·9
Li_2O	140·0	70·0	Tl_2O_3	87·6	43·8	SeO_2	57·1	57·1
Na_2O	100·9	50·4	CO (gas)	29·2	29·2	WO_3	65·5	32·7
K_2O	98·2	49·1	CO_2 (gas)	97·2	97·2	Cl_2O (gas)	17·9	−8·9
Rb_2O	94·9	47·4	SiO_2	180·0	180·0	I_2O_5	45·3	22·6
Cs_2O	99·98	50·0	TiO_2	97·8	97·8	PbO	50·3	50·3
AgO	7·0	3·5	ZrO_2	177·5	177·5	PbO	63·4	63·4
Cu_2O	43·8	21·9	N_2O (gas)	—17·5	−8·8	SnO	70·7	70·7
CuO	37·7	37·7	NO (gas)	21·6	−21·6	SnO_2	141·3	141·3
Au_2O_3	11·5	5·8	NO_2 (gas)	2·0	−2·0	FeO	65·7	65·7
CaO	131·5	131·5	P_2O_5	365·3	182·6	Fe_2O_3	195·6	97·8
SrO	131·2	131·2	As_2O_3	156·4	78·2	Fe_3O_4	270·8	90·3

MgO	143·4	143·4	Sb_2O_5	231·2	115·6	MnO	90·9	90·9
ZnO	84·8	84·8	HgO	21·5	21·5	Mn_3O_4	328·0	109·3
CdO	66·3	66·3	PdO	21·0	21·0	MnO_2	125·3	125·3
Hg_2O	22·2	11·1	PtO	17·0	17·0			

In reviewing the oxides of all the elements, it will be apparent that the proportions of combined oxygen are not always the same. The elements, indeed, can be arranged roughly into natural groups determined by the composition and properties of what D. I. Mendeléeff regarded as the different typical oxides they form. This has been done in Table II.

Many of the elements form a number of different oxides, and in that case the same element might fall into two or more different groups. This is well illustrated by the family : iron, manganese, cobalt, and nickel. The RO oxides of these elements are readily oxidized to sesquioxides of the type R_2O_3, and these same elements also form still higher oxides of the type, RO_2, and, in the case of manganese, there is evidence of a yet higher oxide, Mn_2O_7. Under a pressure of about 12 atmospheres, at 480°, oxygen [3] oxidizes the oxides of lithium, sodium, potassium, and barium to peroxides of the type R_2O_2 ; and a small proportion of a peroxide is formed with cobalt and nickel oxides ; lead oxide gives red lead Pb_3O_4 ; antimony oxide gives the tetroxide Sb_2O_4; chromium sesquioxide gives chromium chromate Cr_2O_4 or $CrCrO_4$. Beryllium, calcium, strontium, zinc, cadmium, aluminium, boron, thallium, silicon, zirconium, tin, bismuth, molybdenum, tungsten, uranium, and ferric oxides do not change.

TABLE II.—OXIDES OF THE ELEMENTS.

Oxide.	Corresponding group of elements.	Character of oxide.
M_2O	(H), Li, Na, K, Cu, Rb, Ag, Cs, Au	Basic
MO	Be, Mg, Ca, Zn, Sr, Cd, Ba, Hg	Basic
M_2O_3	B, Al, Sc, Ga, Y, In, La, Yb, Tl	The first oxide B_2O_3 is weakly acidic; the others are basic
MO_2	C, Si, Ti, Ge, Zr, Sn, Ce, Pb	The first two are acidic; the last one is basic; and the others are both basic and acidic, becoming more basic with increasing atomic weight
M_2O_5	N, P, V, Nb, Di, Er, Ta, Bi	These oxides are acidic; Bi_2O_3 is also basic
MO_3	O, S, Cr, Se, Mo, Te, W, U	Acidic and become less and less acidic as the atomic weight increases; VO_3 is also feebly basic
M_2O_7	F, Cl, Mn, Br, I	Acidic. The highest oxide is represented by M_2O_7. No definite oxide of Br or F is known
MO_4	Fe, Ni, Co; Ru, Rh, Pd; Os, Ir, Pt	The first triad forms feebly basic sesquioxides; RuO_4 and OsO_4 are the only representatives of the highest oxide. These are feebly acidic. The lower oxides are feebly basic

Oxygen is closely related to the elements of the sulphur, selenium, and tellurium family. The changes in the physical characters of the oxides show regular gradations with increasing atomic weight in harmony with the periodic classification. Regularities have been traced in the specific gravity, atomic volume, volatility, stability, reactivity with water, heats of formations, etc. According to G. H. Bailey [4] in the even series of Mendeléeff's table:

I.	II.	III.	IV.	V.	VI.	VII.	VIII.
Li_2O	BeO	B_2O_3	CO_2	N_2O_5	CrO_3	Mn_2O_7	FeO_4
K_2O	CaO	Sc_2O_3	TiO_2	V_2O_5	MoO_3	——	RuO_4
Rb_2O	SrO	Yt_2O_3	ZrO_2	Nb_2O_5	WO_3	——	OsO_4

The oxides of the first four groups are so stable that they undergo no decomposition at temperatures below 1750°; nitrogen pentoxide decomposes below 50°, and, further on, the oxides are more stable the higher the atomic weight—uranium oxide, UO_3, appears to be an exception. In the horizontal series, the stability of the oxides decreases from left to right as the atomic weight increases. The behaviour of the RO_4 oxides of the eighth group is also in keeping with these generalities. Osmium octoxide is more stable than ruthenium octoxide, and there is a doubt about the existence of the corresponding iron compound.

Many substances are oxidized at ordinary temperatures—*e.g.* nitric oxide, a colourless gas, oxidizes to reddish-brown nitrogen, peroxide, NO_2, in air at ordinary temperatures; the alkali metals; ferrous and manganous hydroxides; etc. In some cases the oxidation is so vigorous that the heat developed inflames the mass. This is the case, for instance, with hydrogen phosphide, P_2H_4; silicon hydride, Si_2H_6; zinc ethyl, $Zn(C_2H_5)_2$; etc. Some of the metals in a very fine state of subdivision are oxidized in air—*e.g.* pyrophoric iron, nickel, cobalt, etc. In some cases the oxidation is specially stimulated by exposure to sunlight—*e.g.* lead sulphide, PbS. becomes lead sulphate, $PbSO_4$; carbon chloride, C_2Cl_6, forms a mixture of carbonyl chloride, $COCl_2$, and trichloroacetyl chloride, $CCl_3.CO.Cl$; phosphorus trichloride, PCl_3, forms phosphoryl chloride, $POCl_3$; etc. The presence of the noble metals, and of cobalt, nickel, etc., in a fine state of subdivision, may enormously accelerate the speed of oxidation.

The influence of water in chemical reactions.—Water plays an important *rôle* in many reactions. If water be dropped on to a mixture of iodine with one-sixth of its weight of aluminium powder, the reaction proceeds so rapidly as to inflame the mass. There are, however, cases in which the minute trace of water vapour which is present in an imperfectly dried gas, controls the reactivity of the gas. For instance, H. B. Baker (1886)[5] showed that dry sulphur, dry phosphorus, and dry carbon burn with great difficulty or not at all in dry oxygen. Similarly, H. B. Dixon (1880) showed that carbon monoxide reacts with oxygen with greater difficulty, if it be thoroughly dried—*e.g.* if moist, a mixture of the two gases readily detonates, but not if dried. Numerous other reactions have been notified which are arrested if the reacting materials be dried. In fact, many **perfectly dried substances often appear to be chemically inert, whereas they react vigorously if a trace of moisture be present.**

The fact is quite old. Near the end of the eighteenth century, for instance, T. Bergmann[6] noticed that the "regulus of manganese" remains bright in dry air, but not in moist air; the illustrious C. W. Scheele also noted in 1786 that pyrophorus will not oxidize in air dried by quicklime, and he inferred that "the water usually present in the atmosphere is the chief cause of the burning of pyrophorus." Mrs. Fulhame, too, in her remarkable brochure, *An Essay on Combustion with a view to a new art of dying and painting* (London, 1794), showed "beyond the power of contradiction" that water is necessary for the reduction of the metallic oxides, and for the oxidation of the metals. She found, for example, that gold chloride cannot be reduced by hydrogen gas if moisture be excluded. The effect of moisture is not to promote the reduction by breaking up the salt into minute particles, nor by condensing the gas and so bringing the hydrogen into closer contact with the metallic oxide; for, if either of these views were correct, ethereal and alcoholic solutions of the metallic salt should prove as effective as water. This is not the case. Neither ether nor alcohol promotes the reduction if water be absent. Mrs. Fulhame believed that the reaction—oxidation or reduction—took place in two stages. In the first place, carbon monoxide decomposed the water, forming carbon dioxide and liberating hydrogen; thus—$CO+H_2O=CO_2+H_2$ (nascent); finally, the nascent hydrogen united directly with the free oxygen, reforming water—$2H_2$ (nascent)$+O_2=2H_2O$. Consequently, the oxygen which unites with the carbon monoxide to form carbon dioxide is not obtained directly from the oxygen gas mixed with the carbon monoxide, but from the water. H. B. Dixon[7] developed quite an analogous theory as a result of an important investigation on the oxidation of carbon monoxide, and he submitted that carbon monoxide is oxidized by steam with the liberation of hydrogen,[8] and that the hydrogen then unites with oxygen to reform steam. These results make it probable that steam does really undergo "a cycle of chemical reactions whereby it gives up oxygen to carbon monoxide and returns to its original state." H. B. Dixon also proved that other gases like hydrogen sulphide, ethylene, formic acid, ammonia, pentane, and hydrogen chloride will determine the explosion of carbon monoxide and oxygen; while sulphur dioxide, carbon disulphide, carbon dioxide, cyanogen, and carbon tetrachloride are quite ineffective. Hence, he inferred that *not only steam, but all substances which will form steam under the conditions of the experiment, are capable of determining the explosion.*

M. Traube (1882) observed that traces of hydrogen peroxide are generally formed during the oxidation of carbon monoxide, and he suggested that hydrogen peroxide, H_2O_2, is an intermediate product in the oxidation of hydrogen or carbon monoxide,; and that the water acts catalytically by acting as a link in the cyclic changes: $CO+H_2O+O_2=CO_2+H_2O_2$; and $CO+H_2O_2=CO_2+H_2O$. Dixon, however, showed that the hydrogen peroxide is most probably a by-product in the oxidation of moist carbon monoxide. In the oxidation of hydrogen, M. Traube supposed that the water acted catalytically :

$$\begin{matrix}H\\ \dot{H}\end{matrix}+\begin{matrix}HOH\\ HOH\end{matrix}+\begin{matrix}O\\ \dot{O}\end{matrix}=\begin{matrix}HOH\\ HOH\end{matrix}+\begin{matrix}HO\\ H\dot{O}\end{matrix}\ ;\quad \text{and}\quad \begin{matrix}HO\\ H\dot{O}\end{matrix}+\begin{matrix}H\\ \dot{H}\end{matrix}=\begin{matrix}HOH\\ HOH\end{matrix}$$

In reality we have not got much further than Mrs. Fulhame (1794) in working out the mechanism of this reaction. This gifted woman said :

> Water is essential both to the reduction and oxygenation of bodies, and is always decomposed in these operations. . . . In every instance of combustion water is decomposed, and one body oxygenated by the oxygen of the water, while another is restored to its combustible state by the hydrogen of the same fluid.

It must be added that the water as a catalytic agent does not necessarily accelerate the speed of all reactions. W. S. Millar, for example, found that the speed of decomposition of diazoacetic ester by picric acid in alcohol solutions is retarded in a marked degree if a small amount of water be present, and this the more with isobutyl alcohol than with ethyl or methyl alcohol as solvent.

The physiological action of oxygen.—In 1667, Robert Hooke[9] clearly demonstrated before the Royal Society that a continual supply of air is necesssary for the maintenance of life. In an experiment on a dog with its ribs and diaphragm removed, and described as "an experiment made by Mr. Hooke of preserving animals alive by blowing through their lungs with a bellows," he emphasized

> It was not the subsiding or movelessness of the lungs that was the immediate cause of death, or the stopping of the circulation of the blood through the lungs, but the *want* of a sufficient *supply of air*.

In 1674, J. Mayow showed that one constituent of air is alone active, and further that this constituent is the same as that on which ordinary combustion depends. He called the active constituent *spiritus nitro-æreus*, which was later identified with oxygen. From his experiments with mice, etc., he concluded :

> It is manifest that air is deprived of its elastic force—decreased in volume—by the breathing of animals very much in the same way as by the burning of a flame ; and, indeed, we must believe that animals and fire draw particles of the same kind from the air.

The importance of oxygen in the maintenance of animal life was emphasized by M. de Condorcet's term *l'air vital*—the life maintaining constituent of air.[10] It is the only gas capable of supporting respiration. There are, however, a few micro-organisms—*e.g.* the mould *mucor racemosus*, and the butyric acid ferment—which are killed by oxygen, and they are able to live and multiply without air. L. Pasteur called them *anaerobic organisms*. E. Weinland found that intestinal worms can normally exist in the absence of oxygen ; and A. Pütter found that the leech can live two days without oxygen.

The oxygen is carried by the blood to the various tissues in the body, and the waste products are carried away by the same liquid. The circulating blood is oxidized in the lungs of land animals, and in the gills of water animals. In insects, the blood is oxidized in a system of ramifying tubes called *tracheæ* in which the air is periodically changed by muscular movements and diffusion. Fish are dependent upon the air dissolved in water for the oxygen they need for respiration. According to E. A. Birge and C. Juday, the dissolved oxygen is deficient in the lower layers of water in 129 inland lakes of Wisconsin. This is attributed to the thermal stratification of the water owing to the greater specific gravity of the colder water hindering vertical circulation, and the depletion of the oxygen in the colder layers by the respiration of animals and plants, by the direct oxidation of dead organic matter, and by the decomposition due to the action of bacteria. A deficiency has also been noted in the lower layers of certain tidal waters which is similarly caused by stratification due to the greater specific gravity of the under-run of sea water hindering vertical circulation.

Warm-blooded animals die very rapidly in an atmosphere containing no oxygen. A man at rest becomes suddenly unconscious after about ten breaths of such an atmosphere; and very small animals, such as a mouse or a sparrow, in which the breathing is far more rapid than in a man, are killed within a few seconds, death being much faster than by drowning. When pure oxygen is breathed no noticeable effect is produced for many hours. As A. L. Lavoisier first showed, and many subsequent observers have also found, breathing pure oxygen causes no increase in the oxidation processes within the body. Paul Bert found, however, that oxygen at a pressure of over three atmospheres has a rapid poisonous effect on warm-blooded animals, accompanied by diminution of oxidation processes. This poisonous action is also produced in living organisms of all kinds. Pure air of which the pressure is raised so high as to give the same partial pressure of oxygen has the same effect. More recently, Lorrain Smith showed that exposure for two or three days to pure or nearly pure oxygen produces inflammation of the lungs; and the higher the partial pressure the sooner the inflammation appears. It was formerly supposed that poisonous organic matter is exhaled in the breath along with CO_2. All recent investigation has shown that this view is without foundation. "It has been often asserted," adds L. Hill, "that there is some organic poison exhaled with the breath. I have carefully sifted the evidence on which this assertion is based, and find that there is none worthy of evidence."

Air normally contains nearly 21 per cent. of oxygen by volume. When the oxygen is reduced to about 17·5 per cent. the flame of a candle or oil-lamp is extinguished. A man or animal is, however, not appreciably effected by so small a diminution in the oxygen percentage. On the other hand, if the atmospheric pressure, and consequently the partial pressure of oxygen, be diminished to a third the man or animal is greatly affected and soon dies, while the flame continues to burn almost as well as before. Roughly speaking, the flame responds to the *percentage* of oxygen in the air, while the animal responds to the *partial pressure* of oxygen. H. C. Dallwig, A. C. Kolls, and A. S. Lowenhart (1915) found that the flame of a candle is just extinguished when the partial pressure of oxygen is 116·4 mm. of mercury when this lowering is produced by adding nitrogen to air, whereas the flame is first extinguished at 19·8 mm. if the lowering is effected by reducing the total pressure of the atmosphere. Pure oxygen can be breathed for many hours without harm, and is used in a pure state in mine-rescue apparatus and in resuscitating persons poisoned by carbon monoxide. During the war the continuous administration of air containing an increased percentage of oxygen was used with striking success in the treatment of lung-inflammation caused by poison-gas; and similarly enriched air is now coming into extensive use in medical cases of other kinds.

Uses of oxygen.—Mixtures of liquid oxygen and petroleum are violently explosive. It is said that a lighted candle falling into a bucket of liquid oxygen in 1903 "sent G. Claude to the hospital in a very pitiable condition." Liquid air, or rather liquid air rich in oxygen, furnishes an explosive—called *oxylignite*—when mixed with charcoal, or cotton wool. 3-cm. cartridges charged with one part of carbon, one part of petroleum, and eight parts of liquid oxygen were tried experimentally in cutting the Simplon tunnel. The cartridges were exploded by an electric fuse, or a mercury fulminate cap. The chief objection is that the cartridges must be used within a few minutes after being charged, or the oxygen will evaporate. This objection might be an advantage under some circumstances, since a mis-fired shot becomes harmless in a very short time. The cartridges must also be prepared immediately before use, so that there are no dangers during transport.

The temperature of the hydrogen flame burning in air at 0° is, according to P. Mahler,[11] 1960°; of the carbon monoxide flame, 2100°; and of the acetylene flame, 2350°. Oxygen is used in conjunction with hydrogen for the *oxy-hydrogen blowpipe*, and with acetylene for the *oxy-acetylene blowpipe* used in welding, metal-cutting, etc. Thick steel plates can be cut by directing a stream of oxygen on the heated metal. Metal cutting or welding by the oxy-acetylene or oxy-hydrogen blowpipe has proved to be a remarkable labour-saving process. It has been estimated that 70 per cent. of oxygen consumed in the United Kingdom is used in cutting metals in shipbuilding and repairing yards, steel works, and engineering shops. Oxygen is used in the ventilation of submarines, etc., and for medical purposes; it is employed in the oxidation and thickening of oils to be used in making varnishes and linoleum. It is sometimes used to hasten the maturing of spirits; and the oxidation of alcohol by *mycoderma aceti* in vinegar manufacture. Oxygen has been recommended in the bleaching of paper-pulp, etc., where a fine stream of oxygen is said to effect a saving in the consumption of bleaching powder.[12] It has also been proposed to use carburetted oxygen—a safe mixture of oil and oxygen—as a motive gas for engines, for illuminating purposes,[13] in organic "combustion analyses," etc.

The determination of oxygen in a gas.—The property of rekindling a glowing splint is possessed by only one other gas—nitrous oxide—and the two gases are distinguished by a bubble of nitric oxide—oxygen gives red fumes, nitrous oxide does not. The methods for measuring the amount of oxygen in a gas depend on its absorption by various liquids and solids. For instance: (1) a solution of cuprous chloride in hydrochloric acid. The colourless solution becomes greenish-brown owing to the formation of cupric oxychloride. The exhausted solution is restored by keeping it in contact with copper shavings away from air. (2) An alkaline solution of pyrogallol freely absorbs oxygen forming a dark brown liquid—if the solution be saturated with oxygen, some carbon monoxide may be formed. This solution was used by J. von Liebig in 1851.[14] (3) Clean moist copper absorbs oxygen. The absorption soon ceases owing to the formation of a film of oxide; this can be washed off by an ammoniacal solution of ammonium carbonate. The gas containing oxygen is introduced into a vessel containing copper shavings and the ammoniacal solution, the liquid is displaced and the copper absorbs the oxygen, the return of the ammoniacal liquid displaces the gas. (4) Clean sticks of phosphorus are sometimes employed for absorbing the gas. (5) A solution of chromous chloride in hydrochloric acid; and (6) an alkaline solution of ferrous tartrate, also absorb oxygen.

The atomic weights of hydrogen and oxygen.—The early determinations of the combining ratios of hydrogen and oxygen by H. Cavendish (1781), A. L. Lavoisier and M. Meunier (1788), M. Monge (1788), J. Dalton (1803), and W. H. Wollaston (1814) are of great historical interest; but the results are not considered accurate enough to be worthy of consideration in deducing best representative values of these data. Several methods have been used in evaluating the ratio H : O. The accurate determination of this ratio has proved to be of extreme difficulty. The subject has been well discussed by B. Brauner,[15] J. Sebelien in his *Beiträge zur Geschichte der Atomgewichte* (Braunschweig, 1884), and by F. W. Clarke in his *A Recalculation of the Atomic Weights* (Washington, 1910).

I. *Gravimetric methods.*—In these methods of determining the ratio H : O, the hydrogen and oxygen may each be weighed separately, and the water also weighed. More usually two of these three quantities are determined, and the third estimated by difference. The various methods include: (i) Those in which the hydrogen and oxygen are weighed, and the water estimated by difference;[16] (ii) those in which the oxygen and water are weighed, and the hydrogen estimated by difference;[17] (iii) those in which the hydrogen and water are weighed, and the oxygen estimated by difference;[18] and (iv) those in which the hydrogen, oxygen, and water are all weighed—*synthèse complète.*[19] According to F. W. Clarke, the best representative value is O=15·8779 if H=1; and H=1·00769 if O=16.

II. *Volumetric methods.*—Volumetric methods include those in which the volumes of the hydrogen and oxygen are measured and the water estimated by difference; and those in which either the volume of the oxygen or of the hydrogen, or both are measured and the resulting water weighed. Determinations of the ratio of the combining volumes of hydrogen and oxygen[20] (Cap. III), give as the best representative value of the ratio H : O=1·0077 : 16.

. III. *Gas densities.*—Determinations of the relative densities of hydrogen and oxygen[21] furnish for hydrogen the atomic weight 1·00777 ; and for oxygen, 15·8767.

IV. *Physico-chemical methods.*—A number of other methods[22] have been employed. For example, *the method of critical constants* by A. Leduc and P. Sacerdote, Lord Rayleigh, A. Jaquerod and O. Scheuer, and by D. Berthelot furnished H : O=1·00777 : 16 ; *the method of limiting densities* by P. A. Guye, D. Berthelot, and A. Leduc furnished H : O=1·00775 : 16 ; and *the method of molecular volume* by A. Leduc furnished H : O=1·0076 : 16.

V. *Indirect determination.*—J. Thomsen determined the amount of ammonia required to saturate a given amount of hydrogen chloride, then, given the atomic weights of nitrogen and chlorine (O=16), the atomic weight of hydrogen can be computed.

Dry hydrogen chloride was passed into a weighed flask containing water coloured with litmus and weighed—5·0363 grms. of hydrochloric acid were absorbed ; dry ammonia was passed in until the liquid was almost neutral and the flask again weighed. The excess of ammonia or acid was determined by titration with standard acid or alkali—2·3523 grms. of ammonia were used to neutralize 5·0363 grms. of hydrogen chloride. Hence, $HCl : NH_3 = 5·0363 : 2·3523$. If the atomic weight of chlorine be 35·457 and of nitrogen 14·044, the atomic weight of hydrogen is 0·9989. The uncertainty as to the value of the atomic weight of nitrogen here affects that of hydrogen.

J. S. Stas[23] determined the relation of silver to ammonium chloride and bromide. Given the atomic weights of nitrogen, chlorine, and bromine (O=16), the atomic weight of hydrogen follows. The mean of Stas' results with the chloride and bromide gave H : O=1 : 15·9229 ; or 1·00598 : 16. J. Dewar and A. Scott (1887) tried to use the substituted ammonias—*e.g.* triethylamine, $N(C_2H_5)_3$—in place of ammonia, but the difficulties involved in purifying the triethylamine make the method undesirable.

§ 10. The Origin of the Terms: Acid, Alkali, Base, Salt

> However convenient the classification of oxides into acids and bases might be for an elementary presentation of chemistry, a glance from the vantage ground of facts not usually referred to in elementary courses, shows such classifications to be imperfect and arbitrary to a degree.—D. CARNEGIE (1894).

The early chemists appear to have gradually learned to arrange certain substances into two groups according as these substances possessed certain qualities in common with vinegar or with wood ashes. The former were called **acids** (*acidus*, acid) and the latter **alkalies** (Arabian, *alkali*, ashes of a plant), because the alkalies were generally obtained by calcining various materials and reducing them to ashes. The word *acid* was probably first used in a concrete sense for vinegar, and it then came to be used for certain substances which tasted " sharp " or sour like vinegar—

the acid of soured wine; the term *alkali* was used for crude potash; and *salt* has been used from the earliest times for culinary salt. Aristotle employed the term *salt* for the evaporated lixivium of wood ashes.[1] Disocorides and Pliny employed the same term for crude soda, and generally for substances which could be recovered from their solution in water by evaporation. About the time the works of "Basil Valentine" were written, the *vitriols* were regarded as metallic salts, and the term salt came to be employed for that constituent of a substance which could not be destroyed by calcination, and among the alchemists the term was used to represent the principle of solidity. H. Boerhaave, T. Bergmann, and R. Kirwan used solubility in water as one criterion for salts, but this led to the separation of substances of a similar nature into separate groups.

Although the three terms—acid, alkali, and salt—were first applied to specific substances, their meanings have changed so that they no longer designate the names of things, but are employed as generic or class names to indicate what certain things will do; otherwise expressed, they are the names of certain chemical functions. The generic term only becomes specific when an adjective is affixed—*e.g.* sulphuric acid.

The great solvent or corrosive action of the acids was well known to the ancients. This is emphasized by Pliny's story of Cleopatra and the pearls; and Livy's and Plutarch's fantastic story of Hannibal cutting a passage through the Alps by dissolving limestone rocks by means of vinegar. In his *Reflections upon the hypothesis of alcali and acidum* (London, 1684), Robert Boyle summarized the properties of acids as substances which (1) have a sour taste; (2) dissolve many substances (corrosive); (3) precipitate sulphur from alkaline solutions of sulphur; (4) change the tint of many vegetable blue colours (*e.g.* blue litmus) red; and (5) lose their acid characteristics when brought into contact with the alkalies. H. Boerhaave (1732)[2] divided the acids into *acida vegetantia*, or those derived from plants; and *acida fossilia*, or those derived from mineral substances. Soon afterwards, J. van Helmont (1736) called the latter, *acides minéraux*, and included them in the class containing sulphuric, hydrochloric, and nitric acids.

J. B. van Helmont (1640), F. Sylvius de la Boé (1659), N. Lemery (1675) and H. Boerhaave (1732), at first, applied the term *alkali* to bodies which effervesced with acids, but R. Boyle recognized as alkalies certain substances which do not act in this manner. R. Boyle considered the alkalies to be substances which (1) possessed detergent and soapy properties; (2) dissolved oils and sulphur; (3) restored vegetable colours reddened by acids; and (4) had the power of reacting with acids to produce indifferent substances. The idea connoted by the term **base** is much older than the word; *base* stands in generic relations with *alkali*. F. Sylvius de la Boé recognized the distinction between acids and bases in 1659, although the idea was familiar to chemists before his time; this is emphasized by the fact that acids and alkalies have a strong disposition to unite chemically. In 1744, G. F. Roulle employed the word base for any substance which unites with an acid to form a salt, and which gives to the salt *une forme concrete ou solide;* the term is now usually applied to oxidized bodies with properties which are complementary to the acids; the term includes the earths, alkalies, metallic oxides (calces), and all substances which produce salts by reacting with acids. It was soon found that some substances with alkaline qualities did not melt or change when heated, did not effervesce with acids, and were almost insoluble in water—these substances were called **earths**.

With these criteria, it is possible to classify the oxides formed by burning carbon, sulphur, phosphorus, sodium, iron, etc., in oxygen into acidic, basic, or neutral oxides:

ACIDIC OXIDES.	BASIC OXIDES.	NEUTRAL OXIDES.
Carbon	Sodium	Iron
Sulphur	Calcium	Copper
Phosphorus	Magnesium	Tin

The properties of acids and alkalies or bases were thus opposed to one another; for when mixed together, the one neutralized the activity of the other. Although each component of the mixture is itself pungent or corrosive, the final product is usually mild and inoperative. J. B. van Helmont, about 1640, used the term **saturation,** and a few years later, O. Tachen gave one of the first rational definitions of a **salt,** for he said that all salts can be resolved into an acid and an alkali, and very soon, the term *salt* came to be used for the products of the interaction of acids and alkalies or bases. John Mayow, in his essay *On the combination of contrary salts* (Oxford, 1669), recognized the dual nature of salts, and showed that although the acid and alkali, when they meet, unite together to form a salt, yet they do not destroy one another since both may be afterwards recovered from the salt. According to N. Lemery (1675), during saturation, the base is "cloyed or filled with acid," and a *sel sale* was defined as an alkali charged with an acid. G. E. Stahl (1723) called the substance which united with the acid to form sodium chloride, *materia illa quæ sali corpus præbet.* H. Boerhaave (1732) stated that an alkali is understood to be saturated with an acid when a point is reached at which the product is neither acid nor alkaline; the resulting product was called a **neutral salt**—*salia, sic dicta jam neutra.* H. Boerhaave also spoke of *salia alcalina,* and of *salia acida;* and he regarded the vitriols as semi-metals.

It was soon recognized that many substances could not well be grouped with the acids and bases although they possessed qualities characteristic of acids or bases. Thus *aluminium ammonium sulphate*—alum—forms a solution with water which has a sour taste, deprives sodium hydroxide of its alkaline qualities, and turns blue litmus red; copper sulphate reddens blue litmus; *sodium carbonate* and *sodium borate* turn red litmus blue, etc. Conversely, substances may be grouped as acids and bases, even though they have no action on litmus, *e.g. silicic acid,* H_2SiO_3, has no action on blue litmus, and yet it is an acid; similarly, *copper oxide,* CuO, is a base without action on red litmus.

What is the source of the acidity of acids ?—Otherwise expressed, why are the acids acidic, and the bases alkaline ? J. J. Becher (1669), G. E. Stahl (1723), and other early chemists postulated the presence of a principle of acidity—all acids in common were supposed to be impregnated with more or less of a *primordial or primitive acid.* For example, F. Sylvius de la Boé and J. F. Meyer [3] supposed both acids and alkalies owed their peculiar properties to the presence of a common principle which the former termed *fiery matter* and the latter *acidum pingue.* When the alkalies came to be divided into caustic and effervescent, it was assumed that the transformation of caustic into effervescent lime was due to the effervescent lime transferring its *acidum pingue* to the effervescent alkali. G. E. Stahl assumed that acids, alkalies, and salts contained one common ingredient—namely, the primitive acid; and that the three were transmutable *inter se* by adding or subtracting primitive acid. The alkalies were supposed to contain less primitive acid than acids or salts. T. Bergmann postulated a *principle of acidity* and a *principle of alkalinity,* but he admitted that while "chemistry was not able to extract these two universal principles, there is not the least doubt that they are different and opposite to each other." Not till 1755 did J. Black [4] demonstrate qualitatively and quantitatively that the loss of fixed air changes an effervescent into a caustic alkali, and the union with fixed air changes a caustic into an effervescent alkali. N. Lemery considered it to be self-evident that the ultimate particles of acids had sharp edges or hooks which gave the acids their peculiar properties. His proof was:

> I hope nobody will dispute whether an acid has points or not, seeing that it is demonstrated by every one's experience, that an acid pricks the tongue like anything keen and finely cut; but a demonstration and convincing proof that an acid consists of pointed parts is that not only all acid salts do crystallize with edges, but all dissolutions of different things caused by acid liquors, do assume this figure in their crystallization.

This argument is invalid, for the crystals of nearly all compounds—whether acidic alkaline, or neutral—have sharp edges. The lesson is obvious. What is self-evidently an hypothesis must not be advanced as if it were an inviolable fact.

A. L. Lavoisier, following J. Mayow (1669) and C. W. Scheele (1777), renounced the peculiar fancies involved in the terms primordial acid, principle of acidity, etc., and ascribed acidity to the universal presence of oxygen, the acid-producer. Consequently, Lavoisier's *oxygen* is the acidifying principle under another guise. J. Mayow got very near to the same theory of acidity in 1669. This hypothesis can now be tested.

§ 11. Acids

Acid is rather the name of a function than the name of a substance.—MILLS.

In his study of the properties of oxygen, A. L. Lavoisier noticed that when certain elements were burnt in oxygen, the resulting oxide forms an acid with water—*e.g.* carbon, sulphur, and phosphorus. Hence, Lavoisier jumped to the conclusion (1777) that " oxygen is an element common to all acids, and the presence of oxygen constitutes or produces their acidity." He also considered oxygen to be the essential constituent of all acids. The very name *oxygen*, given to this element, was derived from Greek words signifying " the generative principle of acids "—ὄξυς, sour, and γείνομαι, I produce—because " one of the most general properties of this element is to form acids by combining with many different substances ; " hence also the German term for oxygen *Sauerstoff*, meaning " acidifying stuff." In his *Considérations générales sur la nature des acides*, and his *Mémoire sur l'existence de l'air dans l'acide nitreux* (1777), A. L. Lavoisier considered that the difference in the various acids depended on the nature of the substance or substances united with the oxygen ; he called the non-oxygenated part of an acid a simple or a compound *acidifiable base*. The mineral acids are usually oxygenated compounds of simple acidifiable bases—carbon, sulphur, nitrogen, phosphorus—the vegetable and animal acids—tartaric and oxalic acids—are oxygenated compounds of the compound acidifiable bases. Lavoisier's theory of acidity made him unprepared to find water or oxidized hydrogen exhibiting no signs of acidity, and there is a possibility that his hypothesis prevented his discovering the composition of water. *L'analogie*, said Lavoisier,[1] *m'avait porté invinciblement à conclure que la combustion de l'air inflammable devoit également produire un acide.* The difference between analogy and fact, added Berthollet, is just the difference between probability and certainty. For a time, *le principe oxygène* was almost a fetish with the French chemists ; but, with increasing knowledge, it was found that **Lavoisier's oxygen theory of acids** led to confusion and error, and it was gradually abandoned by chemists when it was recognized that :

1. **Some oxides form alkalies, not acids, with water.**—*E.g.* sodium, potassium, and calcium oxides. As Humphry Davy expressed it, " the principle of acidity of the French nomenclature might now likewise be called the principle of alkalescence."

2. **Some acids do not contain oxygen.**—In 1785, J. C. de la Métherie [2] had maintained as a paradox that oxygen does form a necessary constituent of acids.

This idea was ridiculed by A. L. Lavoisier, but C. L. Berthollet showed, in 1787, that hydrocyanic (prussic) acid is a compound of carbon, nitrogen, and hydrogen, but contains no oxygen; and he also came to a similar conclusion with regard to hydro-sulphuric acid. But for some time Lavoisier's reputation had more weight than Berthollet's facts. In 1810–11, Humphry Davy proved that hydrochloric acid is a compound of hydrogen and chlorine and that no oxygen could be detected in the compound. In 1813, H. Davy also proved that hydriodic acid contained hydrogen and iodine, but no oxygen. Hence, added H. Davy, "acidity is not connected with the presence of any one element;" and he appears to have regarded the acidity of a substance as a kind of resultant whose direction is hydrogen.

It must be added, however, that when these substances are thoroughly dried so as to remove all traces of water they do not show acidic qualities. Water is always present when these substances manifest their acidic properties, and water is itself a compound of hydrogen and oxygen. Hence, a very good case might be made out for an extension of Lavoisier's hypothesis, but solutions of ammono-bases and ammono-acids in liquid ammonia would then have to be considered because this solvent has no oxygen.

As a result of H. Davy's work, the acids came to be classed as **hydracids**—acids containing no oxygen; and **oxyacids**—acids formed from acidic oxides. In 1815, H. Davy suggested the possibility that hydrogen, not oxygen, gives the acid characters to the acids; but he did not rush to the other extreme and say that all hydrogen compounds are necessarily acids. In the same year, 1815, P. L. Dulong's study of oxalic acid led him to the view that there is no essential difference between oxygenated and non-oxygenated acids. He supposed oxalic acid to be a compound of oxygen with carbon dioxide, and salts of oxalic acid to be formed by replacing the hydrogen of the acid by the metals. In this way, hydrogen and the metals were opposed to the salt-forming radicles.

There is no one property which we can use as an absolute criterion or decisive test of acidity. In a crude sort of way, it can be said that *acids usually have a sour taste, are usually corrosive, redden the blue colour of vegetable substances* (*e.g. litmus*) ; *and contain hydrogen, part or all of which can be replaced when the acid is treated with a metal, metallic oxide, hydroxide, or carbonate.* Acids are known which have a sweet taste—*e.g.* amidophosphoric acid; acids are known which are not corrosive; and alkalies have hydrogen replaceable by a metal as is shown when, say, aluminium is treated with alkali lye. *Alum*, as indicated above, does not contain replaceable hydrogen, and it would not therefore be classed as an acid, although it is sour, corrosive, and colours blue litmus red. Sodium bisulphate has a sour taste, is corrosive, reddens blue litmus, and contains replaceable hydrogen, but it is not usually regarded as an acid because of its mode of formation. Again, methane, CH_4, is not considered to be an acid although it has hydrogen replaceable by a metal, and the resulting compound is not called a salt, *e.g.* zinc methide, $Zn(CH_3)_2$.

However, we are yet far from a satisfactory definition of acids, although, as we shall see later, a fair definition can be made in terms of the ionic hypothesis in spite of the fact that so far as *practical applications* are concerned, definitions in terms of the ionic hypothesis are not very different from those under consideration, the difference is then rather a question of nomenclature.

Naturally the student delights in clear, sharp-cut definitions, and teachers of science have many temptations to frame definitions and draw boundary lines which do not exist in nature. "Definitions," said R. Hunter, "are the most accursed of all things on the face of the earth."

§ 12. Salts

The relation of acid and base in a salt is one of the main grounds of all theoretical reasonings (on chemical combination).—W. WHEWELL.

There is perhaps no inquiry which has thrown so much light on a multitude of combinations which the want of method had permitted to be confounded, as Rouelle's observations on the characters of the salts.—C. L. BERTHOLLET (1803).

In modern chemistry the term *salt* is a descriptive term applied to a distinct class of substances, and not to any particular individual. A salt is produced by replacing all or part of the hydrogen of an acid by a metal or basic radicle. For instance, zinc displaces the hydrogen of sulphuric acid: $Zn+H_2SO_4=ZnSO_4+H_2$, forming the salt zinc sulphate. C. Gerhardt[1] regarded salts as *corps binomé*, liable to double decomposition; and J. J. Griffin regarded them as compounds of two radicles. Hence J. von Liebig (1838), and C. Gerhardt (1843) defined acids to be "salts of hydrogen":

SO_4—BIVALENT RADICLE.		Cl—UNIVALENT RADICLE.	
Hydrogen sulphate (sulphuric acid)	H_2SO_4	Hydrogen chloride (hydrochloric acid)	HCl
Zinc sulphate	$ZnSO_4$	Zinc chloride	$ZnCl_2$
Sodium sulphate . . .	Na_2SO_4	Sodium chloride	NaCl

Salts of the **binary acids** (*i.e.* acids compounded of two elements like hydrochloric acid, etc.) are usually named by dropping the prefix *hydro* and changing the termination *-ic* into *-ide*. Thus the acids just named furnish chlorides, fluorides, etc. To show what chlorides, etc., are in question, the name of the corresponding element (or elements) is introduced in an adjectival sense. Thus we have sodium chloride, potassium chloride, calcium chloride, etc. The names of the elements are thus used adjectivally in the same sense that the words stone, brick, and wood prefixed to house are adjectival, and indicate the kind of house in question. Some radicles free from oxygen, *e.g.* CN or Cy, behave as if they were single elements. Thus hydrocyanic acid—HCN—is treated as if it were a binary acid, and its salts are accordingly named *cyanides*.

The salts of the **ternary acids** (*i.e.* acids with three elements) are named by changing the *-ic* termination of the acid into **-ate,** or the *-ous* termination of the acid into "**-ite,**" and adding the word so obtained to the name of the base or bases forming the salt. The sulphuric acid forms *sulphates*—*e.g.* sodium sulphate; nitric acid, *nitrates*—*e.g.* calcium nitrate; sulphurous acid, *sulphites*—*e.g.* ammonium sulphite; perchloric acid, *perchlorates*—*e.g.* potassium perchlorate; hypochlorous acid, *hypochlorites*—calcium hypochlorite; carbonic acid, *carbonates*—*e.g* calcium carbonate, etc. Hence, some years ago, the name of the basic element used to be modified to give it an adjectival form: hydric chloride; potassic chloride; calcic chloride; etc. This system has been abandoned unless it is desired to distinguish between -ous and -ic compounds—*e.g.* ferrous chloride and ferric chloride, etc. Consonant with the definition that acids are salts of hydrogen, nitric acid, HNO_3, has been called hydrogen nitrate; hydrochloric acid, HCl, hydrogen chloride; sulphuric acid, H_2SO_4, hydrogen sulphate.

In **normal salts** all the displaceable hydrogen of the acid is replaced by the base. For instance, sodium sulphate—Na_2SO_4—is a normal salt because all the replaceable hydrogen of sulphuric acid is displaced by sodium. In **acid salts** only part of the replaceable hydrogen has been displaced, acid sodium sulphate—$NaHSO_4$—contains half the replaceable hydrogen of sulphuric acid, and half as many equivalents of sodium as normal sodium sulphate. If an acid contains two or more replaceable hydrogen atoms, it does not follow that all need be displaced by the same element. These ideas can be illustrated graphically—sulphur sexivalent:

$\begin{matrix}HO\\HO\end{matrix}>S\ll\begin{matrix}O\\O\end{matrix}$

Sulphuric acid.

$\begin{matrix}NaO\\HO\end{matrix}>S\ll\begin{matrix}O\\O\end{matrix}$

Acid sodium sulphate.

$\begin{matrix}NaO\\NaO\end{matrix}>S\ll\begin{matrix}O\\O\end{matrix}$

Normal sodium sulphate.

$\begin{matrix}NaO\\KO\end{matrix}>S\ll\begin{matrix}O\\O\end{matrix}$

Sodium potassium sulphate.

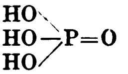
About 1754, F. G. Rouelle[2] distinguished the *neutral salts* of a given base from the *acid salts* with an excess of acid, and basic salts with an excess of base, and he showed the action of some of these salts on vegetable dyes. A. Baumé (1770) objected to F. G. Rouelle's classification—neutral, acid, and basic salts—for he maintained that the neutral salts are the only true salts, and that the basic and acid salts are mixtures of neutral salts respectively with an excess of bases or acids. The question was discussed later, whether the proportion of acid and base in the two salts is constant so that there are but two combinations—those with a maximum and those with a minimum proportion of acid—or whether combinations exist with intermediate proportions dependent on the circumstances under which the salts are formed. C. L. Berthollet (1803) advocated the latter alternative, but this was not generally accepted, and guided by the law of multiple proportions the two salts are usually considered to be combinations of acid and base in two definite and fixed proportions. When deviations from these proportions are observed, it is supposed that a *mixture* of normal and acid salts, or of the normal or acid salt with an excess of uncombined acid or base, is in question.

Sometimes the term "hydrogen" is used in place of "acid" for the acid salts, and sometimes the prefix bi- or di- is appended to the term for the acid in the salt. Thus, acid sodium sulphate is also called sodium hydrogen sulphate, sodium bisulphate, as well as mono-sodium sulphate, etc. Originally, the Latin prefixes bi-, etc., were applied to the name of the acidic and the Greek prefixes di-, etc., to the name of the basic part of a salt, so that sodium disulphate would not mean the same as bisulphate. Colloquially, the prefixes bi-, etc., are used for the acid salt—*e.g.* sodium bicarbonate, $NaHCO_3$; sodium bisulphite, $NaHSO_3$, etc.—possibly because a term like sodium hydrogen carbonate appears to be pedantic outside the lecture room.

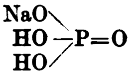
The normal salts are sometimes called **neutral salts** in the sense that all the hydrogen has been neutralized or displaced from the acid. These salts, however, are not necessarily *neutral* to litmus—thus normal zinc and copper sulphates react towards litmus as if they were acids; borax, sodium nitrite, and normal sodium carbonate react as if they were alkalies. The confusion in the use of the term *acid* may also be noted. It can be used as a noun to denote a particular class of compounds now under discussion; and also as an adjective to represent a certain quality or property—*e.g.* the behaviour towards blue litmus—characteristic of the class acids. Accordingly, some acid salts are *acid* to litmus, *e.g.* sodium hydrogen sulphate; others are *alkaline*, *e.g.* sodium hydrogen carbonate, acid potassium tellurate; others again are *neutral*, *e.g.* disodium hydrogen phosphate. Usually the normal mercurous, mercuric, cupric, chromic, ferric, stannous, stannic, antimonious, and bismuthous salts with the common acids have an acid reaction—redden blue litmus; while the borates, carbonates, chromates, hypochlorites, nitrites, phosphates, silicates, sulphides, and sulphites have an alkaline reaction—turn red litmus blue.

The mode of defining a neutral salt as a compound obtained by mixing an acid with a base until the product is neutral to litmus is ambiguous and therefore objectionable; the close relation between salts which are and salts which are not neutral to litmus does not allow them to be distinguished from one another. Hence, J. J. Berzelius proposed to retain the term *neutral* for those salts like potassium and sodium sulphates which are neutral to litmus, and to take no account of the behaviour of the other metallic salts towards litmus, but rather be guided by their analogy with the salts which are neutral to litmus. This extension of the term neutral is not free from objections. When the term neutral salt is now employed, it is usually understood to be synonymous with normal salt.

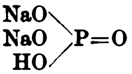
It is sometimes necessary to use the prefixes mono-, di-, tri- . . . to discriminate between the different salts of one acid. Thus with phosphoric acid—phosphorus quinquevalent:



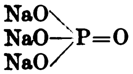
Phosphoric acid.



Monosodium phosphate.



Disodium phosphate.



Normal or tri-sodium phosphate.

It would be a mistake to assume that all the hydrogen of an acid is replaceable by a base. Thus, so far as we know, hypophosphorous acid—H_3PO_2—has only one of its three hydrogen atoms replaceable by a metal. No one has ever prepared Na_2HPO_2. Following the recommendation of J. von Liebig (1857): **The number of atoms of hydrogen in one molecule of an acid which are replaceable by a metal, or a radicle, is termed the basicity of the acid.** Thus hydrochloric acid—HCl—is monobasic because each molecule of hydrochloric acid contains one replaceable hydrogen atom; sulphuric acid—H_2SO_4—is dibasic; phosphoric acid—H_3PO_4—is tribasic; and ferrocyanic acid—H_4FeCy_6—is tetrabasic because the four hydrogen atoms can be replaced by equivalent atoms of the basic elements—say four of potassium, two of calcium, etc. Hypophosphorous acid—H_3PO_2—is monobasic because only one of the three hydrogen atoms can be replaced by a metal.

Alcohols and ethers.—The normal alcohols, *methyl alcohol*, CH_3OH; *ethyl alcohol*, or simply alcohol, $C_2H_5.OH$; etc., are related to water in that one hydrogen atom of water is replaced by a univalent hydrocarbon radicle. When both hydrogen atoms of water are replaced by univalent hydrocarbon radicles, the so-called *ethers* are formed; thus, $(CH_3)_2O$ represents *methyl ether* or *methyl oxide*; and *ethyl ether* or ethyl oxide or simply *ether* is represented by $(C_2H_5)_2O$; and *methyl ethyl ether*, by $(CH_3)(C_2H_5)O$. Graphically,

$\begin{matrix}H\\H\end{matrix}\!>O$

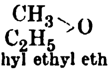
Water.

$\begin{matrix}C_2H_5\\H\end{matrix}\!>O$

Ethyl alcohol.

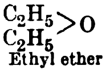
$\begin{matrix}C_6H_5\\H\end{matrix}\!>O$

Phenol.



$\begin{matrix}CH_3\\C_2H_5\end{matrix}\!>O$

Methyl ethyl ether.



$\begin{matrix}C_2H_5\\C_2H_5\end{matrix}\!>O$

Ethyl ether.

The hydrogen of the residual OH-group in the alcohols can be replaced by a metal —*e.g.* sodium dissolves in ethyl alcohol with evolution of hydrogen. When the solution is heated to 200° in a current of hydrogen to drive off the excess of alcohol, the white powder which remains is *sodium alcoholate*, $C_2H_5.ONa$, which seems to suggest that water and alcohol have acidic properties in that they contain replaceable hydrogen. These compounds are included in the subject matter of organic chemistry.

§ 13. Neutralization

Neutrality measured by means of a colouring matter is but a hypothesis.—J. S STAS (1865).

A solution of sulphuric acid, like other acids, colours blue litmus red; and a solution of sodium hydroxide, like other alkalies, colours red litmus blue. It is possible to mix the acid with the alkali so as to furnish a solution which neither tastes nor reacts towards litmus like sulphuric acid or like sodium hydroxide. If too much acid be present the litmus will be coloured red, and blue if too much alkali be present. The mixture on evaporation furnishes a crystalline solid which neither colours blue litmus red nor red litmus blue. The colour of a violet solution of litmus is not affected. The product of the reaction is said to be **neutral,** and the process of neutralization consists in adding an acid to an alkali, or an alkali to an acid, until a neutral substance is obtained. The result of the reaction is called a **salt.** The salt contains the metal of the alkali, and the radicle of the acid. The litmus used to determine the point of neutralization is called the **indicator.** Several other indicators besides litmus are available; *e.g.* phenolphthalein furnishes a pink coloration with alkaline solutions, and is colourless with acids and neutral solutions;

methyl orange is yellow with alkalies, pink with acid, and orange with neutral solutions. Poirrier's soluble blue gives a blue colour with acids and with carbonates, and red with alkalies. The petals of white flowers usually change to yellow when placed in alkaline solutions and back to white when placed in acids ; red and purple flowers usually become green or greenish-blue in alkaline solutions, and back to the original or a brighter red colour in acids ; yellow flowers are usually not affected by acids or alkalies. Yellow turmeric becomes reddish-brown in alkaline solution. Litmus and phenolphthalein solutions can each show the presence of about 1·8 parts of hydrochloric acid per million parts of solution, while methyl orange will show 3·7 parts of this acid per million.

It will be observed that the determination of the neutral point is here referred arbitrarily to the behaviour of litmus, because when compounds are arranged into classes, acidic, alkaline, and neutral, the members of the different classes are not the same when different indicators are used. For instance, salts of the heavy metals—alum, ferric chloride, ferrous sulphate, etc.—are usually acid to both litmus and phenolphthalein as indicators, and neutral to methyl orange ; borax, sodium and potassium bicarbonates, and sodium citrate are alkaline to litmus and methyl orange, but neutral to phenolphthalein ; while sodium phosphate is neutral to litmus and phenolphthalein, and alkaline to methyl orange. When free phosphoric acid is titrated with sodium hydroxide, it appears to be a monobasic acid if methyl orange (*i.e.* the commercial dimethylaminoazobenzene sulphonate) be used as indicator ; to be a dibasic acid with litmus or phenolphthalein ; and to be a tribasic acid with Poirrier's soluble blue. Again, free boric acid does not affect methyl orange, but it reacts acid with both litmus and phenolphthalein after adding an equal volume of dilute sodium chloride solution ; and an aqueous solution of potassium sulphite is neutral to phenolphthalein, but it turns violet litmus blue. It therefore follows that **acids and alkalies have only a relative existence.** This was emphasized by J. Freind[1] in 1709, for he pointed out that the corrosive and colorimetric properties of acids are often shared alike with the alkalies, so that a substance which is termed an alkali if referred to one body, might be called an acid by the very same writers if referred to another body ; and added : " In vain we endeavour to fix the boundaries which separate each kind."

Other properties of acids and alkalies have been employed to determine the neutral point and also the point where a normal salt is formed when an acid is treated with an alkali and conversely. The index of refraction, electrical conductivity, and the freezing point may be cited in illustration. E. Cornec (1909)[2] showed that when the lowering of the freezing point of a solution is plotted with the composition for all proportions of acid and base, the minimal points in the curve correspond with sharply defined salts and bends occur where partly stable compounds occur. Thus, when $\frac{1}{2}N$-sodium hydroxide is added in gradually increasing quantities to $\frac{1}{2}N$-hydrochloric acid, the lowering of the freezing point falls regularly from 1·885° to 0·890° when equivalent proportions are present, and then regularly rises to 1·705°, the value for sodium hydroxide. The curve, Fig. 5, thus consists of two straight lines which intersect at a point corresponding with sodium chloride. Sulphuric acid and sodium hydroxide give a well-defined minimum corresponding with Na_2SO_4, but there is no sign of the formation of an acid salt, $NaHSO_4$, in the solution. Hence, it is inferred that the acid sulphate dissociates completely in solution into the normal sulphate and free acid : $2NaHSO_4 \rightarrow Na_2SO_4 + H_2SO_4$. Phosphorous acid, H_3PO_3, behaves like a dibasic acid giving a minimum point with Na_2HPO_3 ; hypophosphorous acid, H_3PO_2, behaves like a monobasic acid ; arsenic and phosphoric acids with sodium hydroxide give minima corresponding respectively with Na_3PO_4 and Na_3AsO_4, and bends or terraces in the curve for phosphoric acid correspond with the partial formation of NaH_2PO_4 and Na_2HPO_4 ; analogous bends in the arsenic acid curve. These two acids with ammonia give curves with minima corresponding respectively with $(NH_4)_2HPO_4$ and $(NH_4)_2HAsO_4$. Chloric acid, $HClO_3$, and perchloric acid, $HClO_4$, give graphs characteristic of monobasic acids ; selenious acid, H_2SeO_3, dithionic acid, $H_2S_2O_6$, and carbonic acid, H_2CO_3, all behave as dibasic acids ; hypophosphoric acid, $H_4P_2O_6$, and pyrophosphoric acid, $H_4P_2O_7$, behave like tetrabasic acids.

As a corollary from Richter's law of proportionality that acids and alkalies unite in constant proportions to form salts, it follows that **when two neutral salt solutions mutually decompose one another, the newly formed products are also neutral,** because the amount of base neutralized by a certain weight of one acid is also neutralized by an equivalent weight of another acid. In illustration, when a neutral aqueous solution of sodium chloride is added to an equivalent solution of silver nitrate, the solution remains neutral after the precipitation of the silver chloride. It also follows from Richter's law that if one metal be precipitated by another metal from a neutral salt, the neutrality is maintained. T. Bergmann (1785) knew that when one metal is precipitated by another from a neutral salt solution, the neutrality is not disturbed, which he interpreted in terms of the phlogiston theory by assuming that the quantities of two metals which are united with the same amount of acid contain the same amount of phlogiston. **Richter's law of neutrality**—*Neutralitätsgesetz*—is obviously a special case of the law of reciprocal proportions which, as previously shown, was recognized a few years later. J. J. Berzelius (1827) unfortunately confused the work of Wenzel and Richter on this subject, and the mistake was continued by later writers up to about 1841.

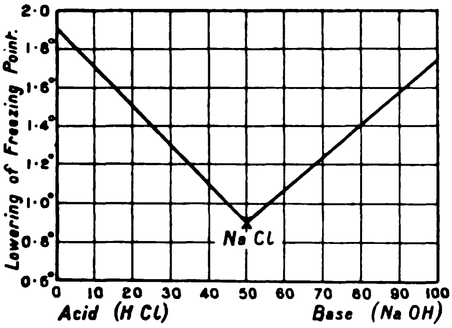

Fig. 5.—Lowering of the Freezing Point of Solutions of Sodium Hydroxide and Hydrochloric Acid.

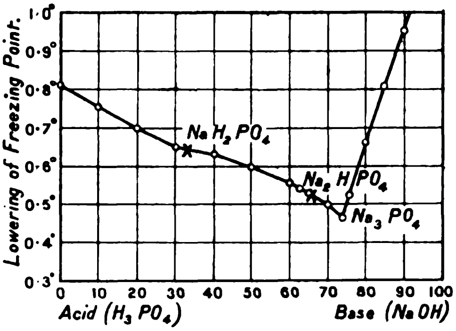

Fig. 6.—Lowering of the Freezing Point of Solutions of Sodium Hydroxide and Phosphoric Acid.

Neutralization versus hydrolysis.—The process of neutralization of a basic hydroxide by an acid is attended by the formation of a salt and water. We shall find later that some salts—*e.g.* zinc sulphate, sodium carbonate, potassium cyanide, etc.—are partially decomposed—*i.e.* hydrolyzed—by water into acid and base. The action of water on such a salt or base is thus an example of an opposing reaction ; hydrolysis is opposed to neutralization :

$$\underset{\text{Neutralization}\longrightarrow\qquad\qquad\longleftarrow\text{Hydrolysis.}}{H_2SO_4+Zn(OH)_2=ZnSO_4+2H_2O}$$

In some cases, however, the amount of hydrolysis is inappreciable, and the process of neutralization is so complete that it can be employed for measuring the quantity of acid or base in a given solution. Hence, the chemical action of water as a solvent can be neglected in many chemical reactions, but in other cases the solvent is of prime importance, when it determines the nature of the compound formed. Probably most of the examples of normal salts, which furnish acid or alkaline solutions, are hydrolyzed by water, and the acidic or alkaline properties of the aqueous solutions are due to the corresponding products of hydrolysis.

Acidimetry and alkalimetry.—A **standard solution** containing a known amount of acid or base per litre is prepared, and just sufficient of this solution is added to neutralize a solution of a given base or acid. The volume of the standard solution required for the purpose is noted. It is possible to calculate the amount of "chemically pure" substances present in the given solution from the volume of the standard solution required for the neutralization. **A solution containing one equivalent weight of the acid or base element or compound expressed in grams per litre is called a normal solution,** written "N-solution," and a solution containing one-tenth the concentration of a normal solution is called a **decinormal solution,** written "$\frac{1}{10}N$-solution." **The equivalent weight of a base is that quantity which just completely neutralizes one molecular weight of a monobasic acid; and the equivalent weight of an acid is that quantity which contains unit weight of replaceable hydrogen.** Thus 36·47 grams of HCl per litre gives a normal solution of hydrochloric acid; and 49·04 grams of H_2SO_4 per litre gives a normal solution of sulphuric acid. Here the molecular weight of the latter acid is 98·08, and the acid is dibasic, for it contains two replaceable hydrogen atoms; and, by definition:

$$\text{Equivalent of acid} = \frac{\text{Molecular weight of acid}}{\text{Basicity of acid}}$$

that is, the equivalent of sulphuric acid is $98·08 \div 2 = 49·04$. A normal solution of sodium hydroxide contains 40 grams of NaOH per litre, and a litre of a normal solution of any acid so far considered will just neutralize a litre of normal solution of any base.

EXAMPLES.—(1) Suppose that a 50 c.c. burette be charged with a normal solution of sodium hydroxide, and suppose that the amount of HCl in 500 c.c. of a dilute solution of hydrochloric acid be in question—acidimetry—pipette 50 c.c. of the acid into a beaker and add a few drops of litmus. The alkali solution is run from the burette into the beaker until the addition of but one more drop of acid is needed to change the red litmus to blue. Suppose that 42 c.c. of the normal sodium hydroxide has been run from the burette. The argument runs: The neutralization $NaOH + HCl = NaCl + H_2O$ shows that 40 grams of sodium hydroxide correspond with 36·47 grams of HCl; and 1000 c.c. of NaOH has 40 grams of sodium hydroxide, which is equivalent to 36·47 grams of HCl. Consequently 42 c.c. of the standard sodium hydroxide solution is equivalent to 1·53 grams of HCl per 50 c.c. of the given acid, or 15·3 grams of HCl are present in 500 c.c. of the given acid.

(2) Suppose that 42 c.c. of a decinormal solution of sulphuric acid were required to just neutralize 50 c.c. of a solution of potassium hydroxide, how many grams of potassium hydroxide would be contained in a litre of solution? A normal solution of sulphuric acid—H_2SO_4, molecular weight 98—contains 49 grms. of the acid per litre, and a $\frac{1}{10}N$-solution contains 4·9 grms. per litre, and this is equivalent to 5·6 grms. of potassium hydroxide per litre. Hence 52 c.c. of the $\frac{1}{10}N$-H_2SO_4 are equivalent to 0·235 grm. of KOH per 50 c.c. of the given solution. Ansr. 4·7 grms. of potassium hydroxide per litre.

Similar remarks apply to the determination of alkalies—alkalimetry—by standard solutions of the acids. This process of analysis is called *volumetric analysis* in contradistinction to *gravimetric analysis*, which involves several weighings during each determination. In volumetric analysis, the preparation of the stock of standard solution may involve one or two weighings; the stock of standard solution may serve a great number of analyses. Experimental details are discussed in laboratory text-books.

W. Ostwald employed the term **mol** as an abbreviation for **gram-molecule**, that is, a weight of a compound equivalent to the molecular weight expressed in grams—*e.g.* one gram-molecule or one mol of sulphuric acid, H_2SO_4, is 98 grms.; and 147 grms. of absolute sulphuric acid contains $147 \div 98 = 1·5$ mols or gram-molecules. F. Fichter (1914) proposed **val** for a **gram-equivalent**, that is, a weight of a compound numerically the same as the equivalent weight expressed in grams—*e.g.* one gram-equivalent or one val of sulphuric acid is 49 grms. A **millimol** is equivalent to a milligram molecule; and a **millival** to a milligram equivalent, etc. The term mol is in fairly common use, but val is not used in place of equivalent weight.

§ 14. Bases

> We maintain that hydrogen is an essential not an accidental constituent of all acids and alkalies.—J. P. COOKE (1876).
>
> Philosophically, acids and bases ought to be regarded as salts.—A. NAQUET (1864).

The term base—Greek βάσις, a base—was originally intended to express the idea that the metal or metallic oxide was the more important constituent, the foundation, or base so to speak, of a salt. This idea was dropped when it was recognized that the acidic constituent of a salt is just as important as the basic constituent. The idea persists in chemistry text-books where the salts are described under the basic element.

As a first approximation to a satisfactory definition, it was said that **a base is a substance which reacts with an acid to produce a salt and water.** For instance, zinc oxide reacts with sulphuric acid to produce zinc sulphate and water : $ZnO+H_2SO_4=H_2O+ZnSO_4$. Sodium hydroxide reacts with sulphuric acid to produce sodium sulphate and water: $2NaOH+H_2SO_4=2H_2O+Na_2SO_4$. The oxides of the non-metallic elements are usually but not always acidic, and the oxides of the metals are usually but not always basic.

H. Zeitler (1917)[1] illustrates the formation of water during the union of an acid and base to form a salt by placing a stick of dry alkali hydroxide in a jar of dry hydrogen chloride. After a short time, the glass is bedewed, and the alkali is covered with crystals of the alkali chloride.

As a rule, the bases include the oxides and the hydroxides of the metals, but for convenience, certain groups of elements are called bases, although they form salts by direct addition or combination without the separation of water, *e.g.* ammonia—NH_3, hydroxylamine—NH_2OH, hydrogen phosphide—PH_3, etc. Thus, gaseous ammonia and hydrogen chloride form ammonium chloride: $NH_3+HCl=NH_4Cl$. Liquid ammonia dissolves but does not colour phenolphthalein, and it is an open question whether it should be called a base. However, the aqueous solution of ammonia probably forms ammonium hydroxide, NH_4OH, which does behave like the regular bases in this respect: $NH_4OH+HCl=NH_4Cl+H_2O$.

The definition of a base indicated above is highly unsatisfactory because it involves the definition of an acid, and we have just acknowledged that a satisfactory definition of an acid is not yet possible. Hence the definition of a base defines the unknown in terms of the unknown—*ignotum per ignotum.* Alkali and base are not synonymous terms. Every alkali is a base, but every base is not an alkali. The alkali oxides form very soluble hydroxides with marked basic properties, *e.g.* potassium hydroxide. The oxides of the alkaline earths form sparingly soluble hydroxides with less marked basic properties, *e.g.* calcium hydroxide. The other oxides, as a rule, do not react directly with water, and the hydroxides are made indirectly. **An oxide cannot be classed as acidic or basic unless it can be shown to produce corresponding salts.** These facts are sometimes summarized in a scheme resembling:

				Examples.
Bases	Metal oxides and hydroxides	React directly with water	Very soluble	Alkali oxides
			Sparingly soluble	Alkaline earth oxides
		Do not react directly with water		Iron and copper oxides
	Hydrides of certain non-metals and their derivatives			Ammonia, phosphine

The process of synthesizing a salt from an acid and base can be reversed. In 1803, J. J. Berzelius and W. Hisinger[2] showed that aqueous solutions of the salts are resolved into their proximate constituents—acids and bases—by the passage of an electric current; and they demonstrated that during the electrolysis of an aqueous solution of a salt, the acid accumulates about the positive and the base about the negative pole. This is readily illustrated by electrolyzing an aqueous solution of a neutral salt in a U-tube. The liquid is coloured violet with litmus. In a short time, the liquid about the negative pole becomes blue, and that about the positive pole red.

Peroxides.—We have seen how barium oxide, BaO—barium bivalent—when heated under certain conditions forms barium peroxide—BaO_2. The peroxides contain a higher proportion of oxygen than the normal oxides. Barium oxide with sulphuric acid forms barium sulphate and water: $BaO+H_2SO_4=BaSO_4+H_2O$. It is therefore a base. Barium peroxide forms barium sulphate, water, and oxygen when likewise treated with sulphuric acid: $2BaO_2+2H_2SO_4=2BaSO_4+2H_2O+O_2$. The hypothetical salt, $Ba(SO_4)_2$, not $BaSO_4$, corresponds with barium peroxide. Hence, barium peroxide is not a basic oxide. If $Ba(SO_4)_2$ or a related salt could be prepared, then barium peroxide would, by definition, be a basic oxide.

G. H. Bailey[3] showed that the tendency of the typical oxides of Mendeléeff's table is to form higher oxides—peroxides—without regard to the stability of the oxide; with the *even* series, this tendency is greater in a given (vertical) family of elements the higher the atomic weight; and in the horizontal series, also, there is a tendency to associate with oxygen in passing from left to right, *i.e.* with increasing atomic weight. In the *odd* series, taken vertically, there is less tendency to form peroxides as the atomic weight of the positive element increases, and the attraction for oxygen grows feebler as the atomic weight increases in passing from left to right, although there is a disposition for the attraction to become more marked as the extreme right of the period is reached. The constitution and properties of the peroxides is discussed later.

Amphoteric oxides.—Lead dioxide or peroxide, PbO_2—lead quadrivalent—can be regarded as a basic oxide because it forms the corresponding salt—$PbCl_4$—with hydrochloric acid. But PbO_2 also forms salts—plumbates—with bases, *e.g.* potassium plumbate, $O=Pb=(OK)_2$. Hence, a substance may be both acidic and basic according to circumstances. Aluminium hydroxide—aluminium tervalent—is a base, because, when treated with an acid, it forms a salt—aluminium chloride, $AlCl_3$—and water:

$$Al(OH)_3+3HCl=AlCl_3+3H_2O$$

But aluminium hydroxide when treated with a base, say, sodium hydroxide, also forms a salt—sodium aluminate, $Al(ONa)_3$—and water:

$$Al(OH)_3+3NaOH=Al(ONa)_3+3H_2O$$

Hence, aluminium hydroxide acts towards an acid like a base, and towards a base like an acid. Such oxides can be called **intermediate oxides,** or **amphoteric oxides**—from the Greek ἀμφότερος, both. Zinc oxide is an intermediate oxide. Stannic oxide, $O=Sn=O$—tin quadrivalent—forms stannic sulphate, $SO_4=Sn=SO_4$, and also sodium stannate, $O=Sn=(ONa)_2$; hence, stannic oxide is also an intermediate oxide.

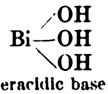
Basic salts.—On comparing the graphic formulæ of the hydroxides of sodium (univalent), lead (bivalent), and bismuth (tervalent):

$Na-OH$

Uniacidic base.

$$Pb<\begin{matrix}OH\\OH\end{matrix}$$

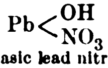
Biacidic base.



$$Bi\begin{matrix}/OH\\-OH\\\backslash OH\end{matrix}$$

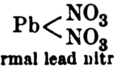
Teracidic base.

with the graphic formula for mono-, di-, and tri-basic acids we naturally inquire if the OH or hydroxyl group can be replaced by acid radicles one by one so as to furnish what would be called uni-, bi-, and ter-acidic bases. In the particular examples just selected, salts corresponding with $Pb(OH)NO_3$ and with $Pb(NO_3)_2$; or



$$Pb<\begin{matrix}OH\\NO_3\end{matrix}$$

Basic lead nitrate.



$$Pb<\begin{matrix}NO_3\\NO_3\end{matrix}$$

Normal lead nitrate.

are known. The former is called *basic lead nitrate*, the latter *normal lead nitrate*, or simply lead nitrate. Similarly, $Bi(OH)_2NO_3$, *basic bismuth nitrate*, and normal bismuth nitrate, $Bi(NO_3)_3$, are known. The basic salts are thus intermediate in composition between the normal salts and the basic oxides; they are usually derived from the more feeble bases—MgO, ZnO, PbO, CuO, Bi_2O_3, Al_2O_3, etc. As a rule, the basic salts unite readily with other salts to form complexes or double salts (*q.v.*).

The basic salts are usually prepared by the action of water or of bases—potassium hydroxide, aqueous ammonia, etc.—on solutions of the normal salts. Some basic salts form well-defined crystals, others are more or less amorphous, ill-defined, mud-like precipitates about which doubts can be raised whether they are really homogeneous chemical individuals, for their composition varies with the conditions under which they are formed, with the amount of washing the precipitate has suffered, and even with the way the solutions have been mixed. A great many basic salts have been reported which are probably mixtures or partially decomposed compounds. Accordingly, there have been many differences of opinion as to the basic salts of many of the elements; as one writer has expressed it, "the principle employed in selecting which are true individuals and which are mere mixtures has been left to individual taste." The phase rule, to be described later, furnishes a rational basis which can often be employed in deciding which precipitates are mixtures and which are compounds.

There is need for a clear understanding of the term *basic*: Na_2O represents a basic compound (oxide); HNO_3 represents a monobasic compound (acid); and $BiO.NO_3$ represents a basic compound (salt). Similarly, HNO_3 represents an acid; $CuSO_4$ has an acid reaction; $NaHCO_3$ represents an acid salt; and NaOH represents a monoacid base. Two of these have an acid and two an alkaline reaction.

The basic salts are usually, not always, less soluble in water than the corresponding normal salts.

§ 15. Hydroxides and Anhydrides

> Acids and alkalies are compounds having the same general molecular structure, and the differences between acids and alkalies, and, we might add, the differences between individual acids and individual alkalies, depend on the nature of their radicles.—J. P. COOKE (1876).

We have seen that sulphur dioxide and phosphorus pentoxide form acids with water:

$$\underset{\text{Sulphur dioxide.}}{SO_2} + H_2O = \underset{\text{Sulphurous acid.}}{H_2SO_3}; \text{ and } \underset{\text{Phosphorus pentoxide.}}{P_2O_5} + 3H_2O = \underset{\text{Phosphoric acid.}}{2H_3PO_4}$$

The water in these compounds has completely lost its identity, and it is generally supposed to produce a new class of bodies called **hydroxides.** Every element, excepting fluorine and the argon family, appears to form one or more hydroxides, directly or indirectly. The heats of formation of a few hydroxides[1] from their elements and water are indicated in Table III. If the heat of formation of the oxide, Table I, be deducted from these values, the heat of conversion of the oxide into the hydroxide will be obtained. For the formation of these hydroxides from these elements add on the heat of formation of the corresponding amount of liquid water, *viz.* H_2O—68·36 Cals., and $\frac{1}{2}H_2O$—34·18 Cals.

TABLE III.—HEATS OF FORMATION OF SOME HYDROXIDES.

Hydroxide.	Cals.	Hydroxide.	Cals.	Hydroxide.	Cals.
KOH	68·99	$Tl_2O_3.xH_2O$	86·34	$Mn(OH)_2$	94·77
NaOH	67·69	$Sn(OH)_2$	68·09	$MnO(OH)_2$	116·33
$Cu(OH)_2$	37·52	$SnO(OH)_2$	133·50	$Fe(OH)_2$	68·28
$Au_2O_3\,xH_2O$	13·19	$Pb(OH)_2$	125·16	$Fe_2O_3.xH_2O$	191·15
$Ca(OH)_2$	146·47	H_3PO_4	200·06	$Co(OH)_2$	63·40
$Sr(OH)_2$	146·14	H_3AsO_4	113·09	$Co_2O_3.xH_2O$	149·38
$Ba(OH)_2$	146·50	H_3SbO_4	114·39	$Ni_2O_3.xH_2O$	120·38
$Mg(OH)_2$	148·96	$Sb(OH)_3$	83·71	$Pd(OH)_2$	22·71
$Zn(OH)_2$	82·68	$Bi(OH)_3$	68·87	$PdO(OH)_2$	30·43
$Cd(OH)_2$	65·68	H_3PO_3	125·16	$PtO(OH)_2$	17·88
$Al_2O_3.xH_2O$	388·92	H_2SO_4	124·56	$Pt(OH)_2$	19·22
Tl(OH)	22·73	$TeO(OH)_2$	77·18		

The oxides from which the acids are produced do not contain the elements of water. They are called **anhydrides,** or **acid anhydrides**—from the Greek *α*, without; ὕδωρ, water. Thus SO_2 is not only called sulphur dioxide, but also sulphurous anhydride; and P_2O_5 is not only phosphorus pentoxide, but phosphoric anhydride. An anhydride can be regarded as the residue left when the elements of water are removed from the oxyacids. Thus sulphuric acid, H_2SO_4, less water, gives sulphuric anhydride—SO_3—also called sulphur trioxide; sulphurous acid, H_2SO_3, less water, gives sulphurous anhydride—SO_2. It is generally supposed that sulphurous anhydride in combining with water forms a compound containing quadrivalent sulphur and two univalent hydroxyl—OH—groups, that is, $SO(OH)_2$. The reaction is symbolized:

$$O{=}S{=}O + H-OH \rightarrow O{=}S{<}{}^{OH}_{OH} \quad \text{(sulphurous acid)}$$

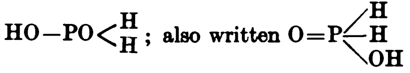
and sulphuric acid is considered to be a compound containing sexivalent sulphur and two hydroxyl groups, $SO_2(OH)_2$. The reaction is symbolized:

$$\genfrac{}{}{0pt}{}{O}{O}{\gg}S{=}O + H-OH \rightarrow \genfrac{}{}{0pt}{}{O}{O}{\gg}S{<}{}^{OH}_{OH} \quad \text{(sulphuric acid)}$$

If the acids be regarded as salts of hydrogen, it can be argued that water is a basic oxide which unites with an acid anhydride to form a salt, *e.g.* SO_3 (acidic oxide) $+H_2O$ (basic oxide)$=H_2SO_4$ (salt), by analogy with $SO_3+K_2O=K_2SO_4$. Isaac Newton called water a salt. It is easy to show that with the regular definitions of acid and base, the fame of venerable sulphuric acid—the mother of acids—can be attacked. Representing sulphuric acid as just indicated, the two hydroxyl groups can be replaced one by one with other acid radicles, *e.g.*

$$\genfrac{}{}{0pt}{}{O}{O}{\gg}S{<}{}^{OH}_{Cl} \qquad\qquad \genfrac{}{}{0pt}{}{O}{O}{\gg}S{<}{}^{Cl}_{Cl}$$

where the hydrogen of the hydrochloric acid, HCl, is displaced by the bivalent radicle SO_2, "analogous with the formation of magnesium chloride, $MgCl_2$, by the substitution of the hydrogen of hydrochloric acid by the bivalent atom Mg" in magnesium hydroxide, $Mg(OH)_2$. This shows how the definitions of acid and base, if not applied with care, may lead into a bewildering labyrinth. Enough has been said to show that **an acid anhydride with water forms an acid, and with a base it forms a salt:** $ZnO+SO_3=ZnSO_4$ (zinc sulphate). Sulphurous acid can also be regarded as sulphurous hydroxide—$SO(OH)_2$; and phosphoric acid—phosphorus quinquevalent—as phosphoric hydroxide—$PO(OH)_3$. The basicity of an acid is generally supposed to correspond with the number of hydroxyl groups it contains. The hydrogen of the hydroxyl groups is supposed to be the *displaceable hydrogen* referred to in the definition of acids. Monobasic hypophosphorous acid—H_3PO_2—is supposed to be $H_2PO(OH)$; or



$$HO-PO\begin{matrix}<H\\<H\end{matrix}\text{; also written } O=P\begin{matrix}\diagup H\\ -H\\ \diagdown OH\end{matrix}$$

because there is only one displaceable hydrogen atom per molecule. The hydrogen atoms directly united to the phosphorus atoms are not supposed to be replaceable by the bases, but the hydrogen of the single hydroxyl group is displaceable.

The basic oxides are sometimes called **basic anhydrides,** and they too form hydroxides with water, *e.g.* calcium oxide, CaO—calcium bivalent—with water forms calcium hydroxide, $Ca(OH)_2$:

$$Ca=O + H-OH \rightarrow Ca\begin{matrix}<OH\\<OH\end{matrix}$$

From this point of view water can be regarded as hydrogen hydroxide, H—OH, analogous with K—OH, potassium hydroxide, and Na—OH, sodium hydroxide. Water itself behaves in some respects as if it were an acid, and in others as if it were a base. In view of the regular definition, it could be reasonably argued that if water be an acid, sodium hydroxide, NaOH, is an acid salt, and sodium oxide, Na_2O, a normal salt

$$\begin{matrix}H\\H\end{matrix}>O$$

Water.

$$\begin{matrix}Na\\H\end{matrix}>O$$

Sodium hydroxide.

$$\begin{matrix}Na\\Na\end{matrix}>O$$

Sodium oxide.

Excluding certain carbon compounds, the hydroxides of the non-metallic elements are usually but not always acids, and the hydroxides of the metals are usually but not always bases. The term *hydroxide* is generally reserved for compound of the basic oxides with water; and the term *anhydride* is usually reserved for the acid anhydrides. The compounds of the basic anhydride with water (hydroxides) were once called **hydrates**—*e.g.* potassium hydroxide was called potassium hydrate, etc. The term **hydrated salt** is applied more or less vaguely to compounds which contain the elements hydrogen and oxygen in the proportion required to form water—combined water.

§ 16. The Polar Theory of Chemical Combination.

Strife between opposite tendencies is the parent of all things.—HERACLEITUS (*c.* 450 B.C.).

Nature is constantly labouring after repose by the balance and neutralization of contrary tendencies; and so far as polar forces enter into her economy, she seeks harmony by means of discord, and unity by opposition.—W. WHEWELL (1840).

Every chemical action is fundamentally an electrical phenomenon. . . . Electricity is the first cause of all chemical action.—J. J. BERZELIUS (1812).

In some early conjectures on chemical affinity, Isaac Newton (1714) assumed that electrical and chemical phenomena were both due to attractive forces acting at insensibly small distances. He said:

> The attraction of electricity reaches to sensible distances and so has been observed by vulgar eyes; but there may be others which reach to so small distances as to have hitherto escaped observation. Possibly electrical attraction reaches to small distances, even without being excited by friction.

Newton seems to have regarded the intensity of chemical affinity to be inversely proportional to the composition of compound particles. The more complex the aggregates the weaker their affinity. Newton, however, did not consider that the facts were sufficiently well known to justify further conjectures, for he said:

> We must learn from the phænomena of nature what bodies attract one another, and what are the laws and properties of the attractions before we inquire the cause by which the attraction was performed.

H. Davy's electrical theory of chemical affinity (1807).—After W. Nicholson and A. Carlisle (1800) had decomposed water, and J. J. Berzelius and W. Hisinger (1803) had decomposed salts by the electric current, chemists began to suspect that electrical and chemical forces were closely related. H. Davy took up the subject about 1806, and in his paper *On some chemical agencies of electricity* (1807), he showed that sulphur and copper can be charged with opposite electricities by friction—the former negatively, the latter positively—just as A. Volta (1792) proved that when two metals touch one another, they develop electricity—each assuming an electric charge of opposite sign to the other. H. Davy tried to show that the chemical activity of a substance is dependent upon its electrical condition, for he said:

> As the chemical attraction between two bodies seems to be destroyed by giving one of them an electrical state different from that which it naturally possesses; that is, by bringing it artificially into a state similar to the other, so it may be increased by exalting its natural energy. Thus, whilst zinc, one of the most oxidizable of metals, is incapable of combining with oxygen when negatively electrified in the circuit, even by a feeble power; silver, one of the least oxidizable, easily unites to it when positively electrified; and the same thing might be said of other metals.

Davy argued that in the act of combination, the reacting substances by contact acquire electrical charges of opposite signs; and that chemical combination is accompanied by a neutralization or exchange of electricities of opposite signs between the combining substances. Thus, an acid unites with an alkali because the former acquires an electronegative and the latter an electropositive charge; oxygen acquires an electronegative charge, and it unites with metals which acquire an electropositive charge; similarly, electronegative sulphur unites with electropositive copper producing electrically neutral sulphide. When the quantity of electricity which is neutralized in the act of combination is restored, the compound is decomposed, and the original products are reproduced. As a climax, H. Davy virtually said that chemical affinity is nothing but electrical energy; for example, in his *Elements of Chemical Philosophy* (London, 1812), he said:

> Electrical effects are exhibited by the same bodies when acting as masses, which produce chemical phenomena when acting by their particles; it is not therefore improbable that the primary cause of both may be the same, and that the same arrangement of matter, or the same attracting powers which place bodies in the relations of positive and negative—*i.e.* which render them attractive of each other electrically, and capable of communicating attractive powers to other matter—may likewise render their particles attractive, and enable them to combine when they have full freedom of motion.

Davy did not follow up his ideas about the relations between electrical disturbance and chemical decomposition, on the theoretical side, but he applied the principle as an instrument of decomposition, and solved some questions of the very greatest importance to the growing science, for it led him to the isolation of the alkali metals—potassium and sodium.

The idea of acidity involves two concepts—(*a*) an antagonistic force which is reciprocated by the alkalies; and (*b*) a great tendency to unite with bodies generally. In 1809, A. Avogadro published a paper entitled, *Idées sur l'acidité et l'alkalinité*.[1] H. Davy's experiments on electrolysis suggested to A. Avogadro the idea of a chemical force which is polar at the moment of action, and which not only determines the union of an acid and alkali, but also chemical changes generally. According to Avogadro:

> All the phenomena are easily explained if we consider acid and alkali antagonism as purely relative properties, only becoming somewhat absolute when referred to a middle

substance A which has the acid antagonism with reference to B, and which may possess the alkaline antagonism with reference to a third substance C. What are then termed acids and alkalies are merely bodies which have the acid or alkali antagonism in respect of certain other bodies whose position in the scale is approximately indicated by certain properties, such as inability to affect vegetable blues. . . . The degree of acidity or alkalinity of a compound depends upon the degree of those properties in its constituents. . . . Of two substances in the act of combination, one always plays the part of acid, and the other of alkali; and it in this antagonism which constitutes the tendency to combination, or affinity properly so called.

Accordingly, said A. Avogadro, different substances can be arranged in series, the position of each marking its true affinity to any predecessor or successor. Oxygen and sulphur would come first in the series, hydrogen and carbon last, with the neutral salts in the middle of the series. The measure of chemical antagonism is electric heterogeneity or oxygenicity. A substance is the more oxygenic the less it is oxidizable.

The essence of polarity is the contrast of opposing qualities such as is exhibited by the so-called north and south poles of a magnet where unlike poles attract and like poles repel one another; by the two states of static electricity—positive and negative; and by the phenomena of electrolysis—as interpreted by C. J. T. von Grotthus (1805), H. Davy (1806), and M. Faraday (1834)[2]—where the atoms or radicles have opposite polarities to that of the electrode about which they accumulate. Atoms with opposite polarities combine readily, while those with the same polarity have little or no tendency for union. "In every part of nature," said R. W. Emerson, "we meet with polarity. . . . An inevitable dualism besets nature so that each thing is a half, and suggests another to make it a whole." J. J. Berzelius considered that "the form of crystalline substances presupposes an effort on the part of the atoms to touch one another by preference at certain points, and this shows that the particles probably exhibit an electric or magnetic polarity."

J. J. Berzelius' electrochemical theory (1819–48).—J. J. Berzelius further expressed his view that the electrical charges on the particles were the controlling factors in chemical reactions. Berzelius' views were described in his *Essai sur la théorie des proportions chimiques et sur l'influence chimique de l'électricité* (Paris, 1819), and he took quite a different view from H. Davy as to the way the electrical charges on the particles produce chemical action. While H. Davy considered the electrical charges to be the consequence of contact or of mutual action between heterogeneous particles, Berzelius believed that each elementary atom is endowed with two kinds of electricity and has in consequence two electrical poles; these poles differ in strength so that the resultant effect is to make each atom appear as if it were positively or negatively electrified. Thus, Berzelius distinguished electropositive and electronegative elements according to which charge prevailed; the kind of charge carried by an element was determined by the appearance of the element at the positive or negative pole when a compound of the element was electrolyzed. The varying degrees of chemical affinity were supposed to imply that different substances were charged with varying quantities of electricity. Consequently the elements were arranged in series according to the magnitude of the charge, and Berzelius thus obtained an electrochemical series with the alkali metals at one end of the series, and oxygen at the other:

Potassium
Sodium
. . . .
Zinc
Lead
Gold
. . . .
Fluorine
Nitrogen
Sulphur
Oxygen

Oxygen was supposed to be the most electronegative substance of all, and was assumed to be always electronegative. In order to explain the variations of chemical affinity with temperature, the electric polarity was further supposed to vary with temperature. To explain why sulphur has a greater affinity for oxygen than for, say, gold, when both oxygen and sulphur are electronegative, Berzelius assumed that the absolute quantity of positive electricity on sulphur is much greater than on gold, and since elements attract one another by their contrary poles, sulphur exerts a stronger attraction for oxygen than for gold. Thus, an element might be positively polar with some elements, and negatively polar with others—sulphur, for instance, is positive with oxygen, and negative with hydrogen and the metals. In the case of the caustic alkalies, too, said J. J. Berzelius, water plays the part of an acid ; and when it unites with an acid (anhydride), it plays the part of a base.

According to J. J. Berzelius, chemical combination consists in the attraction of the dissimilar poles of the reacting units, and, in consequence, the neutralization of opposite electric charges. If opposite electrical charges be exactly balanced, an electrically neutral compound, chemically inactive, is supposed to be formed. Berzelius explained double decomposition by his electrochemical theory in these words :

> Every chemical action is an electrical phenomenon dependent upon the electrical polarity of the particles, and everything which appears to be the result of chemical affinity is really due to the electrical polarity of some bodies being stronger than that of others. When the compound AB is decomposed by a substance C, the affinity of C for A is greater than that of B for A, and C must possess a stronger electrical polarity than B. . . . If two bodies AB and CD react so as to produce two new bodies AD and BC, it follows that the electric polarities in the latter pair of bodies are better neutralized than in the former.

These statements may or not may be true, but the argument is not sound, for it is assumed that because B is displaced by C from its combination with A, the affinity of C for A is greater than that of B for A ; it is further assumed that affinity and electrical polarity are the same, and to state that this proves that the electrical polarity of C for A is greater than B for A is arguing in a circle.

When, say, sodium unites with oxygen to form the base sodium oxide, Na_2O ; or sulphur with oxygen to form the acid anhydride sulphur trioxide, SO_3, primary compounds, or **compounds of the first order**, are formed ; these primary compounds are made up of atoms having opposite polarities, thus :

$$\overset{+}{Na}_2\overset{-}{O} \qquad \overset{+}{Ca}\overset{-}{O} \qquad \overset{+}{S}\overset{-}{O}_3 \qquad \overset{+}{C}\overset{-}{O}_2$$

The electrical attractions are not supposed to be always exactly neutralized during the formation of these primary compounds ; the basic oxides were supposed to have an excess of positive electricity and the acid anhydrides an excess of negative electricity ; the excess causes a further attraction between the acidic and basic radicles resulting in the formation of **compounds of the second order,** for example ·

$$\overset{+}{H_2O}+\overset{-}{SO_3} \qquad \overset{+}{Na_2O}+\overset{-}{SO_3} \qquad \overset{+}{CaO}+\overset{-}{CO_2} \qquad \overset{+}{K_2O}+\overset{-}{Cl_2O_5}$$

and these again might similarly form **compounds of higher orders,** for example, said Berzelius, alum must be looked upon as the product of a reaction between aluminium and potassium sulphates, the former acting as a negative, the latter as a positive radicle :

$$\overset{+}{K_2SO_4}+\overset{-}{Al_2(SO_4)_3}=K_2SO_4.\overset{+}{Al}_2(SO_4)_3$$

similarly the union of an anhydrous salt with water may be regarded as a combination of the positively charged anhydrous salt with negatively charged water :

$$\overset{+}{K_2SO_4.Al_2(SO_4)_3}+24\overset{-}{H_2O}=K_2SO_4.Al_2(SO_4)_3.24H_2O$$

Similarly, potassium chloride, KCl, acts as a base towards platinum tetrachloride, $PtCl_4$, and these two salts unite to form a compound with a composition corresponding with $2KCl.PtCl_4$. Berzelius' ideas were embodied in the chemical formulæ in use about 1820. For example :

	Present formulæ.	Berzelius' formulæ.
Sodium sulphate	Na_2SO_4	$Na_2O.SO_3$
Sulphuric acid	H_2SO_4	$H_2O.SO_3$
Calcium carbonate	$CaCO_3$	$CaO.CO_2$
Potassium chlorate	$KClO_3$	$K_2O.Cl_2O_5$

The idea of compounds of different orders is fairly old, for, as previously shown, Isaac Newton had as clear ideas on this subject as Berzelius. Joseph Black has told us in his *Lectures on the Elements of Chemistry* (Edinburgh, **1.** 281, 1803) :

> The older chemists gave the name *mixt* to chemical compounds consisting of two ingredients which we have never been able to reduce to simpler ingredients. Particles of a mixt compound with particles of another mixt formed particles of a *compound ;* the union of two compounds formed a *decompound ;* the union of two decompounds formed a *supercompound ;* etc.

Chemists did not long use the terms indicated by J. Black, although there is a tendency to retain the idea of J. J. Berzelius' compounds of different orders, *e.g.* A. Werner (1893) used the idea in his theory of the ammino-compounds.

The main objections to Berzelius' hypothesis are as follows : In the first place, contrary to Berzelius' assumption that different substances are charged with *varying quantities* of electricity, M. Faraday proved that on electrolysis, *definite and fixed quantities* of electricity are associated with the atoms of matter, although the atoms of the same kind of matter in different compounds, on electrolysis, might be charged with different yet definite quantities of positive or negative electricity. Secondly, after Avogadro's hypothesis had been established, Berzelius' theory was thought to be incompatible with such a comparatively simple reaction as $2H_2+O_2\rightarrow 2H_2O$, for the compound nature of oxygen is due to different electrical charges on the component atoms of the molecules; at first sight this does not agree with the supposed identity of the resulting two molecules of water. Berzelius accordingly denied the diatomic nature of the elementary gases. Thirdly, J. B. A. Dumas (1834) showed that the hydrogen atoms in compounds like CH_4 can be replaced one by one by atoms of chlorine. J. J. Berzelius had postulated that hydrogen is an electropositive element, and chlorine an electronegative one, as exemplified by hydrogen chloride. Here in Dumas' substitutions, a negative element can be exchanged for a positive element without fundamentally altering the chemical character of the resulting compounds. It would be easy to modify Berzelius' theory to meet these difficulties.

J. J. Berzelius entangled his electrochemical theory with other hypotheses as to the structure of compounds which ultimately brought about its fall ; but the electrochemical theory should be considered on its merits apart from the subsidiary hypotheses. "There is life after death in the case of a good doctrine," said I. Remsen in 1903 ; "and the spiritual part of the electrochemical hypotheses of Berzelius, so to speak, lives to-day as the doctrine that atoms of the elements carry electric charges which are the cause of their chemical activity." H. Davy himself pointed out that his statement of the mode of action of the electrical forces is so general that half a dozen essentially different schemes might be devised, each in agreement with the hypothesis that "the forces termed chemical affinity and electricity," as Faraday expressed it, "are one and the same ; " or that "chemical affinity is a consequence of the electrical attractions of particles of different kinds of matter." This hypothesis, developed by H. von Helmholtz (1881), R. Abegg (1906), J. Stark (1908), and J. J. Thomson (1914), is that which is generally accepted to-day, and will be described later.

§ 17. Binary and Unitary Theories of the Constitution of Acids and Salts

> We understand a phenomenon historically when we are clear in our minds concerning the external conditions and habits of thought from which it sprung; and when its mainsprings of action and its purposes, as well as the effects which have proceeded from it, are distinctly traceable.—P. CARUS (1892).

The fundamental idea in Lavoisier's system is the dualism or polarity of compounds. The acids were regarded as compounds of the acidifiable bases with oxygen, and salts were compounds of acids with oxygenated compounds of the metals or radicles. Lavoisier's oxygen theory was accepted by J. J. Berzelius (1815), and by J. L. Gay Lussac (1816). The former adapted the dualistic theory to his electrochemical hypothesis of chemical combination. He said:

> Assuming that every chemical compound is solely dependent upon two opposing forces —positive and negative electricity—every compound must be composed of two parts held together by their mutual electrical forces. Hence, every compound body, whatever be the number of its constituents, can be separated into two parts one of which is positively and the other negatively electrified. Sodium sulphate, for example, is obtained not from sulphur, oxygen, and sodium, but from sulphuric acid and soda each of which can itself be separated into positive and negative constituents.

All acids and salts were accordingly supposed to have a binary or dualistic structure. Berzelius assumed that there is no redistribution of the atoms during the formation of sulphuric acid by the action of water, H_2O, on sulphur trioxide, SO_3; and accordingly he represented the constitution of sulphuric acid by the formula $H_2O.SO_3$. J. J. Berzelius (1815) did not at first accept Davy's demonstration (1810–15) that some acids—*e.g.* hydrochloric acid—are free from oxygen, because it disturbed the uniformity of his dualistic or binary system of chemical combination, but between 1820–5, he abandoned this prejudice, and recognized the existence of non-oxygenated acids, although he fought for his dualistic or binary hypothesis to the end of his life. He died on August 7th, 1848.

T. Graham's theory of acids (1833).—In his *Ueber die neueren Gegenstände der Chymie* (Breslau, 1796), J. B. Richter described some experiments which pointed to the generalization: The same constant weight of *Lebensluftstoff* (oxygen) is combined with those weights of metal which are required to saturate a constant amount of acid; otherwise expressed, the quantities of the various bases required to saturate a constant amount of acid contain the same weights of oxygen. J. J. Berzelius substantiated "this discovery of the meritorious investigator J. B. Richter" by experiments described in his paper entitled, *Versuch die bestimmten und einfachen Verhältnisse aufzufinden nach welchen die Bestandtheile der anorganischen Natur mit einander verbunden sind* (1811–2); and about 1826, chemists generally held the opinion that the metal oxides contain one atom of the metal to one atom of oxygen, and that one molecule of the metal oxide united with one molecule of the acid to form a molecule of neutral salt. T. Graham, however, proved that this hypothesis is erroneous, for in his *Researches on the arseniates, phosphates, and modifications of phosphoric acid* (1833), he demonstrated the existence of three distinct acid hydrates of phosphoric oxide, P_2O_5—then written PO_5. Keeping to the modern notation, the three hydrates had respectively 3, 2, and 1 molecules of water per molecule of phosphoric oxide, and corresponded with the formulæ:

$P_2O_5.3H_2O$	$P_2O_5.2H_2O$	$P_2O_5.H_2O$
Orthophosphoric acid.	Pyrophosphoric acid.	Metaphosphoric acid.

These hydrates were respectively regarded as "terphosphate, biphosphate, and phosphate of water." Graham further showed that the molecules of water in these three acids could be replaced one by one with basic oxides so that three sodium salts of orthophosphoric acid, with its three molecules of basic water, are possible; two with pyrophosphoric acid, with its two molecules of basic water; and one with metaphosphoric acid, which has only one molecule of basic water. He exhibited the constitution of the phosphoric acids and their salts of soda in tabular form:

		Oxygen in the		
		Soda.	Water.	Acid.
First class	Phosphoric acid	0	3	5
	Biphosphate of soda	1	2	5
	Phosphate of soda.	2	1	5
	Subphosphate of soda	3	0	5
Second class	Pyrophosphoric acid	0	2	5
	Bipyrophosphate of soda	1	1	5
	Pyrophosphate of soda	2	0	5
Third class	Metaphosphoric acid	0	1	5
	Metaphosphate of soda	1	0	5

The result of Graham's work was to show (i) that acids may contain the equivalent of *n* molecules of water which can be replaced by basic radicles to form salts; and (ii) the number of molecules of acid required to form a neutral salt is not necessarily equal to the number of molecules of the base, as was supposed to be the case from the experiments of Richter and Berzelius.

J. von Liebig's theory of polybasic acids (1838).—J. von Liebig followed up Graham's work, and in a paper entitled, *Ueber die Constitution der organischen Sauren* (1838), he adduced examples proving that the molecules of all acids are not equivalent to one another; in other words, acids may be mono-, di-, tri-, . . . basic, according as the acid contains one, two, three, . . . molecules of water which can be replaced by the corresponding number of molecules of the base. This is sometimes called Liebig's theory of polybasic acids. Liebig also said when two and more than two molecules of the base combine with one molecule of the acid, and only one molecule of water is separated during the operation (that is, fewer than the number of equivalents of the fixed base), a **basic salt** is produced. J. von Liebig proved that the products of decomposition of organic acids and salts are different under different conditions, and thus demonstrated the fallacy of the then prevalent assumption that the products of decomposition of a compound prove that they are present as such in the original compound. Every theory based on processes of decomposition, said J. von Liebig, is incomplete and insufficient.

Again, J. von Liebig showed that when lime is neutralized with sulphuric or hydrochloric acid, the same amount of water is formed. According to Berzelius' dualistic theory, in the one case water was present in the sulphuric acid ready formed; and in the other case, the water is produced during the reaction. It cannot be supposed that there is any essential difference between these two reactions, because in both it is most probable that the metal of the lime replaces the hydrogen of the acid, and the hydrogen of the acid combines with the oxygen of the lime to form water. Hence, there is no difference in kind between the action of the so-called oxyacids and hydracids. J. von Liebig thus brought the reactions between most of the acids and bases under one common scheme: Acid+base=salt+water. Acids, said J. von Liebig, are particular compounds of hydrogen in which the latter can be replaced by the metals.

> Neutral salts are those compounds of the same class in which the hydrogen is replaced by an equivalent of the metal. Those substances at present called anhydrous acids acquire the property of forming salts with metallic oxides, for the most part, only on the addition of water; or they are compounds which decompose the oxides at a high temperature. . . . At ordinary temperatures no salt can be produced without water, and the constitution of the salts is analogous to that of the hydrogen compounds which we call acids. The principle of Davy's theory is that the capacity of saturation of an acid is dependent upon the hydrogen, or upon part of the hydrogen, which it contains, so that if the other elements of the acid are

collectively called the radicle, the composition of the radicle does not possess the slightest influence on this capacity.

On grounds of probability and convenience, J. von Liebig thus advocated a hydrogen theory of acids analogous to that previously suggested by H. Davy and P. L. Dulong. To recast the words of J. J. Berzelius, sodium sulphate is a compound of sulphur, oxygen, and sodium, but there is nothing to show that it is composed of a basic oxide, Na_2O, with an acid anhydride, SO_3. Acids are regarded as combinations of simple or compound radicles with replaceable hydrogen; and salts are derivatives of the acids formed by replacing the hydrogen of the latter by metals or equivalent radicles. This form of the hydrogen theory of acids was opposed by J. J. Berzelius to the end of his life (1848), because he saw in it evidence against his own dualistic view of the composition of acids and salts. J. von Liebig's theory is strictly dualistic in that the replaceable hydrogen in acids is contrasted with the acidic radicle.

A. Laurent and C. Gerhardt's unitary hypothesis.—While the hydrogen theory of acids was developing, Berzelian dualism was fighting a losing battle with organic chemistry, as described previously; and it received its severest blow with the advent of A. Laurent and C. Gerhardt's unitary hypothesis, where it was shown that the molecules of a compound are to be regarded as simple edifices, as J. B. A. Dumas expressed it, and not double buildings; molecules are capable of modification by the exchange of one of their constituent elements for another. The unitary hypothesis denies the existence of separate and opposing components in any particular compound; it represents acids and salts by similar formulæ to the hydrogen theory, but it does not insist upon their containing any definite compound, radicle, or their being composed according to any particular type; although it does place compounds with analogous properties in the same class to express the influence of each element on the united properties of the compound.

CHAPTER IX

WATER

§ 1. The Cycle of Water in Nature

> I am the daughter of Earth and Water
> And nursling of the Sky ;
> I pass through the pores of the Ocean and Shores ;
> I change, but I cannot die.—THE CLOUD.

WATER is widely distributed in nature in its three states of aggregation—steam or aqueous vapour, liquid water, and solid ice or snow. It has been estimated that three-fourths of the surface materials on the crust of the earth is water. Animals and plants contain a large proportion of combined water—*e.g.* fish contains the equivalent of about 80 per cent. ; beef, 60–62 per cent. ; the human body, 70 per cent. ; aquatic plants between 95 and 99 per cent. ; and ordinary land plants, 50–75 per cent. A great many rocks contain water—combined and absorbed. Clay, for example, contains up to 14 per cent. of combined water.

Water plays a vital part in the nutrition of animals and plants ; indeed, it is absolutely indispensable to animal and vegetable life. It is universally employed as a solvent, and it is utilized as a thermal agent in refrigeration and heating, where it is valuable on account of the magnitude of its heat of fusion, and its specific heat ; it is also similarly used in steam engines. In short, water is employed for countless purposes by man ; and it is the cause of the most striking phenomena in nature.

The circulation of water in nature—the water cycle.—All the water on the earth passes through a remarkable cycle of changes. The heat of the sun leads to the evaporation of water from the seas, etc. ; water vapour is only 0·62 times as heavy as an equal volume of air, and consequently it rises into the upper regions of the atmosphere, as well as diffuses into and mixes with the atmospheric air. The temperature of the ascending vapour gradually decreases, and consequently a plane must be reached where the air is saturated with moisture. The vapour will then condense in the form of fine drops of water—mist or clouds. The fine drops coalesce into larger drops. Ultimately, the condensed water must descend again to the earth as dew, rain, snow, or hail. The wind distributes the vapour. The heat given up during the condensation of the vapour is distributed or carried from the hotter regions—where evaporation is fastest—to the colder regions—where the vapour is condensed—thus helping to stretch the temperate regions nearer to the poles. The water which is sprayed, as rain, etc., on the surface of the globe, does a certain amount of physical and chemical work. On the chemical side, water helps in the decomposition and weathering of rocks ; and on the physical side, it transports matter in suspension from the higher to the lower levels. The soluble matters ultimately collect in the seas.

Thus the water cycle involves : (1) evaporation from the oceans, seas, lakes, etc. ; (2) condensation in the upper regions of the atmosphere as a fine mist of distilled water where it collects as clouds ; (3) further condensation followed by rain ; (4) percolation of the rain-water through the soil and its accumulation on an impervious bed of rock, whence it is forced to the surface, as spring water, by the pressure of the superincumbent water ; and (5) the collection of spring and surface waters by the streams and rivers to be forwarded to the sea. The river thus returns the water whence it came to commence anew the never-ending cycle. P. B. Shelley has described the idea in a charming manner in his well-known poem—*The Cloud.* It must be added that a relatively small proportion of the water which finds its way into the ground is "fixed" by reacting with certain silicates and other minerals forming hydrated silicates, hydrated alumino-silicates, etc.—*e.g.* kaolinite, $Al_2O_3.2SiO_2.2H_2O$; selenite, $CaSO_4.2H_2O$; etc.

Rain-water.—When rain falls on the surface of the earth, part of it sinks deeply underground to reappear as spring water; about 25 per cent. drains off directly into streams and rivers; a part is retained as the ground water of soils; and a part returns by evaporation directly to the atmosphere. Rain, in its journey through the air, dissolves oxygen, nitrogen, carbon dioxide, chlorides, and ammoniacal and nitrate nitrogen. It also carries down dust—organic and inorganic. Rain-water, particularly if collected near the sea in high winds, contains sodium chloride; and if collected near towns, contains sulphur compounds—sulphur dioxide and sulphuric acid—derived from the products of combustion of coal. When evaporated to dryness, 10,000 parts by weight of rain-water will give about 0·34 part of solid matter; most of this consists of sodium chloride and organic matter. Rain-water contains in solution 0·013 per cent. of dissolved nitrogen; 0·0064 per cent., oxygen; and 0·0013 per cent., carbon dioxide. The rain which falls at the end of a shower is less contaminated than that which falls at the beginning, because the atmosphere is washed, so to speak, during the earlier part of the shower. According to F. W. Clarke's important work, *The Data of Geochemistry* (Washington, 1916),

> As a carrier of ammonia, nitric acid, sulphuric acid, and chlorine, rain-water performs a function of the highest significance to agriculture, but whose geological importance has not been generally recognized. Rain and snow collect these impurities from the atmosphere in quantities which vary with local conditions, and redistribute them on the soil.

The average of a number of analyses of rain-water at Rothamsted (England) [1] gave 2·71 lbs. of ammoniacal nitrogen per acre per annum, and 1·13 lbs. of nitric nitrogen. In most cases ammonia is in excess, but in the tropics the reverse seems to obtain. At Barbados,[2] 1·009 lbs. of ammoniacal nitrogen and 2·443 lbs. of nitric nitrogen were annually deposited per acre. Similarly, 14·87 lbs. of chlorine as chlorides were deposited annually per acre at Rothamsted, and 180·63 lbs. at Ceylon.

Spring and mineral water.—Directly the rain-water strikes the ground, it begins to attack and dissolve various rocks, decaying organic tissue (humic compounds), etc., forming *surface and ground water.* It is estimated that between 25 and 40 per cent. of the rainfall, in temperate regions, soaks into the ground. In its journey underground the percolating water—*underground water*—loses most of its organic matter and dissolves more or less mineral matters—compounds of calcium, magnesium, and sodium; carbon dioxide; etc. The greater the depth to which the water sinks the greater the amount of solid matter it can dissolve. Water under great pressure is a powerful solvent. Sooner or later the water which has percolated underground will be forced to the surface as *spring water.* If the spring water holds an unusual amount of some particular constituent in solution which gives it a marked taste, or some specific property, the term *mineral water* is applied. Mineral waters do not necessarily contain a large excess of mineral matters in solution. The water from mineral springs is often named according to some special constituent dissolved in the water, or from the locality of the spring. *Fresh water* is a vague term applied to a natural water which does not contain much dissolved impurity; to natural water as distinct from salt or sea water; etc.

Chalybeate waters contain ferrous carbonate—*e.g.* Tunbridge; Buxton; the Excelsior Spring, Saratoga, N.Y.; the Hot Springs of Arkansas; Homberg; etc. *Sulphur waters* contain hydrogen sulphide and other sulphur compounds, alkaline sulphides, etc., *e.g.* Baden; Carlsbad; Harrogate; Bath; Aachen; the Red Sulphur Spring, Sharon, N.Y.; etc. The water of the Steamboat Springs in Nevada has borates and deposits a sinter containing arsenic, antimony, mercury, lead and copper sulphides, as well as traces of gold and silver. *Saline waters* contain salts of various kinds, for instance, magnesium sulphate and chloride which give the water a bitter taste—*e.g.* Bath; Epsom; Seidlitz; Friedrichshall, Ofen; Cheltenham; etc. *Sodium sulphate and sodium carbonate*—*e.g.* Marienbad; Carlsbad; etc. *Carbon dioxide* (*acid reaction*)—*e.g.* Apollinaris (imitations of this and other mineral waters are made artificially; the natural water is bottled and exported). *Carbon dioxide with sodium carbonate* (alkaline reaction.)—*e.g.* Vichy; Neuenahr; etc. *Carbon dioxide with sodium chloride*—*e.g.* Ems; Neider-Selters; etc. *Sodium* and other chlorides—*e.g.* Homberg; Aachen; Baden Baden; Congress Spring, Saratoga, N.Y.; etc. Some waters contain *iodine and bromine compounds*—*e.g.* Congress Spring, and Excelsior Spring, Saratoga, N.Y.; Woodhall Spa; etc. *Arsenic*—*e.g.* Roncegno; Levico; etc. *Lithia*—*e.g.* Congress Spring, Saratoga, N.Y.; etc. *Boric acid*—*e.g.* Yellowstone Park; Chaguarama Valley (Venezuela); Tuscany; etc. *Silica*—*e.g.* the Hot Springs of Iceland, New Zealand, Yellowstone Park, etc. *Hard waters* have calcium and magnesium carbonates and sulphates in solution. The waters of some springs, particularly in volcanic districts, issue at an elevated temperature, hence the term *thermal waters, e.g.* the Hot Springs of New Zealand (about 60°); Teplitz (39°–49°); Vichy (32°); San Bernardino, California (40°–78°); etc. For an extensive bibliography on the different natural waters, see C. Doelter, *Handbuch der Mineralchemie*, Dresden, **3**. i, 889, 1918; and H. von Fehling, *Neues Handwörterbuch der Chemie*, Braunschweig, **11**. 745, 1915. For a bibliography of British mineral and chemical waters, see W. H. Dalton, *B. A. Rep.*, 859, 1888.

River water.—Spring water collects in rivers and streams. Of the total rainfall on all the land of the globe per annum—29347·4 cubic miles—J. Murray[3] estimates that the rivers of the world discharge about a quarter—or 6524 cubic miles—into the sea per annum. Rivers contain not only the dissolved and solid matters in suspension furnished by spring waters, but also organic matter derived from plants growing on the sides and bottom of the river, and also drainage from the villages and towns through which the river passes. The river, in virtue of its greater volume and force, carries along a considerable amount of suspended solids. River water also contains in solution matter dissolved from the land which it drains, and this the more the further the river is away from its source. Thus, the Irwell near its source has about 0·008 per cent. of dissolved solids, and at Manchester nearly 0·056 per cent. The waters of the Dee (Scotland), draining slate and sandstone rocks, contains about 0·0056 per cent. of solid matter, about one-fourth of this being calcium salts; the Thames, draining chalk rocks, contains about 0·03 per cent. of solid matter, two-thirds of which are calcium salts. F. W. Clarke estimates that 2,735,000,000 tons of solid matter in solution are annually carried to the ocean by rivers. This does not include suspended matter.

Sea-water.—Just as spring water flows into the rivers, the rivers flow into the sea carrying their dissolved salts, and suspended matters which have not been deposited in transit. Consequently, the salts in sea-water have probably been all derived from the land, and hence it has been said that sea-water holds the *débris* of ancient continents in solution. Indeed, attempts have been made to estimate the age of the sea from the time required for the accumulation of the salt it contains. For example, it has been estimated that the rivers of the world discharge some 160 million tons of salt into the sea every year, and that the seas hold in solution some 144 billion tons or 120 million tons per cubic mile, enough to cover the whole of the present dry land with salt to a depth of 400 ft. Consequently, if these estimates be somewhere near the mark, and if present conditions are not very different from those which prevailed in former times, it must have taken at least 90 million years to accumulate the amount of salt now present in the seas.[4] Estimates of the volume of the water of the ocean vary from 302,000,000 to 323,722,150 cubic miles.

The vapour which rises from the sea by evaporation is almost pure water; hence, unless the dissolved matters are continuously removed, sea-water must be gradually getting more and more salty. The sea in regions where there is a large rainfall has less soluble salts than elsewhere. Sea-water contains a relatively large proportion of soluble salts—the Atlantic contains from 3·301 to 3·737 per cent. of solids in solution. The composition of the dissolved solids in a number of lakes and seas is indicated in connection with NaCl. Where the evaporation is greatest we naturally expect to find the greatest proportion of salts in solution. The water on the surface, for example, usually contains more salt than water deeper down; similarly, the Mediterranean contains from 3·836 to 4·115 per cent. and the Indian Ocean from 3·553 to 3·668 per cent. of solids in solution; whereas the White Sea contains 2·598 to 2·965 per cent.; the Black Sea, 1·826 to 2·223 per cent.; and the Baltic, with its numerous fresh-water tributaries, and less evaporation, contains between 0·3 and 0·8 per cent. of solids in solution. Salts accumulate in land-locked or partially land-locked seas and lakes much faster than in the sea. In illustration, the Red Sea contains from 5·085 to 5·854 per cent. of solids in solution; Owens Lake (California), 7·2 per cent.; the Dead Sea contains 19·215 to 25·998 per cent.; the Great Salt Lake (Utah), 14·994 to 23·036 per cent.; the Caspian Sea, 12·67 to 28·50 per cent.; and the Elton Lake (Russia), 26·5 per cent. These masses of water behave as if they were exposed in a large evaporating basin, for the salts accumulate in the water and are deposited in crystalline masses on the shores of the lakes as the water evaporates. Average spring water contains ten times as much silica as sea-water. If all the salts in sea-water are derived from the land, it might be asked: Where have the silica and calcium salts gone? The deficiency is said to be adequately explained by the abstraction of these substances from sea-water by the marine animals and plants. Diatoms and sponges, for example, use silica to make their skeletons and shells; while corals and shell fish use calcium carbonate for making their skeletons and shells. It has been estimated that a single oyster requires the lime in about 50,000 times its weight of sea-water to make its shell. So that while fresh supplies of silica and lime salts are being continuously poured into the sea, the store is being steadily removed.

Potable and drinking water.—It is claimed that the natural waters in particular localities contain impurities specially favourable to certain industries, and conversely in other localities. Hence, "in the brewing of malt liquors," said T. Bergman (1778), "the baking of bread, the bleaching of linen, dyeing, the preparing of hides and skins, and in a number of other arts, the quality of the water employed is of no small consequence, that unless one be chosen fit for the purpose, the whole process fails." Potable water—that is, water fit for human consumption—is obtained principally from rivers and lakes, and also from wells—artesian and otherwise. The inorganic or mineral matters usually found in solution in natural water are not directly injurious to health. The purification of water for towns and cities is a very important practical problem for the chemist. The best process can be adopted only after a careful study of the local conditions, and the nature of the impurities. Water should be freed from pathogenic (disease-producing) bacteria, and from suspended impurities. This is generally done by filtration through large filter beds made from layers of sand and gravel, extending in some cases over an acre of ground. In special cases, a Pasteur-Chamberlain's bougie (candle), made of unglazed and porous earthenware, and shaped like a hollow candle, is arranged to screw on to the water tap. The water is forced through the earthenware by the pressure of the main and trickles through the aperture below. Bacteria, organic matter, etc., collect on the inside of the bougie as a slimy layer which clogs the filter. The bougie must be frequently cleaned or replaced (1) to permit the free passage of water; and (2) to remove the layer of slimy organic matter which serves as a medium for the growth of bacteria. In some cases the living organisms in water are killed by the addition of minute traces of poison—ozone, sodium hypochlorite, copper sulphate, etc. The salt last named also prevents the growth of green algæ which are sometimes very troublesome.

To maintain the purity of the water supply up to the proper standard, it is necessary to make (1) a periodical critical examination of the source from which the water is obtained; (2) regular bacteriological examinations for pathogenic germs; and (3) chemical examinations for nitrogenous organic matter—albumenoids, etc.—upon which bacteria feed; and for the products of bacterial life—free ammonia, ammonium nitrate, and nitrate. The presence of these substances in water throws it under suspicion.

§ 2. The Purification and Distillation of Water

Water is purified on a small scale by distillation. The water is boiled in a flask or boiler, and the steam is condensed back to the liquid condition by passage through a tube, about which a continual steam of cold water flows. To economize space, the condensing tube is generally coiled as a spiral—called the worm—and kept in a tank through which cold water continually flows. It might be added that the counter-current principle applied to condensers did not originate with J. von Liebig, but was employed by a French chemist in 1770, by C. Weigel in 1771, and by J. Gadolin.[1] The form of apparatus sometimes employed in the laboratory with the ordinary Liebig's condenser for distilling small quantities of liquid, is easily modified so as to prevent the steam coming in contact with rubber or cork stoppers, etc. —nothing but glass. The condenser is fitted to the distilling flask by ground joint; rubber or cork stoppers are not used. Much more compact condensing arrangements[2] are available with some of the more recent vertical condensers. The form illustrated in Fig. 1, for example, has been recommended for preparing water for bacteriological purposes. Water as free as possible from ammonia should be employed; river water is therefore objectionable. A small amount of volatile organic matter if present will be carried over with the first rush of steam, and soluble matters derived from the glass receiver and condenser may be found in the distillate. Tubes of quartz glass, block-tin, or silver for the condenser are better than glass, since the water acts very much more vigorously on glass than it does on quartz, tin, or silver. Distilled water which has been kept some time in a glass bottle cannot be used satisfactorily in the analysis of silicates, because it contaminates the silicate undergoing analysis with some of the constituents to be determined. In very special cases silver, gold, and platinum vessels have to be used as condensers and receivers. J. S. Stas[3] obtained water free from volatile organic matter by mixing 4 or 5 per cent. of potassium permanganate or manganate with the water in the boiler. Some potassium hydroxide was also added to keep the solution *très alcalin*. The distillate was mixed with aluminium sulphate, or with potassium or sodium hydrogen sulphate, and again distilled to eliminate ammonia, etc. G. A. Hulett recommended distilling the water twice—once after the addition of sulphuric acid and potassium permanganate; and the second time, after the addition of baryta water so as to get rid of carbon dioxide. According to W. R. Bousfield,[4] potassium hydrogen sulphate gives very satisfactory results in keeping back ammonia and traces of basic impurities; and according to

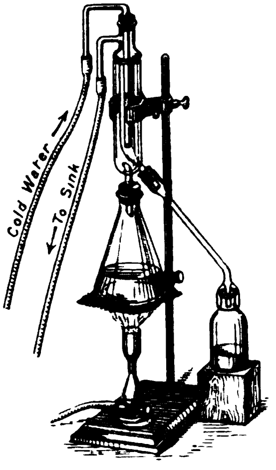

FIG. 1.—Distillation Apparatus

R. Bourdillon, phosphoric acid acts very much the same—about 0·5 per cent. of potassium hydrogen sulphate will suffice.

The purest water so far prepared has an electrical conductivity of $0{\cdot}043 \times 10^{-6}$ reciprocal ohms at 18°, and for ordinary conductivity experiments, **conductivity water**—water with a conductivity of 10^{-6} to 3×10^{-6} reciprocal ohms—is considered satisfactory. The former can be prepared only by distillation in vacuo, and it cannot be kept without absorbing impurities—carbon dioxide, ammonia, etc.—from the air, and these quickly increase the conductivity of the water. Thus, F. Kohlrausch and A. Heydweiller [5] found that a freshly prepared sample of water distilled in vacuo had a specific conductivity of $0{\cdot}05 \times 10^{-6}$ to $0{\cdot}11 \times 10^{-6}$; and after prolonged exposure to air, $0{\cdot}66 \times 10^{-6}$. Water which has been distilled in air always contains carbon dioxide, and F. Kohlrausch says that such water can be freed from much of this gas by passing through it a current of air which has been scrubbed in a tower of soda-lime. It is now usual to pass a stream of scrubbed air through the condenser in which the water is being condensed. The flask or bottle in which the conductivity water is stored should be made of good Jena glass; it should be fitted with a paraffined cork; it should be arranged with a stoppered syphon for draining off the water as required; and the air entering the bottle as the water is removed should pass through a tube packed with soda-lime.

§ 3. The Effect of Temperature and Pressure on the Volume of Water

> Not only in the matter of solutions, but in other more strictly physical relations, it is a misfortune that the *rôle* of a typical liquid was assigned to water.—G. F. STRADLING (1901).

Although at ordinary temperatures water is a clear limpid liquid, it forms a crystalline solid—ice—at temperatures below 0°, under atmospheric pressures, and it forms a gas—steam—at temperatures exceeding 100°. In 1803, J. Southern [1] made some measurements to determine how much water was required to furnish one cubic foot of steam at various pressures. A litre of liquid at 100° occupies 1696 litres when it is changed to saturated vapour; and at 0°, a litre of liquid forms 205,093 litres of saturated vapour. The great expansion experienced when water passes into steam has been suggested as a substitute for gunpowder for discharging projectiles; and in 1824, J. Perkins constructed a steam gun which gave results rivalling those obtained with gunpowder.

A. Winkelmann measured the relative density of water vapour, standing in equilibrium with the liquid, when the density of air is taken as unity:

Pressure	0·5	1·0	2·0	3·0	4·0 atm.
Temperature	81·7°	100·0°	120·6°	133·90°	144·0°
Density	0·63357	0·64026	0·64838	0·65400	0·65860

The theoretical density on the assumption that the molecular weight of water is 18·02 is 0·6224; the observed densities agree with the assumption that the molecular weight of water is between 18·33 and 19·06. This means that a small fraction of the molecules in water vapour are polymerized.

O. Knoblauch, R. Linde, and H. Klebe [2] have calculated the specific volume of water vapour, if it obeyed the ideal gas laws, to be

$$v_0=\frac{82{\cdot}1}{18{\cdot}016}\cdot\frac{760}{p}T$$

and the percentage deviations from the calculated (v_0) and observed (v) values, when p is constant, are

Temperature .	100°	110°	120°	130°	140°	150°	160°	170°	180°
v-v_0 . . .	1·6	2·0	2·5	3·1	3·5	4·5	5·1	6·0	6·8

The ice and water molecule theory of W. C. Rontgen.—The physical properties of water differ widely from those of most liquids, and the list of anomalous properties is a long one. In order to explain these, W. C. Röntgen (1891) [3] assumed that water is a mixture of two kinds of molecules which he called **ice molecules** and **water molecules.** The ice molecules were supposed to form a mass more complex but less dense than water molecules. Similarly, in I. Traube's theory of liquids, the existence of what he called *gasogenic molecules* and *liquidogenic molecules* is postulated. The former would be represented by steam molecules, and the latter by water molecules. If $(H_2O)_n$ represents the ice molecules, $(H_2O)_m$ the water molecules, and H_2O the steam molecules, then

$$\underset{\text{Ice mols.}}{m(H_2O)_n}\rightleftharpoons\underset{\text{Water mols.}}{n(H_2O)_m}\rightleftharpoons\underset{\text{Steam mols.}}{(m+n)H_2O}$$

Increase of temperature⟶ ⟵Decrease of temperature
Increase of pressure⟶ ⟵Decrease of pressure

The diminution in volume which occurs when ice changes into liquid water corresponds with the passage of ice into water molecules, because the ice molecules have the less density and occupy a greater volume than the sum of the volumes of the corresponding water molecules.

The following hypotheses enable most of the so-called abnormal properties of water to be explained: (1) Liquid water contains at least two kinds of molecules—respectively called ice molecules and water molecules; (2) Low temperatures favour the accumulation of ice molecules; (3) High pressures favour the accumulation of water molecules; pressure dissociates the more complex molecules; and the greater the pressure, the less the proportion of ice molecules in the liquid; (4) The passage of ice into water molecules is accompanied by a contraction, and conversely; (5) The passage of ice into water molecules absorbs heat and is therefore said to be an endothermal reaction, and conversely for the reverse change; (6) In spite of the heterogeneous character of liquid water, this liquid freezes at a constant temperature because there is a definite equilibrium concentration for each molecular species at each temperature; and (7) The proportion of ice molecules in the liquid is reduced when a salt is dissolved therein. The anomalous properties of water are thus referred to the presence of special kinds of molecules in liquid and solid water; these molecules, too, are invested with special properties to fit the facts. This is a dangerous method of investigation, but there is an overwhelming mass of evidence to justify the procedure.

There is a definite equilibrium concentration between the ice molecules and the water molecules at each temperature, and C. S. Hudson [4] represents this by the curve *C*, Fig. 2; the solubility of the ice molecules will also vary with temperature, as represented by the curve *S′*, Fig. 2. Above the freezing temperature, the solubility of the ice molecules in the water molecules is greater than the equilibrium concentration and the solution is not saturated; at temperatures below the freezing point the liquid is supersaturated with ice molecules and the water can freeze; at the freezing point, the equilibrium concentration of the ice molecules is equal to their solubility. The addition of soluble salts to the liquid lowers the equilibrium concentration and solubility of the ice molecules, and thus lowers the maximum density and freezing point of the liquid.

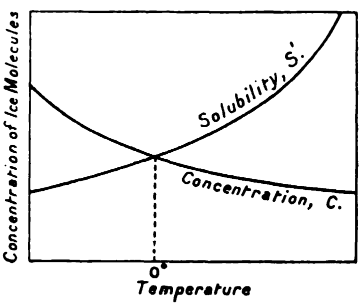

Fig. 2.—Equilibrium Concentration and Solubility of Ice Molecules at Different Temperatures (Diagrammatic).

The thermal expansion of water.—It was known to the Arabian writer Al-Khazini in the twelfth century that water contracted when cooled, and expanded when heated, and that ice was specifically lighter than water. His measurements were so accurate that they are quite in accord with those adopted at the present day. He found ice to have a specific gravity of 0·965, and hot water 0·958 when water at ordinary temperatures is taken as unity. G. Galilei also discussed the expansion which occurs when water is heated, and the contraction which occurs when water is cooled.

The coefficient of thermal expansion α, or $(dv/dt)_p/v$—that is, the increase in volume per unit volume per degree rise of temperature at a constant pressure—of water, and of a few other liquids for comparison, is

	Water.	Mercury.	Sulphuric acid.	Alcohol.	Ether.	Benzene.	CS_2.
α . . .	0·00048	0·00018	0·00063	0·00113	0·00155	0·00125	0·00119

The coefficient increases with a rise of temperature. J. Meyer found for water,

	20°	40°	60°	100°	140°	180°	200°
α . . .	0·000110	0·000217	0·000305	0·000452	0·000584	0·000722	0·000788

These numbers agree with the values of G. A. Hirn, and G. Tammann and K. Zepernick between 100° and 143°. The observed expansion of water with rise of temperature is assumed to be the joint effect of (*a*) a decrease in volume due to the change of ice into water molecules; and (*b*) the normal expansion due to the further separation of the molecules. The higher the temperature the less the proportion of ice molecules to be changed into water molecules, and the thermal expansion becomes proportionally greater.

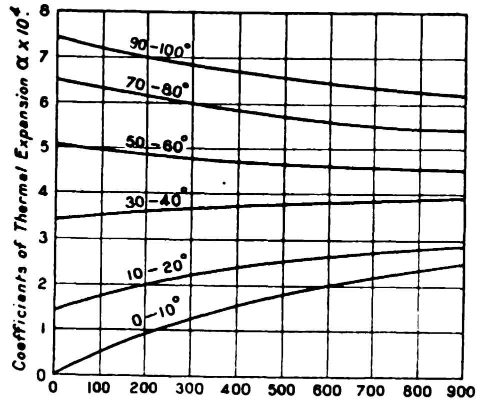

Fig. 3.—Coefficients of Thermal Expansion of Water at Different Temperatures and Pressures.

Excluding water, the coefficients of thermal expansion of about eleven liquids—including alcohol, carbon sulphide, etc.—which have been tried, diminish the higher the pressure. For example, E. H. Amagat (1893)[5] found the following values for the coefficient of expansion of ether ($\times 10^6$) at different temperatures and pressures:

Pressure (atmospheres) . .	50	100	200	600	800	1000
$\alpha \times 10^6$ from 0° to 20° . .	1511	1445	1319	1045	958	900
$\alpha \times 10^6$ from 138° to 198° .	—	—	2156	1165	1008	890

With water, E. H. Amagat found that the coefficient of thermal expansion at a constant temperature for temperatures up to 50° increases with increasing pressures as indicated in the first five vertical columns of Table I; about 50°, the reverse obtains, for the coefficient of expansion decreases with an increase of pressure, and water then behaves like other liquids which have been tried. Consequently, *water behaves like a normal liquid at temperatures exceeding* 50°. E. H. Amagat's and F. Auerbach's values for the effect of pressure on the mean coefficient of thermal expansion of water are illustrated by Fig. 3. The horizontal lines, Table I, represent the coefficient of thermal expansion at different temperatures when the pressure is constant. Up to a pressure of 3000 atm., the coefficient steadily increases as the temperature rises, no matter what be the pressure provided it be constant. E. H. Amagat's and G. Tammann's results for the effect of pressure on the volume of water at different temperatures are illustrated in Fig. 4—volumes are denoted by ordinates, temperatures by abscissæ

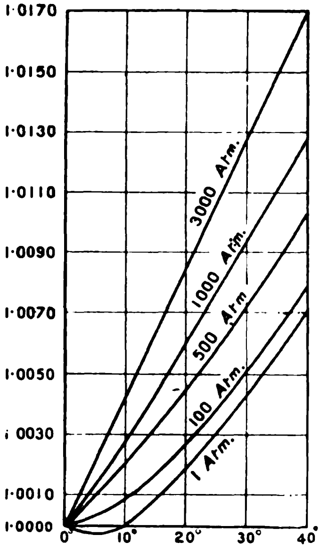

Fig. 4.—The Effect of Pressure on the Volume of Water at Different Temperatures.

J. H. Vincent found the linear coefficient of expansion of ice between —10° and 0° to be 0·0000507 ; and J. Dewar found the mean coefficient of expansion of ice between 0° and —188·7° to be 0·00008099—about a quarter of the value between 0° and 10°, and half the value between 4° and 100°.

The Florentine Academicians discovered in 1670, that there is a certain temperature at which liquid water possesses a maximum density, but the temperature at which water acquires this state was not determined with any degree of precision until J. A. Deluc[6] noticed that the anomaly obtained when water is used as a liquid in thermometers corresponds with 5° as the temperature of maximum density. Count Rumford (1805), J. G. Tralles (1807), G. C. Hällström (1827), and C. M. Despretz (1836) made careful measurements of this constant, and the more recent work of P. Chappius (1897) and L. C. de Coppet (1904) gives numbers ranging from 3·980° to 3·983° for the **temperature of maximum density of water;** while, according to J. D. van der Waals, the temperature of maximum density is 4·18° in vacuo, and 4·08° under the normal pressure of one atmosphere. E. H. Amagat found the temperature of maximum density was lowered to 3·3° by a pressure of 41·6 atm., to 2·0° by a pressure of 93·3 atm., and to 0·6° by a pressure of 144·9° atm. According to S. Lussana, the temperature of maximum density is lowered to 4·10—0·0225(p—1), by a pressure of p atm.

Table I.—The Coefficient of Thermal Expansion of Water at Pressures ranging from 1 to 3000 Atm.

Pressure in atmospheres.	Mean coefficient of thermal expansion × 10^6.									
	0°-10°.	10°-20°.	20°-30°.	30°-40°.	40°-50°.	50°-60°.	60°-70°.	70°-80°.	80°-90°.	90°-100°.
1	14	149	267	334	422	490	556	—	—	—

1000	259	293	343	396	437	474	512	554	581	610
2000	364	356	416	423	469	—	—	—	—	—
3000	391	420	433	440	469	—	—	—	—	—

The water molecules *en masse* have a relatively greater density than ice molecules, and hence occupy a smaller volume. During the melting of ice, however, only a certain fraction of the ice molecules are changed into water molecules, and the resulting liquid is a solution of ice molecules in water molecules. Any further application of heat results in (*a*) a decrease in volume arising from the transformation of the ice into water molecules; and (*b*) an increase in volume due to the joint thermal expansion of both the ice and water molecules. The observed effect is the difference between these two opposite effects. In passing from 0° to 4°, the expansion due to the thermal expansion is masked by the contraction due to the breaking down of a definite proportion of the ice molecules; from 4° upwards, thermal expansion overbalances the contraction due to the changing molecules; while at about 4°, the two effects just balance one another. The temperature of the maximum density of water is reduced by increasing the pressure, because the proportion of ice molecules in water is reduced.

C. M. Despretz's study of the effect of salt solutions on the temperature of maximum density led him to the conclusion that *the lowering of the temperature of the point of maximum density of water caused by the addition of a soluble salt is directly proportional to the concentration of the solute.* F. Rosetti did not succeed in finding any definite relation between the lowering of the temperature of maximum density and the lowering of the freezing point produced by a dissolved salt, for although a definite ratio was obtained for a given solute at different concentrations, a different ratio was obtained with a second solute. Consequently, while the lowering of the freezing point depends only on the concentration of the solute, *the lowering of the temperature of maximum density depends on the nature as well as on the concentration of the solute.* L. C. de Coppet noticed that for solutions of salts of a given family of metals, the lowering of the temperature of maximum density is sensibly the same for a given acid radicle. Each acidic and each basic radicle produces its own effect, and the joint effect is the sum of the separate effects. R. Wright has established a similar rule for the salts of the dibasic acids, and the salts of the alkaline earths.

TABLE II.—THE VOLUME OF WATER BETWEEN —10° AND 320° (VOLUME AT 4° UNITY).

The variation of the volume of water with temperature has been the subject of researches extending from the beginning of the nineteenth century up to the present time. The more recent determinations are due to K. Scheel (1892),[7] W. Kreitling (1892), P. Chappius (1897), and to M. Thiesen, K. Scheel, and H. Dieselhorst (1900) of the Physikalisch Technischen Reichsanstalt. The results obtained by the latter, between 0° and 40°, are indicated in Tables II and III. The numbers in the sixth and seventh decimal places are deleted, and the fifth decimal raised one unit when the deleted figures exceed 50. The data from 40° to 100° are by M. Thiesen (1904); those from 0° to —10° are mean values of data by J. J. Pierre (1845), H. Weidner (1866), and F. Rosetti (1871); and those from 100° to 320° are mean values from measurements by W. Ramsay and S. Young (1893), J. J. Waterston (1863), and G. A. Hirn (1867).

TABLE III.—THE SPECIFIC GRAVITY OF WATER BETWEEN —10° AND 320° (SPECIFIC GRAVITY AT 4° UNITY).

Temperature θ	Specific gravity at θ° when the specific gravity at 4° is unity.

10×3	70	68	66	—	—	—	—	-	—	—

The volume v of water for a temperature θ between 0° and 33° can be represented by K. Scheel's formula $v=v_0\ (1-0{\cdot}46427\theta+0{\cdot}0585053\theta^2-0{\cdot}0_7 67898\theta^3+0{\cdot}0_9 50024\theta^4)$. The coefficient of expansion of ice is 0 04375. J. Duclaux assumed that the expansion of water for temperatures between —10° and 150° is a composite effect of two opposing forces: (1) the relation between the temperature and the expansion of a liquid constituted of simple molecules which can be represented by a parabolic formula $a+b\theta+c\theta^2$; and (ii) the increase in the volume due to the polymerization of the constituent molecules whereby the volume of the liquid becomes specifically greater as the number of polymerized molecules increases on the falling temperature. Assuming that the expansion is almost proportional to the number of polymerized molecules, it can be represented by Kn/T, where K and n are constant, and T is the absolute temperature. Consequently, the observed expansion is the sum of the two separate effects. The constants a, b, c, n, and k can be evaluated from M. Thiesen, K. Scheel, and H. Dieselhorst's data, so that the volume v of the water at θ°, when $T=273+\theta$, is

$$v=0{\cdot}991833+0{\cdot}000225208\theta+0{\cdot}0000028447 5\theta^2+\frac{0{\cdot}061695711}{273+\theta}$$

A. Hess found the specific volume of ice at 0° to be 1·0236; and J. Dewar calculates that at absolute zero, the specific volume of ice will be 0·9584.

M. Thiesen (1904) represented the relation between the specific gravity D of water and the temperature θ, between 25° and 100°, by the empirical formula:

$$D=1-\frac{(\theta-3{\cdot}982)^2}{466{,}700}\cdot\frac{(\theta+273)\ (350-\theta)}{(\theta+67)\ (365-\theta)}$$

while M. Thiesen, K. Scheel, and H. Dieselhorst have modified an older formula of D. I. Mendeléeff, and have represented the specific gravity of water by the expression:

$$D=1-\frac{(\theta-4)^2}{118{,}932+1366\cdot75\theta-4\cdot13\theta^2}$$

for temperatures between 0° and 30°. If the water contains air in solution, its specific gravity is reduced; but above 20°, the effect is negligibly small; the difference rises steadily from 0·0000025 at 0° to a maximum 0·0000034 at 8°, and then steadily falls to 0·0000004 at 20°.

Both H. Kopp and I. Traube[8] have shown that the **molecular volumes** of liquids—that is, the molecular weights divided by the respective specific gravities—are additive properties in that they can be represented as the sum of the molecular volumes of their components, and the results computed on this assumption agree with the observed values. Water is exceptional in that the observed molecular volume is larger than the computed result; it is therefore inferred that the molecular weight is larger than that represented by the simple formula H_2O, and I. Traube has shown that a molecule corresponding with $(H_2O)_3$ or H_6O_3 gives a better agreement between theory and observation. According to D. Berthelot, the molecular v of a liquid at the absolute temperature T is related with the critical temperature T_c and critical pressure P_c (atm.) by the expression $v=11\cdot4\,T_c/P_c(2T_c-T)$. When applied to water at 16°, the molecular volume appears to be 25 in place of 18; hence, the molecule is more condensed than corresponds with the formula H_2O.

The curve, Fig. 7, was obtained by plotting the volume of a given mass of water at different temperatures; it shows that water above 4°, like most liquids, expands when heated and contracts when cooled; but for temperatures below 4° the curve is abnormal, for the water expands when cooled, and contracts when heated. If the specific gravity of water at 4° be taken as unity, it follows that water becomes specifically lighter when the temperature is raised or lowered beyond this point. The temperature of maximum density of water, 4°, is often taken as a standard, or unit of reference for specific gravity, etc.

The expansion of water when cooled from 4° to 0° is very small, but that minute quantity has a very important bearing in nature. When the water on the surface of, say, a lake is cooled, it contracts. The heavier cold water sinks, and the warm water rises. This circulation cools the temperature of the whole body of water down to 4°; any further cooling results in the formation of specifically lighter water. Accordingly, this remains on the surface, and circulation ceases. Finally, as a result of this remarkable and abnormal property, when the temperature of the atmosphere falls to 0°, a surface film of ice is formed. *Ground ice* or *anchor ice* may be formed at the bottom of the more shallow rapidly moving streams when the cooling water is thoroughly mixed, and not allowed to settle in layers. If the water did not expand as the temperature falls to 0°, the whole body of water would freeze from below upwards and produce profound climatic changes, since the larger amount of ice formed in winter would materially affect the temperature for the rest of the year. The remarks do not apply to salt (sea) water which contracts as the temperature is lowered down to the freezing point, but sea water shows a temperature of maximum density at −3·21°. Indeed, C. M. Despretz (1839) showed that the temperature of maximum density of salt (sodium chloride) solutions is lowered almost proportionally with the amount of salt in solution; thus,

Per cent. sodium chloride . . .	0	0·05	0·1	0·4	0·8
Temperature maximum density . .	4°	3°	1·8°	−5·6°	−16·6°

Similar results have been obtained with other salts, and S. Lussana (1895) has shown that the effect of an increasing pressure is to still further reduce the temperature of maximum density. Thus, with solutions containing 0·5 per cent. of sodium chloride, the temperature of maximum density is $3\cdot35-0\cdot0177(p-1)$, where p

denotes the pressure in atmospheres ; and with 1·44 per cent. solutions of the same salt, the temperature of maximum density is $0·77-0·011(p-1)$.

In the act of freezing, water expands so that 100 c.c. of liquid water at 0° gives approximately 110 c.c. of ice at the same temperature. In 1665, Robert Boyle[10] found the specific gravity of ice to be 0·903 because he observed that the volume of water on freezing expanded 11·12 per cent. This result has no pretension to exactitude because of the uncorrected errors due (i) to strains in the containing glass during freezing ; (ii) to the probable presence of minute cracks in the artificially frozen ice ; and (iii) to the presence of varying amounts of dissolved gases. Similar remarks apply to the early determinations indicated by L. Playfair and J. P. Joule, who found a mean value of 0·9184. A more accurate determination was made by C. Brunner (1845), who found the specific gravity of ice at 0° is 0·9180 ±0·000039 ; G. Duvernoy gave 0·922 ; R. Bunsen (1870) gave 0·9165±0·00003 ; A. Leduc (1906), 0·9176. J. Plücker obtained 0·91580±0·000008 ; H. Kopp's not very exact value (1855) is 0·907 ±0·0007 ; L. Dufour's value (1860) is 0·9178±0·0005 ; J. von Zakrzewsky's (1892), 0·916710 at −0·7°. E. L. Nichols (1899) emphasized the difference of the order of 1 or 2 parts in 1000 in the results obtained between artificial ice 0·91615 and natural ice 0·91807. This does not mean that the two forms of ice are different, but that the differences are due to strains set up in the artificial ice in the act of freezing ; E. L. Nichols believes that these disappear in time, and the specific gravity then attains its final value. In 1901, H. T. Barnes and H. L. Cooke found the specific gravity of natural ice from the St. Lawrence river to be 0·91661±0·00007 ; J. H. Vincent (1902) obtained 0·9160. According to J. Dewar, the specific gravity of ice at −188·7° is 0·92999 ; and he calculates that at absolute zero, the specific gravity would be 0·9368 so that ice can never be cooled until it has the same specific gravity as water has at 100°.

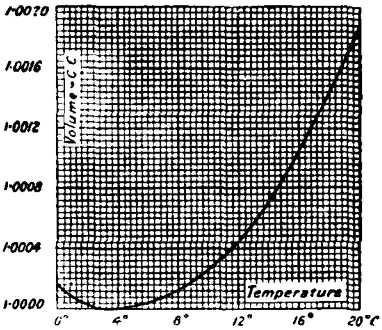

FIG. 5.—Relations between the Volume and Temperature of Water.

The specific gravity of ice at 0° varies with its mode of formation from 0·9159 to 0·9182 ; the specific gravity of water at 0° is 0·999867. Accordingly, ice floats on the surface of water. The expansion of water during freezing is an important factor. The expansion may burst the intercellular tissue of plants by freezing the cell-sap ; the expansion may disrupt the fibres of flesh, so that the frozen meat appears rather more pulpy than ordinary meat. If water freezes in pipes, the expansion of water in the act of freezing may burst the pipe, and water will leak when the ice thaws ; water freezing in the surface crevices of rocks, splits and widens the fissures so that the surface crust of the rock appears to disintegrate during a thaw. The *débris* collects as *talus* at the foot of the rocks, ready to be transported by water to lower levels. Hence this simple force plays an important part in the weathering and decay of rocks, building stones, etc., in countries exposed to alternate frost and thaw ; and, adds J. Tyndall : "The records of geology are mainly the history of the work of water."

In an old experiment of Rumford's usually cited to illustrate the low thermal conductivity of water a piece of ice was weighted to keep it at the bottom of a cylinder of water. It was then possible to boil the water by heating the cylinder near the top, and this without melting the ice. The experiment further illustrates what would happen if water did not exhibit the anomalous expansion on freezing. Instead of the ice being buoyed up to the surface it would sink to the bottom of lakes, etc. The warmer water would remain on the surface in summer so that the ice would increase in winter and persist in summer until a great portion of the water on the surface of the earth would be permanently frozen. As it is, the temperature at the bottom of a body of fresh water cannot get below the temperature of maximum density, for if the water be cooled further it rises to the surface and is there frozen. The ice thus hinders the further cooling of the water which remains in the liquid state.

The change in volume of water with increasing temperatures above 40° is represented by a curve concave towards the temperature axis, while with salt solutions this curve is flatter, approximating to a straight line with highly concentrated solutions. The curves for solution and solvent thus cross each other as illustrated in Fig. 6. According to P. de Heen,[11] for lithium, sodium, potassium, and ammonium chlorides the points of intersection are respectively 30°, 55°, 50°, and 35°; for calcium, barium, magnesium, and aluminium chlorides, respectively 45°, 50°, 35°, and 37°; for sodium and potassium sulphates, 60°; for sodium and potassium carbonates, respectively 67° and 65°; and for potassium and ammonium nitrates, 70°.

The compressibility of water.—In 1620, Francis Bacon subjected water to pressure, by squeezing it in a lead sphere; the water passed through the pores of the metal. The Florentine Academicians tried a similar experiment with a gold vessel in 1667, and came to the conclusion that water is incompressible. J. Canton,[12] in 1762, was probably the first to establish the compressibility of rain-water, sea-water, mercury, spirit of wine, and oil of cloves; and, in 1764, he showed that the compressibility decreases as the temperature is raised. J. Perkins, in 1826, also showed that the compressibility decreases as the pressure is increased—quickly at first, and afterwards more slowly. Experiments on this subject were made by H. C. Oersted (1822), D. Colladon (1827), and by H. V. Regnault (1848), and have been continued from that time to the present day.

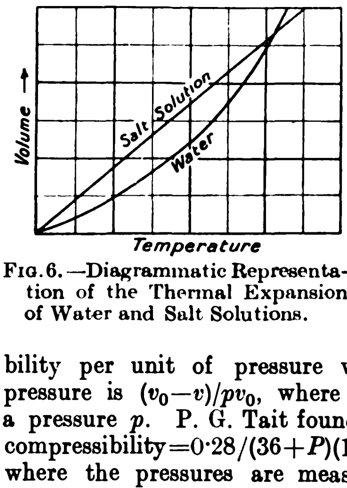

FIG. 6.—Diagrammatic Representation of the Thermal Expansion of Water and Salt Solutions.

The compressibility of a liquid is the fractional change in volume, dv/v, which occurs per unit change of pressure. The **coefficient of compressibility,** $\beta=-dv/vdp$, is numerically equal to the decrease in volume per unit volume produced by unit change of pressure. The average compressibility per unit of pressure which occurs on the application of p units of pressure is $(v_0-v)/pv_0$, where v_0 is the initial volume, and v the volume at a pressure p. P. G. Tait found for fresh water the empirical formula: Average compressibility$=0·28/(36+P)(150+\theta)$. Some results are shown in Table IV where the pressures are measured in tons per sq. in., showing that the compressibility decreases: (*a*) with an increase of pressure; (*b*) with a rise of temperature; and (*c*) when the water has salts in solution—the ratio of the compressibility of sea water and fresh water is nearly 0·92. The coefficient of compressibility of water per atmosphere, near 0°, is given in the following table with that of a few other liquids for comparison:

Water.	Mercury.	Alcohol.	Ether.	Benzene.	Carbon disulphide.
0·000050	0·0000038	0·000093	0·000164	0·000085	0·000078

T. W. Richards and his co-workers find a compressibility of $42·1\times10^{-6}$ at 20° between 100 and 500 megabars; $43·3\times10^{-6}$ between 100 and 300 megabars; and $40·9\times10^{-6}$ between 300 and 500 megabars. G. A. Hulett and T. Peczalsky have also measured the compressibility of water. Liquids in general are but slightly compressible. The volume of water is reduced but 0·00005th part of its volume per atmosphere pressure at 0°. According to P. G. Tait,[13] this small compressibility means that if sea-water were quite incompressible the average level of the sea-water would be raised 116 feet higher than it is to-day, and about 4 per cent. of the present land surface would be submerged. The compressibility of liquids, including water, decreases with rising pressure, temperature constant; because the compressibility decreases faster than the volume. The compressibility of liquids other than water increases with rise of temperature, that is, the thermal expansion decreases with rise of pressure as shown by the vertical column, Table V, for water above 50°. This is the behaviour which would be expected from a liquid composed of particles of constant volume, but separated by spaces which can be changed in size by pressure and temperature. With water the compressibility first decreases with a rise of temperature up to about 50°. This is shown by the vertical columns in Table V below 50°—at a higher temperature, the compressibility of water increases with rise of temperature as is the case with other liquids. The minimum temperature is but slightly affected by a change of pressure, but it becomes less and less pronounced with a rise of pressure until it has almost disappeared at a pressure of 3000 kilograms per sq. cm. Again, according to E. H. Amagat (1877), the compressibility of ether at 13·7° under 11 atmospheres pressure is 0·000168, and at 100°, 0·00056 of its volume per atmosphere. With water, the reverse obtains, and the compressibility falls to a minimum at about 63°, and then increases. Thus, C. Pagliani and G. Vicentini (1884)

TABLE IV.—COMPRESSIBILITY OF WATER.

Temperature	Fresh water.			Sea-water.		
	1 ton.	2 tons.	3 tons	1 ton.	2 tons.	3 tons.

10000	—	—	—	—	—	—	—	—	8046	8050

found the coefficient of compressibility, β, of water, per atmosphere, at different temperatures :

Temperature	0°	2·4°	49·3°	66·2°	77·4°	99·2°
$\beta \times 10^7$	503	496	403	389	398	409

The inversion at about 60° is supposed to be the joint effect of (*a*) the diminution which attends the passage of ice into water molecules, and (*b*) that due to the squeezing of the molecules together. The higher the temperature the less the disturbance arising from the former ; at about 63°, it becomes negligibly small. Under very great compression, E. H. Amagat (1891) found that water behaves like a normal liquid, showing that under great pressures virtually all the ice molecules are probably transformed into molecules of one kind. Hence, as indicated above, the temperature of maximum density of water is lower the greater the pressure. Under great pressures, too, ice can be melted, because pressures prevent the formation of or depolymerizes the ice molecules. At still greater pressures further complications arise. The compressibility at different pressures, expressed in kilograms per sq. cm. at 0° and 22°, found by P. W. Bridgman, are :

Pressure . .	500	1000	2000	4000	6000	7000	11,000
Compressibility at 0° .	0·0224	0·0414	0·0735	0·1195	0·1520	0·1644	—
Compressibility at 22° .	—	0·0383	0·0679	0·1137	0·1465	0·1600	0·2042

The disturbances have been traced by G. Tammann and P. W. Bridgman to the transformation of ordinary ice into a number of different allotropic forms.

Table V, showing the volume water at different temperatures and pressures, was compiled by P. W. Bridgman in an important memoir : *Water, in the liquid and five solid forms, under pressure* (1912). Some results are plotted in Fig. 7. The pressure and volume at 0° are indicated on each curve. Each curve is drawn to scale, but, for the sake of compactness, the curves for the different pressures have been brought together, otherwise the curves would have been about ten times their present distance apart. Up to 3000 kilograms pressure, the expansion at 0° is increased with a rise of pressure ; but at higher pressures, the expansion decreases with rising pressure. There thus appears to be a maximum in the curve between 0° and 20°. The relation between the temperature and volume of a given mass of a normal liquid at a constant temperature is illustrated by the curve *A*, Fig. 8, where the expansion is greater the higher the temperature. With an abnormal liquid like water, after passing the minimum at the temperature of maximum density, it might be expected that there would be a limit to the increase in volume with decreasing temperatures when all the water molecules have been converted into ice molecules ; and the liquid might be expected to behave in a normal manner and decrease in volume with a fall of temperature. The volume temperature curve *B*, Fig. 8, would represent the behaviour of such a liquid. With water, the exploration is prevented by freezing, but such a curve has been actually realized by P. W. Bridgman with water under a constant pressure of 1500 kilograms per sq. cm.—Fig. 8.

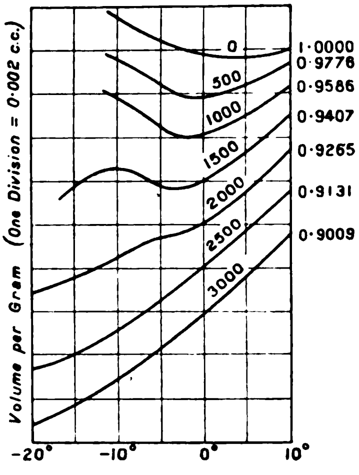

Fig. 7.—Relation between Temperature and Volume of Liquid Water at various constant Pressures.

According to O. Tumlirz (1909),[14] the data obtained by E. H. Amagat for the relation between the pressure p and volume v of liquids at the absolute temperature T, can be represented by the equation $(p+\mathrm{P})(v-b)=RT$, where R and b are constants for any given substance, and P, the internal pressure, is a function of temperature only, and is evaluated from the experimental data. The results apply very well for pressures up to 3000 kilograms per sq. cm., but not so well for P. W. Bridgman's results up to 10,000 kilograms per sq. cm. The values given by the formula for the compressibility become small too rapidly at high pressures, so that the observed compressibility remains larger than the values calculated by O. Tumlirz's formula valid at lower pressures. One possibility is that b is not constant, and that the molecules themselves are compressible, apart altogether from the closing up of the intermolecular spaces. D. Tyrer compared the coefficients of isothermal and of adiabatic compressibilities of water between 1 and 2 atm. pressure, and found at 0°, 70°, and 100°, the former to be respectively $502{\cdot}8\times10^{-7}$, $452{\cdot}9\times10^{-7}$, and $418{\cdot}8\times10^{-7}$, and the latter respectively $502{\cdot}5\times10^{-7}$, $424{\cdot}5\times10^{-7}$, $429{\cdot}0\times10^{-7}$. If β be the ordinary isothermal compressibility, *i.e.*—dv/vdp, and a the adiabatic compressibility, C_p the specific heat at constant pressure, v the specific volume, T the absolute temperature,

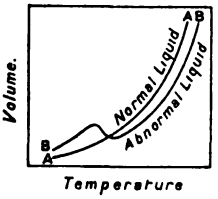

FIG. 8.—Volume Temperature Curves of Liquids.

$$a=\beta-\left(\frac{T}{vC_p}\frac{dv}{dT}\right)^2$$

T. W. Richards and C. L. Speyers find the compressibility of ice between 100 and 500 megabars, at —7·03°, to be 0·000012, that is, about one-fourth the compressibility of water at a neighbouring temperature. K. R. Koch found the elastic modulus of ice to be 626 kilograms per sq. cm.

According to W. C. Röntgen and J. Schneider, and M. Schumann (1887),[15] the coefficient of compressibility, β, of aqueous solutions of salts is less than that of water, and this the more the more concentrated the solution. Thus, with solutions of potassium chloride,

Per cent. potassium chloride . .	0	2·52	5·35	10·68	16·81
$\beta\times10^7$	500	481	424	400	354

The facts are explained by the assumption that the proportion of ice molecules is less in aqueous solutions than in pure water. W. C. Röntgen and J. Schneider could not confirm M. Schumann's observation that the compressibilities of aqueous solutions of potassium, calcium, ammonium, and strontium chlorides are greater than that of water, for they always found a lower compressibility with these solutions than with water. G. de Metz also found that cane sugar also diminishes the compressibility of aqueous solutions in a similar manner; and T. W. Richards and S. Palitzsch, that the compressibility of aqueous solutions of urethane at 20° rapidly decrease with increasing concentration from $42{\cdot}25\times10^{-5}$ for pure water to $38{\cdot}91\times10^{-6}$ with 39·4 per cent. solutions; the compressibility then increases at first slowly and then rapidly with increasing concentration. The results agree in showing that the first effect of dissolving anything in water is to dissociate the ice molecules; increasing the pressure or temperature acts in the same direction. With normal liquids there is an increase in the compressibility with increasing concentration. K. Drucker found that the compressibility of aqueous solutions of organic acids likewise show a minimum in the compressibility curve. The compressibility coefficient of solutions of salts in water usually increases as the temperature rises. According to J. Guinchant (1901), with pressures up to 4 atm. the volume of the dissolved substance does not change; the observed change is solely due to the medium.

The tensile strength of liquids.—About 1850, M. Berthelot[16] filled a glass tube nearly full of liquid, removed the air, sealed the tube, heated the tube until the liquid almost filled the interior, and allowed the whole to cool slowly to the ordinary temperature. The liquid continued to fill the tube so that the volume of water was $\frac{1}{420}$th larger than it should be for the given temperature; with alcohol the volume was $\frac{1}{93}$rd and ether $\frac{1}{50}$th larger. This represents the **tensile strength of water** to be 50 atm., and over 100 atm. in the case of alcohol and ether. R. H. Worthington found 17 atm. for the breaking strain of alcohol. J. Stefan and O. Tumlirz calculated a strength of about 2000 atm. for alcohol on the assumption that the internal pressure is a measure of the theoretical tensile strength. H. M. Budgett found a breaking strength for water of nearly 900 lbs. per sq. in., or about 60 atm. O. Reynolds recorded the fact that when a liquid is flowing through a pipe with a constriction, the velocity may be so high that the corresponding diminished pressure of the liquid is sufficient to break it. He regarded the effect as a boiling of the liquid under diminished pressure. S. Skinner and F. Entwistle regard the phenomenon in the constricted tube as a true tensile rupture produced in the moving liquid, and in their study of the effect of temperature on the rupture of water flowing through constricted tubes, they found indications that the tensile strength of water becomes zero at about 320°, a temperature approaching the critical point of water, and by forcing the liquid through a capillary constriction until the speed in the capillary is sufficient to produce rupture, they found that the tensile strength becomes zero in the neighbourhood of 245°. J. Larmor found that if J. D. van der Waals' equation holds in the liquid state, a negative pressure can subsist only at $\frac{27}{32}$nd of the absolute critical temperature, meaning that the tensile strength could subsist up to 538° K. or 265°.

§ 4. The Vapour Pressure of Water—Fusion and Boiling

> So long as a body retains its normal state of aggregation and properties we can observe an increase of temperature corresponding with an increase in molecular energy, but as soon as the destruction of form begins to take place, the increase of temperature no longer becomes sensible and the energy is directed to breaking up the structure of the body and to keeping its molecules apart. When this has been accomplished, and not till then, the additional energy imparted again produces accelerated motion, and the substance gets hotter and hotter.—W. ANDERSON (1887).

When a liquid evaporates in an open space, there is apparently a continual flow of the molecules from the surface of the liquid into the space outside, and evaporation proceeds at a steady rate, as long as the significant conditions remain constant. The vapour pressure of water in the atmosphere varies because a state of equilibrium has not been attained between the water and the atmosphere. Water is therefore evaporating slowly, and K. Jablezynsky and S. Przemysky [1] have emphasized that the rate of evaporation is a slow process of diffusion from the layers in the immediate vicinity of the water which are saturated with vapour to the surrounding atmosphere; but, in consequence of secondary disturbances, the water never attains a state of equilibrium with the atmosphere.

The conditions which favour rapid evaporation are important to the chemical engineer because so many operations on a large and on a small scale are dependent on this process. John Dalton made a first approximation to the laws of evaporation in 1803; he said:

> Some liquids evaporate much more quickly than others. The quantity evaporated is in direct proportion to the surface exposed when all other circumstances are alike. An increase in the temperature of the liquid is attended with an increase of evaporation, not directly proportional. Evaporation is greater where there is a stream of air than where the air is stagnant. Evaporation from water is greater the less the humidity previously existing in the atmosphere when all other circumstances are the same.

The speed of evaporation depends on: (i) *The nature of the liquid.* B. G. Babington showed that the speed of evaporation of solutions of many salts is less than for water, and this the more the greater the concentration. Sea-water, for example, evaporates approximately 5 per cent. slower than fresh water under similar conditions. (ii) *The temperature of the liquid and that of the surrounding air;* the rate of evaporation of water increases roughly with temperature, and it is roughly proportional to the saturation pressure at that temperature when the general humidity of the air is low. If the water surface be colder than the dew-point temperature, evaporation is negative and condensation begins. (iii) *The pressure of the atmosphere.* The presence of one gas retards the diffusion of other gas molecules of like or different nature; consequently, when the vapour pressure is comparatively small, the rate of evaporation varies nearly inversely as the total barometric pressure. (iv) *The hygrometric state of the air.* As a first approximation, the rate of evaporation is directly proportional to the difference of the temperature of the wet and dry bulb hygrometers. (v) *The rate at which the vapour is removed from the surface of the liquid.* The speed of evaporation increases as the velocity of the wind, but the exact rate is not certain. D. J. Fitzgerald finds the rate of evaporation is approximately represented by $\frac{1}{60}(p_1-p_0)(1+\frac{1}{2}/w)$ inches per hour, where w represents the velocity of the wind in miles per hour. (vi) *The area of the evaporating surface.* The rate of evaporation increases as the area of the evaporating surface, but not necessarily at the same rate. John Dalton supposed the rates were proportional, but with a circular area in still air, the speed of evaporation increases approximately as the square root of the surface area.

The relation between the rate of evaporation of a liquid from a circular area of radius r and the pressure of the gas when P denotes the barometric pressure, that is, the total pressure of gas and vapour; and p_1, the vapour pressure of the liquid at the evaporating surface or the saturation pressure of the liquid, and p_0 is the vapour pressure in free air at a great distance from the evaporating surface, is, according to J. Stefan,

$$\text{Rate of evaporation} = 4rk \log \frac{P-p_0}{P-p_1}$$

where k is a constant. This expression represents the rate of evaporation into still air from a circular tank or pond filled flush with a relatively extensive plane which neither absorbs nor gives off any vapour. When p_0 and p_1 are small in comparison with P, this expression reduces to: Rate of evaporation$=4rk(p_1-p_0)/P$. The evaporation from an elliptical surface under similar conditions when the major and minor axes, a and b, do not differ greatly, is obtained by substituting $\sqrt{ab}$ in place of r. When the major axis is several times larger than the minor axis, the ratio of evaporation from elliptical surfaces is much greater than from circular ones. Curiously enough, the mass of vapour which evaporates from the surface of a liquid in a given time is not proportional to the surface area, as was once supposed, for the rate of evaporation is not the same on all parts of the surface, being fastest near the edges, and slowest near the centre. Rather is the rate of evaporation more nearly proportional to the linear dimensions—thus with a circular vessel, the rate of evaporation is more nearly proportional to the square root of the area, *i.e.* to the radius than it is to the area of the circle. If the evaporation takes place into still air from a vertical tube of fixed length and constant cross section, when h represents the distance of the surface of the liquid from the top of the tube ; a, the cross-sectional area of the tube : p_1 and p_2, the partial pressures of the vapour at the free end of the tube and at the evaporating surface respectively :

$$\text{Rate of evaporation} = \frac{ka}{h} \log \frac{P-p_2}{P-p_1}$$

where k is a constant whose value for any given liquid can be determined since all the remaining terms can be measured. Given k, therefore, the rate of evaporation of the given liquid from a circular tube or well can be computed from the total gas pressure and the vapour pressures at the surface of the liquid and at the top of the tube. P. Vaillant found the rate of evaporation of a liquid, *i.e.* the quantity of liquid evaporated per second, is proportional to its molecular weight, M, and the four-thirds power of the maximum vapour pressure p ; so that the speed of evaporation$=KMp^{\frac{4}{3}}$, where K is a constant$=0{\cdot}43$ for normal liquids. For water, $K=3\times0{\cdot}43$, which means that this liquid is polymerized.

Kinetic theory of evaporation.—The molecules of a liquid are probably much closer together than is the case with gases, and they are accordingly subjected to the action of comparatively powerful intermolecular forces. Diffusion also shows that the molecules of a liquid are in motion, but, in consequence of great overcrowding, the number of collisions must be comparatively great. The molecules in the body of the liquid are attracted by the other molecules, equally in all directions, but at the surface the molecules can be attracted inwards alone. What will happen to a molecule which, in the course of its wanderings, reaches the surface ? If its velocity be great enough, the molecule will rush upwards beyond the range of attraction of the other molecules in the liquid, and thus, passing into the space above, become an integral part of the surrounding gas or atmosphere. On the other hand, if the velocity of the escaping molecule be not great enough to carry the molecule so far, the upward velocity of the molecule will become less and less, and finally the molecule will fall back and plunge into the liquid again. The case is somewhat analogous with the behaviour of a stone thrown up into the air. If the stone were projected upwards with a sufficient velocity, say 50,000 feet per second, it would leave the earth never to return. Many of the molecules which leave the surface of the water fall back again ; those which leave and do not return reduce the volume of the liquid, and finally lead to complete evaporation. Just as the kinetic energy of some of the molecules of a liquid carries them into the space above, so does the kinetic energy of the molecules of the gas phase cause them to penetrate into and become an integral part of the liquid.

Evaporation from and condensation on the surface of a liquid are thus continuous processes whose ratio may be any value whatever. When both values appear to be zero, condensation and evaporation are really progressing at equal rates. As usually understood, the term evaporation refers to the net loss, and condensation the net gain in a given time. Raising the temperature of the liquid accelerates the motions of the molecules and so hastens the process of evaporation. A draught of air across the surface also favours the passage of the molecules away from the atmosphere above the evaporating liquid and reduces the chance of return.

Steam may be wet or dry. These qualities are of great importance in boiler and engine trials. Wet steam is water vapour which has minute globules of liquid water mechanically entrained with the vapour. This may arise (i) by ebullition ; water is projected into the steam space, part falls back, but part is carried along with the current of steam. (ii) The steam may be subject to variations of pressure, and some water is condensed as a mist during the adiabatic expansion of steam ; and (iii) some water may also be condensed to mist as the steam passes through pipes which are losing heat by radiation, etc.[2]

The cooling effect during evaporation.—In J. D. van der Waals' theory of liquids, the mutual attraction of the particles of the liquid is the restraining force which keeps them more or less together; this force has been estimated to be very great—some hundreds of atmospheres. During vaporization, the particles break away from the surface in spite of this attraction; this cannot be done without a supply of energy, and the curious fact is that the escaping molecules attract the required energy from the rest of the liquid so that a liquid becomes cooler during evaporation. In 1755, W. Cullen placed water under a bell jar from which the air was rapidly withdrawn,[3] evaporation was so rapid that the water was cooled until it froze; similarly, by placing some liquid sulphur dioxide and water in a red-hot platinum crucible the water therein has been frozen by the rapid evaporation of the sulphur dioxide. The kinetic theory shows how this can occur. During evaporation, the fleetest molecules can alone escape from the liquid; the more sluggish molecules cannot get beyond the range of attraction of the molecules remaining in the liquid. The surface of the liquid acts as a kind of grid separating the faster from the slower moving molecules. The fleetest molecules have the greatest kinetic energy, and the temperature of a mass of molecules is proportional to the average kinetic energy of the molecules. If, therefore, the fastest molecules escape, the more sluggish molecules will remain behind, and the average velocity of the molecules of the liquid must be reduced. Hence **a liquid which is evaporating is cooling rapidly.** Observations show that the temperature of a vapour is never very far from that of the liquid which produces it, and it is therefore assumed that the attraction of the liquid reduces the mean kinetic energy of the escaping particles down to near the mean kinetic energy of the liquid, so that the kinetic energy of the molecules of the vapour like that of the molecules of the liquid varies from zero upwards.

To illustrate the cooling effect of evaporation, a little ether is placed in a small beaker with a few drops of water on the underside, the water will freeze if the ether be evaporated quickly by blowing a jet of air across the surface. Advantage is taken of this fact to solidify carbon dioxide by the rapid evaporation of liquid carbon dioxide; and to solidify hydrogen by the rapid evaporation of liquid hydrogen. If a large test tube containing liquid air be fitted with a one-hole rubber stopper fitted with a tube connected with an air pump, the tube becomes so cold that the outside air, in contact with the test tube, is liquefied. The rapid evaporation of the liquid air inside the tube may even produce cold enough to freeze the contents solid. The principle is also utilized in cold storage, etc.

If water be placed in a flask dipping in boiling water, its temperature remains many degrees below the boiling point owing to the cooling effect of the evaporating water; but if the water in the flask be covered with a layer of oil, its temperature rises to that of the bath, and bubbles of vapour pass through the oil.[4]

The heat of vaporization and fusion.—A relatively large amount of energy is needed to transform a gram of water into steam. The thermal energy, or the work done in accelerating the motion of the individual molecules and at the same time imparting to the molecules sufficient momentum to tear them apart against the attraction of those molecules remaining in the liquid is measured by the so-called latent heat of vaporization. The amount of heat required to turn one gram of water at 100° into steam at 100° reported by different observers[5] ranges from the 532·0 to the 538·9 cals. per gram. T. W. Richards and J. H. Mathews found at 100°, 538·1 cals., and A. W. Smith, 540·7 cals. per gram. Few methods of measurement have been so unsatisfactory as those employed for the latent heat of vaporization, and the published data are very discordant, due partly to impure materials but mainly to faults in the method of measurement. The best representative value may be taken as 540 cals., or 9·73 Cals. per gram-molecule at 100°. This is the **latent heat of vaporization** of water at 100°. The number means that steam at 100° has the equivalent of 537 cals. of energy—internal or potential—more than liquid water at 100°, or that 537 cals. of thermal energy are needed to convert a gram of liquid water at 100° into steam at 100°. In symbols, for a gram-molecule (that is, 18 grams of water): $H_2O_{liq.} \rightarrow H_2O_{gas} - 9·7$ Cals., meaning that during the passage from the liquid to the gaseous state, energy equivalent to 9·7 Cals.

in becoming latent or potential, so to speak, is charged on to the molecules—probably as kinetic energy of translatory motion. This energy is degraded as heat when steam at 100° is cooled to liquid water at 100°. The values[6] for 0° range from 599·92 to 587·5 cals. per gram. The best representative value may be taken as 587·7 cals. per gram, or 10·69 Cals. per gram-molecule. The latent heat of vaporization of water is the highest known. and this also helps to moderate the earth's temperature, for it absorbs heat during its evaporation in torrid climates, and gives it up during condensation in cooler climes. These properties of water also help to regulate the temperature of living organisms.

During the change from liquid to vapour, a volume v_1 of liquid expands to a volume v_2 of vapour. The total change in volume is therefore v_2-v_1, and this expansion occurs in spite of the fact that the atmosphere continually acts as if it were a weighted piston which has to be pushed back as the liquid expands into vapour. If p denotes the pressure of the atmosphere, the work done during the expansion can be represented by the product $p(v_2-v_1)$. If the volumes be expressed in c.c., the thermal energy equivalent to the work $p(v_2-v_1)$ will be $0{\cdot}00003183\,p(v_2-v_1)$ cals. If then l represents the observed latent heat of expansion, and E that portion which is spent in overcoming external work, the so-called **external heat vaporization**, the residue, $l-E$, will represent the heat actually spent in doing internal work as the substance expands; this is the so-called **internal heat of vaporization** λ, where $l-E=\lambda$. According to R. Clausius, the relation between the three latent heats of vaporization of water and temperature, $\theta°$, is

$$l=607-0{\cdot}708\theta\,;\quad E=31{\cdot}6+0{\cdot}083\theta\,;\quad \lambda=575{\cdot}4-0{\cdot}791\theta.$$

Many other formulæ have been published. According to F. Henning,[7] the effect of temperature on the latent heat of water is given by the expression $l=93{\cdot}706(366{\cdot}25-\theta)^{0{\cdot}31312}$, which deviates from the observed values by 0·3 per cent. at 140°, and by 0·2 per cent. at 180°. At the critical temperature, 366·25°, the latent heat l is zero. Better agreement between the observed and calculated results at $\theta°$ between 100° and 140° is given by the formula: $l=538{\cdot}46-0{\cdot}6422(\theta-100)-0{\cdot}000833(\theta-100)^2$, which in many cases can be simplified to $l=539{\cdot}66-0{\cdot}718(\theta-100)$. W. Nernst represents the molecular heat of the vaporization of ice at $T°$ by $11938+3{\cdot}5T-0{\cdot}0096T^2$ cals. F. Henning's observations of the latent heat of vaporization of water l in Cals. (15°), at different temperatures θ, and L. Holborn and F. Henning's values for the saturation pressure p and the temperature coefficient $dp/d\theta$ in mm. of mercury per degree, are indicated in Table VI.

TABLE VI.—HEATS OF VAPORIZATION OF WATER AT DIFFERENT TEMPERATURES.

$\theta°$ C.	l cals.	$\frac{dl}{d\theta}$	p mm Hg.	$\frac{dp}{d\theta}$	v_2 c c.
30	579·3	—	31·71	1·819	33010
40	574·0	0·54	55·13	2·939	19600

160	496·6	0·72	4633	117·7	307·1
170	489·4	0·72	5937	143·4	243·0
180	482·2	—	7514	172·7	194·7

Similar remarks might be applied to energy changes during the melting of ice as to the vaporization of liquid water; and similarly with the freezing of liquid water into ice, and the condensation of steam to liquid water. In the case of melting ice, one gram of ice at 0° in melting to liquid water at 0° requires about 80 cals.—this is the so-called **latent heat of fusion**—in symbols, for one gram-molecule (that is, 18 grms.), $H_2O_{\text{solid}} \rightarrow H_2O_{\text{liquid}} - 1{\cdot}44$ Cals. When compared with other liquids, the freezing point of water is high; the latent heat of fusion also, if liquid ammonia be excluded, is the largest which has yet been discovered. All these properties of water play an important part in regulating the temperature of the earth, for a comparatively large amount of heat must be abstracted from a large body of water before it can freeze, and this helps to prevent an excessive fall of temperature in lakes and seas. The latent heat of fusion of ice was first investigated by J. Black [8] near the beginning of the nineteenth century, and culminated in the important work of H. V. Regnault (1847), in which 79·25 cals. was obtained for the latent of fusion of ice. Other determinations at 0° range from the 79·20 cals. per gram of E. Leduc (1906) to the 80·025 of R. Bunsen (1870). L. F. Guttmann (1907) introduced certain corrections in A. W. Smith's data, and then obtained 79·67, the identical result obtained by W. A. Roth (1907). The best representative value may be taken as 79·7 cals. per gram or 1·436 Cals. per gram-molecule—it is interesting to note that this result is identical with the 79·7 cals. obtained by J. Black in 1762. According to O. Petterson, the value drops to 77·71 at −2·8° and to 75·99 at −6·62°. According to P. W. Bridgman (1912), the latent heat of the transformation of ice into water at different temperatures is:

Temperature . . .	−20°	−15°	−10°	−50°	0°
Latent heat	57·7	62·5	68·0	73·7	79·8 cals.

O. Petterson has studied the application of Kirchhoff's equation $d\lambda/dT = C_2 - C_1$ to water when C_2 denotes the specific heat of the liquid, and C_1 the specific heat of the solid. The results were satisfactory When the fusion temperature T is lowered 1°, the latent heat of fusion λ diminishes $C_2 - C_1$ calories. Similar relations hold for other substances. The latent heats of fusion of some common metals are:

Iron.	Copper.	Silver.	Zinc.	Gold.	Tin.	Lead.
69·0	43·0	24·3	22·6	16·3	13·82	4·0 cals.

If secondary changes—*e.g.* decomposition during fusion—do not occur, all substances exhibit characteristic latent heats of fusion and vaporization. In virtue of these facts, it follows that weight for weight a liquid contains a greater amount of energy than a solid, and a gas contains a greater amount than a liquid. In order to change a solid to a liquid, or a liquid into a gas, energy must be *added* to the substance, and for the converse changes, gas to liquid, or liquid to solid, energy must be *withdrawn* from a substance. In general, when a substance passes from one physical state to another, a definite amount of energy is simultaneously added to or withdrawn from the substance. The energy needed for the evaporation of natural waters is mainly derived from the "heat paid out by the sun."

Most solids expand in passing from the solid to the liquid state; according to G. Vicentini and D. Omodei (1886),[9] one volume of the following elements changes δv volumes on melting:

	Cadmium.	Mercury.	Phosphorus.	Lead.	Tin.	Potassium.	Sodium.
δv . .	0·047	0·037	0·035	0·034	0·028	0·026	0·025

corresponding with a 3·3 per cent. average expansion, and the melting point of all these solids is raised by pressure. Water, on the contrary, contracts nearly 9·1 per cent. on melting. As P. W. Bridgman has shown, the freezing temperature of water is lowered approximately 1° for each 100 atmospheres in accord with the fact that the specific volume of ice is greater than that of liquid water; but when the pressure has reached 2115 atmospheres, the freezing temperature begins to rise again, because a form of ice denser than the liquid appears. Hence, the maximum pressure obtained by cooling water in a closed vessel is 2100 atmospheres, and pipes capable of withstanding this pressure would never burst by the freezing of water. *The molecular theory of the raising of the melting point by pressure* is somewhat as follows: The mean distance between the molecules of a solid vibrating about their centres of oscillation, is increased when the temperature is raised; this causes the solid to expand. When the mean distance increases to such an extent that the motion of one molecule does not retard those of the others, the molecules start migratory motions, and the solid is said to melt. If, at the melting point, pressure is applied, the molecules are forced nearer together, and a further rise of temperature is needed for the solid to melt. An increase of temperature is needed to counterbalance the increased pressure. The reason the melting point of ice is lowered by pressure depends on the fact that an increase of pressure facilitates the conversion of the complex ice molecules to simpler water molecules. A somewhat similar phenomenon probably occurs with sulphur trioxide which also expands on solidifying. Mutual attractions draw the molecules of water together during solidification; this requires an expenditure of energy, for there is an evolution of heat during the passage of water into ice. The latent heats of fusion and vaporization of water are abnormally high:

	Water.	Mercury.	Sulphuric acid.	Acetic acid.	Benzene.
Latent heat of fusion . .	79·89	2·8	22·82	46·4	30·39
Latent heat of vaporization .	536·4	62	122·1	79·8	94·4

The approximately 80 cals. required to fuse a gram of ice at 0° do not solely represent the purely physical change, but probably include the latent heat of dissociation corresponding with the change of some ice to water molecules, and the solution of the remaining ice molecules in the water molecules. Similarly with the heat of vaporization, there is here allowance to be made for the passage of some complex water molecules into the simpler steam molecules.

The effect of pressure on transition points.—Let unit mass of a liquid pass into vapour at each of the temperatures T and $T+dT$, and let the respective vapour pressures be p and $p+dp$; further, let the volume of the liquid be v_1 and the volume of the vapour v_2 when the pressure is p, the external work done during the vaporization of unit mass be $p(v_2-v_1)$, and if λ denotes the internal latent heat of vaporization per gram, we have $E-L=\lambda$, and for a small change of pressure dp, the work dE will be $(v_2-v_1)dp$. Substituting these values of $E-L$ and of dE, *i.e.* respectively $W-Q$ and dW, in H. von Helmholtz's equation (indicated later), there remains:

$$\lambda=T\frac{dp}{dT}(v_2-v_1)$$

a relation often called **E. Clapeyron's equation,**[10] because an equation similar in meaning was deduced by E. Clapeyron (1834). The same result follows another way. For equilibrium between heat energy, $(\lambda/T)/dT$, and volume energy, $(v_2-v_1)dp$, in any given change, $(\lambda/T)/dT$ must be equal to $(v_2-v_1)dp$, where v_2-v_1 represents the increase in molecular volume by the change under consideration. Obviously, if any five of the six terms are known, the sixth can be calculated.

The fraction dp/dT is sometimes called the **pressure coefficient** because it represents the change of pressure dp which occurs with unit change of temperature. In words, **the molecular heat of vaporization of a substance is equal to the product of the absolute temperature into the pressure coefficient and the change of volume which occurs when the substance changes its state.** It is easy to see that an analogous expression will be obtained if a similar argument be applied to any change of state—liquefaction, vaporization, sublimation, allotropic and other physical and chemical changes—and Q can be used in place of λ, where Q denotes the heat of transformation. Hence, said P. Duhem (1902): *Tous les changements d'état physique ou de constitution chimique dépendent des mêmes lois générales.*

If the latent heat of a change of state be positive, then the raising or lowering of the transition point with unit change of pressure (dT/dP) is dependent on whether the volume v_2 is greater or less than the volume v_1. If the volume of the material decreases during a change of state so that v_2 is less than v_1, the transition point will be lowered by pressure, and if the volume increases during the change of state so that v_2 is greater than v_1, the transition point will be raised by pressure. This furnishes a general rule for the effect of pressure on transition points: **an increase of pressure favours that state which has the smaller volume.** The latent heat of fusion of ice is always positive, and consequently, as a corollary from Clapeyron's equation, it follows that *an increase of pressure lowers the temperature of transformation of substances which contract on passing from one state to another*, for if v_2 be less than v_1, dp and dT must have opposite signs in order that λ and T may remain positive; but if the pressure be increased, dp must be positive, and dT will therefore be negative, and an increase of pressure will lower the temperature of the transformation—*e.g.* ice, bismuth, bismuth sulphide, cast iron, nitre, and sulphur trioxide contract on melting, hence, their melting points are lowered by increase of pressure. Another corollary: *an increase of pressure raises the transition temperature of substances which expand on passing* from one state to another; for if λ and T are positive, and v_1 be greater than v_2, dp and dT must have the same sign, and if dp be positive, dT will also be positive—*e.g.* the boiling points of liquids are raised by an increase of pressure; so are the melting points of solids like phosphorus, sulphur, lead, tin, and many other metals which expand on melting.

In 1850, M. Faraday[11] drew attention to the fact that when two moist pieces of ice are in contact, pressure is not essential for the solidification of two moistened surfaces of ice. J. Thomsòn (1860) tried to explain Faraday's experiment by capillary action, but M. Faraday showed that this could not be the case because the blocks froze together when under water as well as when in air. From a suggestion made by J. Hooker, J. Tyndall applied the term *regelation* to the phenomenon, and both he and J. D. Forbes explained regelation by assuming that the melting point of ice in the interior of a mass is lower than the normal freezing point at the surface. Hence, it was assumed that when the two surfaces come into contact, they become interior parts of the enlarged block and thus the water film is at once frozen. The explanation now generally accepted is that water at 0° is a saturated solution of ice molecules; and a film of water at 0° with ice on both sides would grow together by natural crystallization, without the need for introducing the effects of pressure. This phenomenon is not to be confused with the lowering of the freezing point of water by pressure. This latter is probably more truly a regelation because the ice can be squeezed into water by pressure, and the ice re-forms when the pressure is removed.

W. Spring has also shown that many metals liquefy under great pressures, and an increase in volume (decrease in specific gravity) has been observed after many metals have been subjected to external mechanical forces—pressure, twisting, rolling, etc.; thus the specific gravity of bismuth changed as follows:

Pressure in atmospheres	1	18,000	27,000	36,000
Specific gravity	9·783	9·779	9·655	9·586

The increase in volume which persists after the pressure has been withdrawn is supposed to be due to the dislocation of the molecules of the solid as it was passing to the liquid condition under the influence of a gradually increasing pressure, and that pressure was relieved too quickly to give the molecules sufficient time to take up the condition characteristic of the solid state.

EXAMPLES.—(1) If the melting point of ice under a pressure of one atmosphere is 0°, what will be the melting point of ice under a pressure of n atmospheres, and also in vacuo when the latent heat of ice is 80 cals. and one c.c. of liquid at 0° furnishes 1·09 c.c. of ice at 0°? One atmosphere pressure is equivalent to 1033·3 grms. of mercury per sq. cm., and since 1 cal. is equivalent to 47,600 dynes, or 80 cals. are equivalent to 80 × 47,600 dynes, $T=273$, $dp=1033{\cdot}3$, $dp=n-1$; $v_1-v_2=0{\cdot}09$; and dT, the melting point of ice under a pressure of n atmospheres, is $-0{\cdot}0074(n-1)$; the melting point of ice in vacuo when $n=0$ is 0·0074°. Lord Kelvin found a change of 0·0072° per atmosphere pressure. According to E. Riecke (1912), if the pressure be p atm., the melting point of ice is lowered $\theta=0{\cdot}00036p$.

(2) Water boils at 100° under normal atmospheric pressure and at 100·1° under a pressure of 1·00355 atm. The volume of one gram of steam at 100° is 1645·55 c.c., and of liquid water at the same temperature 1·04 c.c. Show that the latent heat of steam at 100° is nearly 532·6 cals. The deviation from the observed 537 cals. rests on the inaccuracy in the values assigned to dp and dT.

(3) L. T. Reicher (1883)[12] found that when sulphur changes from α- to β-sulphur at the transition temperature 95·6°, there is an expansion of 0·0000126 c.c., the latent heat involved in the transformation being 2·52 cals. Hence compare the computed change in the transition temperature with change of pressure with the value 0·05° per atmosphere observed by L. T. Reicher. $dT/dp = 368 \cdot 6 \times 0 \cdot 0000126 \div 2 \cdot 52 = 0 \cdot 045°$ per atmosphere.

In the special case of vaporization when the volume v_1 of the liquid is very small in comparison with v_2 the volume of the vapour, v_1 can be neglected without sensible error; and if the ordinary gas law, $pv=RT$, describes the behaviour of the gas, Clapeyron's equation becomes $p\lambda=RT^2(dp/dT)$, which can be written in the equivalent forms:

$$\frac{1}{p}\cdot\frac{dp}{dT}=\frac{\lambda}{RT^2};\quad\frac{d\log p}{dT}=\frac{\lambda}{RT^2}$$

This is called **Clapeyron and Clausius' equation**—after R. Clausius (1851)—and it is supposed to represent the observed data more accurately than Clapeyron's at low temperatures, when the vapour pressure is small.

EXAMPLE.—Water at 760 mm. pressure boils at 373° absolute, and dp/dT, the variation of the vapour pressure, is 27·12 mm. per degree. Hence, if $R=1 \cdot 985$ cals., the molecular heat of vaporization is $(1 \cdot 985 \times (373)^2 \times 27 \cdot 12) \div (760 \times 18) = 547 \cdot 5$ cals., a number about 2 per cent. too large.

Vapour pressure.—Suppose that a liquid is evaporating in a closed vacuous space. The fleetest molecules cannot escape into boundless space, and consequently they accumulate as a gas or vapour in the space above the liquid. The concentration of the vapour in the space above the liquid will go on increasing. The molecules of the vapour behave like the molecules of an ordinary gas, and consequently a certain percentage will plunge back into the liquid. The number of molecules which return to the liquid from the space above per second of course increases as the concentration of the vapour increases, although the rate at which the molecules leave the liquid probably decreases as the concentration of the vapour increases. **When the number of molecules which return to the liquid in a given time is equal to the number of molecules which leave the liquid in the same time, the vapour must be saturated, and the system in equilibrium.** With the notation previously used:

$$\text{Water}_{\text{liquid}} \overset{100°}{\rightleftharpoons} \text{Water}_{\text{steam}}$$

The equilibrium, it will be observed, is not a passive (static) condition—that is, a state of rest—for both processes are active (kinetic). There is a shower of molecules streaming into the liquid, and an efflux of molecules away from the liquid. The effect of one is neutralized by the other; neither can produce any visible result. Anything which disturbs this equality—*e.g.* a desiccating agent or a condenser in the space above (as in distillation), etc.—will alter the conditions. Experiments show that **at a given temperature the vapour pressure of a liquid in contact with its own liquid is a constant quantity, but it increases as the temperature rises, and is independent of the absolute amount of vapour and of liquid present in the system.** It is easy to see this. If the surface of the liquid be doubled, it is true that twice as many molecules will leave the surface in a given time, but twice as many molecules will return.

The higher the temperature of the liquid the swifter will be the movements of the molecules; the greater the relative number of molecules escaping from the liquid per second into the supernatant atmosphere; and the greater the resulting pressure. The vapour pressure of water at 0° is just equal to 4·60 mm. of mercury.

This means that if a little water be introduced into the Torricellian vacuum of a barometer, at 0°, the mercury will be depressed from 760 mm. to 755·4 mm. If the mercury barometer be 760 mm. high, and a drop of water be introduced so that there is a film of liquid water on the surface of the mercury, the height of the mercury column will be reduced one-half if the temperature be raised to 81°, because the vapour pressure of water at that temperature is nearly 380 mm. of mercury. The higher the temperature, the greater the vapour pressure, provided all the water is not vaporized; but for any assigned temperature, the vapour pressure of water has one fixed and definite value. The effect of temperature on the vapour pressure of liquid water is indicated in Tables VII and VIII, and on the corresponding vapour pressure of ice in Table VIII. These tables of physical constants are very useful. E. W. Morley (1912) has said:

> The importance of physical constants is that each one holds condensed in a small volume the essence of many observations. Some constants are like the words in a dictionary or the figures in a mathematical table. Such constants must be determined and tabulated in order that the call for them may be answered without delay or waste of time.

The equilibrium pressures of water vapour in contact with the liquid—*i.e.* the vapour pressure of water at different temperatures—have been measured by H. V. Regnault, G. Magnus, L. P. Cailletet and E. Colardeau, and others. The results in Table VII up to 70° are based on the measurements of K. Scheel and W. Heuse; from 70° to 100°, on the measurements of H. F. Wiebe; and from 100° to 370° on the measurements of L. Holborn, F. Henning, and A. Baumann. In illustration, the vapour pressure of water at 95° is 634·01 mm., and at 150°, 3568·7 mm.

TABLE VII.—THE VAPOUR PRESSURES OF WATER OVER THE LIQUID BETWEEN −16° AND 370°.

The vapour pressure of ice is less than that of water, and is quite appreciable. Determinations have been made by H. V. Regnault,[13] L. Rolla, etc. The results in Table VIII are based on the measurements of K. Scheel and W. Heuse. The vapour pressure of ice explains how ice and snow can evaporate at temperatures below 0°, without melting to liquid water. The curve *ROO*, Fig. 9, represents the vapour pressure of liquid water, and the curve *PO*, the vapour pressure of ice. W. Nernst calculates that at —20° the vapour pressure of water is 0·940; at —73°, $2·5 \times 10^{-3}$; and at —173°, $6·6 \times 10^{-16}$.

The exact relation between the temperature and pressure of a vapour in contact with its own liquid is not known. Quite a number—between thirty and forty—of empirical formulæ has been proposed. J. Dalton's, the earliest,[14] represented the pressures increasing in geometrical progression while the temperatures increased in arithmetical progression. In symbols, if p_0 be the pressure at 0° and p the pressure at $\theta°$, $p=p_0a\theta$, or, what is the same thing, $\log p=a+b\theta$, where a, a, and b are constants; but H. V. Regnault's exact measurements on vapour pressures proved J. Dalton's rule to be inaccurate. A number of formula of this type but with more terms have been employed, *e.g.* J. B. Göbel (1905) represented the vapour pressure of water, p, at $\theta°$ in the vicinity of 0° by $p=0{\cdot}4600+0{\cdot}03293\theta+0{\cdot}00105\theta^2+0{\cdot}0000167\theta^3$; and for ice, $p=0{\cdot}45996+0{\cdot}03741\theta+0{\cdot}001895\theta^2+0{\cdot}0000716\theta^3$. *W. J. M. Rankine's vapour pressure formula* (1849) is one of the favourites; G. Kirchhoff, in 1858, and A. Dupré, in 1869, employed similar formulæ. W. J. M. Rankine represents the vapour pressure p, at the absolute temperature T, by the expression:

TABLE VIII.—THE VAPOUR PRESSURE OF WATER OVER ICE BETWEEN 0° AND −65°.

Temperature.	Vapour pressure of ice in mm. of mercury.									
	0	1	2	3	4	5	6	7	8	9
−0	4·579	4·215	3·879	3·566	3·277	3·009	2·762	2·533	2·322	2·127
−1	1·947	1·780	1·627	1·486	1·356	1·237	1·127	1·026	0·933	0·848
−2	0·770	0·699	0·633	0·574	0·519	0·469	0·424	0·383	0·345	0·105
−3	0·280	0·252	0·226	0·203	0·182	0·163	0·146	0·131	0·117	0·105
−4	0·094	0·083	0·074	0·066	0·059	0·052	0·047	0·042	0·037	0·033
−5	0·029	0·026	0·023	0·021	0·021	0·018	0·016	0·012	0·010	0·009
−6	0·008	0·007	0·005	0·004	0·003	0·003				

$$\log p=a+\frac{b}{T}+c\log T \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The constants, a, b, c of this formula have a physical meaning in that they are related to the other properties of matter—specific heat, vaporization, and molecular weight. For water, between −100° and 365°, P. Juliusburger gives $\log_{10}p=9{\cdot}30027-21113{\cdot}2T^{-1}-0{\cdot}28771\log_{10}T$ mm. of mercury. Rankine's formula has also been deduced by H. Hertz, J. W. Gibbs, M. Planck, and O. Stern from reasoning based on the assumption that Boyle's law is valid, meaning that the formula is strictly applicable only with very small pressures. *J. D. van der Waals' vapour pressure formula*

$$\log\frac{p_c}{p}=f\left(\frac{T_c}{T}-1\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

has also been largely used. Here $p_c=164940$ mm., and $T_c=374°$ or $647{\cdot}09°$ K. respectively denote the critical pressure and absolute critical temperature; f is a number which H. von Jüptner and H. Happel found to vary partly with the nature of the substance and partly on the temperature; and L. Schames found that there is a minimum value of f which is the same with all substances at the same reduced temperature. The value of f falls from 3·3261 at 0° to a minimum 3·1244 at 215°, and rises to 3·2283 at 360°. I. W. Cederberg found that $f=a\beta^{(T/T_c-\gamma)^2}$, where a denotes the minimum value of f; β is a constant; and γ the reduced minimum temperature. For water, $a=3{\cdot}1244$; $\beta=1{\cdot}7887$; and $\gamma=0{\cdot}7500$. The deviations calculated from the observed results, between −173° and the critical point, with $\log p_0/p=a\beta^{(T/T_c-\gamma)^2}(T/T_c-1)$, are less than 0·01 per cent. J. D. van der Waals' formula may be written $\log p=(\log p_c+f)-fT_c/T$, which resembles Rankine's formula with the $c \log T$ term missing. Introducing W. Nernst's values for the constants,

$$\log p = -\frac{13512}{4·571T} - \frac{10·089}{1·985} \log T + 23·86774$$

P. E. Brunelli (1917) claims that $\log p = 23·08647 - 4·5 \log T - 2980·46T^{-1} - 0·00278T + 0·000002825T^2$ represents the vapour pressure of water over a longer range of temperature than any hitherto proposed. T is taken to be $273·09+\theta$. C. E. Carbonelli represents the vapour pressure p at the absolute temperature T, below the critical temperature, T_c, by the expression

$$\log \frac{p_c}{p} = \frac{T_c - T}{T} \log \frac{aT_c}{T}$$

where a is a constant characteristic of the liquid. It is 2·21503 for carbon disulphide; 2·58124 for chloroform; 3·6765 for alcohol; 2·92714 for water; 2·80416 for ethyl ether; 2·64664 for benzene; 2·79064 for sulphur dioxide; 2·92481 for cyanogen; and 2·79 for ammonia. A. March deduces for the vapour pressure p at the absolute temperature T

$$p = p_c e^{-\beta(T_c/T - 1)}$$

from Maxwell and Boltzmann's theorem, J. D. van der Waals' theory and the quantum theory; p_c and T_c respectively denote the critical pressure and temperature; β is a constant whose value depends on the nature of the substance.

W. Nernst deduced a vapour pressure formula from Clausius and Clapeyron's equation $\lambda = T(v_2 - v_1)dp/dT$, where the unit of mass is the gram-molecule; λ is the molecular heat of evaporation or sublimation; v_2 and v_1 the specific volumes of gas and liquid or solid phase respectively; p is the pressure of the saturated vapour at the absolute temperature T. If the effect of temperature T and pressure p upon the specific volume v, and if the heat of evaporation be known, then the results substituted in the Clausius-Clapeyron equation will give a relation between p and T. W. Nernst adopts the empirical formulæ:

$$p(v_2 - v_1) = RT\left(1 - \frac{p}{p_c}\right); \text{ and } \lambda = (\lambda_0 + AT + BT^2)\left(1 - \frac{p}{p_c}\right) \quad . \quad (3)$$

where A and B are constants; R is the gas constant. The result of the substitution is $\lambda_0 + AT + BT^2 = T^2Rd \log p/dT$; or, after integration $\log p = -\lambda_0/RT + A \log T/R + BT/R + \mathbf{C}$, where $\mathbf{C}$ is the constant of integration. If the gas constant R be 1·985 and ordinary logarithms are used, *W. Nernst's vapour pressure formula* for water becomes

$$\log p = -\frac{\lambda_0}{4·571T} + \frac{A}{1·985} \log T + \frac{B}{4·571} T + \mathbf{C} \quad . \quad . \quad (4)$$

The constants λ_0, A, and B can be evaluated through the second of equations (3), and also indirectly by the relation $d\lambda/dT = C'_p - C_p$, where C'_p is the molecular heat of the liquid or solid, and C_p that of the vapour. The numerical values for any particular liquid can be also obtained by substituting the corresponding values of p and T for three different temperatures, and solving the resulting equations.

It has been found that the so-called constant $\mathbf{C}$ is, for normal substances, characteristic of the molecule to which it refers, and is independent of the physical state of the substance, so that $\mathbf{C}$ is the same for the vapour pressure formulæ of both liquid and solid carbon dioxide. This has been established for a number of substances by E. Falck and C. F. Mündel. Consequently $\mathbf{C}$ is called the **chemical constant** of the molecules of the substance in question, and it enables the chemical equilibrium of a reacting system to be computed when the thermal value of the reaction is known.

The second of equations (3) represents the observed relations between the heat of evaporation λ and temperature T fairly well, and W. Nernst found that in a great number of cases A is 3·5; hence, W. Nernst's vapour pressure formula becomes

$$\log p=-\frac{\lambda_0}{4{\cdot}571T}+1{\cdot}75\log T+\frac{B}{4{\cdot}571}T+\mathbf{C} \quad . \quad . \quad (5)$$

It will be observed that Nernst's vapour pressure formula is dependent on the validity of the first of equations (3), which for small pressures reduces to Boyle's law, and this law is more nearly in accord with observations the smaller the pressure. Hence, **C** is best evaluated at low pressures. The first of equations (3) is also dependent on J. D. van der Waals' law of corresponding states, and does not apply to those abnormal substances which deviate from that rule. Water is one of the abnormal substances, and its vapour pressure does not follow the rule. W. Nernst (1910) therefore assumed that doubled molecules are present in aqueous vapour corresponding with $(H_2O)_2 \rightleftharpoons 2H_2O$; and if D be the observed vapour density, and D_1 the theoretical value, the degree of dissociation γ is $\gamma=(D-D_1)/D_1$. Hence, W. Nernst represents the **vapour pressure of water** by the formula :

$$\log p=\log\frac{1+\gamma}{\gamma}-\frac{2936{\cdot}39}{T}-4{\cdot}94\log T+23{\cdot}44837 \quad . \quad . \quad (6)$$

H. Levy also deduced an expression for the vapour pressure of water on the assumption that the molecules of the liquid are partially associated into dihydrol molecules. For the **vapour pressure of ice,** p mm. of mercury, at $\theta°$, M. Thiesen gives $\log (p/p_0)=9{\cdot}632(1-0{\cdot}000036\theta)\theta/T$, where T is the absolute temperature, and p_0 the vapour pressure at 0°. He also gives $\log p=8{\cdot}891p_0\theta/(252+\theta)$. W. Nernst found

$$\log p=-\frac{2611{\cdot}7}{T}-1{\cdot}75\log T-0{\cdot}00210T+6{\cdot}5343$$

which he afterwards altered to $\log p=$

$$-\frac{5896}{T}+4\log T+3\log(e^{\frac{226}{T}}-1)+6\log(e^{\frac{1200}{T}}-1)-0{\cdot}020837\times10^{-15}T^6+0{\cdot}76876$$

to accommodate the results with the quantum formula for the specific heat of ice. The two formulæ give equally good results, and therefore, for calculations, the simpler type is preferred. S. Weber's measurements of the vapour pressure of ice accord well with the simpler form of W. Nernst's vapour pressure formula :

$T°$ K. . . .	203·96°	199·55°	190·36°	185·51°	177·01°	175·21°
°C. . . .	−69·13°	−73·54°	−82·73°	−87·58°	−96·08°	−97·38°
p obs. . .	2·92	1·50	0·338	0·141	0·029	0·020
p calc. . .	2·936	1·504	0·338	0·145	0·0293	0·0205

The calculated value for 79·79° K., or 193·30°, is $1{\cdot}3\times10^{-23}$ mm. ; and for 157·61° K., or 115·48°, 0·00040 mm. K. Scheel and W. Heuse, and M. Thiesen and K. Scheel found the vapour pressure of liquid water at 0° to be 4·5788 ± 0·0008 mm. of mercury ; and for ice, 4·5785 mm. The vapour pressure of ice and water are the same at the triple point, and therefore, practically speaking, the vapour pressure of water will be the same for ice and undercooled water at the triple point.

The pressure and volume relations of dry saturated vapours have not been represented by a satisfactory equation, and the law pv^n=constant, which is applicable for the permanent gases, does not give a constant index with the vapours. B. Leinweber[15] found that for steam the exponent n varies within wide limits for large pressures, but for low pressures up to 0·35 atm. n is fairly constant.

The distinction between a gas and a vapour.—The distinction between a gas and a vapour is somewhat vague. If the elastic fluid be very far from its temperature of liquefaction, or above its critical temperature, it is generally called a **gas** ;

and **vapour** if it is near its temperature of liquefaction, or below its critical temperature. Oxygen, nitrogen, etc., at ordinary temperatures are gases; whereas water or alcohol on evaporation furnish vapours. Otherwise expressed, **a gas is an elastic fluid at a temperature above its critical temperature, and a vapour is an elastic fluid below its critical temperature, but in a liquid state.** The term **permanent gases** was once applied to gases like oxygen, nitrogen, etc., because they could not be liquefied by any known process. The term has lost its significance since all known gases which have been tried have been liquefied, and all but helium solidified. However, the term permanent gas is sometimes even now applied to gases which approach nearest to the ideal gases, and which deviate least from the gas laws of Boyle and Charles.

Boiling or ebullition.—Steam or water vapour is an invisible colourless gas which condenses to a visible cloud of small particles when it comes in contact with the atmosphere. This is readily shown by boiling water in a flask; inside the flask, the vapour is invisible, and a cloud of minute water particles—condensed steam—appears where the steam comes in contact with the cold air. Raising the temperature of an evaporating liquid increases the average speed of the molecules, and favours rapid evaporation. When the temperature is high enough, the exposed surface of the liquid is not sufficient to allow the swift-moving molecules to escape fast enough, bubbles of vapour are accordingly formed *within* the liquid. Each bubble as it forms rises to the surface—increases in size as it rises—and finally escapes into the atmosphere. The process of vaporization by bubble formation is called **boiling**; and the temperature at which boiling commences, the **boiling point** of the liquid. When the vapour pressure of the liquid is the same as the external pressure to which the liquid is subjected, the temperature does not usually rise any higher. Increasing the supply of heat increases the rate at which evaporation proceeds, or at which bubbles are formed. Hence it is sometimes convenient to define: **The boiling point of a liquid is the temperature at which the vapour pressure of the liquid is equal to the external pressure exerted at any point on the liquid surface.** The external pressure may be exerted by the atmospheric air, by vapour and air, by other gases, etc. Hence, the vapour pressure curve not only represents the vapour pressures of a liquid at different temperatures, but it also shows the boiling points of that liquid under different pressures. Water boils at 100° and 760 mm. pressure. The greater the pressure, the higher the boiling point; and conversely, the less the pressure, the lower the boiling point—roughly, the boiling point changes about $\frac{1}{27}°$ C. per mm. change of pressure for a few degrees above and below 100°. These phenomena occur with liquids generally, and it is therefore necessary to state the pressure when giving the boiling point of a liquid—although if no pressure is stated, 760 mm. is understood. Thus at Quito (9350 feet above sea-level), with the barometer at its average height, 525·4 mm., water boils at 90·1°; and on the top of Mount Everest (29,002 feet), barometer at 255·3 mm., water would boil at 72°. Table IX represents the boiling points of liquid water at atmospheric pressures ranging from 680 to 799 mm. of mercury.

From Clapeyron's equation, and Trouton's rule for water, and remembering that $pv=2T$ cals. when v represents a gram-molecule of saturated vapour, $dt/dp=T/13p$, and if $p=760$ mm., $dT=Tdp/9880$. Consequently, the change dT produced in the absolute boiling temperature T of a liquid when the pressure changes by the small amount dp, will be $dT=0{\cdot}0001012T.dp$. Accordingly, a change of $dp=1$ mm. in the pressure of a liquid boiling at $T=373°$ K, will produce a change, $dT=0{\cdot}0377°$, in the boiling point. The observed result is 0·0370°—approximately $\frac{1}{27}°$ per mm. change of pressure. The formula similarly gives approximate values for liquids other than water. A comparison of the boiling points of some metals in vacuo and at ordinary pressures are indicated in the following scheme:

	Mercury.	Cadmium.	Zinc.	Potassium.	Sodium.	Silver.
In vacuo . .	155°	450°	550°	365°	418°	1360°
At 760 mm. . .	357°	749°	920°	667°	742°	2070°

As a rule, if the boiling point has been observed at a pressure p not far removed from the normal, it can be reduced to the standard by adding or subtracting $c(760-p)(273+b)$, where b denotes the observed boiling point at a pressure p, and c is a constant approximately 0·00010 for water and alcohols.

TABLE IX.—THE BOILING POINTS OF WATER AT DIFFERENT PRESSURES.

Height of barometer 0° mm	Boiling points °C.									
	0	1	2	3	4	5	6	7	8	9
68	96·915	955	996	*036	*076	*116	*156	*197	*237	*277
69	97·317	357	396	436	476	516	555	595	635	674
70	97·714	753	792	832	871	910	949	989	*028	*067
71	98·106	145	184	223	261	300	339	378	416	455
72	98·493	532	570	609	647	686	724	762	800	838
73	98·877	915	953	991	*029	*067	*104	*142	*180	*218
74	99·255	293	331	368	406	443	481	518	555	592
75	99·630	667	704	741	778	815	852	889	926	963
76	100·000	037	074	110	147	184	220	257	293	330
77	100·366	403	439	475	511	548	584	620	656	692
78	100·728	764	800	836	872	908	944	979	*015	*051
79	101·087	122	158	193	229	264	300	335	370	406

The asterisk means that the number in front of the decimal is to be raised one unit.

The boiling point of a liquid is raised either by increasing the external (atmospheric) pressure; or by the increase of pressure which occurs when a liquid is heated in a closed vessel. The rise in the boiling point which occurs when a liquid is heated in a closed vessel fitted with a safety valve was first utilized by Denis Papin in a digester or autoclave for softening bones, and described in his *La manière d'amollir les os* (Amsterdam, 1681). In *la marmite de Papin,* a temperature of 130° was obtained, and the corresponding pressure—Table VII—was 2025·6 mm. of mercury, on the assumption that water is alone confined in the boiler. The solvent action of water at this temperature and pressure is much greater than at 100°—the maximum temperature attainable under normal atmospheric pressure. Conversely, observations on the boiling points of a liquid at different pressures also show the vapour pressures of the liquid at different temperatures. Thus, the vapour pressure of water at 0° is 4·6 mm.; and water at a pressure of 4·6 mm. boils at 0°. Hence, liquids which decompose at their boiling point under ordinary atmospheric pressure can frequently be distilled without decomposition at the lower boiling temperature obtained by reducing the pressure. Hydrogen peroxide can be cited in illustration. Hence, the so-called process of **distillation under reduced pressure,** or, as it is sometimes less accurately styled, **distillation in vacuo.** S. T. Preston[16] and G. J. Stoney have estimated that there are not less than $2·7 \times 10^{19}$ molecules per cubic centimetre of gas at n.p.t.; when the gas is reduced to the lowest obtainable pressure, say, $\frac{1}{10000}$th atmosphere, there are still $2·7 \times 10^{9}$ molecules per c.c. Hence, in the best of so-called vacua, an enormous number of molecules is still present. E. Fischer and F. Penzoldt estimate that one part of musk in ten million parts of air and one part of mercaptan in fifty thousand million parts of air could be detected by the sense of smell.

The critical temperature of water.—There is a continuous diminution in the additional temperature required to overcome the effect of an increased pressure on the boiling point of water. This is shown by the following numbers:

Pressure	1		5		10		15		20		25		30 atm.
Boiling temperature .	100°		152°		180°		199°		213°		213°		235°
Rise per 5 atm. pressure		52°		28°		19°		14°		12°		10°	

Hence, it appears likely that a temperature will ultimately be reached at which an additional pressure will require no additional rise of temperature to convert the liquid into vapour. Above that temperature, the temperature of vaporization will be independent of the pressure. This deduction involves an extrapolation, and hence there may be a flaw in the reasoning—the curve, for example, may be asymptotic and approach but never reach the condition just indicated. Experiment shows, however, that **there is a critical temperature, nearly 366°, at and above which no known pressure can condense water vapour into the liquid condition.** At this temperature, the vaporous and liquid states merge into one. It is probable that all other volatile substances have their own particular critical temperatures; for instance, the critical temperature of hydrogen is nearly —271°, and of oxygen —119°. The **critical pressure** of water is 194·6 atm., the **critical volume,** 0·003864,[17] and the **critical density,** between 0·329 and 0·429.

Measuring the volume of moist gases.—In 1801, John Dalton showed that **the mass of vapour required to saturate a given space at a given temperature, and consequently also the vapour pressure of a given liquid, is the same whether the vapour be by itself, or associated with other gases upon which it has no chemical action.** In other words, the total pressure of a mixture of gas and vapour is the sum of the partial pressures of each constituent; hence, added J. Dalton (1801):

> If the aërial atmosphere was at once annihilated, leaving only its aqueous portion, this would be but little augmented, because it already exists in the air nearly at a maximum of that which the temperature can produce and support. The suppression of the obstacle will only accelerate the evaporation, without sensibly augmenting the absolute quantity.

When a gas is confined over water, the observed volume of the gas is determined by the mass of the gas as well as by the temperature and the barometric pressure. By Dalton's law the total pressure of the gas is the joint effect of two partial pressures: (1) the partial pressure of the water vapour at the observed temperature; and (2) the partial pressure of the gas under observation. Hence the barometer reading does not represent the pressure of the gas alone, but rather the pressure of the gas plus the pressure of the water vapour. To find the latter, note the temperature, and Table VII furnishes the desired vapour pressure of water expressed in millimetres of mercury. This must be subtracted from the observed pressure (barometer) in order to find the pressure of the gas at the temperature in question.

EXAMPLE.—What is the volume of 4½ litres of a gas at 0°, 760 mm., when it is measured in contact with water at 15°, and the barometer reads 767·8 mm.? From Table VII, the vapour pressure of water at 15° is 12·8 mm. Hence the gas is really under a partial pressure of 767·8 − 12·8 = 755 mm. of mercury. The problem is now to be solved like the example previously indicated. The answer is 4·24 litres.

The boiling points of liquids.—As a rule substances formed with a large evolution of heat, and highly associated substances have a high boiling point. In 1801, J. Dalton[18] suggested that different liquids, at temperatures equally distant from their boiling points, have the same vapour pressure; or, if θ be the boiling point of the substance under normal pressure, and t_1 the boiling point of the same substance at another pressure; and if θ_2 and t_2 be the corresponding boiling points of another substance, then, $\theta_1-\theta_2=t_1-t_2$. C. G. Schmidt found the rule to be valid for the series of fatty acids—formic, acetic, propionic, butyric, . . ., acids—but not the corresponding alcohols, and numerous workers[19] have found the rule to be invalid when applied to liquids generally. U. Dührung,[20] in 1878, maintained that if θ_1 and θ_2 respectively denote the boiling points of two liquids under the same pressure; $\theta_1=a+b\theta_2$ when a and b are constants, and W. Ramsay and S. Young found a similar rule applicable to some organic liquids; for, if T_1 and T_2 represent the absolute boiling temperatures of two liquids under a pressure p, and T_1' and T_2' the boiling temperatures under another pressure p', the ratios $T_1/T_2=T_1'/T_2'$ =constant. As a rule, however, the relation is not so simple, and W. Ramsay and

S. Young find that $T_1'/T_2'=T_1/T_2+a(T_1'-T_1)$ better expresses the result, or, when a is very small, $T_1'/T_2'=T_1/T_2+a(T_2'-T_2)$.

According to P. Walden,[21] for a great number of non-associated organic liquids, the boiling temperature T_b is related with the specific cohesion a^2 in sq. mm. by the empirical expression $Ma^2/T_b=1\cdot16$, where M denotes the molecular weight of the substance; since σ, the surface tension in dynes per cm., is equal to $4\cdot9a^2D$, where D is the density of the liquid, $\sigma v/T_b=5\cdot67$, where v denotes the molecular volume.

Many attempts have been made to establish a relationship between the boiling points and the composition of members of the same homologous series of carbon compounds. H. Kopp,[22] for instance, noticed that every addition of CH_2 raised the boiling point of some series by about 19°, and he laid down the rule: the same differences in the chemical composition or organic compounds correspond with the same differences in the boiling points; but C. Schorlemmer [23] showed that with the monohalogens of the normal paraffins, the differences were not constant, but decreased 2° at each step. It was soon found that Kopp's rule was not at all general, and many empirical formulæ have been proposed, but these are usually applicable only to a limited number of homologous series,[24] and usually over but a limited range of a particular series. Many of these formulæ are described in W. Nernst and A. Hesse's *Siede und Schmelzpunkt* (Braunschweig, 1893), and in W. Marckwald's *Ueber die Beziehungen zwischen den Siedepunkten und der Zuzammensetzung der chemischen Verbindungen* (Braunscheweig, 1898). J. Walker had some success with the formula $T_b=aM^b$, where a and b are constants for particular series, but vary from series to series; M represents the molecular weight; and G. G. Longinescu,[25] with the formula $T_1/T_2=M_1n_1^{\frac{1}{2}}/M_2n_2^{\frac{1}{2}}$, where M_1 and M_2 respectively denote the molecular weights of liquids with n_1 and n_2 atoms per molecule, and boiling points T_1 and T_2. G. G. Longinescu's formula can also be represented in the form $(T_b/100D)^2=n$; where T_b represents the boiling point; D the density of the liquid at 0°; and n the number of atoms per molecule. For water, $n=12$, while for the normal molecular weight 18, n should be 3. Hence, says G. G. Longinescu the molecule of water must be more complex than $(H_2O)_4$. P. Pawlewsky found about seventeen organic liquids in which the difference between the boiling points under normal pressure and the critical temperature was the same; but further investigations have shown that the rule is not even roughly applicable to liquids generally. This is illustrated by the penultimate column of Table X, from S. Young's *Stoichiometry* (London, 1908). The last column, however, shows that the ratio of the absolute critical temperature, T_c, and the absolute boiling temperature, T_b, is more nearly constant, as pointed out by C. M. Guldberg in 1890,

$$\frac{T_c}{T_b}=1\cdot7$$

This rule, however, is but a rough approximation, though it may be employed to get an idea of the critical temperature of a substance.

TABLE X.—RELATION BETWEEN THE BOILING POINT AND THE CRITICAL TEMPERATURE.

Substance	Critical temperature T_c.	Boiling point T_b.	Difference T_c-T_b.	Ratio $\frac{T_c}{T_b}$
Hydrogen . .	35°	20°	15°	1·75
Oxygen . . .	154	90·5	63·5	1·70
Methane . . .	191	108·3	82·7	1·76
Octane . . .	569·2	398·8	170·4	1·43
Benzene . . .	561·5	353·2	208·3	1·63
Water . . .	633	373	260	1·59

According to T. E. Thorpe and A. W. Rücker, if D_1 and D_2 denote the densities of a liquid respectively at the absolute temperatures T_1 and T_2, the critical temperature T_c is $0·50125(T_2D_1-T_1D_2)/(D_1-D_2)$; or, if V_b denote the specific volume at the boiling point,

$$T_c=\frac{T_bV-273}{2(V_b-1)}$$

According to S. Young, the quotient p_cv_c/T_c, where p_c, v_c, and T_c respectively denote the critical pressure, volume, and temperature, is approximately 22 for normal liquids; water gives the value 26·4. W. Herz showed that the ratio increases in homologous series with an increase in the number of carbon atoms.

Relation between heat of vaporization or fusion and the boiling or freezing point.—In 1823, C. M. Despretz[26] showed that the heat of vaporization L of a liquid divided by the increase in the specific volume which is experienced by the liquid in passing into the state of vapour, is equal to the result obtained with any other liquid at a temperature where the vapour pressures are equal; that is, if v_l and v_g be the specific volumes of a substance in the liquid and gaseous states at its boiling point, $L=k(v_g-v_l)$, where k is a constant, the same for all liquids. J. D. van der Waals has given a theoretical foundation for C. M. Despretz's rule, and shown that if the absolute temperatures of any two liquids be the same fraction of their respective critical temperatures, then the volumes of the liquids and of their saturated vapours is the same fraction of their critical volumes. C. M. Despretz's rule agrees well with many liquids. Assume that Q, the latent heat of vaporization in R. Clausius' equation, $d(\log p)/dT=Q/RT^2$, does not vary with temperature, and that the molecular weight of the substance in the two states of aggregation is the same, it follows, on integration, that $\log p=-Q/RT+$a constant; otherwise expressed, $Q=T\{R(\text{constant}-\log p)\}$, where the bracketed term is constant at the standard pressure p. Hence, the heat Q required to vaporize one gram-molecule of a substance is equal to the absolute boiling temperature, at atmospheric pressure, multiplied by a number which is always the same. A rule analogous to this was proposed by F. Trouton (1884): **The molecular heat of vaporization of a liquid is proportional to the absolute boiling temperature**; or, the quotient of the molecular heat of vaporization and the absolute temperature of the boiling point at one atmospheric pressure is a constant. This is known as **Trouton's rule,** in symbols $M\lambda/T=$a constant which approximates to 20, when L represents the molecular heat of vaporization, which is the product of the latent heat of vaporization (per gram of liquid) into the molecular weight M of the substance; and T represents the boiling point of the liquid on the absolute scale. R. Schiff (1886) found the rule valid for organic liquids, particularly those in related groups. The following examples illustrate Trouton's rule:

	Carbon disulphide, CS_2.	Phosphorus trichloride, PCl_3.	Stannic chloride, $SnCl_4$.	Hydrogen sulphide, H_2S.	Water, H_2O.
Latent heat of vaporization (λ) .	86·7	51·4	30·5	124·4	537
Molecular heat of vaporization .	6384		7962	4230	9666
Boiling point	46°	76°	113·9	−61·6°	100°
Absolute boiling point (T) . .	319°	349°	386·9°	211·4°	373°
Trouton's constant ($\lambda M/T$ or L/T)	20·32	20·07	20·49	20·01	25·9

R. de Forcrand has made a simple extension of Trouton's rule: **The molecular heat of solidification of a gas is proportional to its absolute boiling point (760 mm.)**; so that if L and S respectively denote the molecular heats of vaporization and fusion, $(L+S)/T=$a constant which for a number of substances falls between 28 and 32. If λ and s respectively denote the molecular latent heats of vaporization and solidification at constant pressure, and M the molecular weight of a substance, Trouton's and Forcrand's rules can be respectively symbolized:

$$\frac{\lambda M}{T}=20 \qquad \frac{(\lambda+s)M}{T}=30$$

It is generally considered that Trouton's rule is near the mark for substances in the normal condition, or rather, when the molecules of the substance are the same in the liquid and in the gaseous condition. There are two cases :

(i) *Trouton's constant is greater than* 20. Illustrating by example, ethyl alcohol, C_2H_5OH, furnishes an abnormally high value, *viz.* 26·9 (=9443÷351·4). This is attributed to the association of the molecules $(C_2H_5OH)_n$ in the liquid state, while the molecules of the vapour are normal, C_2H_5OH. Consequently, the observed latent heat of vaporization is the sum of two factors : (*a*) The heat absorbed during the conversion of the molecules of liquid C_2H_5OH into vapour C_2H_5OH ; and (*b*) the heat absorbed during the depolymerization, $(C_2H_5OH)_n = nC_2H_5OH$, in the liquid at its boiling point. Water is another example with Trouton's constant 25·9 ; nitric oxide, 27·7 ; etc.

(ii) *Trouton's constant is less than* 20. Acetic acid, CH_3COOH, furnishes an abnormally low value for Trouton's constant, *viz.* 12·7 (=5094÷391). If the molecules of a vapour are associated and the molecules of the liquid are non-associated, the observed molecular heat of vaporization will be less than would be the case if the molecules were not associated in passing into the state of vapour because heat is evolved during the polymerization of the molecules. In the case of acetic acid, it happens that liquid and vapour molecules are associated to approximately the same extent, and if the molecular latent heat be taken for $(CH_3COOH)_2$ the quotient is normal.

Trouton's rule thus enables an estimate to be made of the molecular complexity or the molecular weights of substances at their boiling points. Thus, iodine approximates I_3 ; sulphur, $S_{8\cdot3}$; mercury, $Hg_{1\cdot18}$; nitric acid, $(HNO_3)_{1\cdot37}$; etc. Even among non-associated substances, however, Trouton's constant may increase considerably with temperature if the substances chosen have widely different boiling points. Thus :

	Hydrogen.	Oxygen.	Carbon disulphide.	Aniline.
Absolute boiling point . . .	20·4	90·6	319	457
Trouton's constant	10·4	18·13	20·4	23·1

W. Nernst (1906) employed the empirical formula $\lambda/T = 8{\cdot}5 \log T$; or $\lambda/T = 9{\cdot}5 \log T - 0{\cdot}007T$; E. C. Bingham (1906), $\lambda/T = 17 + 0{\cdot}011T$; and R. de Forcrand, $\lambda/T = 10{\cdot}1 \log T - 1{\cdot}5 - 0{\cdot}009T + 0{\cdot}0000026T^2$ to represent the increase in the value of Trouton's constant with temperature. W. Hess found that Trouton's rule gave irregular results with homologous carbon compounds.

H. Crompton[27] introduced the idea of valency in Trouton's formula ; P. W. Robertson, the cube root of the atomic or molecular volume ; W. Nernst, specific cohesion ; E. Baud, the change of volume at the melting point ; J. de Guzman, the coefficient of viscosity ; H. Tsutsumi, the specific resistance ; H. S. Allen and K. Honda, electronic frequency ; and H. G. Wayling, Moseley's atomic number. If N be the sum of the atomic numbers of the atoms of the elements forming a compound, and T the absolute temperature of the melting point, H. G. Wayling writes N/T=a number ranging from 2 to 5. The salts with water of crystallization have higher values ; G. N. Lewis represents the relation between the heat of vaporization, the absolute temperature T, the coefficient of expansion of the liquid a, the density D, and the coefficient of compressibility β, by $\lambda = -Ta/D\beta$, when the liquid is normal, and not polymerized or associated.

J. H. Hildebrand argues that the quotient of the heat of vaporization by the absolute boiling point represents the increase in the entropy of a substance during vaporization, per atmosphere pressure, and hence the term *entropy of vaporization* can be employed for this ratio at temperatures other than the boiling point. Trouton's rule fails for normal substances at extreme temperatures, because the constant is greater the higher the boiling point. J. H. Hildebrand further showed that by plotting log p against log T in Clapeyron and Clausius' formula

$$\frac{d \log p}{d \log T} = \frac{\lambda}{RT}$$

the tangent to the resulting curve at any point represents the entropy of vaporization at that temperature divided by R. If Trouton's rule be valid, the tangents to the curves for different substances should have the same slope at a value of log p, corresponding to one atm.; in reality, the slopes of the curves for equal values of log p, increase regularly with log T. Consequently, the entropy of vaporization of different substances cannot be the same at equal pressures, but rather at pressures which increase in some way with the temperature. J. H. Hildebrand found that the tangents to the curves at points cut by a line whose equation is $\log p = \log T + K$, where K is a constant, have the same slope "with a remarkable degree of precision."

For vapours at a low enough concentration to obey the gas law $p=RTC$, where C denotes the molecular concentration, $\log p = \log T + \log RC$, and hence $\log RC = K$, and therefore along such a line C is constant. Hence, *the entropy of evaporation is the same for all normal liquids, not as in Trouton's rule when the vaporization takes place at the same pressure (one atmosphere), but when it takes place at the same concentration of vapour; i.e.* when the mean distance between the molecules is the same. J. H. Hildebrand extrapolated the experimental data for λ and T for values of C arbitrarily selected to correspond with 0·00507 gram-molecules per litre. The values of L/RT_c, where T_c refers to equal concentrations of vapour, are between 13·1 and 13·9 for normal liquids and above 16 for associated liquids. There is no systematic deviation with temperature, and the deviations are much less than with Trouton's rule.

It will be observed that when a molecule escapes from a liquid to a vapour, it is relieved of the high internal pressure which exists in the liquid, and it may conceivably expand with an absorption of an amount of energy e so that the entropy of vaporization becomes $(\lambda+e)/RT$. The value of e is probably greater than for molecules containing the larger numbers of atoms, but in general the value of e is probably small in comparison with λ, for most of the energy of vaporization is expanded in overcoming intermolecular attraction, and but little in the expansion of the molecule itself. With associated liquids, energy is further expanded in the dissociation of complex molecules into simpler ones, and the total entropy of vaporization is greater than the normal value. For liquids at low temperatures where the specific heats change rapidly with changes of temperature, deviations from the rule at low temperatures might be anticipated.

§ 5. Gibbs' Phase Rule

> The phase rule is one of the most comprehensive generalizations known to man. It is of unlimited application, and offers an accurate and ready means of classifying all states of physical and chemical equilibria.—W. MAYERHOFER (1893).

On plotting the vapour pressures of water at different temperatures, a curve *OQ*, Fig. 9, is obtained. This gives the vapour pressure of water corresponding with any given temperature when the liquid and vapour are in contact, and in equilibrium. Call this the **steam line,** or **vaporization curve.** The ordinate of *O* represents the vapour pressure of water at 0°; at lower temperatures the water freezes. Plot in a similar manner the vapour pressures of ice at different temperatures, and the curve *OP*, called the **hoar-frost line,** or the **sublimation curve,** is obtained. Under these conditions, there is no intermediate liquid state, vapour condenses at once to a solid, and the solid passes directly into vapour. Solid iodine, below its melting point 114°, also vaporizes without liquefaction; arsenic can be liquefied only be melting the element under pressure; since under ordinary conditions, arsenic sublimes without fusion. It is found that the effect of pressure on the melting point of ice can be represented by a curve *ON*, Fig. 9. The left-to-right downward slope of the curve shows that the melting point of ice is lowered by increasing the pressure. Thus the melting point of ice at different pressures, according to G. Tammann (1900), is approximately:

Pressure	260	490	1100	1790	2020 atm.
Melting point . . .	−2°	−4°	−10·11°	−17·6°	−20·59°

and *in vacuo*, ice melts at +0·0075°. To emphasize these relations the curves in the diagram are slightly exaggerated. The curve *ON* is called the **ice line** or **fusion curve ;** it represents the melting point curve of ice under uniform pressures. Before progressing further, it will be convenient to fix special meanings to three terms : component, phase, and degree of freedom or variance.

Components.—The components of a system are the individual substances which are not decomposed in the process. The number of components chosen to represent a system is the smallest possible. The components may be elements, or compounds which behave in a system, for the time being, *as if* they were elements. There is only one component in the system just considered, namely, water—H_2O ; and the components in an aqueous solution of sodium chloride are water (H_2O) and sodium chloride (NaCl). A solution of sodium sulphate in water in a closed vessel contains four elements—sodium, sulphur, oxygen, and hydrogen—but neither the sodium sulphate nor the water is liable to decomposition under the conditions of the experiment. Hydrogen cannot be removed without simultaneously removing oxygen, nor can sulphur be abstracted without taking away sodium and oxygen at the same time. Accordingly, while the composition of the system can be expressed in terms of four components, two are necessary and two are superfluous, for, if the quantities of any pair of these four elements are stated, the other two can be computed. Hence, only two components are involved, namely, water (H_2O) and sodium sulphate (Na_2SO_4).

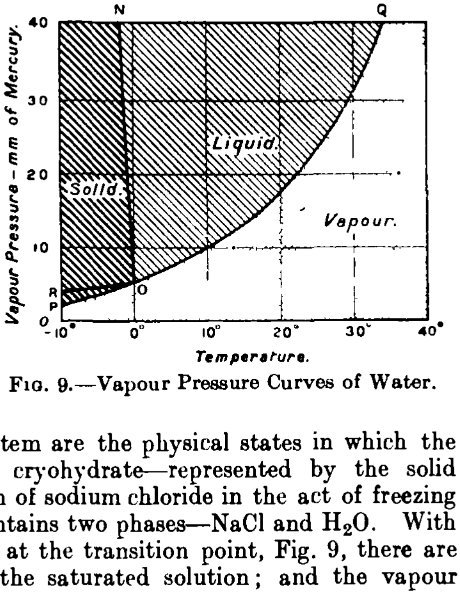

FIG. 9.—Vapour Pressure Curves of Water.

Phases. — The components may group themselves in various ways. They may pass from one physical state to another, as when water boils or freezes ; they may form simple solutions, as when salt dissolves in water ; they may combine with one another in various ways, as when sodium sulphate (Na_2SO_4) forms the decahydrate ($Na_2SO_4.10H_2O$), etc. **Every homogeneous state—solid, liquid, or gaseous —which the components can produce is called a phase.** The phases of a system are the physical states in which the components can exist. A eutectic or cryohydrate—represented by the solid which separates from an aqueous solution of sodium chloride in the act of freezing —is not a phase because the eutectic contains two phases—NaCl and H_2O. With an aqueous solution of sodium sulphate at the transition point, Fig. 9, there are four phases—Na_2SO_4 ; $Na_2SO_4.10H_2O$; the saturated solution ; and the vapour arising from the solution. With freezing water, there are three phases—ice, water, and vapour. In homogeneous systems there can be only one phase, *e.g.* aqueous solutions, solid solutions, gaseous systems ; and in heterogeneous systems there are always two or more phases.

Variance or degrees of freedom of a system.—It will be remembered that the **condition of equilibrium** of a gas with respect to temperature, pressure, and volume is defined by the equation, $pv=RT$, for R is a numerical constant whose value depends upon the units of measurement. If only one of these variables be fixed, say the volume, the state of the system will remain undefined, because the gas can retain one fixed volume, and yet have very different values for temperature and pressure. Two of the three variables must be known before the state of the system can be defined unequivocally, without ambiguity. If any two of the three variables be fixed, the third variable can assume only one definite value. The two fixed variables are said to be arbitrary or **independent variables ;** the third variable, which can be calculated from the condition of equilibrium ($pv=RT$) when the two independent variables are known, is called the **dependent variable.** Another term sometimes used for the independent variable is **degree of freedom ;** the number of degrees of freedom is also called the **variance** of the system (that is, the variableness of the system, from the Latin *variabilis*, variable). The gaseous system under consideration has two degrees of freedom because two physical conditions can be varied independently. **The degree of freedom or variance of a system is the number of independent variables which must be fixed before the state of the system can be defined without ambiguity.** The gaseous system defined by the equation, $pv=RT$, is **bivariant,** because it has two independent variables, or two degrees of freedom. The system consisting of liquid water and vapour has two variables : vapour pressure and temperature. So long as liquid water is present, the pressure is determined solely by its temperature; given either the pressure or the temperature, the other can be determined from the relation symbolized in the vapour pressure curve—Fig. 8. Hence the state of the system is defined by two variables—the one is dependent, the other independent. In other words, the system has one degree of freedom, that is, the system is **univariant.**

Triple point.—The three curves PO, OQ, and ON—Fig. 9—represent the conditions of equilibrium of three two-phase systems : solid-vapour, vapour-liquid, and solid-liquid respectively. These three curves meet at the point O. Here three phases can coexist in equilibrium. Hence the point O is called a **triple point.** The co-ordinates of the triple point are: pressure, 4·57 mm.; temperature, 0·0076° C. If the pressure or temperature be altered ever so little one of the phases—ice or liquid water—will disappear and a two-phase univariant system represented by a point on one of the curves OP, OQ, ON will appear. At the triple point the system is **invariant.** Confining our attention, for the moment, to the liquid and solid, and neglecting the vapour, we can define: **The freezing or melting point is the temperature at which both solid and liquid can exist side by side in contact with one another without changing.**

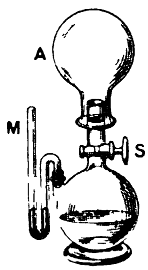

Fig. 10.—Experiment on the Phase Rule

Gibbs' phase rule.—J. W. Gibbs (1876-78) discovered an important relation between the number of components, the phases, and the degrees of freedom of a system. According to one setting of **Gibbs' phase rule, a system will be in equilibrium when its variance is equal to the number of components in the system less the number of phases increased by 2.** In symbols :

$$F=C-P+2$$

where C denotes the number of components, P the number of phases, and F the variance or degrees of freedom of the system. Otherwise expressed, P must be equal to or less than $C+2$, that is, a system of C components in a state of equilibrium cannot have more than $C+2$ phases. **The number of possible variations in the physical conditions of temperature, pressure, and concentration, without changing the number of phases, is two more than the difference between the number of components and the number of phases.** Conversely, the number of phases in a system can be determined from the maximum number of possible variations in the physical conditions. The phase rule thus serves as a test for stable states of equilibrium. Suppose the system water and steam, Fig. 10, be in equilibrium ; the vapour pressure indicated by the manometer M is not altered if the cock S be closed, and the globe A removed. This experiment emphasizes the fact that unlike chemical equilibria in homogeneous systems, **the equilibrium between different phases—heterogeneous equilibrium—is independent of the amount of substance in each phase,** a milligram of a solid in a saturated solution will be as truly in equilibrium as a kilogram. Accordingly, **the phase rule is a qualitative, not a quantitative**

criterion of equilibrium, it says nothing definite about the amount of each phase.

Derivation of the phase rule.—The following argument is based on that of H. W. B. Roozeboom.[1] A system is in stable equilibrium when its free energy has a minimum value. If a system has several phases in contact with one another, each phase can be regarded separately. Consider solid barium peroxide, BaO_2, in contact with gaseous oxygen and solid barium oxide, BaO. If some oxygen can pass from the gaseous to the solid phase, some of the monoxide will pass into the dioxide. If E_1 denotes the change in the free energy per unit mass of oxygen added to the one phase, and E_2 the corresponding change in the free energy for the same component removed from the other phase, the total change in the free energy per unit mass of oxygen will be E_2-E_1; if this magnitude be negative, oxygen will pass from phase 1 to phase 2, and conversely; if the system is in stable equilibrium, E_2-E_1 must be zero, and $E_1=E_2$. More generally, **for stable equilibrium, the free energy of each component in every phase must have the same value,** and no other condition is necessary.

If a heterogeneous system in equilibrium contains P phases and C components, and if each phase be supposed to contain a certain amount of each one of the C components, it follows that the *composition* of unit mass of each phase will be fixed when the amounts of C—1 of the components which the phase contains are known, for the amount of the remaining component is determined by difference. Since the composition of each phase is quantitatively defined by C—1 variables, the composition of P phases, otherwise expressed, the composition of the whole system, will be fixed by $P(C-1)$ variables. Besides composition, however, r other variables—temperature, pressure, etc.—can change independently, and consequently, *the state of the system will be defined by* $r+P(C-1)$ *variables.* These variables can be determined by remembering that the free energy of each component in each phase can be represented by an equation which is a function of the pressure, temperature, composition (concentration), etc.; but since any change in one phase implies a corresponding change in each of the remaining $P-1$ phases, the changes in each component will be described by $P-1$ separate equations. When the system is in equilibrium, the free energy of each component in every phase must be equal, and therefore, *the free energy of the* C *components in the system will be described by* $C(P-1)$ *equations.* Consequently, for equilibrium, the number of undetermined variables F in excess of the number of equations will be $F=r+P(C-1)-C(P-1)$, an expression which reduces to the phase rule for r independent variables, and one dependent variable: $F=C-P+r$. When in addition to composition, the state of the system is defined by pressure or temperature, $r=2$, and the rule reduces to $F=C-P+2$.

Invariant systems.—An invariant system has no degrees of freedom, and the state of such a system cannot therefore survive a change of temperature or pressure. In that case $F=0$, or $P=C+2$. This means that the system will have $C+2$ phases, if it is in equilibrium. If there be one component in the system, as in the case of water at the triple point, three phases can coexist in equilibrium—ice, liquid water, and steam. Otherwise expressed, if a system has three phases and one component, the phase rule tells us that it will be invariant, and therefore the slightest alteration of pressure or temperature will cause one of the phases to disappear. Again, in a system with three components—bismuth oxide, nitric anhydride, and water—and five phases—solution, vapour, and three solids—the system is invariant, and the three solid phases can exist at one temperature, one pressure, one concentration of the solution. Three phases of one substance cannot exist in equilibrium in one system—say, sulphur with two liquid and one vapour phase; or water with one solid, one liquid, and one vapour phase—and have an extended range of coexistence for the two non-vapour forms, because such a system must be invariant, and therefore cannot exist except at a single temperature and pressure.

Univariant systems.—These systems have one degree of freedom, and when the system is in equilibrium, $F=1$, or $P=C+1$. If one of the variables be known, the state of the system can be determined as indicated above. If the system bismuth oxide, nitric anhydride, and water has two solid phases, it will be univariant, and the system can exist at different temperatures or with different concentrations of the solution, but at any assigned temperature, the liquid in equilibrium with the two given solid phases cannot vary in concentration.

Bivariant systems.—These systems have two degrees of freedom, and hence $F=2$, or $P=C$. Two variables must be known before the state of the system can be determined. A saturated solution in the presence of an excess of the solute is univariant, but bivariant if not saturated. In the former case there are two components and three phases—solid, solution, and vapour; in the latter case there are two components and two phases. Hence in the one case, $F=2+2-3$; and in the other, $F=2+2-2$. Again, in the region *PON*, Fig. 9, the system will be bivariant, because there is only one phase and one component. Pressure and temperature may be altered without interfering with the state of the aggregation of the ice so long as the variations keep within the boundary lines *PO* and *ON*. The same remarks may be applied to the condition of the water represented by points in the regions *NOQ* and *POQ*. In the system bismuth oxide, nitric anhydride, and water previously considered, if only one solid phase is present the system will be bivariant, and the solid can be in equilibrium at a constant temperature with a solution of varying concentration, or with a liquid of a fixed concentration at different temperatures.

Modification in the phase rule with restricted systems.—One of the chief difficulties in the application of the phase rule turns on the proper selection of the components. For example, if the four substances concerned in the system, $HgSO_4+H_2O\rightleftharpoons HgO+H_2SO_4$, be considered as components of the system, the variance will be one more than would be the case if mercuric oxide, water, and sulphur trioxide be regarded as the components. It will be observed that in the first case there is a limiting condition, for the concentration of the sulphuric acid is determined by that of the mercuric sulphate. **Each independent relation or fixed condition among the components of a system reduces the variance of the system by one.** Limitations and restrictions may be introduced from chemical necessity or by arbitrary choice. For example, in the reaction $2H_2+O_2\rightleftharpoons 2H_2O$ at a high temperature, the number of components may be taken as one since the free hydrogen and oxygen are always in the fixed proportions characteristic of water vapour; there is also one gaseous phase, and the system is accordingly bivariant. On the other hand, if the number of components be taken as two—hydrogen and oxygen—there is one restriction on the ratio of their concentrations, and the system has accordingly two degrees of freedom.

There are several different but equivalent methods of selecting the components. For example, what is here called component has also been called an *individual* (T. W. Richards, 1916), *constituent* (W. D. Bancroft, 1906), or *system-component* (F. Wald, 1906), and the true number of components C in a system is then regarded as equal to the number n of individuals less the number of restrictions r, so that $C=n-r$. In the equilibrium $CaCO_3\rightleftharpoons CaO+CO_2$, the system has one degree of freedom if no restriction be placed on the temperature or pressure, but if the temperature or pressure be fixed, there is one restriction, and the system is invariant. There is not a chemical limitation in the quantities of lime or carbon dioxide because adding more of either constituent without altering the pressure has no effect on the equilibrium. In a dilute solution containing potassium nitrate, potassium chloride, and potassium bromide in equilibrium with its vapour, in addition to the water there are the four components, K, NO_3, Cl, Br, subject to the limitation that the gram-molecular concentration of the potassium must be equal to the sum of the concentrations of the three radicles, NO_3, Cl, and Br. In a similar solution of potassium nitrate and sodium chloride, the components may be regarded as water plus the two salts; this makes the system tervariant; but if the five components, water, potassium, and sodium, and the two radicles, NO_3 and Cl, be considered as components, it is necessary to reduce the corresponding variance of the system by two owing to the two limitations imposed by the necessity for the concentration of the potassium and nitrate radicle to be equivalent and likewise for that of the sodium and chlorine radicle. This makes the variance of the system three the same as before.

Object of the phase rule.—The phase rule is (1) a method of grouping into one class, systems which behave in a similar manner. It is essentially a method for the classification of states of equilibrium. Systems having the same variance behave in an analogous manner under the influence of variations in temperature, pressure, and volume or concentration. It makes no difference whether the changes be chemical or physical. As indicated above, the phase rule also tells us (2) whether the phases of a heterogeneous system are those necessary for equilibrium ; (3) it is of assistance in identifying chemical individuals among a series of basic salts or solid solutions. This it does by indicating the variance of the system which, in turn, indicates whether or not the existing constituents have such a degree of stability that they can survive a change of temperature or concentration. A knowledge of the conditions of equilibrium of a system containing solution and solid may therefore show whether one or a mixture of two solid phases is present. The phase rule is therefore a help and guide in the interpretation of complex phenomena ; a set of facts may be under investigation and a number of explanatory hypotheses may be devised. The phase rule will select which hypotheses are worthy of being tested by direct experiment, and which can be rejected as fundamentally unsound. There are some differences of opinion as to the utility and value of the phase rule. Those who have done successful work with its aid are usually enthusiasts, but some say that it is an " over-ridden hobby " and dub it the " phrase rule."

Modification for systems affected by other than mechanical and thermal energy.—Other variables (electricity, gravitation, capillary tensions, etc.) besides concentration, pressure, and temperature may modify the state of equilibrium of some systems. Thus, light modifies the state of certain chemical equilibria. This introduces another degree of freedom, and the phase rule must be modified to allow for the action of light on systems sensitive to this agent. Accordingly, the phase rule would then read $F=C-P+3$. W. D. Bancroft (1906)[2] adds : Experience shows that there are many kinds of active light, and the phase rule would have to be altered accordingly ; usually, however, a beam of light can be treated as though it were homogeneous if the intensities of the constituent rays are varied uniformly. Similar remarks apply *mutatis mutandis* to other agents, *e.g.* variations in volume, the silent electric discharge, etc. Usually only mechanical energy (pressure) and thermal

TABLE XI.—CLASSIFICATION OF SYSTEMS BY THE PHASE RULE ($F=C-P+2$).

System.	Components. *C.*	Phases. *P.*	Degrees of freedom or variance. *F.*
Freezing water . . .	Water	Liquid ; solid ; vapour	Invariant
Water above 0°. . .	Water	Liquid ; vapour	Univariant
Unsaturated solution of sodium chloride	Water ; salt	Solution ; vapour	Bivariant
Saturated solution of sodium sulphate at transition point	Na_2SO_4 ; H_2O	Na_2SO_4 ; $Na_2SO_4 10H_2O$; solution ; vapour	Invariant
Freezing eutectic—sodium chloride and water	Water ; salt	Two solids ; one liquid ; vapour	Invariant
Solution of oxygen in water	Oxygen ; water	Gas ; liquid	Bivariant
Steam and metallic iron in a closed vessel	Iron ; oxygen (hydrogen)	One gas ; two solids	Univariant
$2NO_2 \rightleftharpoons N_2O_4$ . . .	NO_2	One gas	Bivariant
$2H_2+O_2 \rightleftharpoons 2H_2O$ . .	Hydrogen ; (oxygen)	One gas	Bivariant
Heated mercuric oxide (over 400°)	Mercury ; (oxygen)	Gas and solid	Univariant
Heated barium peroxide .	Barium oxide ; (oxygen)	Two solids ; one gas	Univariant
$n\mathrm{CNOH}_{\mathrm{gas}} \rightleftharpoons \mathrm{C}_n\mathrm{N}_n\mathrm{O}_n\mathrm{H}_{n\,\mathrm{solid}}$	CNOH	One gas ; one solid	Univariant
Heated $CaCO_3 \rightleftharpoons CaO+CO_2$	CaO ; (CO_2)	One gas ; two solids	Univariant

energy (temperature) come into play, and the rule then reads, $F=C-P+2$. In the application of the phase rule to alloys, minerals, and solutions when the vapour pressure is negligibly small, only two variables need be considered—concentration or volume, and temperature. For such condensed systems, the phase rule reads :

$$F=C-P+1$$

Granite, composed of quartz, SiO_2 ; felspar, $K_2O.Al_2O_3.6SiO_2$; and mica, say, $K_2O.3Al_2O_3.6SiO_2$, has three components : SiO_2, Al_2O_3, and K_2O ; and three solid phases : mica, quartz, and felspar. The system is univariant. It is also in equilibrium, because not being at a transition point, it is able to survive a small variation of temperature without changing the state of the system.

Examples.—Table XI shows the phase rule classification of some typical systems. A component in brackets is regarded as being restricted by stoichiometrical relations.

§ 6. Undercooling, Supersaturation, and Metastability

A metastable system, though stable, is constantly menaced by a spontaneous transformation.—G. URBAIN (1912).

Undercooling.—Heat a solution of sodium thiosulphate to, say, 70° in a glass flask ; stir the molten mass with a thermometer as it cools ; read the thermometer every two minutes ; and finally plot the results on squared paper. A curve—called a **cooling curve**—resembling that illustrated in Fig. 11, *A*, will be obtained. The terrace in the cooling curve at 56° shows that a change of some kind takes place in the nature of the cooling substance at 56°. The terrace corresponds with the temperature at which solidification or freezing was in active progress. The sudden slackening in the rate of cooling corresponds with the evolution of the latent heat of fusion as the liquid solidifies. Repeat the experiment, but do not agitate the liquid ; take care that the cooling liquid is quite still and protected from dust by, say, a loose plug of cotton wool in the neck of the flask. A cooling curve like that shown in Fig. 11, *B*, will be obtained. The liquid does not freeze, and no abnormal behaviour can be detected in the cooling curve. The liquid " ought to " crystallize at 56°, but it does not. Drop a crystal of sodium thiosulphate into the liquid mass. The contents of the flask seem to solidify with almost explosive rapidity, and the thermometer immediately indicates a rise of temperature. The phenomenon is illustrated by Fig. 11, *C*. The liquid sodium thiosulphate at a temperature below 56°

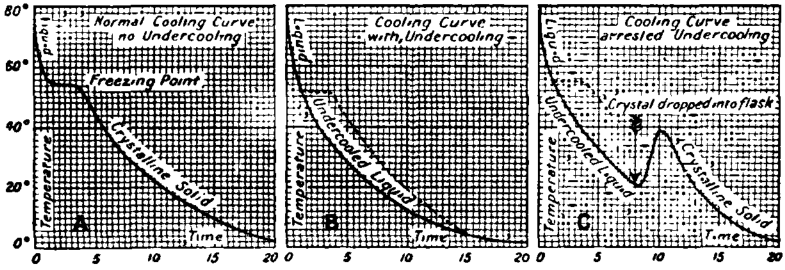

FIG. 11.—Cooling Curves of Molten Sodium Thiosulphate.

is said to be **surfused,** or, better, **undercooled.** The liquid may be kept in the surfused or undercooled condition an indefinite time, and the process of solidification can be started, in general, only by the introduction of a crystal of the same type as that which is formed during the solidification of the given substance. Often a fleck of the right kind of dust floating in the air suffices to upset the state of apparent equilibrium. Clear glasses and pottery glazes are solutions of silicates which have congealed to hard masses without crystallizing.

Supersaturation.—Similar phenomena occur if water be saturated with Glauber's salt—$Na_2SO_4.10H_2O$—at 30°. Make sure that no excess of solid is in contact with the liquid, and let the solution cool as before—without agitation and without dust. Probably no salt will separate from the solution. The solubility curve of this salt tells us that the solid " ought to " separate from the system as the temperature is reduced. Here is another case of apparent, false, or metastable equilibrium. If a solution holds more salt than corresponds with the normal solubility curve of the salt, the solution is said to be **supersaturated.** Although the solution can be kept an indefinite time in this condition, **the seeding or inoculation of a supersaturated solution** by the introduction of a very minute quantity of a crystal of the dissolved salt will upset the state of apparent equilibrium. According to W. Ostwald,[1] as little as 10^{-8} gram of salol suffices to start the crystallization of undercooled salol, and with sodium chlorate, 10^{-10} gram is needed. The crystal fragment becomes the centre or nucleus from which crystals radiate into the solution on all sides. Similar results can be obtained with aqueous solutions of sodium acetate, sodium chlorate, etc. The following illustrative experiment is due to G. R. Robertson:

> A solution of 5 grms. of benzil in hot alcohol is filtered while hot into a 250 c.c. flask, heated to boiling, and set aside in a warm place to cool. The flask is fanned so as to cool the glass walls, condense alcohol on the sides, and wash down any benzil into the body of the liquid and so prevent marginal crystallization. The liquid can thus be cooled to 15° without crystallization. A minute fragment of benzil is then dropped into the centre of the flask, and a complex of lemon yellow crystals spreads radially through the mass of liquid. The experiment can be adapted to lantern.

According to A. L. Potilitzin (1893), salts forming hydrates which have a considerable dissociation pressure in dry air at ordinary temperatures usually form supersaturated solutions readily ; while salts forming hydrates which do not readily dissociate in dry air or in vacuo do not usually form supersaturated solutions so readily. Calcium sulphate, $CaSO_4.2H_2O$, is an exception, for it does not lose water at ordinary temperatures, and it forms supersaturated solutions.

In 1795, J. T. Löwitz [2] found that any crystal will not do for the inoculation. Thus, if a crystal of nitre be introduced into a mixed solution of nitre and Glauber's salt, prepared hot, and subsequently cooled, the nitre alone crystallizes out, while if the solution be seeded with Glauber's salt, the latter alone crystallizes from the solution ; and D. Gernez tried the action of 220 different substances on supersaturated solutions of Glauber's salts, and found 39 to be active stimulants ; 18 of the 39 substances were insoluble, and lost their activity after washing with water, and drying while protected from dust, and the remaining 11 substances lost their property when purified by recrystallization. Hence, D. Gernez assumed that the 39 substances which had inaugurated the crystallization of sodium sulphate all contained this salt as an impurity. In H. A. Miers' experiments on the crystallization of the organic compounds, salol and betol, it was found that the substances did not crystallize at first when allowed to cool in open vessels in the laboratory ; but after a time, when the air of the laboratory had become impregnated with dust, presumably containing minute grains of both substances, crystallization readily occurred in open vessels exposed in the laboratory. **The fragment of crystal used for seeding must be either a fragment of the same salt as that in solution or of an isomorphous salt.**

The particular salt which separates is to some extent determined by the nature of the inoculating salt. For example, J. T. Löwitz found that a crystal of potassium nitrate introduced into a supersaturated solution of both potassium nitrate and sodium sulphate was followed by the separation of nitre alone, while a crystal of sodium sulphate in a similar solution gave a crop of crystals of sodium sulphate alone. If fragments of both salts were added to a similar solution, crystals of both salts were simultaneously deposited. L. de Boisbaudran[3] found the addition of copper sulphate to solutions of nickel sulphate gave short thick prisms of nickel sulphate, while magnesium sulphate or ordinary nickel sulphate gave fine needle-like crystals. The crystallization of a supersaturated solution is not always induced by the addition of isomorphous substances, as L. de Boisbaudran, C. Tomlinson, and others have assumed from the fact that a supersaturated solution of nickel sulphate commenced to crystallize by contact with zinc sulphate.

It is possible that in some cases of seeding by isomorphous salts, the effect is due to the presence, as impurity, of the salt to be crystallized. Thus, N. Dhar (1916) showed that no change is induced in solutions of copper sulphate by the addition of crystalline sulphate of magnesium, manganese, iron, cobalt, zinc, or cadmium; sodium selenate has no effect on supersaturated solutions of sodium sulphate, strontium chloride on solutions of calcium chloride, or sodium nitrate on solutions of silver nitrate. This shows that the induced crystallization of supersaturated solutions is not a sufficient test for isomorphous substances. Similarly, a solution may be supersaturated with respect to the hydrate of one salt and not another. Thus, C. E. Linebarger (1893) showed that at 10° it is possible to prepare four different solutions of manganous sulphate saturated respectively with the hexa-, penta-, tetra-, and trihydrates. For example, at 10°, the solubility is

	$MnSO_4.6H_2O$	$MnSO_4.5H_2O$	$MnSO_4.4H_2O$	$MnSO_4.3H_2O$
Parts $MnSO_4$ per 100 of water	71	68	64	61

If a crystal of one of the three lower hydrates be added to a saturated solution of the hexahydrate a separation of the crystals of the lower hydrate will occur. Thus, by adding a pentahydrate crystal, the corresponding crystals will be deposited, more hexahydrate would pass into solution, and be deposited in turn as pentahydrate. This will continue until all the hexahydrate has been transformed into the pentahydrate. A supersaturated solution of ammonia alum, $Al_2(SO_4)_3.(NH_4)_2SO_4.24H_2O$, will deposit the same salt if sown with crystal fragments, but according to A. Piccini and V. Fortini (1902), if sown with fragments of octahydrated ammonium thallic alum, $Tl_2(SO_4)_3.(NH_4)_2SO_4.8H_2O$, crystals of $Al_2(SO_4)_2.(NH_4)_2SO_4.8H_2O$, not $Al_2(SO_4).(NH_4)_2SO_4.24H_2O$, separate.

It is possible to distinguish between a *saturated* and a *supersaturated* solution by bringing each in contact with more of the solid. If the solution is unsaturated, more solid will dissolve; if saturated, none will dissolve; and if supersaturated, solid will separate until the solution is saturated. The concentration of an unsaturated solution is less, while the concentration of a supersaturated solution is greater than that of a saturated solution.

Related phenomena.—Many other examples of related phenomena are known. In analytical work the slow appearance of precipitates in dilute solutions is very common. Pure water may be easily cooled to —3° or —4° without the appearance of ice if kept quite still while the temperature is reduced; and the water can be easily cooled to —6° or —7° if a layer of oil be placed over the surface of the cooling water. The undercooling of water was observed by D. G. Fahrenheit[4] in 1724, and the undercooling of freezing mercury by T. Hutchins in 1783. The vapour pressure of *liquid* water from about 30° to —10° is represented by the curve *QOR*, Fig. 9; if the water freezes at 0°, the vapour pressure curve of the solid from 0° to —10° is given by the curve *OP*. In the former case the curve *QO* does not show a break or abrupt change of direction at *O*, and in the latter case it does. Phosphorus, sulphur, etc., behave in a similar manner. W. C. Roberts-Austen[5] measured the undercooling of gold, copper, and some other metals, and A. D. van Riemsdyk showed that the sudden flashing of gold beads during cupellation is due to the crystallization of an undercooled liquid. The melting points of solids usually appear somewhat higher than their freezing point. Thus, sodium hydroxide is said to melt at 310°, and to solidify at 290°. The phenomenon is attributed to supercooling carrying the observed freezing point below its true value, or to a slight lagging in the speed of the change.

Ice has not been heated above 0° without melting, but liquid water can be heated to 105° or 106° without boiling. When the boiling does start, it proceeds with almost explosive violence. The phenomenon is called **bumping.** In 1772, J. A. de Luc noted that the bubbles of air which develop in a liquid while it is being heated serve as nuclei for the generation of the bubbles of vapour formed when the liquid boils, and he found a liquid free from dissolved air could be heated to 130° without boiling. F. Donny heated water to 137° without boiling, and observations in the same direction were made by D. Gernez, G. Krebs, W. R. Grove, etc. By suspending drops of water in a mixture of olive and linseed oils—which has the same specific gravity as water, and a high boiling point—L. Dufour (1863) raised water to 178° without boiling. P. J. Coulier (1875) found that dust-free air saturated with moisture may be cooled below the normal temperature of condensation : and John Aitken [6] (1880) showed that dust is necessary for the formation of fogs and raindrops, so that in perfectly clean dust-free air, aqueous vapour does not condense, and mist does not form. Without solid nuclei cooling vapours may become supersaturated.

The vapour pressure of small drops of liquid.—There is an exception to the general observation that at any given temperature the vapour pressure of a given liquid is always the same whatever be the *mass* of the liquid. In 1870, Lord Kelvin (W. Thomson) [7] showed that the vapour pressure of a liquid with a concave surface must be less than that of the same liquid with a plane surface. If a capillary tube, *A*. Fig. 13, dips in water confined in a closed vessel, it follows that the vapour pressure of the liquid at *a* must be less than that of the liquid at *b* ; and that the vapour pressure p_0 at *b* must be equal to the vapour pressure *p* at *a* plus a pressure *h* equivalent to the weight of a column of the vapour of height *ab* and the same sectional area as the bore of the capillary tube. For equilibrium, $p_0=p+h$, otherwise there would be a perpetual circulation of the liquid owing to distillation from *a* to *b* or conversely, while the height of the liquid in the capillary remained constant. The converse of the above can be extended to convex surfaces. The vapour pressure of a minute spherical drop of liquid (convex surface) must be greater than that of larger masses of liquid with approximately plane surface.

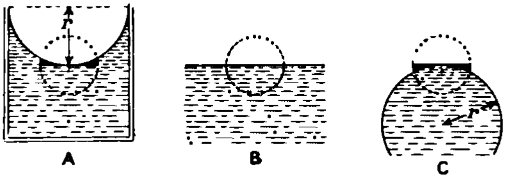

FIG 12

If p_0 denotes the vapour pressure of a liquid with a plane surface, and p its vapour pressure for a convex surface with a radius of curvature r, then, if S denotes the specific gravity of the liquid, and s that of the vapour, and σ the surface tension (or pressure) of the liquid, Lord Kelvin showed that with common logarithms, $\log (p_0/p)=2\sigma s/2{\cdot}3rp_0S$. For example, with water, $\sigma=80$; s, 0·00081 at 0° and 760 mm. ; p_0, 1014000 ; S is unity, $\log(p_0/p)=0{\cdot}56\times10^{-7}/r$. When r is large, say 10^{-1} to 10^{-4} cm., the ratio p_0/p is nearly unity, and only when r approximates to the millionth of a centimetre will the vapour pressure of a liquid be sensibly greater than that of a plane surface. The formula was deduced from thermodynamics by E. Warburg and R. von Helmholtz ; and from the molecular theory by G. F. Fitzgerald, J. Stefan, and B. Galitzine. The vapour pressure of an electrically charged surface was studied by R. Blondlot, N. Schiller, A. Gouy, and W. Kistjakowsky ; and the effect of a magnetic field has been studied by P. Duhem and J. Königsberger.

The kinetic theory interprets the phenomenon by showing that the inter-attraction of the molecules of a liquid on a molecule partially immersed, as illustrated by the dotted circle, *B*, Fig. 12, will be *less* than on a molecule similarly situated with respect to a concave surface, *A*, Fig. 12; and *greater* than a molecule similarly situated in a convex surface, *C*, Fig. 12. The differences in these magnitudes is illustrated by the blackened portions of *A* and *C*, Fig. 12, and it will be obvious without a mathematical demonstration. The greater the molecular attraction on the partially immersed molecules the less the vapour pressure of the liquid, and the less the tendency to evaporation; the smaller the drop of liquid the more convex the surface, and the greater the tendency to evaporation. Accordingly, in a given space the larger drops of liquid will grow at the expense of the small ones. Hence, a space saturated for a liquid with a plane surface is not saturated for minute drops, and this explains the observation that it is difficult for small drops of vapour to form in a space supersaturated for a plane but not for a convex surface. If small drops were momentarily formed they would at once evaporate. If dust particles be present the water will first condense upon them, and the liquid spread out on them will have a large radius of curvature so that re-evaporation will be comparatively slow, and the liquid has time to evaporate—assuming the nearer the ratio p_0/p approaches unity, the slower the evaporation.

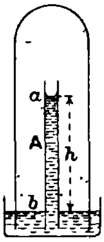

Fig. 13. — (Diagrammatic).

Metastable and labile states of supersaturation.—Inoculation or seeding is usually necessary to start the process of crystallization of a supersaturated solution; and yet the supersaturation may be carried so far that the crystals will grow spontaneously in the solution without seeding. Indeed, it is possible to draw a **supersaturated solubility curve** representing the concentration of a solution at different temperatures where the supersaturation is so great that crystallization will begin spontaneously without inoculation. The idea is illustrated in Fig. 14, where the region between the normal solubility curve and the supersolubility curve represents what W. Ostwald[8] called the **metastable state,** where inoculation is necessary to inaugurate the process of crystallization; and the region beyond this, below the freezing point, represents the so-called **labile or unstable state** where crystallization may start spontaneously without inoculation. *E.g.* a solution of sodium nitrate at 20° is saturated when it contains 45·8 per cent. of the salt, and it is *labile* when it contains over 48·8 per cent.; between these two concentrations the solution is metastable. Similarly, solutions of sodium bromide saturated with the hydrate, NaBr.2H$_2$O, at 30°, are in a labile condition, and crystallize spontaneously at temperatures between 5° and 16°; they are in a metastable condition above 19°.

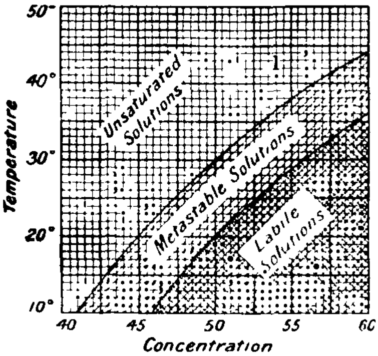

Fig. 14.—Labile and Metastable Equilibria of Saturated Solutions (after H. A. Miers).

The existence of the metastable and labile states was predicted by W. Ostwald in 1897, and demonstrated experimentally by H. A. Miers[9] and his co-workers in 1906. Can a metastable liquid be made to crystallize in any other way than by introducing a solid crystal? Ordinary shaking, scratching, and the like fail to provide the necessary stimuli. According to H. A. Miers,

> If the growth of a crystal is really the coming together of vibrating particles which cohere with one another . . . is it not possible that we may be able to communicate these vibrations to a supersaturated solution, which is so densely crowded that it is ready to crystallize, by some other means than by inoculating it with an appropriate crystal? . . . Some knowledge of those movements may be obtained by studying the sort of shock or movement, if there be any such, which starts crystallization in supersaturated solutions.

S. W. Young did succeed in making water and metastable salt solutions crystallize by applying mechanical shocks of sufficient intensity-mechanical hammers striking on metallic anvils. For instance, water was made to freeze at —0·02° without the addition of ice, with repeated blows of sufficient intensity. H. A. Miers and F. Isaac crystallized water at —1·9° without seeding, and H. Hartley and N. G. Thomas observed the formation of ice at —0·5° without seeding.

Supersaturation and the phase rule.—The phase rule, it will be observed, applies to systems in real equilibrium, not to systems in a state of apparent, false, or metastable equilibrium. We are repeatedly confronted with those little-understood phenomena which, for convenience, have been grouped under the general term passive resistance.

The kinetic theory of supersaturation.—The kinetic theory throws a little light on the phenomenon of supersaturation. A saturated solution in contact with the solid is supposed to be closely analogous with a closed vessel containing a liquid in contact with its vapour. When in equilibrium, the same number of molecules pass from the surface of the solid into the solution and return from the liquid to the surface of the solid. If the state of equilibrium be disturbed by evaporation or by lowering the temperature, the equality of the two opposing actions is disturbed and a new condition of equilibrium is established. In the case of a metastable supersaturated solution, the exchange of molecules cannot take place because no free solid is present. Directly a particle of the same substance as the dissolved solid is added, the dissolved substance is rapidly deposited about the submerged particle as a nucleus until the concentration of the solution has reached its normal value. In the case of a labile supersaturated solution, the crowding of the molecules is so great that they are able to form aggregates large enough to serve as nuclei about which the crystals can grow.[10]

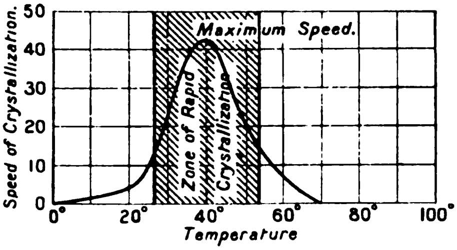

FIG. 15.—The Effect of Temperature on the Speed of Crystallization of Piperine.

The speed of crystallization. — Within certain limits of temperature, the speed of crystallization is greater the lower the temperature.[11] This might be expected if it be assumed that the lower the temperature, the smaller the speed of molecular motion, and the less the probability of a molecule escaping from the sphere of action of a growing crystal; but there is an influence retarding crystallization, for the slower the molecular motion, the greater the viscosity, and the smaller the number of molecules which travel into the sphere of action of a growing crystal. Instead of the speed of crystallization increasing continuously as the temperature is lowered, it reaches a maximum value and then progressively diminishes as the temperature falls, presumably because the viscosity of the groundmass is so great that it is superior to the vectorial forces which arrange the structural units into crystal forms, and completely inhibits their action.

Observations on the influence of temperature on the speed of crystallization can be illustrated by fusing hippuric acid (melting point 188°) in a dish; and making a number of capillary tubes—about 15 cm. long and 1 mm. bore—by drawing out a test-tube in the usual manner of making melting-point tubes. The molten acid is sucked into a warm tube, and immediately cooled under the water-tap. The surfused acid congeals to a glass-like mass as is demonstrated by breaking one of the tubes. If the tubes are warmed, say, in the hot air over a Bunsen's flame, crystallization immediately sets in, although the tubes may be preserved at atmospheric temperatures for some days. The speed of crystallization can be determined by exposing the surfused compound for, say, four minutes to the temperature in question, and then counting the number of centres of crystallization—the greater the number of crystal nuclei, the faster the crystallization. The maximum speed with hippuric acid is attained at about 100°.

G. Tammann's observations (1898) on the rate of crystallization of surfused piperine, melting at about 129°, show that the speed increases with decreasing temperatures down to about 40°; after that, the rate decreases as the temperature falls. The maximum speed is at about 40°. The speed of crystallization of undercooled water has been measured [12] by undercooling water and starting crystallization by introducing a fragment of the solid. The time necessary for the crystals to fill a certain length of the tube gives the linear velocity of crystallization. J. H. Walton and R. C. Judd's values for the linear velocity of crystallization of water in cm. per minute, for water in a tube (12 mm. outside diameter, and 7 mm. internal diameter), were

	−2·0°	−3·61°	−4·67°	−5·86°	−6·18°	−7·10°	−8·19°	−9·07°
Velocity .	31·6	48·4	71·4	107·1	114·7	266·7	415·2	684·0 cm. min.

The internal diameter, and the thickness of the walls of the tube have a marked influence on the results since they determine the rate of cooling of the crystallizing liquid. Spontaneous crystallization of the undercooled liquid prevented measurements being conducted at lower temperatures, and the temperature of maximum velocity of crystallization has not been determined. J. H. Walton and A. Brann measured the effect of forty-five substances on the velocity of crystallization of water supercooled to −9°, and found that all retarded the speed. The retardation is a colligative property. For substances with over eight atoms per molecule, the greater the number of atoms the slower the rate of crystallization; for substances with less than eight atoms per molecule, the power of retardation is a specific property. In dilute solutions, substances which undergo the greatest hydration in solution have the greatest effect in reducing the speed of crystallization; and this is explained by assuming that if the formation of ice crystals is due to a change of the type, $3(H_2O)_2 \rightleftharpoons 2(H_2O)_3$, any part of the solvent would have to be decomposed before crystals could be produced. H. T. Barnes has measured the rate of growth of the ice mantle in R. Bunsen's ice calorimeter. Similar phenomena are shown by glasses and pottery glazes, which are really congealed surfused liquids. There is a special range of temperature peculiar to each surfused compound which is particularly favourable to rapid crystallization—**zone of rapid crystallization.** This is illustrated in Fig. 15.

§ 7. The Allotropic Forms of Water

> Water is water, not a single substance in the proper acceptation of the term, but a mush or mixture; an entirely peculiar material, not to be represented by any one formula, nor spoken of by any single name.—H. E. ARMSTRONG (1913).

The vapour pressure curve of a substance comes to an abrupt end at the critical point, for the liquid ceases to exist. In Clapeyron's equation

$$\lambda = T\frac{dp}{dT}dv$$

at the critical temperature, dv is zero, and consequently also the latent heat of vaporization becomes zero.

Just as a liquid, at a constant pressure, when subjected to a constantly decreasing temperature, solidifies at a definite temperature called the **freezing temperature,** so will a liquid, at a constant temperature, when subjected to a constantly increasing pressure, solidify at a definite pressure—**the freezing pressure.**[1] For example, the freezing temperature of water is 0° under a pressure of one atmosphere, and at +1° the freezing pressure is 7600 atm. The curve of freezing pressure, dT/dp, is convex towards the pressure axis corresponding with the fact that each successive increment of pressure produces a smaller and smaller effect. Every substance has its own peculiar dT/dp-curve, but usually the slopes of the curves for different substances vary within comparatively narrow limits—less than 50° per 1000 atm.

The question has been discussed: What is likely to be the result of extrapolating the observed results for the effect of very high pressures on the course of the melting-point curve? J. H. Poynting and W. Ostwald[2] argue that, when the pressure is great enough, the melting-point curve of a solid will have a critical end-point, analogous to the critical temperature of a liquid. W. Ostwald further suggests that liquid crystals are solids near their critical points at ordinary pressures; and that the effect of pressure is to diminish the vectorial properties of crystals and reduce all matter to an isotropic or amorphous condition. If there be such a critical end-point, dv and λ of Clapeyron's equation should vanish simultaneously, but there is no sign of this in any substance which has been investigated at high pressures—in some cases λ increases rather than diminishes with increasing pressures. G. Tammann, M. Planck, and H. W. B. Roozeboom[3] have also raised objections to this hypothesis. G. Tammann assumes that if the pressure be great enough, all solids can be melted no matter what the temperature. G. Tammann assumes that the pressure-volume curves of liquid and solid will probably cross when $dv=0$ as indicated in Fig. 16; and under that condition, the latent heat will change its sign and be no longer positive, but negative. Under these assumed conditions, the melting point with an increase of pressure will first rise, and then fall; and at the turning point, the melting-point curve will be a maximum. G. Tammann, therefore, represents the melting-point curve as shown in Fig. 17. Inside the curve the crystalline solid is stable; outside, the liquid is the stable form. It is, however, not necessary to develop the idea further because P. W. Bridgman's work would probably have shown some signs in favour of Tammann's assumptions if they were valid at the enormous pressures under which he worked. Although the value of dv becomes smaller and smaller as the pressure increases, there is no sign of dv approaching zero.

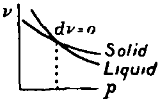

FIG 16.

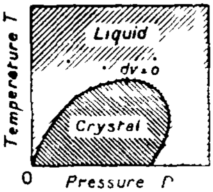

FIG. 17.

There is, therefore, no satisfactory evidence that the melting temperature of a solid will pass through a maximum (G. Tammann) or terminate at a critical end-point (J. H. Poynting) as the pressure increases, but the evidence rather indicates that the melting temperature will rise indefinitely with increasing pressure, or else the solid will change abruptly into another allotropic form. For example, liquid water under very great pressures, at a constant temperature, exhibits some peculiarities which show that the water then freezes, even though the temperature is above the normal freezing point, 0°. The melting point of ice is reduced by pressure, and ice can be melted by increasing the pressure. At temperatures below —22°, however, ice cannot be melted by an augmented pressure, for the ice passes into another variety more dense than water. The denser ice changes back into ordinary ice, specifically lighter than water, when the pressure is removed. G. Tammann (1910) and P. W. Bridgman (1912)[4] have studied the effects of great pressures on the properties of ice, and although the two investigators do not agree in certain details, they are agreed on the main points.

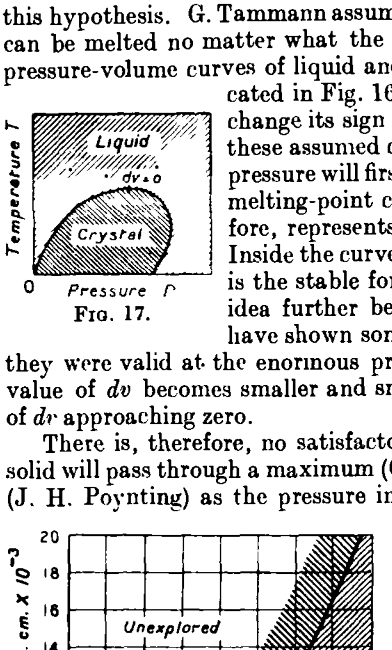

FIG. 18.—P. W. Bridgman's Exploration of the Equilibrium Conditions for the Varieties of Ice.

There are at least four kinds of ice more dense than water. Suppose that ordinary ice—called **ice I**—be maintained at —10° and gradually compressed to about 1000 kilograms per sq. cm., the ice melts to water. The relation between the freezing point and pressure is given by the curve ON, Fig. 18. When the pressure rises to about 4400 kgrm. the liquid freezes to a form of ice denser than water—called **ice V**—and at about 6300 kgrm. pressure, ice V changes to another still denser variety—

called **ice VI.** Again, if the temperature be maintained at —30°, and the experiment repeated, ordinary ice, ice I, changes into another variety—called **ice III**—at a pressure of 2200 kgrm. At —25°, this change is sudden and abrupt, sometimes it takes place with a kind of click. At about 3000 kgrm. ice III changes into another variety—called **ice II**—and with a further application of pressure, ice II passes into ice V, and finally into ice VI. The relations between the temperature and pressure of the five different forms of ice are illustrated in Fig. 18.

In practice, the water is compressed in a suitable cylinder by means of a piston worked by a hydraulic press. At any given temperature, the pressure, measured by a manometer, increases regularly with the displacement of the piston representing the volume of the substance, as shown by *AB*, Fig. 19; when the pressure has attained a certain critical value, *P*, the volume suddenly decreases, *BC*, without the pressure rising at all. Afterwards the pressure resumes its regular rise, *CD*, with the displacement. The pressure at which the piston drops abruptly into the cylinder without producing a rise of pressure is the pressure at which the water freezes at the temperature of the experiment. The pressure at which water freezes is different at every different temperature. A series of pressure-temperature curves, like Fig. 18, is taken to represent the melting curves of ice to water, or transition curves of one form to another. Given the displacement of the cylinder, and the density of the water, the density of the ice can be calculated; and if the temperature and pressure at which the ice melts, and the change in volume which simultaneously occurs are known, the latent heat of fusion of the ice can be computed. All the experiments show is that at certain temperatures and pressures there is an abrupt change in volume. It is inferred that the abrupt change of pressure must be due to a change in the molecular structure of the liquid, either a change of liquid to solid, or from one liquid to another. The latter possibility is rejected because no substance is known with two liquid modifications, and in some cases the solid is stable enough to allow a momentary glimpse to be obtained when the pressure is suddenly released. The estimated densities of the different varieties of ice (water unity) are:

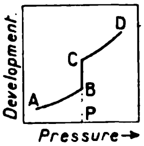

Fig. 19.

	Ice I.	Ice II.	Ice III.	Ice IV.	Ice V.	Ice VI.
Density . .	0·92	1·03	1·04	—	1·06	1·09

The latent heats of fusion of the different modifications of ice to water are not very different from that of ordinary ice; and there is therefore very little heat involved in the transformation of one variety of ice into another. The latent heats of transformation of the different forms of ice into one another and to liquid water at the triple points are indicated in Table XII, along with the volume changes which occur, and the co-ordinates of the triple points.

Table XII.—Properties of the Different Forms of Ice at the Triple Points.
(L denotes liquid water; Roman numbers a particular form of ice.)

Triple point.	Co-ordinates of triple point.		The upper line within the brackets represents the change in volume *dv* in c.c. per gram, and the lower line, the latent heat of transformation in gram calories.					
	Temp. °C.	Press. kgrm. per sq. cm.						
III, L, I	−22·0	2115	III→L	0·0466 +50·9	L→I	0·1352 −56·1	III→I	0·1818 −5·2
II, III, I	−34·7	2170	II→III	0·0215 +12·3	III→I	0·0215 +2·2	II→I	0·2178 +10·1
V, III, L	−17·0	3530	V→III	0·0547 +0·9	III→L	0·0241 +61·4	V→L	0·0788 +62·3
V, II, III	−24·3	3510	V→II	0·0401 −16·0	II→III	0·0145 +16·9	V→III	0·0546 +0·9
VI, V, L	+0·16	6380	VI→V	0·0389 +0·2	V→L	0·0527 +70·1	VI→L	0·0916 +70·3

It will be observed that ice VI is stable above 0°, and with the application of 20,000 kgrm. pressure, *water can be frozen under great pressure even though it be nearly at the boiling point of water under ordinary pressures!* If the pressure upon ordinary ice rises much above 2000 kgrm. the ice changes into ice III which has a less volume, hence, 2000 kgrm. per sq. cm. "is the highest pressure which can be obtained by freezing water in a closed space." As soon as the pressure is removed, the different varieties of ice revert to ordinary ice. If ice II or ice III be at the temperature of liquid air when the pressure is relieved, the change from the unstable to the stable form is slow enough to demonstrate that the ice is really a solid denser than ordinary ice. A variety of ice—called **ice IV**—was announced by G. Tammann, but has not been confirmed by P. W. Bridgman.

The molecular formula of water.—The vapour density of steam is slightly greater than is required for the molecular formula H_2O, and much too small for H_4O_2. It is therefore assumed that steam is a mixture of H_2O molecules with a few H_4O_2 molecules, and it is found that the equilibrium condition for water vapour in the vicinity of 100°, namely, $H_4O_2 \rightleftharpoons 2H_2O$, corresponds with about 91 per cent. of H_2O molecules. According to E. Bose (1908),[5] measurements of the vapour density of saturated water vapour under the pressure of its own vapour at the corresponding temperatures, show that:

Temperature	0°	50°	100°	150°	200°
Pressure	4·6	92·2	760	3581	11688 mm.
Per cent. H_2O molecules	93·4	91·8	91·1	91·0	91·3

An increase in the proportion of the H_2O molecules with a rise of temperature is counterbalanced by the converse effect of the increased pressure. According to G. Oddo (1915), under normal pressure below 32°, some water vapour is dissociated into ions, $H_2O \rightleftharpoons H^{\cdot} + OH'$, and the vapour pressure is almost that required for H_2O.

The estimated **diameter of a molecule** of water vapour is $4·54 \times 10^{-8}$ cm.; the **mean free path**, $4·0 \times 10^{-6}$ cm. at 0° and 760 mm.; the **collision frequency** is $79·80 \times 10^{8}$ per c.c. per sec.; the **molecular velocity** at 0° is 566 cm. per sec.; and the values of J. D. van der Waals' $a=0·01173$, and $b=0·00151$. Lord Kelvin[6] estimated the mean distance between the centres of contiguous water molecules probably lies between 10^{-8} and 5×10^{-10} cm. If the lower limit be used H. J. S. Sand has shown that there are 10^{24} **molecules per c.c.**, or 18×10^{24} molecules of water per gram-molecule of the liquid; this number is regarded as obsolete, and H. J. S. Sand obtained $8·5 \times 10^{23}$ as a better approximation for what is analogous to Avogadro's constant for liquid water.

Liquid water.—The formula of water is so frequently represented by H_2O, that it is easy to acquire the belief that this symbol correctly represents the molecule of the liquid. The molecule of liquid water is much more complex. A comparison of the boiling points of the hydrides of chlorine, HCl, sulphur, H_2S, nitrogen, NH_3, and carbon, CH_4,

	Hydrogen chloride, HCl	Water, H_2O	Hydrogen sulphide, H_2S	Ammonia, NH_3	Methane, CH_4
Boiling point	−83°	+100°	−62°	−33·5°	−164°
Critical temperature	+52°	+360°	+100°	+130°	−90°

has led to the argument that if water were represented by the formula H_2O, and remained in that condition during its condensation from the gaseous (steam) to the liquid state, it would probably fall in line with the hydrides just indicated, and be a gas at ordinary temperatures; that is, instead of boiling at 100°, it would boil at a much lower temperature. The boiling points of liquids are raised by association, and a comparison of the boiling points of water with those of the corresponding hydrides of sulphur, H_2S, selenium, H_2Se, and tellurium, H_2Te,

	Water, H_2O	Hydrogen sulphide, H_2S	Hydrogen selenide, H_2Se	Hydrogen telluride, H_2Te
Boiling point	+100°	−62°	−42°	0°

---

led H. M. Vernon (1891)[7] to infer that the molecule of liquid water is very complex. J. H. van't Hoff (1900) calculated that if water were not associated it would boil at −207°. P. Walden (1900) also argued that the substitution of oxygen by sulphur raises the boiling point of the methyl and ethyl compounds by about 60°, and if a similar difference prevailed with the hydrogen compounds, water should boil at −120°. Thus,

Methyl sulphide, $(CH_3)_2S$	37°	Ethyl sulphide, $(C_2H_5)_2S$	91°	Hydrogen sulphide, H_2S	−61°
Methyl oxide, $(CH_3)_2O$	−23°	Ethyl oxide, $(C_2H_5)_2O$.	35°	Water, (H_2O) .	−120°
Difference .	60°	Difference .	56°	Difference .	59°

H. M. Vernon's deduction is confirmed by the lowering of the freezing points of solutions of water in several other solvents[8] which point to a higher molecular weight for the liquid than is required by the simple formula H_2O ; thus, in *p*-toluidine the molecular weight varies from 28·7 to 33·3, although in phenol and related solvents, acetic acid, liquid hydrogen cyanide, etc., the result corresponds with a molecule H_2O. It is, however, remarkable that so many lines of evidence all converge about Röntgen's assumption that water contains polymerized molecules, *e.g.* the thermal expansion, compressibility, surface tension, viscosity, specific heat, index of refraction, dielectric constant, magnetization, Trouton's rule, J. D. van der Waals' deductions, boiling points, molecular volumes, etc. J. Thomsen[9] also assumed that water has a molecular weight corresponding with $(H_2O)_2$, because the heat developed during the hydration of some salts agrees with the assumption that the water frequently enters into combination in pairs, $(H_2O)_2$.

W. Sutherland's hypothesis of the constitution of liquid water.—W. Sutherland (1900)[10] calls W. C. Röntgen's ice molecules **trihydrol** on the assumption that molecular weight corresponds with $(H_2O)_3$ or H_6O_3 and the water molecules **dihydrol,** $(H_2O)_2$ or H_4O_2 ; the steam molecules are called **hydrol** H_2O. Alternative terms have been suggested : *trioxylene* for trihydrol, and *dioxylene* for dihydrol. Instead of the curve for the variation of the volume of water with temperature—Fig. 5—sweeping round a minimum at about 4°, W. Sutherland makes the line continuous and thus extrapolates a value 1·089 for the density of dihydrol at 0°. This agrees with values deduced in a similar manner from other physical properties of water. Similarly he gets the value 0·88 for the density of trihydrol at 0°. Hence, it follows from the observed density of water at 0°, that 37·5 per cent. of trihydrol and 62·5 per cent. of dihydrol are present. The percentage amounts of hydrol in water at different temperatures, estimated from the observed densities at pressures of one and 50 atmospheres, are indicated in Fig. 20. It is further estimated that at 2300 atmospheres pressure there will be no trihydrol in water at 0°. W. Sutherland also estimates that dihydrol and trihydrol have the following physical properties at 0° :

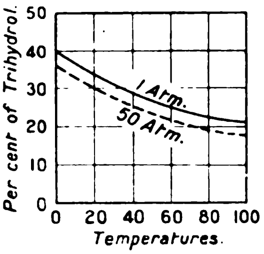

FIG. 20.—Estimated Proportion of Trihydrol in Water at Different Temperatures.

TABLE XIII.—COMPARISON OF THE SUPPOSED PHYSICAL PROPERTIES OF DIHYDROL AND TRIHYDROL.

	Density at 0°.	Compressibility per atmosphere.	Surface tension.	Critical temp.	Specific heat 0°.	Viscosity.	Latent heat calories.	
							Fusion.	Vaporization.
Dihydrol .	1·089	0·000016	78·3	368°	0·8	0·0030	—	257
Trihydrol .	0·88	0·000010	73·3	538°	0·6	0·0381	16	250

A. Piccard estimated that in liquid water at 0° there is 29·1 per cent. of ice ; and in water at 100°, one per cent. of ice. With this assumption, and his observations on the refractory power of water, C. Chéneveau estimates that hydrol at 0° has a specific refraction by J. H. Gladstone and Dale's formula, of 0·3228; and by Lorenz and Lorentz's formula, of 0·2049; the corresponding numbers for hydrol at 100° are 0·3319 and 0·2058. From his experiments on the evaporation and condensation of small drops, C. Barus concludes that water contains different constituents, and that one is more volatile than the other. G. Gillet ascribes all the reactions of water to the hydrol molecules, and he says that a substance is soluble in water because it forms a soluble compound with the hydrol, and this disturbs the equilibrium $(H_2O)_2 \rightleftharpoons 2H_2O$, and that the evolution or absorption of heat in the process of solution is dependent on this reaction. H. Schade believes that the equilibrium constant $nH_2O \rightleftharpoons (H_2O)_n$ varies with temperature, and that the polymerized molecules are present in water in a colloidal form.

J. W. Brühl considered that water is an unsaturated compound with quadrivalent oxygen $H-\dot{O}-H$. W. Sutherland suggests that, on J. W. Brühl's assumption that oxygen is quadrivalent, the dihydrol and trihydrol molecules are constituted as indicated by the graphic formulæ:

$\begin{matrix}H\\H\end{matrix}\!>O$

Hydrol.

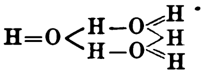
$\begin{matrix}H\\H\end{matrix}\!>O=O<\!\begin{matrix}H\\H\end{matrix}$

Dihydrol.

$\begin{matrix}H_2=O\nabla O=H_2\\ O\\ H_2\end{matrix}$

Trihydrol.

R. de Forcrand believes that the ice molecules are either $(H_2O)_2$ or $(H_2O)_{2\cdot 5}$, and he assumed that oxygen is quadrivalent, and the hydrogen bivalent. As a result, he obtained the graphic formula:



$$H=O<\!\begin{matrix}H-O\lessgtr H\\ \qquad\quad\ H\\ H-O\lessgtr H\end{matrix}$$

In an attempt to account for the properties of dilute solutions, H. E. Armstrong (1908) further assumed that some of these molecules have the same composition but a different structure: thus, the dihydrol molecules, H_4O_2, are assumed to exist in the two different forms:

$\begin{matrix}H\\H\end{matrix}\!>O-O<\!\begin{matrix}H\\H\end{matrix}$

Dihydrone.

$\begin{matrix}H\\H\end{matrix}\!>O<\!\begin{matrix}OH\\H\end{matrix}$

Hydronol.

The former kind are said to be inactive molecules because they are formed by direct association unaccompanied by rearrangement; and the latter are said to be active molecules. When non-electrolytes of the type RX are dissolved in water, active complexes of the hydronol type $HO-RX-H$ and inactive hydrone complexes of the type $RX=OH_2$, as well as polymerides, are supposed to be formed; while with electrolytes, the compound becomes hydrolated by the formation of (*a*) hydronol complexes $HO-RX-H$, and (*b*) complexes of the type $X-H_2O-R$, which are distributed in the solvent. Such solutions, says Armstrong, will be electrolyzed when the composite molecules *a* and *b* act reciprocally on one another under the influence of an electric strain.

If these views about the constitution of water be well-founded, and if these different varieties of ice really exist, it is hardly correct, without some reservation, to say that the passage of ice to liquid water and to steam, and the converse changes, are purely physical changes. P. W. Bridgman appears to think that the different forms of ice arise from a difference in the alignment or arrangement of the molecules whereby each molecule preserves its individuality so that the changes undergone by the different forms of ice are purely physical. In physical processes, the molecules of the substance are supposed to remain intact and unaltered; in chemical processes, on the contrary, the molecules are altered. Is the magnetization of iron a physical or a chemical process? A chemical process if the molecules are changed; and physical, if the molecules are not changed. Selecting one of the many definitions of chemical action, say H. E. Armstrong's (1885),

> Chemical action may be defined as being any action of which the consequence is an alteration in molecular constitution or composition; the action may concern molecules which are only of one kind—cases of mere decomposition, or isomeric change, and of polymerization; or it may take place between dissimilar molecules—changes of combination and interchange.

With this definition, the vaporization of ethyl alcohol would be a chemical process because it is probable that there is a simultaneous depolymerization $(C_2H_5OH)_n \rightleftharpoons nC_2H_5OH$, while the vaporization of carbon disulphide would be a physical process, because, so far as is known, the molecules are not altered in constitution or composition. In this sense, vaporization would be sometimes a chemical and sometimes a physical process. Indeed, the mere raising of the temperature of water involves a change in the composition of the molecules, and is accordingly a chemical change (depolymerization).

§ 8. The Physical Properties of Water

Liquid water freezes at 0° into crystalline ice while water vapour freezes directly into hoar frost, and snow. If water be carefully cooled in a dust-free space it can be reduced to $-12°$ without freezing,[1] and H. C. Sorby cooled water to $-13°$ in a capillary tube 2·5 mm. diameter, and to $-15°$ in a tube of 0·0127 mm. diameter. According to J. Thomson, the freezing point of water is lowered $0·0075n°$ by a pressure of n atmospheres.

Ice appears to be colourless and transparent when pure, but in reality it is pale blue when seen in large masses. Artificially formed ice is often white and more or less opaque. According to R. Pictet, if artificial ice be slowly formed between 0°

and —1·5°, it is as transparent as natural ice ; but if the temperature at which the freezing occurs be below — 3°, the ice appears to be more or less opaque and white, and of low specific gravity, and this the more the lower the freezing temperature. The whiteness and opacity is due to the presence of small air bubbles, 0·01 to 0·5 mm. diameter, mechanically entangled among the elementary crystals during freezing. If precautions be taken to use air-free water, water freezes at very low temperatures to transparent ice. The bubbles of air are developed owing to the reduction in the solubility of the air dissolved in the water as the water freezes into ice.

The formation of *sheet ice* on the surface of an expanse of quiet water as cold weather approaches is interesting. So long as the temperature of water is above 4°, convection currents help to keep a uniform distribution of the temperature, for the cold and denser water slowly sinks, and the warmer layers rise to the surface. As the temperature of the surface falls below 4°, the colder layer remains on the surface and finally reaches the freezing point. Long needles of ice then shoot out from the borders over the top of the water and the crystals ramify outwards until the whole surface is covered with a thin sheet of ice. The sheet of ice then gradually thickens by the conduction of heat through the ice. According to G. Quincke's hypothesis, a freezing liquid is regarded as a liquid jelly which forms invisible foam cells containing water. The lower the temperature, the greater the viscosity of the liquid in the walls and interior of the foam cells. In streams which run too swiftly for the border ice to meet, the so-called *frazil-ice* or *slush-ice* is produced on the surface, but it cannot remain attached and freezes to a continuous sheet. In special circumstances where the bottom of a river can be cooled by the radiation of heat, the so-called *anchor ice,* or *ground ice, bottom ice*—*glâce-du-fond,* or *Grundeis*—may form on the bottom of a river or stream.

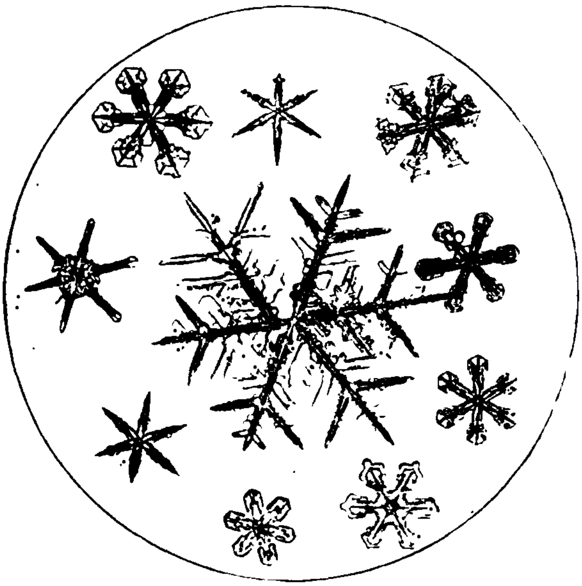

FIG. 21.—Snow Crystals.—G. Hellmann.

Well-defined **crystals** of ice are extremely rare and difficult to measure. According to A. E. von Nordenskiöld, F. Rinne, and A. B. Dobrovolsky, the bipyramidal crystals of ice belong to the hexagonal system and appear as ditrigonal prisms or plates; and P. Groth gives the axial ratio $a : c = 1 : 1·617$; but this, however, is somewhat doubtful. With hail, combinations of the rhombohedron have been reported. Sea-ice is usually a complex of crystal particles with the chief axes at right angles to the surface. The crystals can be often seen when a piece of ice is examined with a lens while a beam of bright light is passing through it. Snow crystals are common; this is readily demonstrated when snow-flakes are examined under a low-power microscope. Over a thousand different patterns have been noted, but all appear in the form of hexagonal (six-sided) nuclei, or six-rayed stars with the rays developed in bewildering complexity—some are rounded, others serrated, others reticulated—but all are of inimitable delicacy and beauty. A rough idea of the form of snow crystals can be obtained from Fig. 21, by G. Hellmann.[2] No two crystals seem to be alike, yet there is no deviation from the hexagonal style of architecture.

Albertus Magnus, of the thirteenth century, is said to have been the first writer to mention the *figura stellæ*, the hexagonal form of snow crystals, and in 1611, J. Kepler, the celebrated astronomer, wrote a pamphlet on six-rayed snow. J. Kepler was greatly impressed by the beauty and regularity of the shapes of the snow stars; but he perforce left unanswered the obvious question: Why are the crystals six-rayed? Why does nature unsparingly fashion such strange contrasts, all built according to one definite type—the six-rayed star—each

> Frail, but a work divine, made so fairily well,
> So exquisite, minute, a miracle of design?
> TENNYSON

Few indeed would deny what an anonymous writer has said: "The chemist is assured that if he could wholly understand a drop of water, he would know the origin and destiny of all things, and hold the key to every happening;" the same remark would apply to a drop of any other liquid. According to M. Trautz, Pontus knew in 1833 that if water be rapidly frozen, it sends out bright flashes of light—**crystallo-luminescence.** The **X-ray structure** of ice has been investigated by A. St. John.

The **viscosity** of water at 0°—that is, the resistance which water offers to flow—is here given along with a few other liquids for comparison:

Water.	Mercury.	Sulphuric acid.	Alcohol.	Ether.	Benzene.	Carbon disulphide.
0·0178	0·0169	0·3195	0·0184	0·0029	0·0089	0·0044

The viscosity of water diminishes with rise of temperature. Thus, G. Zémplen and B. Pogány found 0·010562 at 18°, and, according to R. Hosking and E. C. Bingham and G. F. White,

	0°	20°	40°	60°	80°	100°	124°	153°
Viscosity	0·017928	0·01002	0·006563	0·004730	0·003570	0·00284	0·00223	0·00181

R. Hosking recommends the interpolation formula, $\eta=\eta_0(1+a\theta+b\theta^2)$, for the viscosity η at θ° when the viscosity at 0° is η_0, and when a and b are constants. E. C. Bingham defines the fluidity of a liquid as the reciprocal of the viscosity, and he represents the fluidity ψ as a function of the absolute temperature T such that $T=0·23275\psi-8676·8/(\psi+120)+309·17$. G. F. White and R. H. Twing find the viscosity of undercooled water at −4·7°, −7·23°, and −9·30° to be respectively 0·02121, 0·02341, and 0·02549.

Water at high pressures is less viscous than at normal pressures provided the temperature does not exceed 36°, and this the more the lower the temperature and the lower the pressure. According to L. Hauser (1900),[3] the percentage changes in the viscosity coefficient of water at 400 atmospheres pressure are:

Temperature	90°	70°	51°	40°	35°	29°	18°
Percentage change of viscosity	+3·4	+2·5	+1·6	+0·7	0	−0·3	−1·6

Most other liquids which have been tried become more viscous under an increasing pressure. This also is in harmony with the assumption that with water the smaller the pressure, or the higher the temperature, the less the proportion of ice molecules transformed into less complex molecules, highly viscous ice molecules are replaced by less viscous water molecules. These facts were predicted by W. C. Röntgen (1891) from the hypothesis just outlined, and confirmed by R. Cohen (1891). The viscosity of some aqueous solutions is less than that of water itself owing to the fact that the solute converts enough viscous ice molecules into less viscous water molecules to more than compensate for the increase of viscosity which its own presence imparts. With aqueous solutions of urethane, there is a steady increase in the viscosity with rising concentration, probably because the increase in the viscosity produced by the solute more than compensates the decrease due to the diminishing concentration of the ice molecules. The coefficient of viscosity of water vapour[4] at about 20° is 0·0000975. F. Houdaille found the coefficient of the viscosity of water vapour to be smaller at low pressures, possibly as a consequence of dissociation.

The viscosity of ice is enormously greater than that of water, and it depends on the direction of the crystal axes. The viscosity of ice has been studied by B. Weinberg, J. F. Main, etc. R. M. Deeley[5] found that the viscosity at 0° is 2×10^{10} in a direction perpendicular to the optic axes; while both he and P. H. Parr calculated the viscosity of glacier ice moving in winter to be between 125×10^{12} and $147{\cdot}7\times10^{12}$. The difference is taken to mean that in glaciers, the optic axes of the ice crystals are inclined in different directions. B. Weinberg gives for the relation between the viscosity η and the absolute temperature, $\eta\times10^{-13}=1{\cdot}244-0{\cdot}502T+0{\cdot}0355T^2$. H. Hess (1902) found that a bar cut from glacier ice is slowly deflected when loaded in the middle and supported at both ends. The rate of change varies with the load. When the bar is relieved from the load it slowly recovers, due to what H. Hess regards as a kind of residual elasticity. J. C. McConnel (1891) also showed that a bar of ordinary ice yields continuously to pressure or tension, but if cut from a single crystal, with its length at right angles to the optic axis, it shows no sign of stretching under tension, or yielding to pressure. The crystal is brittle. Consequently, the bending of a bar of ice does not represent a gradual shearing of the ice crystals, but the slipping of a number of layers of finite thickness. This is the probable cause of the so-called plasticity of ice. The recovery of bent ice after the stress is relieved is out of all proportion to known effects in other substances, and is attributed to the slipping back of the forcibly displaced sliding layers. H. Moseley (1871) found **Young's modulus** for ice to be 92,700 kgrms. per sq. cm., and B. Weinberg (1905), 5×10^6 kgrms. per cm. at 1°. H. Hess cut bars of ice with the crystal axis parallel to the width, length, and thickness—1·2 cm. × 2·5 cm. and 4 to 16 cm. long—and measured the **modulus of elasticity** E; the **bending moment**, B grm. cms.; and the viscosity η with different loads as indicated in Table XIV. H. Reusch, R. Koch, and R. Trowbridge have published values for the elasticity constant. H. Hess concludes that for moderate loads the coefficient of viscosity η increases with the duration of the experiment from 15 to 60 to 120 to 300 seconds, and even after only 300 secs. the increase is nearly proportional to the time. For large loads near the point of rupture, the coefficient of viscosity decreases with the duration of the experiment.

TABLE XIV.—ELASTICITY AND VISCOSITY OF ICE.

	Axis parallel to length.			Axis parallel to width.				Axis parallel to thickness.

H. Hess also measured the relation of pressure to the speed of **the flow of ice,** and found that with ice confined in cylinders, the flow increased rapidly with increasing pressure, and when the flow was once started, comparatively small pressures were required to maintain the flow. G. Tammann (1902) and N. Slatowratsky (1905) also studied the velocity of flow of ice, and showed that the **plasticity of ice** is relatively small, but increases rapidly near the melting point. The results with the pressures expressed in kgrm. per sq. cm. are shown in Table XV. J. Dewar (1905) pressed ice into wire-like threads at —80° and 50 tons per sq. in. pressure, but at lower temperatures he did not succeed in doing so.

T. Andrews (1886) measured the **hardness** of ice in terms of the depth of penetration of a steel rod into a cylinder of ice at different temperatures. The results showed that ice remains "almost impenetrable" from about —37° to about —12°; its power of resistance then decreases rapidly to about —7°, and still more rapidly at higher temperatures, until, at the melting point, the ice gives way "almost entirely," when it becomes very soft indeed. Ice on Mohs' scale (resistance to scratching) is said to have a hardness of 1·5. H. Morphy says the **coefficient of friction** of ice for small pressures—up to 14·3 grms.—between −5° and −6° is nearly constant, being 0·36 ± 0·01 ; and for large pressures—above 15 grms.—0·17 ± 0·01.

TABLE XV.—PLASTICITY OF ICE.

Temperature.	Highest pressure of steady flow.	Pressure when rapid increase occurs.	Melting pressure.
− 5·7°	642	665	678
−10·7°	1116	1130	1225
−15·7°	1611	1729	1681
−21·7°	2000	2100	2070
−27·6°	2220	2240	—

The **surface tension** of water is higher than that of all the common liquids, excepting mercury. For example:

Mercury.	Water.	Ammonia.	Benzene.	Acetone.	Alcohol.	Ether.
547	75·0	64·7	29·2	23·3	22·0	16·5 dynes per cm.

Surface tension and specific gravity determine the height to which a liquid will rise in a capillary tube. The high surface tension of water plays an important *rôle* in determining the ascent of this fluid in the capillary pores of the soil. Under ordinary conditions it is estimated that water can rise four or five feet under the influence of its high surface tension; if the surface tension of water were like that of most liquids the liquid would rise but two or three feet.[6] The high surface tension of water thus becomes an important factor in bringing water within reach of plants.

The reported values [7] for the surface tension, σ, of water in moist air at ordinary temperatures range from 7·13 to 7·945 mgrm. per mm. N. Bohr found the surface tension of water at 12° to be $\sigma=73·23$ dynes per cm. or $\sigma=7·465$ mgrm. per mm., and the specific cohesion to be 14·96 sq. mm. Many other determinations of these constants have been made by W. Ramsay and J. Shields. The following values below 40° are by P. Volkmann, and above 40° by C. Brunner:

	0°	10°	20°	30°	40°	50°	60°	70°	80°
σ .	7·692	7·541	7·389	7·237	7·086	6·91	6·73	6·54	6·35 mgrm. per mm.
σ .	75·49	74·01	72·53	71·03	69·54	67·8	66·0	64·2	62·5 dynes per cm.
a^2 .	15·406	15·105	14·821	14·556	14·295	13·99	13·70	13·39	13·08 sq. mm.

According to H. Sentis, the surface tension of water at $\theta°$ is $\sigma=76·09(1-0·002026\theta)$; and according to C. Forch $\sigma=\sigma_0(1-0·00190179\theta-0·0000024991\theta^2)$. The surface tension of water is extremely sensitive towards traces of impurities, and it is very difficult to get quite clean surfaces. G. Quincke (1870), F. von Lerch (1902), and F. Pockels (1899) have measured the surface tension in dynes per cm. at 20° at the interface of water in contact with different immiscible or partially miscible liquids, and their results include

Mercury.	Chloroform.	Carbon disulphide.	Alcohol.	Ethyl ether.	Benzene.	Petroleum.	Turpentine.	Olive oil.
$\sigma=37·47$	2·68	4·122	0·206	1·23	3·365	3·81	1·254	1·81

G. Hagen noted in 1845 that the surface tension of water is gradually reduced by exposure to air; G. Quincke, P. Volkmann, E. Bönicke, A. Kundt, and C. Forch found that from 17° to 18°, for solutions with m gram-molecules of gas per litre, the corresponding change in the surface tension of water per gram-molecule of dissolved gas is $\Delta\sigma/\sigma m$:

	CO_2	N_2O	H_2S	O_2	N_2	Air
m	0·041	0·029	0·127	0·00146	0·00073	0·00087
$\Delta\sigma/\sigma m$	−0·310	−0·307	−0·214	−2·225	−0·88	−1·30

At 17°, in vacuo, that is in saturated vapour, the surface tension of water is about 0·11 per cent. or 0·008 mgrm. per mm. greater than in air at atmospheric pressure.

T. W. Richards and J. H. Mathews found that the compressibility β and the surface tension σ of pure liquids are related approximately as $\beta\sigma^{\frac{4}{3}}=$a constant, while A. Ritzel could detect no simple relation with mixtures of water with other liquids. W. C. Röntgen and J. Schneider found that aqueous solutions of inorganic salts had a higher surface tension and a lower compressibility than pure water; while G. de Metz showed that cane sugar as solute always reduces the compressibility of water, the surface tension of these solutions is sometimes greater and sometimes less than water. K. Drucker found aqueous solutions of some organic acids have smaller surface tensions than water, and that the compressibility at first decreases and then increases with rising concentration. The surface tension of aqueous solutions shows that there is a possible action of the solute in dissociating some of the complex ice molecules in the surface film. T. W. Richards and S. Palitzsch observed that with aqueous solutions of urethane, there is a rapid decrease in surface tension with concentrations up to 40 per cent. of urethane, presumably owing to a decrease in the proportion of ice molecules with greater concentrations, the surface tension decreases in accord with the rule $\beta\sigma^{\frac{4}{3}}=$a constant.

G. Tammann denied the existence of any relation between the internal pressure of a solution—calculated from the thermal expansion—and the surface tension, but W. C. McC. Lewis found the internal pressure and surface tension of all but volatile and colloidal solutions change in the same direction. I. Traube based an explanation of some properties of solutions on the relationship between internal pressure and surface tension; T. W. Richards also interprets the compressibility of a pure substance as being in part contingent on the internal pressure, for the external pressure required to compress a substance to given extent is greater the more the molecules are previously compressed by molecular pressure.

The **specific cohesion** a^2 sq. mm. of water at different temperatures in moist air, is

	0°	10°	20°	30°	40°	50°	60°	70°	80°
a^2 .	15·406	15·105	14·821	14·556	14·295	13·99	13·70	13·39	13·08

It will be remembered that the specific cohesion a^2, is related with the surface tension so that $\sigma=\frac{1}{2}a^2(D-D')$, where D and D' respectively denote the specific gravities of water and moist air. According to L. Weinstein, the value a^2 at a temperature θ between 0° and 95° is $a^2=14{\cdot}987(1-0{\cdot}0014580\theta)$.

R. Eötvös (1886) found that the variations of the molecular surface tension $\sigma=a(Mv)^{\frac{2}{3}}$, with changes of temperature θ, namely, $d\sigma/d\theta$, are nearly the same, 2·12, for all normal liquids, but not so with liquids whose molecular complexity changes with temperature. W. Ramsay and J. Shields (1893) obtained the following values for water when the molecular weight is assumed to be 18:

θ .	0° to 20°	20° to 40°	40° to 60°	60° to 80°	80° to 100°	100° to 120°	120° to 140°
$\delta\sigma/\delta\theta$	0·88	0·95	1·00	1·05	1·09	1·14	1·18

If the molecular weight of water at 0° be taken to be 3×18, and the density of ice be assumed to represent the density of ice molecules, the constant becomes 2·08, very close to that for a normal liquid. Hence, the surface tension of water at 0° is sufficient to change practically the whole of the water in the surface film to ice molecules with a molecular weight 3×18, corresponding with $(H_2O)_3$. It also follows that the surface film of water is not changed very much with temperature up to about 40°, but, at higher temperatures, the surface tension is sufficiently reduced to form appreciable amounts of water molecules less complex than ice molecules. By applying the law for the surface tension of mixtures, and assuming that the surface film contains a mixture of the molecules with a molecular weight 3×18, and water molecules with a molecular weight 2×18, W. Sutherland calculated values for the variation of the surface tension of water in dynes per cm. with temperature which were in close agreement with the observed results, and with R. Eötvös' theory :

	0°	20°	40°	60°	80°	100°	120°	140°
Surface tension .	73·32	70·56	67·55	64·27	60·77	57·11	53·30	49·38

The **coefficients of diffusion** of water vapour into hydrogen, air, and oxygen, at 0°, are respectively 0·687, 0·193, and 0·131 per second.[8] The **velocity of sound** in water vapour is, according to A. Masson, 401 metres per second at 0° ; according to W. Jäger, 402·4 and 410·0 metres per second respectively at 93° and 96° ; and according to W. Treitz, 413 metres per second at 110° ; 417·5 at 120° ; and 424·4 at 130°.

Specific heat.—The specific heat or the amount of heat required to raise the temperature of one gram of liquid water per degree under certain assigned conditions, is taken unity as a standard—*e.g.* the *zero calorie* is the quantity of heat referred to water between 0° and 1° ; the *mean calorie*, to water between 0° and 100° divided by 100 ; and the *15°-calorie*, to water between 14·5° and 15·5°. The specific heat of water, as unity, is here given along with the specific heats of a few other liquids for comparison :

Water.	Mercury.	Sulphuric acid.	Alcohol.	Ether.	Benzene.	Carbon disulphide.
1	0·0334	0·317	0·547	0·529	0·397	0·235

The specific heat of water is abnormally high ; and it is remarkably nearly constant over a comparatively large range of temperature. From the time of H. V. Regnault (1847)[9] up to the present the specific heat of water, at constant pressure, has been the subject of investigation with more and more refined attempts to increase the degree of accuracy. Some of the later determinations almost agree up to the third significant figure. C. Dieterici's results (with the specific heat at 15° unity) are :

0°	10°	20°	30°	40°	50°	60°	80°	100°
1·0088	1·0021	0·9987	0·9984	0·9987	0·9996	1·0008	1·0045	1·0099

rising to 1·1543 at 300°. There is a minimum near 25° of 0·9983. The results of other observers give minima ranging from 12° to 35°. C. Dieterici's formula, referred to water unity at 0° for the specific heat C_p of liquid water at $\theta°$, between 35° and 300° is $C_p=0·99827-0·00016368\theta+0·00000207 36\theta^2$. H. L. Callendar gives for the specific heat C of water between 0° and 20°, $C=0·9982+0·0000045(\theta-40)^2+0·0000005(20-\theta)^3$. and between 20° and 60° the last term is omitted. Accurate measurements have also been made by C. E. Guillaume, A. Cotty, W. R. and W. E. Bousfield, and W. Jäger and H. von Steinwehr. J. Narbutt claims that for $\theta°$ between 0° and 100° the best observations are represented by the formula $C=1·00733-0·0007416\theta+0·000016845\theta^2-0·0000000955 2\theta^3$, when C for 15° is unity ; this gives a minimum between 20° and 30°. According to H. T. Barnes, the specific heat of undercooled water rises to 1·0155 at −5° (water at 15° unity). This is illustrated in Fig. 22. The specific heat of water at constant volume is obtained by computation from the expression $C_v=C_p-9a^2Tv_0/\beta$, where β represents the coefficient of compressibility, and a the coefficient of thermal expansion ; T the absolute temperature ; and v_0 the volume at 0°. When C_p at 0° is 1·0000, C_v is 0·9995. The specific heat of water at 0° is altered −0·0001025 per atmosphere increase of pressure. The specific heat of a solid is usually less, but

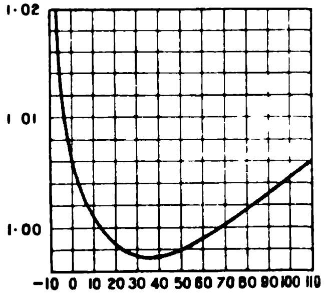

FIG. 22.—The Specific Heat of Liquid Water.

sometimes greater, than that of a liquid, with water the difference is abnormally great. For instance,

	Water.	Lead.	Mercury.	Sulphur.
Specific heat, solid .	0·502 (0°)	0·314 (0°)	0·0319 (−40°)	0·2026 (100°)
Specific heat, liquid .	1·000 (0°)	0·0402 (356°)	0·0333 (0°)	0·234 (120°)

J. Dewar found that the specific heat of ice falls from 0·502 at 0° to 0·463 at −78°, and to 0·146 at −252·5°. W. A. Smith found the specific heat of highly purified ice to be almost constant up to a temperature close to zero, but there is a sensible increase in the specific heat of ordinary ice, owing, it is supposed, to incipient fusion caused by the lowering of the melting point by dissolved impurities. H. C. Dickinson and N. S. Osborne found the specific heat of ice for a temperature θ between −40° and −0·05° to be $C=0{\cdot}5057+0{\cdot}001863\theta-79{\cdot}75\theta^{-2}$ cals. (20°), when the constant was found to diminish from −0·00125 to −0·00005 with increasing purity. Hence it was inferred that the departure of the specific heat of ice from a linear function of the temperature is less the purer the ice, consequently, the specific heat of pure ice is assumed to be $C=0{\cdot}5057+0{\cdot}001863\theta$. F. G. Jackson obtained between 0° and −78·4°, 0·424 ± 0·002; and between 0° and −188°, 0·337 ± 0·001; P. Nordmeyer and A. Bernoulli obtained analogous results; and A. Bogojawlensky worked with 5° intervals between −15° (0·500) and −50° (0·395). According to W. Nernst and F. Koref, the relation between the molecular heat of ice and temperature is represented by the relations $8{\cdot}47+0{\cdot}0276\theta-14{\cdot}0\theta^{-1}$.

The sudden rise in the specific heat of a substance just below its fusion temperature has given rise to some discussion. In some cases this is due to the presence of an impurity. For example, if a salt be present as impurity in water then, above the eutectic point for that salt, the apparent specific heat is increased by the fact that some of the ice melts to produce a larger specific heat than that of solid ice. The rise in the specific heat cannot be explained in this way; silver iodide shows a similar phenomenon, although it may be that different allotropic forms are present, and that with crystals of a one-phase substance, the phenomenon would not occur. G. N. Lewis and G. E. Gibson[10] found that with the exception of a small variation of ice below the melting point, the specific heat of ice can be represented by $\log C_v=0{\cdot}43(\log T-2{\cdot}51)$; accordingly the **entropy** of ice at 0°, calculated from absolute zero, $\phi=\int C_p d\log T$, is 9·96 per gram-molecule; the entropy for the liquefaction of ice is 1·58, at 0°; and the increase of entropy of liquid water from 0° to 25° is 1·58. Hence, the entropy of water at 25° is 16·8 per gram-molecule.

The mean specific heat of water vapour between 100° and 800° and at a constant pressure was found by L. Holborn and F. Henning[11] to be $C_p=0{\cdot}4460(1+0{\cdot}000096\theta)$ cals., and by A. Langen, for temperatures above 1100°, $C_p=0{\cdot}44(1+0{\cdot}00027\theta)$. The specific heat of water vapour at constant volume C_v, and at the absolute temperature T, according to W. Nernst and H. von Wartenberg, is $C_v=5{\cdot}61+0{\cdot}000717T+0{\cdot}0_6312T^2$ cals., or according to M. Pier, between 0° and θ°, $6{\cdot}065+0{\cdot}0005\theta+0{\cdot}0_882\theta^2$, from 1300° to 2500°.
