The minimum in the specific heat curve of water is near 30°. W. Jäger and H. von Steinwehr give 33·5°. This, and other abnormal phenomena, are in agreement with the assumption that the observed specific heat of water is a complicated phenomenon involving both a true specific heat and an endothermal change of ice into water molecules on a rising temperature. If the presence of a substance in solution reduces the proportion of ice molecules in the liquid, it follows that the specific heat of an aqueous solution will be smaller than that of the pure solvent under the same conditions. This agrees with the observed facts, even when due allowance is made for the specific heat of the solute—that is, the dissolved substance; thus, A. Jaquerod (1901) found for solutions of potassium chloride, KCl, at about 16°,

Per cent. KCl . . .	0	2·4	4·8	9·6	19·2	28·8
Specific heat . . .	1·000	0·968	0·938	0·882	0·790	0·720

K. Puschl (1901) has also shown that the specific heats of many aqueous solutions are less than that which would be the case if solvent and solute were in the free state.

According to E. Mallard and H. le Chatelier (1881),[12] the molecular specific heat of water vapour at a constant volume, C_v, at a temperature θ, is $C_v=5{\cdot}91+0{\cdot}00376\theta-0{\cdot}0_6155\theta^2$; and according to J. M. Gray, the specific heat at a constant pressure is 0·3787. L. Holborn and L. W. Austin found the specific heat at constant pressure, between 110° and 270°, to be 0·4639; between 110° and 440°, 0·4713; and between 110° and 820°, 0·4881. The ratio of the two specific heats at 103° or 104° lies between 1·25 and 1·35—say 1·3. W. Freitz found 1·3301 at 110°, 1·3129 at 120°, and 1·3119 at 130°.

The specific heat of water is higher than that of any other liquid, excepting that of liquid ammonia. The general effect of the high specific heat of water is to make the ocean, lakes, and streams absorb on heating or give up on cooling comparatively large amounts of heat which help to maintain the temperature more nearly constant; and to moderate the heat of summer, and the cold in winter. This is shown by W. Zenker's comparison of the normal temperatures of continental and marine climates at different latitudes.

Latitude . .	0°	10°	30°	50°	70°	90°
Continental . .	34·6°	33·5°	24·1°	5·0°	−19·0°	−26·1°
Marine . . .	26·1°	22·7°	18·8°	7·1°	−5·2°	−8·7°

The large capacity of water for heat also helps in the regulation of the temperature by the transport of heat, so to speak, as ocean currents. Water being the chief constituent of the living organism, also favours the regulation of the body temperature. Thus, L. J. Henderson in his *The Fitness of the Environment* (New York, 1913) says:

> Man is an excellent case in point. An adult weighing 75 kgrms. when at rest produces daily about 2400 great calories, which is an amount of heat actually sufficient to raise the temperature of his body more than 32°; but if the heat capacity of his body corresponded to that of most substances, the same quantity of heat would be sufficient to raise his temperature between 100° and 150°.

The **heat conductivity** of liquid water, like that of other non-metallic liquids, is low. Water is a bad conductor of heat.[13] The conductivity may be represented by the number of calories transmitted per second per square centimetre through a centimetre layer with a difference of temperature of 1° between the two faces. The conductivities of a few liquids contrasted with silver is as follows:

Silver.	Mercury.	Water.	Alcohol.	Ether.	Benzene.	Carbon disulphide.
1·530	0·0163	0·00152	0·00055	0·00038	0·00033	0·00027

Consequently, water is one of the best of liquids for conducting heat, but even then, the thermal conductivity is small.

The thermal conductivity of water was determined by C. G. Lundquist in 1869, and he obtained 0·00156 in C.G.S. units at 40·8°; A. Winkelmann (1874), 0·00154 at 40°; H. F. Weber (1880), 0·00124 at 4°, and 0·00143 at 23·6°; R. Weber (1903), 0·00131 (23°); S. R. Milner and A. P. Chattock, 0·001433 (20°); R. Wachsmuth, 0·00129 (4·1°); C. Chree, 0·00124 (18°); L. Graetz, 0·00158 (30°); R. Goldschmidt, 0·00150 (0°); and C. H. Lees, 0·00147 (11°), 0·00136 (25°) with an increase of −0·0055 per cent. per degree up to 45°. The heat conductivity of ice and snow is relatively small, so that they protect the ground against the severe temperatures of a northern winter. The ordinary nocturnal cooling of the soil by radiation under normal conditions of soil exposure is of no significance when the ground is covered with snow. The loss of heat from a river is retarded by the rigidity of the surface sheet of ice which prevents direct contact of air and water. Although the conductivity of ice is rather higher than that of water, the loss of heat by conduction is relatively small in comparison with the heat losses by convection and wind currents which are immediately stopped when a surface sheet of ice is formed. The protective action of snow on the ground is of the greatest importance, for, when dry, as is the case in the severest weather, a covering of snow is one of the best non-conductors of heat. J. D. Forbes first determined the thermal conductivity of ice in 1874, and he found that the conductivity is greater in the direction of the principal axis than it is when perpendicular thereto. In the former case it is 0·0022 and in the latter 0·0021. These numbers represent the number of calories of heat which flow per sq. cm. per second in the direction of the fall of temperature when the temperature gradient is 1° per cm. A. C. Mitchell (1885) found the conductivity of ice to be 0·005; F. Neumann, 0·00573; M. Straneo (1897), 0·30 to 0·0052 in the direction of the principal axis, and 0·005 when perpendicular to that direction. C. H. Lees found the conductivity of ice to be 0·0052 at 3°; 0·0058 at −57°; and 0·0052 at −117°.

The heat conductivity of snow is much less than that of pure solid ice, and in 1885, T. Andrews found ice to conduct heat 122 per cent. better than snow. S. A. Hjelström (1889) found the conductivity of snow to be 0·00051; and H. Abels (1891) found the conductivity of snow to be proportional to the square of its density, or $K=0{\cdot}0068D^2$, and P. Jansson (1901) represented his results by the formula $K=0{\cdot}00005+0{\cdot}0019D+0{\cdot}006D^2$. T. Okada found that the density of snow varied with its depth, for a depth of 10–20 cm., $K=0{\cdot}00028$; and for a depth 20–30 cm., $K=0{\cdot}00045$; his results agreed better with H. Abels' than with P. Jansson's formula.

Optical properties.—Ice is optically positive. Its mean **refractive index** is high; and some have tried to show that Isaac Newton (1749)[14] anticipated the presence of combustible hydrogen in water, or at any rate the relation of water to combustible substances, because he worked with the hypothesis that substances with a high refractive index contained fatty, unctuous inflammable parts. According to C. Pulfrich[15] the refractive index of ice is $\omega=1{\cdot}30645$, and $\epsilon=1{\cdot}30775$ for the B-line; $\omega=1{\cdot}30911$, and $\epsilon=1{\cdot}31041$ for the D-line; and $\omega=1{\cdot}31140$, and $\epsilon=1{\cdot}31276$ for the E-line. According to A. Bertin, ice which is formed from water at rest has its optical axes vertical to the cold surface, and F. T. Trouton explains the greater heat conductivity of ice in the direction of the chief axis as the cause of the orientation of ice crystals vertical to the cold surface. The index of refraction of liquid water[16] at 16° is 1·3349 for the B-ray; 1·3322 for the D-ray; 1·3358 for the E-ray; and 1·3449 for the H-ray.

The refractive index of most transparent substances for light waves of wave-length within the limits of the visible spectrum, increases as the wave-length decreases—*e.g.* with water, alcohol, or carbon disulphide. The wave-length of violet-light is shorter than red-light, and the index of refraction accordingly is greater for violet than for red-light. With an alcoholic solution of fuchsine the reverse obtains, for the violet rays are less refracted than the red rays. According to A. Kundt, this anomalous phenomenon always accompanies great local absorption in the spectrum; and wherever there is a strong absorption band in passing up the spectrum from red to violet, the refractive index is abnormally increased below the band, and abnormally diminished above the band. The refractive index of water decreases from about 1·4 to 1·3 in passing from the violet to the red end of the visible spectrum. If the wave-length of the incident rays be increased upwards of 5 mm., the index of refraction increases to nearly 8·9; and generally with wave-lengths between 6 metres and 6 millimetres, the refractive index is nearly 8·9. There is therefore a big drop in the value of the index of refraction in passing from waves 5 mm. in length—and frequency 6×10^{x}—to the waves of red-light about $\frac{1}{1300}$th mm. in length—and frequency 400×10^{12}. This anomalous behaviour is supposed to be connected with the strong absorption band in the ultra-red spectrum of water. Similar results are obtained with alcohol, the index of refraction of which drops from about five to about half this value in passing from a wave-length 9 metres to about 8 mm.

According to J. H. Gladstone and T. P. Dale's data (1858) for the index of refraction μ, the dispersion equivalent $\mu_H-\mu_A$ and the **dispersive power**

$(\mu_H - \mu_A)/(\mu_D - 1)$ of water are indicated in Table XVI. J. Jamin represents the variation of the index of refraction of water with temperature by the formula $\mu_0 - 0{\cdot}0_4 12573 - 0{\cdot}0_5 1929\theta^2$—there is no maximum at 4°. The index of refraction for the extreme ultra-violet ($214\mu\mu$) is 1·40387; and for the ultra-red ($1256\mu\mu$), 1·3210. E. van Aubel gives 1·102 for the index of refraction of water at the critical temperature. According to J. W. Brühl, the molecular refraction for water by L. Lorenz and H. A. Lorentz's formula is 3·282 for sodium light; and the value calculated from the atomic refractions of hydrogen and oxygen is 4·14.

TABLE XVI.—OPTICAL CONSTANTS OF WATER.

Temperature.	Index of refraction.			Dispersion equivalent.	Dispersive power.
	μ_A	μ_D	μ_H		
0°	1·3291	1·3330	1·3438	0·0147	0·0429
10°	1·3288	1·3327	1·3434	0·0146	0·0439
20°	1·3279	1·3320	1·3427	0·0148	0·0445
30°	1·3270	1·3309	1·3415	0·0145	0·0438
40°	1·3257	1·3297	1·3405	0·0148	0·0449
50°	1·3241	1·3280	1·3388	0·0147	0·0448
60°	1·3223	1·3259	1·3367	0·0144	0·0441
70°	1·3203	1·3237	1·3344	0·0141	0·0435
80°	1·3178	—	1·3321	0·0143	—

Assuming that water is a mixture of two substances, a comparison of the index of refraction for water and ice shows that the specific refraction drops from 0·209680 for ice at 0° to 0·206342 for water at 0°, and subsequently, at 20°, 0·206208; at 60°, 0·206051; and at 100°, 0·206015. The increase in the value of this constant for 100 parts of the following liquids heated from 10° to 20°, is

Ether.	Chloroform.	Ethyl iodide.	Ethyl acetate.	Carbon disulphide.
0·08	0·04	0·05	0·11	0·12

C. Chéneveau found the refractive index of ice and liquid water at 0° to be 1·3095 and 1·3341 respectively, and the specific gravities 0·9176 and 0·99987. The specific refractions by J. H. Gladstone and T. P. Dale's formula are respectively 0·3373 and 0·3341; and by L. Lorenz and H. A. Lorentz's formula 0·2097 and 0·2063 respectively. Similarly, for water at 100° the specific gravity is 0·95838, the refractive index 1·3182, and the specific refractions 0·3320 and 0·2019 respectively. The decrease with water is supposed to show that the normal increase with temperature has superposed upon it a decrease due to a change in the molecular constitution of the molecules of the water so that water is a mixture of two substances in proportions varying with the temperature. The results calculated by C. Chéneveau (1913) on this hypothesis are in agreement with observation. J. Jamin found that difference between the refractive index of dry air and air saturated with aqueous vapour to be $0{\cdot}0_6 726$, an extremely small quantity.

The colour of water.—In 1828, H. Davy[17] described the water from snow and glaciers in different parts of the Alps, as "pure water," and added that "its colour, when it has any depth, or when a mass of it is seen through, is bright blue; and, according to its greater or less depth of substance, it has more or less of this colour." In 1851 R. Bunsen's attention was also directed to the greenish-blue tint of the Icelandic geysers, and he found that purified water in a glass tube blackened on the inside, and two metres long, appeared distinctly blue, and he accordingly denied that water is colourless, but is actually blue. Hence, it is generally considered that the purest water is colourless in moderately thin layers but that it appears faintly blue when viewed in thick layers—say in a tube 2 metres long. According to W. Spring, the blue tint can be closely imitated by a solution of cupric chloride of the proper concentration. Lord Rayleigh believes that the blueness of water at a depth of 4 metres is largely exaggerated by W. Spring, although possibly a fully developed blue may be obtained at much greater thicknesses. Lord Rayleigh says the colour of the transmitted light is a greenish-blue; and he believes that the pronounced blue colour reported by many observers is due to insufficient care being taken to start with white light.

According to W. Spring, the faint blue tint of purified water seems to be dependent upon the presence of oxygen. Liquid oxygen, O_2, is distinctly blue; liquid ozone, O_3, is intensely blue; and hydrogen peroxide, H_2O_2, has rather a deeper blue colour than water, H_2O, so that in hydrogen peroxide the oxygen loses less of its characteristic tint than it does in water. Many organic compounds containing the hydroxyl OH-group are also blue—*e.g.* methyl and ethyl alcohols (CH_3OH and C_2H_5OH) are bluish-green when viewed in a long tube. As the number of carbon atoms increase, making a longer chain, the colour changes into the golden-yellow which is found in liquid hydrocarbon compounds free from hydroxyl. As the carbon chain of the hydroxyl compound increases in length—C_3H_7OH, C_4H_9OH, $C_5H_{11}OH$, etc.—the yellow colour becomes more and more pronounced—with amyl alcohol, $C_5H_{11}OH$, the colour is yellowish-green—until finally the yellow overpowers the blue altogether.

According to J. Aitken (1880), the blue colour of large bodies of water—*e.g.* in china-clay settling pits; in tanks in which water is being softened by the addition of milk of lime; etc.—is an optical effect due to the action of the fine particles suspended in the liquid on the light. J. L. Soret (1869), E. Hagenbach (1870), and J. Tyndall (1871) stated that the water from Lake Geneva is not optically empty, but that the blue colour is possibly due to the scattering of light from numberless colourless particles. H St. C. Deville (1848) and G. C. Wittstein (1861) analyzed a great number of natural waters, and concluded that the brown or yellow waters contain more organic matter and less calcium salt than green waters, this organic matter is brown, and the blue colour of natural waters changes to green, yellow, brown, or black as the proportion of organic matter increases. W. Spring, however, has pointed out that G. C. Wittstein's data really show that the colour of natural water stands in no direct relation with the organic matter or alkali concentration. He showed that with water containing ferric oxide in solution or suspension, the colour is dark mahogany-brown with a concentration of 1 : 10000; golden-yellow with 1 : 1000000; grass-green with 1 : 8000000; and blue like pure water with 1 : 24000000. Similarly with humic matter, the colour is yellowish-brown with a concentration 1 : 500000; green with 1 : 20000000; and blue with 1 : 50000000. Consequently, W. Spring (1905) argues that the green colour of certain natural waters is not due to dissolved calcium salts, but rather to an invisible suspension—probably organic matter and silica. The brown or yellow colour of certain natural waters is due to humus or salts of iron. According to Lord Rayleigh, the apparent colour of the sea is largely determined by the colour of the sky seen by reflection.

A. Secchi found that the red and yellow rays are lacking in the absorption spectrum of sea-water. O. von Aufsess measured the transmission of light in various parts of the spectrum, and found the principal absorption is in the red and yellow; and with the purest water he found practically no absorption above the *F*-line, and a high transparency in this region was attained by many natural waters. Hence, if in sufficiently thick layers such waters must appear blue. The **absorption spectrum** of water is indicated in the diagram, Fig. 23. The infra-red heat rays are strongly absorbed. The maximum absorption is towards the red and orange, the maximum transmitted is towards the blue and green. There are large absorption bands in the spectrum of water [18] at the approximate wave-lengths 1·5, 2·3, 4·75, and 6μ. Water is very opaque to the deep infra-red radiation and the spectrum of numerous narrow absorption bands can be resolved only when the substance is reduced to a highly attenuated vapour; in the liquid state, these groups of small bands coalesce into larger bands. In the visible spectrum, and as far as 0·933μ in the infra-red, a thick layer of water is needed to produce absorption bands. A layer 1 cm. thick absorbs all frequencies beyond 1·4μ; a layer 0·5 mm. thick is quite opaque beyond 2μ; and a layer 0·1 mm. thick is quite opaque beyond 5μ. Beyond 8μ, water is transparent. According to W. W. Coblentz, if infra-red absorption spectrum bands of a hydrated compound be present at wave-lengths 1·5μ, 2·0μ, 3·0μ, 4·75μ, and 6·0μ, and the absorption bands at 1·5μ, 2·0μ, and 4·75μ, are weak while the others are strong, the product is a hydrate because these absorption bands are characteristic of water itself. The presence of a hydroxyl group may cause an absorption band near 3μ, but if water molecules be absent, the other characteristic bands are absent. G. Bode studied the infra-red spectrum of ice.

Water vapour is more transparent than the liquid. About the middle of last century there was an interesting controversy between J. Tyndall[19] and G. Magnus on the absorption spectrum of water vapour. The former obtained a strong absorption, the latter a negligibly small absorption. Other physicists investigated the subject, and it has now been established not only that water vapour absorbs heat rays but also what particular rays are absorbed, and how much of each. Atmospheric water vapour transmits the sun's radiation as far as 11μ, while a layer of liquid 2 cm. thick, and equivalent to the water in the earth's atmosphere, absorbs everything beyond 1·2μ.

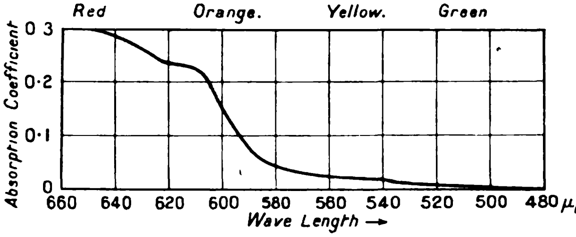

FIG. 23.—The Absorption of Light by Purified Water.

According to M. Faraday, ice is positively electrified by friction with water, and on this fact, L. Sohncke[20] has founded a theory of atmospheric electricity. The **electrical conductivities** of ice and water are very low, and this the more, the greater the degree of purity. With an alternating current of 1000 cycles per sec., the resistance of ice per centimetre cube is given as $7·22 \times 10^7$ ohms; the corresponding conductivity, as 1400×10^{-11}, where with a direct current the conductivity is $1·63 \times 10^{-9}$. With an alternating current of 1000 cycles, the breakdown voltage per cm. is $0·011 \times 10^6$;[21] the specific inductive capacity is 86·4, and with an alternating current of 15 cycles, 429·0. The electrical conductivity of ice, said G. Foussereau (1884),[22] is 15·000 times smaller than that of water, which is represented to have an absolute resistance of 9400 ohms. Ice, at 0°, has an electrical resistance of 4865 megohms, and at —17°, a resistance of 33,540 megohms. Dry ice indeed is considered to be one of the most perfect of insulators. Telephone câbles which are defective in insulating properties through moisture may become all right when the temperature falls below the freezing point.

The specific resistance of water at 15° was found to vary between 118,900 and 712,500 ohms, according to the degree of purity. The higher number was obtained with water distilled three times in a platinum vessel. The resistance of water kept for 24 hours in glass vessels at 15° was found to diminish about one-thirtieth owing to the solvent action of water on the glass; if kept in platinum vessels, the diminution is slower, and it is due to the slow absorption of salts and acid vapours from the atmosphere. F. Kohlrausch and A. Heydweiller[23] purified some water by distillation in vacuo which had a conductivity of $0·043 \times 10^{-6}$ reciprocal ohm per cm. cube at 18°, or $0·015 \times 10^{-6}$ reciprocal ohm at 0°. Twice-distilled water has a conductivity of from 1 to 2×10^{-6} reciprocal ohms. This, said F. Kohlrausch and A. Heydweiller, means that:

> One millimetre of this water has at 0° a resistance equal to that of a copper wire of the same cross-section 40,000,000 kilometres long, a wire that could therefore be wound a thousand times round the earth. This water is probably the purest that has ever existed, whether artificially prepared, or occurring ready formed in nature, not even excepting the water precipitated in the form of clouds in the highest strata of the atmosphere. Simple contact with the air for a short time raised its conductivity tenfold. The impurities still present in the water might be estimated at a few thousandths of a milligram per litre.

F. Kohlrausch further estimates that the specific conductivity of absolutely pure water at 18° is $0{\cdot}038\times10^{-6}$ reciprocal ohm. J. Negreanu found the conductivity of ordinary tap-water to be between 200 and 760 reciprocal ohms at 18°. J. J. Thomson found the conductivity of electrolytes under very rapidly alternating frequencies to be fairly constant up to 10^6 cycles. J. A. Fleming and G. B. Dyke found the conductivities of many solids increased rapidly with the frequency—*e.g.* ebonite at 4600 cycles had a conductivity 6·4 times greater than with 800 cycles. B. van der Pol found that the normal conductivity of sea-water with steady currents is 5×10^{-11}, and for currents of frequency 275, 1070, and 3400, the conductivities are respectively 1·005, 1·002, and 1·001 times the normal value, thus showing that the conductivity of sea-water for all frequencies used in wireless telegraphy is nearly equal to the value for steady currents to within less than a half per cent. K. T. Compton calculated the **ionizing potential** for water vapour from the formula $V=0{\cdot}194(K-1)^{-\frac{1}{2}}$ volts to be 8·64 volts, where K is the dielectric constant, and V the ionizing potential.

The velocity of migration of the H·-ion is $v^{\cdot}=318$ at 18°, and for the OH′-ion, $v'=174$. The concentration C of the ions in gram-ions per litre $C_{H}=C_{OH}$ is $\lambda/\lambda_{\infty}=\lambda/(v^{\cdot}+v')=0{\cdot}0384\times10^{-6}/(318+174)=0{\cdot}78\times10^{-7}$. The conductivity λ increases with temperature:

	0°	2°	10°	18°	26°	34°	42°	50°
$\lambda\times10^{3}$ . .	0·0115	0·0133	0·0233	0·0361	0·0567	0·0833	0·1210	0·1690

The change in the concentration of the H·-ions is about 0·04 per degree. If water be ionized $H_2O \rightleftharpoons H^{\cdot}+OH'$, the equilibrium condition is $[H^{\cdot}][OH']=K'[H_2O]$, where K is the ionization constant, and since the un-ionized water is in very great excess, the term $K'[H_2O]$ is also constant, and hence $[H^{\cdot}][OH']=K$, where K is the so-called *water constant*. The **ionization constant** for water has been worked out by several different methods. S. P. L. Sorenson reduced the more important of these to their values at 18°. S. Arrhenius and J. Shields obtained $K=0{\cdot}73\times10^{-14}$ from measurements on the hydrolysis of sodium acetate; J. J. A. van Wijs, $0{\cdot}83\times10^{-14}$ (hydrolysis of methyl acetate); H. Lunden $0{\cdot}61\times10^{-14}$ (hydrolysis of trimethyl pyridine *p*-nitrophenol); F. Kohlrausch and A. Heydweiller, $0{\cdot}63\times10^{-14}$ (conductivity of water); W. Ostwald and W. Nernst, $0{\cdot}64\times10^{-14}$ (e.m.f. of hydrogen electrode in acid alkali cell); R. Lowenheiz used an analogous process and obtained $0{\cdot}74\times10^{-4}$, and S. P. L. Sorenson obtained $0{\cdot}72\times10^{-14}$ from the e.m.f. of the hydrogen electrode against $0{\cdot}01N$-KCl and the calomel electrode. The best representative value is $[H^{\cdot}][OH']=0{\cdot}73\times10^{-14}$; hence $[H^{\cdot}]=[OH']=0{\cdot}85\times10^{-7}$. This is taken to mean that in a litre of water, at 18°, 0·000085 milligram of hydrogen is present as free hydrogen ions. The ionization constant for water changes rapidly with temperature. R. Lorenz and A. Böhi computed values from their measurements of electrode potentials, and F. Kohlrausch and A. Heydweiller and A. A. Noyes and co-workers from measurements of the electrical conductivity. The results are by no means concordant. R. Lorenz and A. Böhi give:

	0°	18°	25°	30°	50°	70°	90°	99°
$K\times10^{14}$ . . .	0·14	0·72	1·22	1·74	8·8	21·5	53·5	72·0
$[H^{\cdot}]\times10^{7}$ . . .	0·37	0·85	1·10	1·32	2·96	4·61	7·3	8·49

According to C. W. Kanolt (1907), the ionization constant K for water at 0° is $0{\cdot}089\times10^{-14}$; at 18°, $0{\cdot}46\times10^{-14}$, and at 25°, $0{\cdot}82\times10^{-14}$, while A. A. Noyes, Y. Kato, and R. B. Sosman give the concentration of the hydrogen ion, $[H^{\cdot}]$, and the ionization constant K at different temperatures θ, as

θ	0°	18°	25°	100°	150°	218°	306°
$[H^{\cdot}]\times10^7$	0·30	0·58	0·91	6·9	14·9	21·5	13·0
$K\times10^{14}$	8·089	0·46	0·82	48	223	461	168

The **heat of ionization** Q of one gram-molecule of water calculated from the usual formula $\log (K_2/K_1)=Q(T_2-T_1)/RT_1T_2$, is nearly 14 Cals. when $R=1{\cdot}986$ cals.

F. Kohlrausch assumes that each ion is surrounded by a shell or atmosphere of the solvent which differs in some respects from the rest of the solvent; the dimensions of the atmosphere is determined by the character of the ions. In other words, the ions are hydrated. The electrolytic resistance of an ion is a frictional resistance which increases with the dimensions of the atmosphere. F. Kohlrausch continues:

> The relationship between the mobilities of the ions and their temperature coefficients first led me to seek a general explanation for the electrolytic resistance in the idea of a water atmosphere, in order to escape being compelled to explain this otherwise irreconcilable fundamental characteristic of the ions as a *deus ex machinâ*. Assuming as the single fundamental characteristic of each univalent monatomic ion the formation of a water atmosphere, which varies according to the nature of the ion, the mobility of the complex on the one side, and its temperature coefficient on the other, will be functions of the atmospheric formations, and therefore both quantities must hold functional relations to each other. We know at present too little of the molecular forces to attempt to describe this connection more exactly; but for the case in which the water shell is so thick that the ion exerts no force beyond it, the resistance to motion becomes simply a matter of water friction, which explains the fact that the most sluggish ions have nearly the same temperature coefficients as the viscosity. In the case of smaller aggregations, we must remain content with the fact that we have at least the possibility of a fundamental explanation.

W. Nernst assumes that the solvent water is strongly contracted by the presence of free ions, and the observed contraction which occurs during the dissolution of ionized substances is smaller than the molecular volume of the solid—*e.g.* sodium carbonate, magnesium or zinc sulphate, etc. The electrostriction is caused by electrostatic fields of the ions which make the solvent contract in their immediate vicinity.

In addition to the ionization $H_2O\rightleftharpoons H^{\cdot}+OH'$ in which water acts as if it were a monobasic acid, a second stage in the ionization is conceivable, $H_2O\rightleftharpoons HO'+H^{\cdot}\rightleftharpoons 2H^{\cdot}+O''$. where the water acts as if it were a dibasic acid. Nothing definite is known about this second stage of ionization; if it does occur at all, it must be in exceedingly small proportions because the second stage in the ionization of a dibasic acid is always more difficult than the first stage, and the first stage with water is very small.

Many organic substances—fatty acids, oximes, alcohols, etc.—form complex or polymerized molecules when dissolved in hydrocarbons, chloroform, carbon disulphide, or carbon tetrachloride; the complexes are usually broken down into simpler molecules when these substances are dissolved in water, and to a less extent when dissolved in alcohols, ethers, or phenols. The latter class of solvents is said to be ionizing because when saturated with hydrochloric acid the liquids act as conductors of electricity, whereas the former class of solvents is non-ionizing because the liquids are virtually non-conductors under similar conditions. Water is *par excellence* the ionizing solvent. J. W. Brühl [24] explains this by assuming that water is an unsaturated compound containing quadrivalent oxygen $H_2=O=$, or $H-\overset{\cdot}{\underset{\cdot}{O}}-H$, and that the latent valency of water is the cause of the formation of molecular aggregates which in turn makes water an ionizing solvent. The organic solvents, too, which act in a similar way, usually contain hydroxylic oxygen, while those solvents free from oxygen—hydrocarbons, chloroform, etc.—have usually little or no ionizing power. J. W. Brühl cites in favour of the view that water has an unsaturated molecule: (1) Nearly all substances capable of uniting with water are hygroscopic; (2) Numerous hydrates and compounds of water of crystallization exist; and (3) Water is an unusual solvent.

According to R. Abegg, the **dielectric capacity**[25] of ice at −18° is 3·16 for waves approximately $\lambda=5\times10^3$ cm.; while U. Behn and K. Kiebitz give 1·76 and 1·88 for waves $\lambda=75$ cm. at −190°. According to K. Bädeker, the dielectric constant of water vapour under 3 atm. pressure, at 145° is 1·00705 (vacuum unity) or 1·00646 (air unity); and at θ° the dielectric constant is $1{\cdot}00705\{1-0{\cdot}00014(145-\theta)\}$. M. Jona also measured the dielectric constant of water vapour at temperatures ranging from 17·8° to 178·1°. According to Maxwell's rule, the square of the index of refraction μ^2 is equal to the dielectric capacity K for electric fields alternating with a low frequency. C. B. Thwing (1894) found that the dielectric capacity of liquid water with rapidly alternating oscillations (with a wave-length over 10 m.) rises from 79·46 at 0° to a maximum 85·2 at 4°, and falls to 79·4 at 7°. The refractive index μ for long electrical waves is given by the quotient $\mu=\lambda/\lambda'$, where λ and λ' represents respectively the wave-lengths in air and in the compound under investigation. For sufficiently long waves—about 70 cm.—the square of the refractive index μ is equal to the dielectric constant K, or $\mu^2=K$. At 17°–18°, for water, H. Merczyng, A. Colley, H. Rukop, J. F. Smale, B. B. Turner, and P. Drude found:

λ	3·5	4·5	55·5–68·5	long	c. 10^4
μ	6·54	6·88	8·955	9·0	—
μ^2	42·7	47·3	80·26	81·0	—
K	—	—	80·9–81·1	—	80·0

C. Niven found the dielectric constant decreased with increasing temperatures at 0°, $K=90{\cdot}36$; at 7°, 80·06; at 33°, 69·31; at 58·32°, 59·5; and at 83°, 37·97. B. Hopkinson and E. Wilson found that the dielectric constant of ice is nearly 80 with low frequency electrical oscillations between 10 and 100 per second. From Maxwell's rule, the refractive index of ice is 1·41 corresponding with a dielectric constant of about 2; and the dielectric constant of ice with oscillations of a frequency of a million is a number less than 3. Thus, the refractive index of ice for electro-magnetic waves falls to 1·4 for waves of even moderate frequency under conditions where the refractive index of water still remains at 8·9. This illustrates the general observation that when liquids with a high dielectric constant pass into the solid state, the abnormal refractive index is more easily reduced to approximate with the value of μ for the visible spectrum by increasing the frequency. J. A. Fleming and J. Dewar also found that the dielectric constant of ice falls from 80 at about 0°, to nearly 3 at very low temperatures, say −190°, and the refractive index is then 7·6 with waves of low frequency and wave-length 14 mm. The refractive index of ice for light vibrations of wave-length from 14 mm. to 2088 cm. progressively decreases from 1·76 to 1·50. The latter corresponds with a dielectric constant 2·25. R. Blondlot obtained a value 2·6 for oscillations of still greater wave-lengths. R. Abegg at −18°, found for $\lambda=5\times10^3$, $K=3{\cdot}1$; for $\lambda=75$ at −90°, U. Behn and F. Kiebitz found $K=1{\cdot}76$ to 1·88; and E. Beaulard found at 0° $K=\mu^2=1{\cdot}71$. There is a steady, almost linear, change of dielectric capacity with temperature, such that the dielectric constant at θ° between 0° and 76° is $80{\cdot}6\{1-0{\cdot}004583(17-\theta)+0{\cdot}0000117(17-\theta)^2\}$. With short waves (under 1 m.) the dielectric constant is rather greater than with longer waves—at 17°, 80·6 with a wave-length 200 cm., 81·7 for 74 cm., and 83·6 for 38 cm. E. A. Harrington found the dielectric constant of aqueous solutions of sugar, and methyl alcohol to be less the greater the concentration; with aqueous solutions of urea, the reverse obtains.

The high dielectric constant of water is supposed to give a hint as to the cause of the great ionizing power, when contrasted with other solvents, *e.g.*

	Water.	Methyl alcohol.	Ethyl alcohol.
Dielectric constant	81·7	34	26
Per cent. ionization ($\frac{1}{10}N$) Potassium iodide .	88	52	25
,, ,, ,, Sodium bromide .	86	60	24
,, ,, ,, Potassium acetate .	83	36	16

J. J. Thomson's explanation[26] how a high dielectric constant favours ionization is as follows:

> If we take the view that the forces which hold the atoms in the molecules together are electrical in their origin, it is evident that these forces will be very much diminished when the molecule is close to the surface of, or surrounded by, a conductor, or a substance like water, possessing a very large specific inductive capacity (dielectric constant). Thus, let *A*, *B*, Fig. 24, represent two atoms in a molecule placed near a conducting sphere, then the effect of the electricity induced on the sphere by *A* will be represented by an opposite charge placed at *A′*, the image of *A* in the sphere. If *A* is very near the surface of the sphere, then the negative charge at *A′* will be very nearly equal to that at *A*. Thus, the effect of the sphere will be practically to neutralize the electric effects of *A*; as one of these effects is to hold the atom *B* in combination, the affinity between the atoms *A* and *B* will be almost annulled by the presence of the sphere. Molecules condensed on the surface of the sphere will thus be practically dissociated. The same effect would be produced, if the molecules were surrounded by a substance possessing a very large specific inductive capacity. Since water is such a substance, it follows, if we accept the view that the forces between the atoms are electrical in their origin, that when the molecules of a substance are in aqueous solution, the forces between them are very much less than they are when the molecule is free, and in a gaseous state.

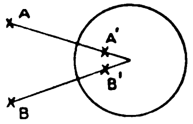

FIG. 24.

P. Dutoit and E. A. Aston[27] suggest that the ionizing power of a solvent is dependent on its degree of polymerization; they show that only polymerized solvents conduct electricity.

Ice is diamagnetic.[28] The coefficient of magnetization when referred to unit mass is $0·7193\times10^{-6}$ at 20° with a temperature coefficient of 0·00013 at 20°; P. Sève found $0·725\times10^{-6}$ at 22°. A. Piccard found that the diamagnetic coefficient of water at 0° is $0·7174\times10^{-6}$, and it changes with temperature, until, at 100°, it attains the constant value $0·7228\times10^{-6}$. The curves showing the relation between the variation of the coefficients of **magnetization** of water with respect to temperature, led A. Piccard (1912)[29] to infer that "in water at ordinary temperatures there are two substances in equilibrium." Determinations of the **magnetic susceptibility** of water[30] by different investigators give numbers ranging from $6·4\times10^{-7}$ to $8·4\times10^{-7}$ for temperatures approximating 20°. A. Piccard's value at 20° is $7·193\times10^{-7}$, and C. H. Hayes' value at 24° is $7·26\times10^{-7}$. The **magneto-optic rotation** of liquid water for a wave-length $\lambda=0·2496\mu$ is 0·1042′ per cm. per unit magnetic field; for $\lambda=0·4046\mu$, the rotation is 0·0293′; for $\lambda=1·000\mu$, the rotation is 0·00410′; and for $\lambda=1·300$, the rotation is 0·00264′. L. H. Siertsema's value[31] for **E. Verdet's constant** for water at 13·4° and the *D*-line is 0·01302; F. Agerer's value at 18°, 0·01309; G. Quincke's value at 21·81° is 0·01414; and L. Arons' value at 23°, 0·01293. J. W. Rodger and W. Watson give for θ° between 3° and 98°, $0·01311\,(1-0·0000305\theta-0·00000305\theta^2)$. L. H. Siertsema calculated the ratio of E. Verdet's constant for light of wave-length λ to the value for the *D*-line at 20°; for $\lambda=0·405\mu$, the ratio is 2·218; for $\lambda=0·589$, unity; and for $\lambda=0·701\mu$, the ratio is 0·700. J. W. Rodger and W. Watson also calculated the molecular rotation for the *D*-line between 4° and 90°, and they also found that the magnetic rotary power of unit depth of water in a magnetic field of unit strength at a temperature θ between 4° and 98° is $0·01311-0·0_64\theta-0·0_74\theta^2$. J. Kerr found that when the wire terminals of an induction coil were embedded in a block of glass placed between crossed nicols, there was a restoration of the light. The restored light could not be extinguished by rotation of the analyzer, and the phenomenon was not therefore a simple rotation of the plane of polarization, but an elliptical polarization resulting from the fact that the medium had become doubly refracting. The phenomenon also occurs with isotropic liquids. It is called **Kerr's electro-optic effect.** If D denotes the path-difference measured in wave-lengths of the two components of the vibration, K the strength of the electric field, then for unit length of fluid, $D=jK$, where j is the so-called Kerr's constant.[32] For light of wave-length $680\mu\mu$, at 20°, G. Lemoine found Kerr's constant to be $3{\cdot}70\times10^{-7}$, which is nearly the value found by R. Leiser for water. W. Obolensky[33] found that water gives a maximum **photo-electric effect** with the extreme ultra-violet rays in the neighbourhood of $\lambda=130\mu\mu$; and, becoming less as the wave-length increases, vanishes completely, when $\lambda=202{\cdot}5\mu\mu$. Ice is more sensitive than water; with rays in the neighbourhood of $\lambda=130\mu\mu$, the activity of water is $\frac{1}{400}$th of that of cupric oxide, and for rays approximating $\lambda=190\mu\mu$, ice surpasses cupric oxide.

§ 9. The Chemical Properties of Water

Water is formed by the direct union of the two elements, such as when one of the elements is burnt in the presence of the other; by the combustion of compounds containing hydrogen in air or oxygen; by the action of hydrogen on certain oxides or compounds containing oxygen; and by the decomposition of many organic and inorganic compounds containing hydrogen and oxygen. Water formed by the combustion of hydrogen in oxygen is reported to contain sometimes hydrogen peroxide, and ozone; and if the oxygen contains nitrogen, both nitric acid and ammonium nitrite may be formed. M. Berthelot[1] has reported that when a gram of hydrogen was burnt in air, 0·000075 grm. of nitric acid, HNO_3, was simultaneously formed; and in oxygen containing 8 per cent. of nitrogen, 0·017 grm. of nitric acid was obtained with a small flame, and 0·071 grm. with a large flame.

A mixture of two volumes of hydrogen and one volume of oxygen is variously styled *detonating gas*, *electrolytic gas*, *gaz tonnant*, and *Knallgas*. The constituents of detonating gas unite to form water (i) when *heated*; (ii) when exposed to an *electric spark*, or to the *silent electrical discharge*;[2] (iii) when merely *in contact with certain metals*—particularly the platinum family—charcoal, etc.; (iv) when directly exposed to *radium rays*;[3] but, according to W. P. Jorissen and W. E. Ringer, there is no perceptible action if the detonating gas in a glass vessel be exposed to radium rays. S. C. Lind found that the velocity of combination of hydrogen and oxygen under the influence of radium emanation is proportional to the amount of emanation present at any time, and to the gas pressure such that $\log (p/p_0)=kE(e^{-\lambda t}-1)$, where E_0 denotes the initial amount of emanation expressed in curies which is decaying proportionally to the factor $e^{-\lambda t}$; k is a constant; and p_0 and p mm. are respectively the initial pressure and the pressure at the time t. Increasing the volume of the gas decreases the velocity constant such that in a spherical bulb of diameter d, $k=84{\cdot}1d^{-2}$. An excess of oxygen gives a velocity constant higher than normal; an excess of hydrogen acts in the opposite direction. For each pair of ions produced by the emanation, about 3·9 molecules of water are formed. From A. T. Cameron and W. Ramsay's measurements, S. C. Lind showed a parallelism between chemical action and ionization, but O. Scheuer found about 5·5 molecules of gas combined for each pair of ions produced, and E. Wourtzel found that in general, the amount of reaction is in excess of ionization. This led

A. Debierne to reject the assumption that ionization is the primary cause of the reaction, and he suggested that the passage of an α-particle through a gas may thermally decompose molecules lying outside the ionization zone. S. C. Lind explains the apparent discrepancy on the assumption that the *recoil atoms* contribute to the ionization. When an atom emits an α-particle at a high speed, the residual atom recoils with a velocity about $\frac{1}{50}$th of that of the emitted particle, and the velocity and corresponding kinetic energy suffice to give the recoil atoms ionizing properties. The resulting calculation shows that there is a statistical agreement between the actual number of ions produced and the number of reacting molecules.

According to T. de Saussure,[4] (v) various organic substances (peas, corn, and humus) in the act of decomposition may stimulate the union of hydrogen and oxygen gases. (vi) J. B. Biot (1805) found that detonating gas combined under *pressure* in an iron tube, but heat developed by the compression may have raised the mixture to the temperature of ignition, for F. de la Roche (1811) observed no combination under a pressure of 50 atm. applied gradually; nor did A. F. E. Degen (1836) observe any signs of the recombination of the gases from the electrolysis of sulphuric acid, at a pressure of 150 atm. H. N. Warren (1893) states that an explosion with the production of flame occurs under these conditions at 180 atm. pressure, but it is not clear from his account whether or not combination occurred—his tubes always burst—he may have simply compressed the gas to the bursting pressure of the tube. (vii) Electrolytic gas may be confined an indefinite time over water or mercury, at ordinary temperatures, in darkness, with no tangible sign of chemical action, but according to H. B. Baker, if detonating gas be ***exposed to sunlight***, there is a slow combination. This no doubt explains the contradictory observations of B. Hooke (1803) and T. de Saussure (1815), for the former claimed that the gases slowly combine on standing some months, while the latter contradicted this statement.

V. Meyer and W. Raum[5] could detect no sign of combination when a mixture of hydrogen with half its volume of oxygen was heated in glass bulbs for 218 days at 100°; at 300° the formation of water could just be detected after 65 days; at 350°, in four bulbs, between 0·5 and 1·9 per cent. had combined in 5 days, and in one bulb 16·4 per cent. in the same time. W. A. Bone attributes this to a slight devitrification of the glass because he found similar accelerations in the speed of the reaction with bulbs partially devitrified. At 400°, says W. A. Bone, we are on the border line where the formation of water may be recognized within a week, but hardly within three days. The reaction then progresses the faster the higher the temperature. H. Helier passed the mixed gases through a glazed porcelain tube packed with pieces of porcelain so as to present a large surface to the gas; he could detect but a slight combination at 180°, and found that the reaction progresses faster and faster as the temperature is raised. At any assigned temperature, there is a limit beyond which no further combination ensues. For example, the percentage amount of water formed at different temperatures was found to be as follows:

200°	260°	300°	311°	376°	498°	637°	825°
0·12	1·6	3·8	9·8	25·1	56·4	85·6	96·1

At 840° the mixture exploded. Water vapour does not dissociate at these temperatures, and accordingly there appear to be two equilibrium states for the reaction: $2H_2O \rightleftharpoons 2H_2 + O_2$, according as equilibrium is approached by decomposing water vapour, or by uniting the elementary gases. Does not this conflict with the general theory of mass action? M. Bodenstein believes that a true state of equilibrium was not obtained by H. Helier, and that if he had heated his mixtures longer, no discrepancy would have been detected. On the other hand, P. Duhem believes that the system in H. Helier's experiment acquired a passive condition called a state of *false equilibrium*. Great differences in speed of the reaction have been obtained by different experimenters, and M. Berthelot has shown that this must be largely due to the nature of the surface exposed to the gas. Indeed, there are many reasons for supposing that the reaction takes place only on the surfaces of the solid; but with the facts available it is at present impossible to infer, with any degree of certainty, what would be the course of the reaction in a vessel with walls absolutely inert.

The union of hydrogen and oxygen, and the decomposition of water vapour under the influence of ultra-violet light in quartz vessels at 150° and at 240° shows that a definite equilibrium—the same at both temperatures—is attained, $2H_2+O_2 \rightleftharpoons 2H_2O$. The work done by the light rays in the reaction $2H_2O \rightleftharpoons 2H_2+O_2$ is about 44·5 Cals. per gram-molecule of water. Small quantities of hydrogen disappear owing to the reduction of silica by moist hydrogen when stimulated by active light rays. No signs of hydrogen peroxide have been detected in the equilibrium mixture, but if a fast stream of the two gases passes through the apparatus, hydrogen peroxide can be detected in the water which is formed; this is thought to indicate that the union of hydrogen and oxygen takes place in two stages: $2H_2+O_2=H_2O_2+H_2=2H_2O$.

Ignition temperatures.—H. Davy,[6] and T. von Grotthus found that a mixture of hydrogen gas and air heated to a temperature below visible redness, rapidly unites to form water without the evolution of light or heat. The temperature at which detonating gas inflames has been measured by E. Mallard and H. le Chatelier (1880) and many others. The numbers are widely divergent. By plunging a bulb containing mixed gases in a bath at a constant temperature, numbers ranging from 518° to 650° have been obtained, and higher results are obtained if an excess of either gas be present; by passing a stream of the mixed gases through a tube in a bath heated on a gradually rising temperature, numbers ranging from 550° to 845° have been reported; and by measuring the adiabatic compression required to just ignite the gas, and calculating the corresponding temperature, K. G. Falk obtained 540° for the mixture $2H_2+O_2$; 514°, for H_2+O_2; and 530°, for H_2+2O_2. According to H. B. Dixon (1910), the ignition temperatures of mixtures of 100 vols. of hydrogen with *n* vols. of oxygen, by adiabatic compression, are:

Vols. of oxygen .	33·33	40	50	100	200	300	400
Ignition point .	557°	542°	536°	530°	520°	512°	507°

Hence, the most easily ignited mixture is not one in which the proportion of hydrogen to oxygen is as 2 : 1, but when the ratio is 1 : 4. H. B. Dixon and H. F. Coward showed that the ignition temperature falls with increasing pressures; and that a stream of hydrogen at a normal pressure ignites between 580° and 590° in an atmosphere of oxygen, and virtually the same in air. The hydrogen gas was led through a narrow tube in the axis of a larger porcelain tube through which a slow current of oxygen or air was passed. The outer tube was heated by an electric current traversing a coil of wire. A constant ignition point was obtained when the diameter of the outer tube and the speed of the current of gas surpassed a certain minimum value. With an orifice 1 mm. diameter, and an outer tube 4·5 cm. diameter, the gas had to be passed at a rate exceeding 9 c.c. per minute to give constant results. The ignition temperatures obtained with the gases in sealed bulbs are rather lower than the ignition points of flowing gases. According to H. F. Coward, C. Cooper, and C. H. Warburton, a flame which filled a 570 c.c. globe has been obtained with the electrolytic gas at a pressure of 5 mm., and a flame travelled through a cylinder 2 metres long with a gas at 8 mm. pressure. These pressures are lower than have been obtained by others, for previous records gave minimum pressures between 34 and 146 mm. The ignition temperature is largely determined by the nature of the spark discharge. The small amount of gas—0·3 to 5·5 per cent.—which remained uncombined, presumably owing to the cooling of the walls, varied inversely as the original pressure of the gas, and was greater the larger the globes.

Lord Rayleigh (1875) has shown that energy is dissipated when a mixture of hydrogen and oxygen at atmospheric pressure is exploded by an electric spark. The spark itself can be neglected because any given spark can explode an indefinitely large quantity of the mixture. If the gas is expanded at constant temperature before the explosion, and, after the explosion, brought back to its former volume, the pressure required to compress the steam will be less than that exercised by the same volume of uncombined gas, and accordingly work is gained in the operation, for less energy is dissipated during the explosion of the expanded gas than is dissipated by the explosion of the condensed gases. If the expansion be increased without limit, the amount of energy dissipated during the explosion becomes indefinitely small; otherwise expressed, the tendency to combine diminishes the rarer the gas, and there must be a point where the gas becomes so rare that the explosion will not take place.

According to H. B. Dixon (1884),[7] the **speed of the explosion wave** in long tubes containing mixtures of hydrogen and oxygen, nH_2+O_2, is

n	8	6	4	2	1	$\frac{1}{2}$	$\frac{1}{3}$	
Speed	3532	3527	3268	2821	2328	1927	1707	metres per sec.

The speed is thus greater in an excess of the specifically lighter gas, hydrogen, than in an excess of the specifically heavier gas, oxygen.

The catalytic action of metals, etc., by contact.—The combination of hydrogen and oxygen can be *inaugurated* at ordinary temperatures where the most refined observations show no signs of chemical combination, and, where the temperature is such that the gases are actually combining, the speed is *accelerated* by the mere presence of a number of different substances—by finely divided platinum in particular. The phenomenon was discovered by H. Davy in 1817,[8] for he remarked that platinum foil or wire heated to a temperature " short of redness " will induce the combination of oxygen with other inflammable gases or vapours; and P. Erman (1819) showed that a temperature of 50°–51° suffices. After E. Davy (1820) had shown that when finely divided platinum damped with spirits of wine became incandescent owing to the heat generated by the oxidation of the alcohol, J. W. Döbereiner described in a brochure, *Ueber neu entdeckte höchst merkwürdige Eigenschaften des Platins* (Jena, 1823), how finely divided platinum will spontaneously induce the rapid combination of hydrogen and oxygen gas. A. Pleischl noticed that when platinum wire has been in the hydrogen flame for some time it becomes corroded, dull, and dark grey; and that the corroded part subsequently gets hot quickest in the jet of hydrogen gas. W. A. Bone also found that the appearance of a piece of silver gauze before and after it has acted as a catalytic agent for hydrogen and oxygen at 400° changed so that the wires originally smooth became quite rough. These facts are taken to show that the reacting gases during the catalytic action are in very intimate contact with the surface film of metal. P. L. Dulong and L. J. Thénard found that while a coil of new platinum wire—0·05 mm. diameter—must be heated to 300° to make it effective, after several ignitions, it acts as low as 50° or 60°. If the wire be immersed in hot or cold nitric acid, and dried at 200°, it acts at the ordinary temperature of the air, and becomes red hot in a jet of a mixture of air and hydrogen; sulphuric acid acts similarly but is less effective; and hydrochloric acid is still less effective. Potassium or sodium hydroxide destroy the activity of the metal.

P. L. Dulong and L. J. Thénard reported that the property acquired by platinum, by the acid treatment, persists but a few hours when the metal is exposed to the air, and 24 hours if confined in a vessel. The treated metal loses its property if exposed for five minutes to a current of dry air, oxygen, hydrogen, or carbon dioxide; ammonia or the alkali hydroxides deprive the metal of its peculiar power. Platinum foil and platinum filings when fresh and clean exploded a mixture of hydrogen and oxygen. They lose this quality if exposed to air for an hour or two, but the property is recovered if the metal be ignited in a covered crucible. Platinum filings prepared under water have no action. The less active forms of the metal may induce the combination of the mixture of hydrogen and oxygen without causing explosion. M. Faraday showed that a platinum plate must have its surface rigorously clean if it is to effect the combination of detonating gas, and he described several methods of cleaning platinum plates in order to make them active stimulants of the union of hydrogen and oxygen. He also found that the surface of the plates loses its activity on exposure to air for 24 hours, but regains it when gently ignited. A platinum plate is active when it has been used as the anode in sulphuric, nitric, oxalic, tartaric, citric, or acetic acid, or in a solution of potassium phosphate, chlorate, or nitrate, or of sodium or copper sulphate; it acquires less power in hydrochloric acid, still less in potassium or sodium carbonate, and none at all in potassium hydroxide.

According to J. W. Döbereiner, spongy *platinum* is effective at ordinary temperatures in inducing the combination of hydrogen and oxygen; the action is at first slow, but as the temperature rises, the action is very fast; while A. Pleischl, and A. de la Rive and F. Marcet found the ash of filter paper saturated with ammonium chloroplatinate is even more effective than spongy platinum, for the action was then apparent at —20°. E. Davy and J. W. Döbereiner found that very finely divided platinum—platinum black—is still more active. Hence, the more finely divided the platinum, the greater its efficiency in stimulating the union of a mixture of hydrogen and oxygen. Platinum black which has not been freed from oxygen can induce the union of the two elements at the temperature of liquid air, —190°.

J. W. Döbereiner, P. L. Dulong and L. J. Thénard, M. Faraday, A. Pleischl, W. C. Henry, and A. de la Rive and F. Marcet obtained similar results with *iridium* and *palladium*; *osmium* acts at 40° or 50°; spongy *rhodium* at 240°; *gold* leaf at 260°; gold paper ash at 50°; and *silver* leaf below 357°; silver paper ash, 120° to 150°. W. C. Henry found finely divided *copper* at 264° does not set fire to a stream of hydrogen but the copper oxidizes; at higher temperatures the powder becomes red hot. E. D. Campbell found an alloy of copper with one per cent. of palladium—*palladized copper*—stimulates the union of hydrogen and oxygen; *cobalt* and *nickel* behave similarly; while P. L. Dulong and L. J. Thénard say copper and nickel act at 300°. W. C. Henry found that *iron* reduced from the oxide induces rapid combination of hydrogen and oxygen at the temperature of reduction. Copper or iron turnings, *zinc* foil, and *charcoal* were reported by W. C. Henry to have no action, but P. L. Dulong and L. J. Thénard found charcoal, *pumice stone*, *porcelain*, *rock crystal*, and *glass* to act below 350°; the action of *fluorspar* is very feeble. P. L. Dulong and L. J. Thénard say that angular pieces of glass are twice as active as rounded pieces of equal surface in stimulating the union of hydrogen and oxygen. *Mercury* at its boiling point has no appreciable action. Devitrified glass bulbs were found by W. A. Bone to accelerate the reaction at about 300°; and M. Berthelot found *barium hydroxide*, *alkali salts*, and *manganese salts* raised the speed of the reaction between 250° and 300°.

R. Böttger found that *ammonia* gas destroys the activity of platinum—even a drop of a solution of ammonia evaporating in a room suffices. The vapour of nitric acid or chlorine restores the activity removed by ammonia. J. S. C. Schweigger adds that *hydrogen sulphide*, *ammonium sulphide*, and particularly *carbon disulphide* render the metal inactive, and the activity is not restored by nitric acid or chlorine. W. Artus showed that the activity may be also destroyed by the traces of hydrogen sulphide present as impurities in hydrogen gas, and M. Faraday showed that hydrogen prepared by the decomposition of water by red hot-iron is not affected by either spongy platinum or platinum foil—presumably because the activity of the catalyst is quelled by the impurities in the gas. According to E. Turner, finely divided platinum does not become inactive when confined 24 hours over mercury in an atmosphere of oxygen, hydrogen, carbon dioxide, or air; it loses part of its power after 5 min. exposure to *hydrogen chloride*, still more in *ethylene* or coal gas; and it becomes inactive in *sulphur dioxide*, hydrogen sulphide, or ammonia.

A little moisture favours the action, for W. French (1900) showed that if the mixture be thoroughly dried, finely divided platinum does not start the reaction. If the metal be wet with water, the action is feeble at first but gradually increases as the water evaporates; similar remarks apply if the metal be wetted with alcohol or ether; and if wetted with sulphuric, nitric, or hydrochloric acid, the metal is inert. W. Henry also found that spongy platinum produces its effect if one volume of detonating gas be mixed with ten volumes of oxygen, hydrogen, nitrogen, or methane; or with six volumes of hydrogen chloride; but it is either prevented or very much retarded by 11 vols. of nitrous oxide; 3 vols. of carbon dioxide; 1½ vols. of ethylene; 1 vol. of cyanogen; or 0·5 vol. of carbon monoxide. Spongy platinum is inactive in a mixture of detonating gas with an equal volume of carbon monoxide, hydrogen sulphide, or ethylene, but platinum black becomes red hot and combination rapidly occurs. E. Turner, M. Faraday, and W. C. Henry also made observations on the retarding effects of carbon monoxide, sulphur dioxide, hydrogen sulphide, hydrogen chloride, ammonia, nitrous oxide, carbon disulphide, and ethylene on the union of detonating gas by finely divided platinum.

According to T. Graham, only impure ethylene retards the activity of spongy platinum; the purified gas does not affect the metal, and he states that in a mixture of ethylene, hydrogen, and oxygen, spongy platinum acts only on the hydrogen, not on the ethylene, so that the two gases may be separated by this agent. W. Henry also noticed that if oxygen be mixed with hydrogen, carbon monoxide, methane, and nitrogen gases, and passed over spongy platinum at 177°, the hydrogen and carbon monoxide are alone oxidized. W. Hempel based a method for analyzing certain mixtures of gases on the power possessed by finely divided palladium or platinum of inducing preferential *fractional combustion* in this manner. H. Landolt also found that hydrogen burns more readily than methane or ethylene in a flame when in the presence of platinum, but W. A. Bone has shown the need for a repetition of these experiments. W. A. Bone and his co-workers found that in explosive reactions the affinity of methane is at least 20 to 30 times greater than that of hydrogen for oxygen. At high temperatures the specific nature of the solid catalytic agent becomes negligible because the reaction takes place so rapidly in the gas phase. W. A. Bone found that hydrogen burns more readily than methane at 500° in the presence of broken firebricks (grog); in borosilicate glass tubes, at 300°-400°, methane, ethylene, and acetylene are burned more quickly than hydrogen or carbon monoxide; E. Jäger says that in the presence of copper oxide at 250°, all the hydrogen in a mixture of hydrogen and methane can be burned without decomposing the methane. W. D. Bancroft adds that at low temperatures the nature of the catalytic agent may determine which of two combustible gases will burn the more readily. Since charcoal causes the oxidation of ethylene to carbon dioxide and water, and since charcoal has very little effect on a mixture of hydrogen and oxygen, it is probable that charcoal will cause the preferential combustion of ethylene in a mixture of ethylene and hydrogen.

There have been many attempts to explain **the mechanism of the catalytic activity** of platinum. J. W. Döbereiner and J. S. C. Schweigger vaguely attributed the phenomenon to the electrical reactions between the different substances concerned in the action. One of the oldest hypotheses is due to A. Fusinieri (1825) and M. Faraday (1834). It refers the action to the absorption or *the condensation of the reacting gases on the surface of the metal*, and the enhanced faculty of combination possessed by the gases in this condensed state. J. Babinet, L. Meyer, G. H. Quincke, and J. J. Thomson also attribute the action in part to the change in the physical condition of the molecules of the reacting gases in contact with the catalytic agent. M. Bodenstein's measurements of the rate of the reaction at the higher temperatures (short of explosion) correspond with a termolecular reaction, $2H_2+O_2=2H_2O$, whereas at lower temperatures the reaction is monomolecular, for the rate of the reaction is then proportional to the pressure of the gas—the rate of absorption of each gas is also proportional to its pressure. Hence it is inferred that the main reaction at low temperatures takes place on the surface of the metal, and is dependent on the rates of absorption of the two gases by the metal, and also on the rate of diffusion of the products of the reaction away from the seat of the reaction on the surface of the metal. C. Ernst also found that the rate of combination of hydrogen and oxygen dissolved in water in contact with electrolytic gas is proportional to the rate of solution of the mixed gases, which in turn is proportional to the pressure of the gases lying above the surface of the water. M. Bodenstein found similar results for the action of Bredig's colloidal platinum in water. This agrees with the observations of W. A. Bone and R. V. Wheeler, W. A. Rowe, etc.

Another hypothesis, suggested by A. de la Rive and F. Marcet (1839) and by C. Engler and L. Wöhler (1901), assumes that there is *a rapidly alternating series of oxidations and reductions of the surface of the metal.* A platinum oxide is first supposed to be formed: $Pt+nO_2=PtO_{2n}$; the oxide is immediately reduced: $PtO_{2n}+2nH_2=2nH_2O+Pt$; the reduced metal is re-oxidized, to be reduced again, and so on indefinitely. In support of the view that the formation of an oxide of platinum is an intermediate stage of the catalyzed reaction, oxidized platinum is stated to be a more active catalytic agent than platinum alone. M. Berthelot and P. Sabatier suggested that a hydride, not oxide of platinum, is formed as the intermediate stage in the reaction.

How the metal carries oxygen to the hydrogen or hydrogen to the oxygen has not been definitely established. W. D. Bancroft sums up the evidence by stating that while the effect of platinum may be due to an oxidation, it is doubtful if this is the case with charcoal and oxygen. In general, with contact catalysis: (i) only those substances which are absorbed by a solid are catalyzed by it; (ii) while the catalytic action of solids may be solely the result of the increased surface concentration in some cases, this is not always the only factor; (iii) a solid catalytic agent may be considered as equivalent to a solvent and may therefore displace the equilibrium; (iv) as a result of selective adsorption we may get different reaction products with different catalytic agents; (v) a catalytic agent tends to produce the system which it absorbs the most strongly.

I. Langmuir[9] mounted a short filament of platinum in a 4-litre bulb; this was electrically heated in a mixture of hydrogen and oxygen in the absence of water vapour, at low temperatures and low pressures, and he found that the rate of the reaction V is directly proportional to the pressure of the oxygen, p_2, and inversely proportional to the pressure of the hydrogen p_1, so that $V=k_1p_2/p_1$, where k_1 is a constant; while at higher temperatures the rate varies with the partial pressures of the two gases, so that the speed of the reaction $V=k_2p_1p_2$, where k_2 is a constant. I. Langmuir here assumed that a certain fraction of the hydrogen molecules which strike the surface of the platinum are condensed, and the layer of hydrogen thus formed distils off at a certain rate; he further assumes that the reaction occurs when the hydrogen molecules strike oxygen on the surface, but not when oxygen molecules strike hydrogen molecules.

The energy of the reaction between hydrogen and oxygen.—According to W. G. Mixter (1903), the **heat of combustion** of a gram of hydrogen at constant pressure to form liquid water at 0° is 33993 cals.; and the mean value of the observations of other recent observers is 34022 cals. with a possible error of about $\frac{1}{10}$th per cent. The **heat of formation** Q, of a gram-molecule of water, $H_2+\frac{1}{2}O_2=H_2O$, at atmospheric pressure, and 0°, is, according to M. Berthelot and C. Matignon[10] (1893), 70·4 Cals. for ice; 69·0 Cals. for the liquid; and 58·1 Cals. for the vapour all at 0°. The change in the heat of combination of hydrogen and oxygen to form a gram-molecule of liquid water per degree change of temperature, can be calculated from G. Kirchoff's equation $dQ/dT=\Sigma(C-C_1)$, where ΣC denotes the sum of the specific heats of the reacting products, and ΣC_1 that of the end-products. Taking the molecular heat of hydrogen as 6·8 cals.; of oxygen, 6·96 cals.; of water, 18 cals., it follows that $dQ/dT=6{\cdot}8+3{\cdot}48-18$, and the heat of formation of a gram-molecule of water decreases 7·72 cals. per degree rise of temperature. The heat of formation Q of water vapour decreases perceptibly with a rise of temperature; it is 50·5 Cals. at 2000°, and 37·1 Cals. at 4000°. W. Nernst and H. von Wartenberg found that at constant pressure, $Q_p=57200+1{\cdot}37T-0{\cdot}000365T^2-0{\cdot}0_6312T^3$ cals. per gram-molecule of the gas, and F. Haber and L. Bruner, at a constant volume, $Q_v=57084-2976T-0{\cdot}00125T^2$ cals.

A platinum plate charged with hydrogen, and a platinum plate charged with oxygen, behave in conducting liquids as if they were electrodes made of the respective gases which conduct electrically. If these electrodes be immersed in a solution of an electrolyte, there is formed a voltaic combination, H_2 | Aqueous solution | O_2 known as *Grove's gas cell,* which gives an electromotive force of 1·15 volts, but the calculated value from H. von Helmholtz's equation (1847) furnishes 1·23 volts at 7° on the assumption that the hydrogen and oxygen are under a pressure of one atmosphere. The free energy of the reaction $H_2+\frac{1}{2}O_2=H_2O$ is therefore equivalent to 475,000 joules. The discrepancy has been attributed to the formation of an oxide of platinum at the oxygen electrode. E. Bose obtained 1·1392+0·015 volts from the gas battery, and this makes the heat of formation of water vapour 52·654 Cals. This agrees with G. Preuner's value. M. de K. Thompson calculated from potential measurements 57·5 Cals. for water vapour, and 67·6 Cals. for liquid water at 0°; J. Thomsen gives 68·3 Cals., C. von Than, 68·43 Cals.; A. Schüller and V. Wartha, 68·25 Cals. for liquid water at 0°. The reported values for the heat of formation of water are therefore very concordant, and G. N. Lewis considers the best representative value to be 68·47 at 0°. J. E. Mills calculates for ice at −273°, 71·4 Cals.

According to W. Nernst and H. von Wartenberg (1906), the **free energy of the reaction** $H_2+\frac{1}{2}O_2=H_2O$ when the two gases are at atmospheric pressure, and at 1000° K. is 90·6 Cals., showing that there is a large positive chemical affinity between those gases at this temperature. G. N. Lewis and M. Randall calculate the free energy of the reaction $H_2+\frac{1}{2}O_2=H_2O$ to be $F=-57410+0{\cdot}94T\log T+0{\cdot}00165T^2-0{\cdot}00000037T^3+3{\cdot}66T$. This makes the free energy of formation of a gram-molecule of gaseous water at 25°, *i.e.* 298° K., −54590 cals. If the vapour pressure of water be 23·8 mm. at 25°, barometer 760 mm., the free energy $=-RT\log(760/23{\cdot}8)=-2053$; the free energy of formation of liquid water at 25° becomes −56640 cals. The value calculated from the heat of dissociation of silver oxide is −56530 cals.; from the dissociation of mercuric oxide, −56650 cals.; and from the e.m.f. of the hydrogen: oxygen cell, −54567. The free energy of the formation of a gram-molecule of ice is −56478 cals.; and the free energy of fusion $H_2O_{solid}=H_2O_{liquid}$ is $F=-1022-9{\cdot}0T\log T+54{\cdot}230T$, or −141·6 cals. at 25° when the heat of fusion is 79·7 cals. per gram, or 1436 cals. per gram-molecule.

The decomposition of water.—Water is fairly stable, and even at the high temperature of the oxyhydrogen flame—estimated to be over 3000°—the amount decomposed is small although quite appreciable. Water is decomposed (i) by exposure to very high temperatures; (ii) by the electrolysis of the liquid; (iii) by passing a series of electric sparks or the silent discharge[11] through the vapour; (iv) by the formation of an electric arc under the liquid—as shown by W. Loeb; (v) by the action of the alkali metals at ordinary temperatures or of other metals at higher temperatures whereby *the oxygen of the water is fixed by the metal, and hydrogen gas escapes*; and (vi) by exposing water to the action of fluorine at ordinary temperatures, or of chlorine or bromine light or heat whereby *the hydrogen of the water is fixed by the halogen, and oxygen escapes.* Again, (vii) W. Ramsay found that water is decomposed by the dissolution of radium salts in the water, whereby a stream of hydrogen is continuously evolved; and (viii) M. Kernbaum, that water is decomposed by exposure to ultra-violet light: $2H_2O=H_2O_2+H_2$.

W. Ramsay and F. Soddy decomposed water acting as solvent with a radium salt as solute, and W. H. Bragg noted what he called "a curious parallelism in numbers" in that the number of molecules of water decomposed was almost exactly equal to the number of ions which would have been produced in air by the emanation employed. K. Bergwitz noted the decomposition of water by the α-rays of polonium deposited on copper, and M. le Blanc showed that the results closely approximated to the requirements of Faraday's law—the ionization and chemical action are of the same statistical order. W. Duane and O. Scheuer also found a close equivalence between ionization and the amount of water decomposed. S. C. Lind showed that the recoil atoms also play a part in producing ionization, and that if ionization by α-particles be alone considered, the chemical effects produced appear greater than corresponds with ionization.

In 1847, W. R. Grove described in a paper, *On the decomposition of water into its constituent gases, by heat*,[12] an experiment in which hydrogen and carbon dioxide were heated in a tube by means of a wire heated white hot by means of an electric current. Carbon monoxide and water were formed, $CO_2+H_2=CO+H_2O$. If carbon monoxide be similarly heated under precisely similar conditions, carbon dioxide and hydrogen are formed $CO+H_2O=CO_2+H_2$. Now, added W. R. Grove,

> It appeared to me ultimately that the ignited platinum had no specific effect in producing either composition or decomposition of the water, but it simply rendered the chemical equilibrium unstable, and that the gases then restored themselves to a stable equilibrium according to the circumstances in which they were placed, with regard to surrounding affinities ; that if the state of mixed hydrogen and oxygen were, at a certain temperature, more stable than that of water, ignited platinum would decompose water as it does ammonia. . . . It now appeared to me that it was possible to effect the decomposition of water by ignited platinum : that supposing the atmosphere of steam in the immediate vicinity of platinum were decomposed, or the affinities of its constituents loosened, if there were any means of suddenly removing this atmosphere, I might get the mixed gases ; or secondly, if quantity had any influence, that it might be possible to so divide the mixed gases by a quantity of neutral ingredient as to obtain them by subsequent separation (or as it were filtration) from the neutral substance.

W. R. Grove then related that when the incandescent wire converted water into steam, some steam was always decomposed, and a small bubble of mixed hydrogen and oxygen gases was formed.

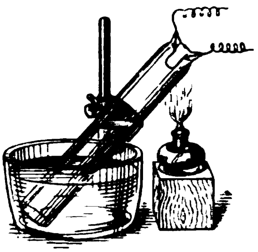

FIG. 25.—W. R. Grove's Experiment.

A glass tube with a piece of platinum wire sealed at the upper end and filled with water, is placed in an inclined position, and heated in its upper part by means of a spirit-lamp as shown in Fig. 25. The platinum wire is heated to incandescence by a suitable battery. In a few moments the lamp is removed, and the water is again allowed to fill the tube. A bubble of mixed gas remains in the tube, and it can be examined. However long the heating be continued no further decomposition occurs, for the equilibrium conditions between the water vapour and the products of decomposition are established immediately the wire becomes incandescent. The experiment was repeated with a similar result when electric sparks were passed from one wire to another inside the tube ; and also when a platinum tube was heated with a blowpipe flame, and no electrical heating employed.

W. R. Grove's work was undoubtedly the starting point of the modern theory of dissociation, even though his explanations are couched in different terms. Ten years after W. R. Grove, the subject was resumed by H. St. C. Deville,[13] who, in 1857, repeated Grove's experiments on a larger scale, and introduced many other ingenious modifications. He was able to collect a relatively large amount of the mixture of oxygen and hydrogen by pouring one to three kilograms of molten platinum into a vessel of water.

H. St. C. Deville also passed the vapour of water through a porous tube of earthenware, placed in the axis of a wider glazed porcelain tube, and passed a current of carbon dioxide in the annular space between the two tubes. The whole was heated in a furnace to about 1300°. The gases from the water dissociated in the inner tube, passed through the porous walls at different rates, and were carried away before they had the chance of recombining in the cooler parts of the tube. The carbon dioxide was removed by absorption in potash. There are two important objections to this experiment—first, it is doubtful if the temperature was high enough to give an appreciable amount of decomposition, and second, there is a possible reaction between the hydrogen and carbon dioxide. In A. W. Hofmann's experiment (1890), a stream of water vapour is quickly passed through a tube containing a strip of platinum foil heated to incandescence by an electric current, and the resulting hydrogen and oxygen are prevented from recombining on cooling. The mixed gases are collected in a cylinder over water.

The word **dissociation** was coined by H. St. C. Deville (1857) and was used synonymously for *decomposition*, but three years later, he used the term to characterize the temporary disjunction of the molecules of certain bodies into their elements at elevated temperatures. He assumed that bodies possess, at a temperature below their decomposing point, a certain tendency to decompose which he called their *dissociation tension*.

E. Mallard and H. le Chatelier (1881) showed that the pressure developed during the explosion of a mixture of hydrogen and oxygen is rather less than that calculated on the assumption that combustion is complete. It was therefore inferred that a small proportion remains uncombined. It will also be observed that the back-reaction, $2H_2O=2H_2+O_2$, the un-burning, so to speak, sets a limit to the temperature attainable in a combustion dependent on the reaction symbolized: $2H_2+O_2=2H_2O$. W. Nernst and H. von Wartenberg were able to show that steam dissociates by heat, and that the reaction is balanced by the recombination of the products of decomposition to re-form water vapour: $2H_2O=H_2+O_2$. Only about 0·00003 per cent. is dissociated at 1000° and 3·98 per cent. at 2500°. The equilibrium constant, K, for the reaction $2H_2O\rightleftharpoons 2H_2+O_2$ is $[H_2]^2[O_2]=K[H_2O]^2$, where the bracketed terms denote concentrations—say partial pressures. If a gram-molecule of water be decomposed into two gram-molecules of hydrogen, and one of oxygen, and if x denotes the degree of dissociation, there will be present $1-x$ gram-molecules of water, x of hydrogen, and $\frac{1}{2}x$ of oxygen. The total volume will be $1-x+x+\frac{1}{2}x=1+\frac{1}{2}x$, and if p denotes the total pressure, the partial pressure of water will be $[H_2O]=p(1-x)/(1+\frac{1}{2}x)$; of hydrogen, $[H_2]=px/(1+\frac{1}{2}x)$; and of oxygen, $[O_2]=\frac{1}{2}px/(1+\frac{1}{2}x)$. By substitution, therefore, the equilibrium equation reduces to

$$K=\frac{px^3}{(2+x)(1-x)^2}$$

If x is small, $K=\frac{1}{2}px^3$, or $\log K=3\log x-\log 2$, at atmospheric pressures when $p=1$. In that case W. Nernst gives $3\log_{10}x=-25050T^{-1}+1{\cdot}75\log_{10}T+0{\cdot}00028T+0{\cdot}1$. W. Nernst and H. von Wartenberg[14] further obtain

$$\log K=11{\cdot}46-\frac{25030}{T}+2{\cdot}38\log\frac{T}{1000}-1{\cdot}38\times10^{-4}(T-1000)-6{\cdot}85\times10^{-8}(T^2-1000^2)$$

The calculated degrees of dissociation at different pressures and temperatures are indicated in Table XVII.

TABLE XVII.—DEGREE OF DISSOCIATION OF WATER AT DIFFERENT TEMPERATURES.

θ° C.	Degree of dissociation, x per cent.			
	$p=10$ atm.	$p=1$ atm.	$p=0{\cdot}1$ atm.	$p=0{\cdot}01$ atm.
727°	0·0000139	0·00003	0·0000646	0·000139
1227°	0·0103	0·0221	0·0476	0·103
1727°	0·273	0·588	1·26	2·80
2227°	1·98	3·98	8·16	16·6

The values agree satisfactorily with W. Nernst and H. von Wartenberg's observations below 2000° and with N. Bjerrum's above that temperature:

	1124°	1288°	1984°	2369°	2488°	2656°
x . .	0·0073	0·034	0·77	4·3	8·6	11·1 per cent.

I. I. Andréeff found that a mixture of hydrogen and oxygen, when exposed to the ultra-violet light from a mercury lamp, unite to form water at a constant speed, which is independent of the concentration of the reacting gases, but is almost proportional to the intensity of the light. Water is also decomposed under the influence of ultra-violet light. The same condition of equilibrium is attained whether a mixture of hydrogen with half its volume of oxygen, or water-vapour be exposed to the light. With an increase in the intensity of light, the equilibrium is displaced in favour of dissociation.

The electrolysis of steam.—In 1858, A. Perrot [15] noticed that when an electrical discharge is passed through steam, there is a kind of electrolysis, and J. J. Thomson found that with *short* sparks, the gases which collect at the negative electrode contain an excess of oxygen, and those at the positive, an excess of hydrogen—the total gas collected corresponds with that obtained in the voltameter exactly as would be obtained with a true electrolysis. It was therefore inferred that the current is conveyed through water vapour in the same manner as through water. With *long* sparks this state of things is reversed and the excess of hydrogen changes over to the negative electrode, and the excess of oxygen to the positive electrode—the hydrogen collected is less than would correspond with a true electrolysis. Hence, adds J. J. Thomson,

> There is this remarkable difference between the electrolysis of steam and water, that whereas in the case of water, the hydrogen always comes off at the negative, and the oxygen at the positive electrode ; in the case of steam, the hydrogen and oxygen come off sometimes at one terminal, sometimes at the other, according to the nature of the spark.

According to D. L. Chapman and F. A. Lidbury, the electrolysis of water vapour does not take place in such a manner that the hydrogen appears at one pole and oxygen at the other, but when water vapour is decomposed by electric sparks, the hydrogen separates at both electrodes, and it has a tendency to accumulate in the neighbourhood of the two electrodes, while the oxygen is driven towards the middle of the spark gap. The nature of the gases collected at the respective electrodes is determined by the velocity of the current of steam, as well as by the nature of the sparks. Hydrogen can diffuse against the stream of water vapour much faster than oxygen. When electric sparks are passed through steam (or other compound gases), the distribution of the products of decomposition is not always the same as when the corresponding liquid is electrolyzed. The decomposition may occur in the entire path of the spark as well as in the neighbourhood of the electrodes. The distribution of the decomposition products about the two electrodes is determined by the position of the tube bringing the current of steam to the electrodes and the relative rates of diffusion of the constituent gases.

Water is *par excellence* a solvent. Aqueous solutions of certain salts can dissolve some substances not soluble in pure water—*e.g.* salts of benzoic, salicylic, and benzenesulphonic acids on certain alkaloids, fats, alcohols, and carbohydrates. The phenomenon is termed *hydrotropism* by C. Neuberg (1916).[16] The **metals** act as reducing agents towards water forming an oxide—usually basic—and liberating hydrogen ; or reciprocally, water acts as an oxidizing agent on the metals—*e.g.* it has been shown that with sodium, $2Na+2H_2O=2NaOH+H_2$; and with iron, $3Fe+4H_2O=Fe_3O_4+4H_2$. The behaviour of the metals towards water was used as an important criterion in L. J. Thénard's and H. V. Regnault's systems of classifying the metals.[17] They first attempted a dichotomous separation into metals whose oxides can be decomposed by heat alone, and those whose oxides cannot be so decomposed. The metals were then arranged in five sub-groups : (1) metals which decompose cold water—*e.g.* the metals of the alkalies and of the alkaline earths ; (2) metals which decompose hot water between 50° and 100°—*e.g.* beryllium, magnesium, etc. and a number of the rare earth metals, etc. ; (3) metals which decompose water at a red heat—*e.g.* zinc, cadmium, tin, iron, nickel, cobalt, chromium, osmium, etc. ; (4) metals which decompose water only at a white heat—*e.g.* copper, lead, etc. ; (5) metals which do not decompose water at any temperature—*e.g.* mercury, silver, gold, and members of the platinum family excepting osmium.

The **halogens** act as oxidizing agents on water liberating oxygen ; or reciprocally, water acts as a reducing agent on the halogens—*e.g.* with chlorine, $2Cl_2+2H_2O=4HCl+O_2$. With **sulphur** and **phosphorus** the hydrogen of the water forms a hydride and the oxygen forms an oxide which may unite with water furnishing an acid: *e.g.* with sulphur over 100°, $2H_2O+3S=2H_2S+SO_2$; and with phosphorus at 250°, $3H_2O+2P=PH_3+H_3PO_3$—if air be present the action occurs at a lower temperature. Some of the non-metals act like the metals and form an oxide—usually acidic—and liberate hydrogen—*e.g.* carbon and **boron** at a red heat. The reaction with **carbon** is symbolized: $C+H_2O=CO+H_2$ and $C+2H_2O=CO_2+2H_2$; there is also a reversible side reaction, $CO_2+H_2\rightleftharpoons H_2O+CO$. Some oxides react with water liberating hydrogen—for instance, in the reaction last symbolized carbon monoxide is decomposed by water vapour forming carbon dioxide and hydrogen; similarly, **manganous oxide** forms the brown oxide, Mn_3O_4, and hydrogen, $3MnO+H_2O=Mn_3O_4+H_2$; **uranium oxide,** UO_2, gives the green oxide, U_3O_8, and hydrogen; **chromous oxide** in acid solution is oxidized by water and hydrogen is slowly evolved; **potassium cobaltocyanide,** K_4CoCy_6, on oxidization by water to the cobalticyanide, K_3CoCy_6, gives off hydrogen [18]; when an alkaline solution of **molybdenous chloride,** Mo_3Cl_6, is warmed, a black precipitate of $Mo(OH)_3$ is produced, and hydrogen is evolved: $2Mo_3Cl_6+18H_2O=6Mo(OH)_3+12HCl+3H_2$. Neither **iodine** nor **aluminium** alone acts chemically on water. but remarkably enough, conjointly these elements attack water with the evolution of hydrogen. J. H. Gladstone and A. Tribe [19] consider that there is first formed a little aluminium iodide, AlI_3, which is immediately decomposed by water whereby aluminium hydroxide, $Al(OH)_3$, and hydriodic acid, HI, are produced: $AlI_3+3H_2O=Al(OH)_3+3HI$; the hydriodic acid immediately attacks the metal re-forming aluminium iodide with the evolution of hydrogen: $2Al+6HI=2AlI_3+3H_2$. Water also reacts with many **metal dioxides** forming hydroxides. For example, with the oxides of the alkalies and alkaline earths a base is formed—thus, with calcium oxide the reaction is symbolized, $CaO+H_2O=Ca(OH)_2$. With the **non-metallic oxides** an acid is formed—thus, the products with sulphur trioxide, SO_3, and water, are sulphuric acid, H_2SO_4, in symbols: $SO_3+H_2O=H_2SO_4$.

Water reacts with many metal **phosphides, silicides,** or **carbides**, respectively forming hydrogen phosphide, silicide, or carbide (hydrocarbon), and the metal oxides or hydroxides: *e.g.* calcium carbide, CaC_2, gives acetylene, C_2H_2, and calcium hydroxide: $CaC_2+2H_2O=C_2H_2+Ca(OH)_2$; similar remarks apply to the carbides of the alkali and alkaline earth metals; aluminium or beryllium carbides give methane, CH_4; and other carbides give various mixtures of hydrogen and hydrocarbons. The **sulphides** and **selenides** of boron, silicon, aluminium, and magnesium are decomposed by water furnishing hydrogen sulphide or selenide, and the metal hydroxide, or, in the case of the non-metals, an acid and the metal hydroxide. The **nitrides** of the metals usually give ammonia with cold or hot water; the metal **hydrides** give hydrogen under similar conditions—the metal hydroxide is formed simultaneously. The **organo-metallic compounds** of the more oxidizable metals give the corresponding hydrocarbon and the metal hydroxide—*e.g.* zinc methide, $Zn(CH_3)_2$, gives methane, CH_4, and zinc hydroxide, $Zn(OH)_2$.

Many **halogen compounds** give the haloid acid and either an oxyhaloid or hydroxide of the other element, *e.g.* with phosphorus pentachloride, PCl_5, hydrochloric acid, HCl, and phosphoric acid, H_3PO_4, are formed: $PCl_5+4H_2O=5HCl+H_3PO_4$; with antimony chloride, antimony oxychloride, $SbOCl_3$, and hydrogen chloride, HCl, are formed by a reversible reaction: $SbCl_5+H_2O=SbOCl_3+2HCl$. The **esters**—studied by M. Berthelot and L. P. de St. Giles [20] in their *Recherches sur les affinités* (1861-3)—are broken down by water—preferably in dilute acid solution; *e.g.* ethyl acetate, $CH_3COOC_2H_5$ forms acetic acid, $CH_3CO.OH$, and alcohol, C_2H_5OH. The reaction gradually slows down, and finally comes to a standstill, when a certain proportion of the four components of the reaction are present:

$$\underset{\text{Ethyl acetate.}}{CH_3CO\,OC_2H_5}+\underset{\text{Water.}}{H\,OH}=\underset{\text{Acetic acid.}}{CH_3CO.OH}+\underset{\text{Ethyl alcohol.}}{C_2H_5OH}$$

The distribution of these four components when the system is in equilibrium depends on their concentration, and on the temperature. The work on this reaction is classical, and it played an important *rôle* in the evolution of the law of mass action. Reactions like the so-called **hydrolysis** of potassium cyanide, KCy, symbolized, $KCy+H_2O=KOH+HCy$; and of ammonium chloride, $NH_4Cl+H_2O=NH_4OH+HCl$, are similar in character, and the ionic hypothesis attempts to describe the mechanism in still more detail. Water also forms a series of hydrated compounds with the elements—*e.g.* $Br_2+10H_2O=Br_2(H_2O)_{10}$, or $Br_2.10H_2O$—or with compounds—*e.g.* $FeSO_4.6H_2O+H_2O=FeSO_4.7H_2O$; and also $Na_2SO_4+10H_2O=Na_2SO_4.10H_2O$. The relations of the water in these compounds to the rest of the molecule has been much discussed.

The different behaviour of one of the two hydrogen atoms in water towards sodium, ethyl iodide, C_2H_5I, and phosphorus trichloride, PCl_3, led W. Ganswindt (1891)[21] to assume that water is hydrogen hydroxide, H—(OH). The argument, however, is rather weak, because it is possible that there is an equal probability of, say, sodium displacing either of the hydrogen atoms in water, H.O.H, but that as soon as one hydrogen atom has been replaced by sodium, the molecule with its one hydrogen atom becomes more resistant. J. W. Brühl (1896) assumed that water contains quadrivalent unsaturated oxygen because water exhibits, beyond most other substances, an unsaturated character—as exemplified by its faculty of forming hydrated and crystalline compounds, and its great solvent and ionizing powers. Hence, J. W. Brühl represents the molecule of water by the formula $H\cdot\dot{O}\cdot H$.

The adsorption of water by solids.—Probably many substances adsorb water vapour, so that after exposure to air, they are covered with a film of moisture which they retain so very tenaciously that it can be removed only by heating to a temperature short of dull redness in vacuo. R. Bunsen estimated that 2·11 sq. metres of glass surface, dried at 20°, lost 22·3 mgrm. of water when heated to 500°. The adsorption of water vapour by glass surfaces has been studied by R. Bunsen,[22] E. Warburg and T. Ihmori, C. J. Parks, etc.; quartz by A. von Dobeneck, L. J. Briggs, etc.; and charcoal by H. W. Foote. The penetration of adsorbed water into insulating materials has been studied by C. J. Rottmann. T. Ihmori also investigated the adsorption of water vapour by platinum, shellac varnish, brass, etc. It has long been known that old soda-glass tubing which has stood in the laboratory some time, becomes very rough when suddenly heated owing to the development of innumerable spits. This is probably due to adsorbed water.

E. Warburg and T. Ihmori divide the water film condensed on the surface of glass into a temporary portion which disappears when the vapour pressure is reduced to zero, and a permanent portion which remains. According to L. J. Briggs, the adsorption of water vapour by quartz is less than with amorphous silica. At 30°, the permanent film condensed on quartz from an atmosphere within one per cent. of saturation, corresponds with a film $2{\cdot}66\times10^{-6}$ cm. thick on the assumption that the film is uniform and has unit specific gravity. C. J. Parks found for glass wool in a saturated atmosphere at 15° a thickness $13{\cdot}3\times10^{-6}$ cm. H. W. Foote and B. Saxton found that the water adsorbed by lampblack is essentially the same as other water, only it does not freeze in the capillary pores until a low temperature, about —35°, is attained.

Pouillet effect.—In 1822, G. S. N. Pouillet[23] showed that porous substances—paper, wool, etc.—and fine powders—glass, charcoal, alumina, etc.—become heated when they are wetted with water—a liquid which exerts no solvent or chemical action on the solid. The phenomenon is now known as the *Pouillet effect.* The rise of temperature amounts to about 1°, and by suitably varying the conditions a rise of nearly 30° has been recorded. One gram of powdered charcoal, according to P. Chappius, evolves 7·425 cals. when wetted with water, and 24·36 cals. when wetted with carbon disulphide, while a gram of powdered alumina evolves 2·747 cals. when wetted with water. For the same liquid and the same powder, the quantity of heat evolved is proportional to the mass of the powder. According to G. Schwalbe, 10 grms. of washed sand gives 0·3 cal., when wetted with 0·5 grm. of water, and 0·8 cal. when wetted with 2 grms. of water, but no further rise of temperature occurred when more water was used; with silicic acid, 1·89 cals. were developed with 5 grms. of water, and 6·16 cals. with 20 grms. of water. T. Tate referred the cause of the Pouillet effect to chemical action, but this hypothesis was considered to be out of the question; G. S. N. Pouillet himself referred the effect to capillary action; C. G. Jungk showed that the effect is possibly due to the exercise of a pressure at the surface of the powder and liquid. C. Cantoni (1866) and L. Meslens (1874) assumed that the water passes into a different state of aggregation when it wets a powder—either into the solid state or some intermediate state between solid and liquid. T. Martini holds that just as a gas becomes a liquid when dissolved by a liquid, so does a liquid become solid when dissolved by a solid; and accordingly, the Pouillet effect is due to the latent heat of solidification. This hypothesis was discountenanced when M. Bellati and L. Finazzi (1902) showed that the specific heat of the water was not diminished by adsorption, as would have been the case if the water was solidified. They also stated that the grain-size of the powder had no influence on the result, but this statement proved to be erroneous; for C. J. Parks (1902) showed that when powdered and dry silica, sand, or glass are wetted with water at the same temperature the heat evolved is proportional to the exposed area of the solid, and is nearly equal to 0·00105 cal. per sq. cm. when the temperature is 7°. G. Schwalbe (1905) then demonstrated that if the temperature is below 4°, there is a negative Pouillet effect, for the water is cooled and not heated; and at 4°, there is neither heating nor cooling. This is in agreement with Lord Kelvin's proof that the temperature change dT due to the change of pressure dp on a liquid whose coefficient of thermal expansion is a, specific gravity D, absolute temperature T, and specific heat at constant pressure C_p, is

$$dT=\frac{aT}{C_pD}dp$$

Since the coefficient of expansion of water changes sign at 4°, there should be a change of sign in the Pouillet effect at the same temperature. Lord Kelvin computes there is a cooling of 0·00026° when a cubic centimetre of water at 0° is subjected to a pressure of 10 atm., and at 10° a rise of temperature of 0·0040°. It is also possible to calculate the compression of the water adsorbed by the powder from the Pouillet effect. The formation of ice within fissures and caves whose mean temperature is not below the freezing point of water, has also been explained by assuming that water below 4° is cooled instead of heated in percolating through the sandy walls of the cave.

§ 10. Hydrates and Hydrated Salts

The term **hydrate** is not used very definitely in chemistry. . It is sometimes loosely employed in contrast with anhydrous. In addition, there are at least three different meanings to the word: (1) *Hydrated colloids* or *colloidal water.*—Silica, and the hydroxides of many of the metals—iron, chromium, aluminium, etc.—pass out of solution in a more or less gelatinous or colloidal condition associated with an *indefinite* amount of water. When dried, the water usually passes off continuously with rise of temperature without any signs of the existence of definite chemical compounds. (2) *Hydrated salts* or *water of crystallization.*—The very *definite* amount of water which is contained in many salts which crystallize from aqueous solutions—*e.g.* sodium carbonate, $Na_2CO_3,10H_2O$, etc.—is called water of crystallization, and several other synonyms have been employed. It is often stated that the molecules of water in compounds containing *water of crystallization* belong to the molecular structure or else exist in them entirely among the other molecules, and belong only to the crystalline structure; on the other hand, the molecule of *water of constitution* is not supposed to exist as such but to be formed when the mineral is decomposed owing to the union of the contained hydrogen with oxygen or hydroxyl groups contained in the molecule. (3) *Hydroxides—acids, alkalies, alcohols*, etc.—The water of hydration appears to be an integral part of the molecule, and it cannot usually be removed without changing the character of the substance. Examples are indicated above, to these are sometimes added the alcohols which are related to water and the ethers as previously indicated by graphic formulæ.

Both hydrate and hydroxide contain the elements of water which can usually be recovered as water when the substance is heated or subjected to the action of a dehydrating agent. It is sometimes assumed that the molecules of water in a hydrated colloid or salt have entered into combination as a whole; while in hydroxides, the constituent atoms have been rearranged, to form quite a different compound. The two terms are therefore used to distinguish two conceptions regarding the relation between the properties and composition of compounds containing water. In the case of hydroxides, the atoms of water and of the oxide are rearranged during the union so as to form hydroxyl or HO-groups. In hydrates the atoms of water either combine as a whole with the compound or enter into some new relation with the rest of the molecule which is different from that which obtains in the case of hydroxides. It is difficult to apply the definitions, hydrate and hydroxide, in practice, for they are largely theoretical; a true hydroxide may be so unstable that it decomposes into water, etc., far more readily than a true hydrate. For example:

Hydroxide . .	$Au(OH)$	$Ag(OH)$	$Tl(OH)_3$	$Zn(OH)_2$	$Al(OH)_3$	NaOH
Decomposes at .	15°	150°	230°	585°	850°	very high

T. Carnelley and J. Walker [1] tried to measure the affinity of the oxides for water by measuring the temperature of dehydration of the hydroxides. They showed that the members of the *even* series of Mendeléeff's table, exhibit an increase in the temperature of dehydration with an increase in atomic weight; and with the *odd* series, there is a decrease in the temperature of dehydration with increasing atomic weight. In the same series of elements, the temperature of dehydration of the hydrated oxides diminishes to the middle member and then increases.

To distinguish hydroxides from hydrates.—The specific or *molecular volume* of compounds formed by the interaction of water has been suggested as a means of throwing light on the difference in the effect produced by water in forming hydrates and hydroxides. The specific or molecular volume is the quotient of the molecular weight by the specific gravity. F. W. Clarke[2] found that in the hydrated chlorides, MCl_2nH_2O, the difference in the molecular volumes of the hydrates and anhydrous salts divided by the number of molecules of water in the hydrated salt, varies from 12·5 to 15·0—average 13·76. If oxides be substituted for chlorides, the corresponding quotient varies from 7·4 to 19·4. Hence, it was inferred that while the specific volume of each H_2O molecule in hydrated chlorides has a mean value 13·74, no simple relations can be traced with the hydrated oxides in which presumably a rearrangement of the atoms of the water molecule has taken place.

W. J. Perkin [3] attempted to distinguish the two types of combined water by measurements of the *magnetic rotatory power*. If the value of this constant for water be unity, and for an anhydrous compound be x, then if the molecular rotatory power of the hydrated compound be increased by unity for each molecule of combined water, it might be concluded that the compound is a hydrate. Thus, the product of the union of formic acid, H.COOH—molecular rotatory power 1·67—with water, 1·676+0·995, and hence the product is a hydrate. With sulphuric acid

	H_2SO_4		$H_2SO_4+H_2O$		$H_2SO_4+2H_2O$
Molecular rotatory power . . .	2·315		3·188		4·113
Difference per molecule of H_2O . .		0·873		0·925	

Hence, W. J. Perkin concluded that the first hydrate of H_2SO, *viz.* $H_2SO_4.H_2O$, is a chemical compound—a hydroxide—which he symbolized, $SO(OH)_4$, while the second hydrated compound, $H_2SO_4.2H_2O$, is a hydrate : $SO(OH)_4.H_2O$.

The period of free vibration of molecular aggregates can be studied by *absorption or emission spectra*. The high temperature generally required to produce emission spectra may complicate the phenomena owing to the dissociation of the radiating body; on the other hand, absorption spectra can be obtained at low temperatures, and this gives more definite knowledge of the molecular complexity. The period of free vibration of an atomic group or radicle is not always greatly modified as the molecular complexity of a series of compounds containing that radicle increases. In 1882, W. de W. Abney and E. R. Festing [4] found that certain radicles showed distinctive absorption bands at particular parts of the spectrum; and ten years later, W. H. Julius demonstrated that a chemical atom may lose its identity in a compound, for the effect is not additive but constitutive; and the absorption spectrum of a compound cannot be predicted from the spectra of the constitutive elements. The intra-molecular character of the certain absorption bands, however, is evidenced by the fact that the important groups of atoms and radicles which occur in chemical compounds have a definite or specific effect upon radient energy, particularly upon the so-called low frequency or infra-red radiation. This effect is manifest by intense absorption bands which occur in definite positions characteristic of the radicle or group of atoms causing these bands.

W. W. Coblentz further argues that the absorption spectrum of a compound with water of constitution will not be the composite spectrum of the anhydrous substance plus water, because the combination with water completely changes the physical character of the molecule; on the other hand, if the molecules or groups of atoms which cause the absorption band undergo no physical change when they combine to form a crystal, or when they enter into solution, the absorption spectrum will be a composite of the absorption bands of the constituents. The heat of hydration, in this latter case, might lead to the inference that a new compound is formed although the bands due to the anhydrous substance and to water are the same in magnitude and position as that which the constituents possessed before they united. The radiometric test makes no distinction between water of crystallization, dissolved or absorbed water, and water of solid solution. The behaviour of water in crystals and in solid solution is identical with that of water in its free liquid state. In illustration, the absorption spectra of selenite, opal, and the zeolites are identical with those characteristic of free liquid water, and therefore it is inferred that the water in these minerals remains intact as a group of molecules; on the other hand, in brucite, $Mg(OH)_2$; diaspore, $AlO(OH)$; bauxite, $Al_2O(OH)_4$; göthite, $FeO(OH)$; muscovite mica, $H_2KAl_3(SiO_4)_3$; tremolite, $CaMg_3(SiO_3)_4$, the water is not present in solid solution or as absorbed water, but is rather constitutional, being an integral part of the molecule. Many of these minerals show a clear absorption band characteristic of the OH group in alcohol.

The infra-red absorption spectra show that the following compounds probably contain *water of crystallization :* heulandite; stilbite; potassium alum; natrolite; scolecite; analcite; colemanite; hexahydrated calcium chloride—$CaCl_2.6H_2O$; trihydrated potassium ferrocyanide, $K_4FeCy_6.3H_2O$; apophyllite; deweylite; thomsonite; gismondite;

blödite; thaumasite; hydrotalcite; varescite; wavellite; vivianite; mellite; and Rochelle salt; while the following compounds contain *water of constitution*: manganite; göthite; bauxite; turquoise; lazulite; hydrargillite; diaspore; datolite; azurite; brucite; prehnite; hydronephelite; pectolite; chloritoid; clinochlore; penninite; tourmaline; the micas; muscovite; biotite; serpentine; talc; epidote; sodium metaphosphate; meta- and ortho-phosphoric acids.

C. Schaefer and M. Schubert[5] have studied the natural infra-red vibrations of solids by the *reflection method* in preference to the absorption method. They obtained characteristic reflection maxima for the SO_4-group in 34 sulphates; and for the CO_3-group in 15 carbonates. In agreement with W. W. Coblentz, they also found that substances containing water of hydration show a reflection maximum between 3·0 and 3·5μ, and a long-wave maximum between 15 and 20μ. The former is displaced in salts like cupric sulphate and the alums containing water of hydration. Water of hydration seems to adapt itself to the symmetry of the crystal, and it is anisotropic in anisotropic crystals, uniaxial in uniaxial crystals, and biaxial in biaxial crystals. L. Vegard and H. Schjelderup studied the structure of crystals by means of the X-ray reflection method with a view of elucidating the *rôle* of the water of crystallization.

§ 11. The Vapour Pressure of Hydrated Salts

If a substance can form a number of definite hydrates, **at any given temperature, each hydrate has its own characteristic vapour pressure.** For instance, from the work of W. Müller-Erzbach, H. Lescœur, and J. L. Andreae,[1] it appears that copper sulphate forms three hydrates with vapour pressures, at 50°:

	Water.	$CuSO_4.5H_2O$	$CuSO_4.3H_2O$	$CuSO_4.H_2O$
Vapour pressure . .	92·0	47·0	30·0	4·5 mm.

Suppose water vapour be slowly admitted to a suitable vessel containing anhydrous copper sulphate at 50°. The two-component system has two solid phases and one vapour phase; accordingly, the system will be univariant, and the vapour pressure will remain *constant and fixed* at 4·5 mm. until *all* the anhydrous copper sulphate has been transformed into a monohydrate: $CuSO_4+H_2O \rightleftharpoons CuSO_4.H_2O$; the system is now bivariant because but one solid phase—the monohydrate—is present, and this can exist in contact with a vapour pressure which varies within certain limits. Hence, further addition of water vapour will be followed by a rise in the vapour pressure. At 30 mm. pressure the bivariant system becomes univariant owing to the appearance of a second phase—the trihydrate. The vapour pressure will then remain constant and fixed at 30 mm. until all the monohydrate has been transformed into the trihydrate: $CuSO_4.H_2O+2H_2O=CuSO_4.3H_2O$. Further additions of water vapour will be attended by a rise of the vapour pressure to 47 mm., and the vapour pressure will then remain stationary until all the trihydrate has been transformed into the pentahydrate: $CuSO_4.3H_2O+2H_2O \rightleftharpoons CuSO_4.5H_2O$. Any further addition of water vapour will raise the vapour pressure until the water condenses to a liquid and gives the vapour pressure of a saturated solution of copper sulphate at 50°. Further additions of water vapour will simply increase the amount of condensed water. When all the copper sulphate has dissolved, the vapour pressure will be determined by the concentration of the solution of copper sulphate.

Conversely, starting with the pentahydrate, the reverse change will occur if water be continually withdrawn from the system. The vapour pressure of the pentahydrate, 47 mm. at 50°, will be maintained as long as the system contains any of the pentahydrate. When all the pentahydrate has decomposed, the vapour pressure will drop suddenly to 30 mm. and remain stationary until all the trihydrate has decomposed; the vapour pressure will then fall abruptly to 4·5 mm. and remain at that value until all the monohydrate has decomposed into anhydrous copper sulphate. These changes are usually shown diagrammatically by curves resembling Fig. 26. Amounts of water, expressed in gram-molecules, are represented on the horizontal axes, and the vapour pressures along the vertical axes. The constancy of the vapour pressure of each hydrate is emphasized by the horizontal terraces on the vapour pressure curve.

This step by step dissociation of the hydrates furnishes a method which is sometimes available for deciding whether or not definite compounds exist at definite temperatures. If definite compounds are produced, the gradual addition or removal of water vapour will alter the vapour pressure curve until a pressure is reached which remains constant for a certain period, and then suddenly assumes a new constant value. It must be added that some (*e.g.* P. Blackman, 1911) consider the dehydration of copper sulphate pentahydrate is comparable with the removal of water from an ordinary aqueous solution; that the alleged breaks in the curve are due to a malinterpretation of imperfect experiments; and that the observed vapour pressures are points on a continuous curve. This, however, does not interfere with the principle involved.

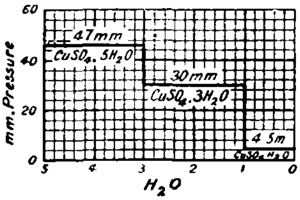

FIG. 26.—Vapour Pressure Curves of the Hydrates of Copper Sulphate.

By measuring the rate of decomposition of hydrated aluminium and ferric hydroxides, W. Ramsay inferred the non-existence of definite hydrates because no signs of any discontinuity was observed in the rate of evolution of water; but he concluded that two were formed with lead oxide—$2PbO.H_2O$ and $3PbO.H_2O$. J. M. van Bemmelen, for similar reasons, believed in the non-existence of definite hydrates of silicic acid. The underlying hypothesis is that differences in the tenacity with which the constituents of water are retained by the molecule, as evidenced by the temperatures at which the water is expelled, are the result of differences in the structure; and that molecules of water which are simultaneously expelled at a definite temperature occupy a similar position in the molecule.

Each hydrate has its own specific vapour pressure at a particular temperature, The average vapour pressure of the water vapour in atmospheric air is equivalent to 8 or 9 mm. of mercury. If the vapour pressure of the hydrate be greater than the vapour pressure of the atmospheric moisture, the hydrate will *lose* water on exposure to the air—in other words, the salt will be **efflorescent;** on the contrary, if the vapour pressure of the hydrate be less than that of the atmospheric moisture, the salt will *absorb* moisture from the atmosphere, and be **deliquescent.** A few illustrations are indicated in Table XVIII.

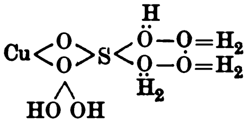
TABLE XVIII.—VAPOUR PRESSURES OF HYDRATES.

Salt.	Vapour pressure, mm.	Property.
$CaCl_2.6H_2O$	3·2	Deliquescent
$FeCl_3.6H_2O$	6·0	Deliquescent
$Na_2SO_4.10H_2O$	27·8	Efflorescent
$Na_2CO_3.10H_2O$	24·2	Efflorescent

Whether a salt effloresces or deliquesces depends on the humidity of the atmosphere in which it is confined. Thus, A. Vogel found that while hydrated copper sulphate may be preserved unaltered for years, it effloresces rapidly in air dried by sulphuric acid or calcium chloride. H. Watson also showed that sodium carbonate does not effloresce between 6° and 12° in air with the dewpoint at 3° or 4°, but it does effloresce in air at 14·4° when the dew point is at 8·9°; Glauber's salt effloresces in air at 14·4° when the dew point is at 9·4°, but not when the dew point is over 10°. According to H. Lescœur,[2] the vapour pressure for the deliquescence of hexahydrated strontium chloride is 11·5 mm., and for efflorescence 5·6 mm. at 20°. It is therefore possible to predict whether or not a salt will have a tendency to efflorescence or deliquescence in an atmosphere of known humidity when the vapour pressure of the hydrate is known.

A. C. Cumming, J. R. Partington, W. N. Rae, and F. Ephraim have shown that when certain crystalline salts are dehydrated, the vapour pressure may rise very slowly or even remain constant for a time, and then rise rapidly to the normal value required for the given temperature. The suspended transformation, lagging, or period of induction is shown by copper sulphate, $CuSO_4.5H_2O$; sodium carbonate, $Na_2CO_3.10H_2O$; barium chloride, $BaCl_2.2H_2O$; racemic acid, $C_4H_6O_6.H_2O$; the double sulphates, $M'_2SO_4.M''SO_4.6H_2O$; some ammino-salts; etc. M. Faraday showed that a perfectly sound crystal of hydrated sodium carbonate, phosphate, or sulphate does not effloresce readily on exposure to the atmosphere; indeed, M. Faraday found such crystals may be kept for years in an open dish without efflorescing. If, however, the change has commenced at any point, it will spread quickly throughout the whole mass; and this is in accord with the phase rule $F=C-P+2$. In the perfect crystal there are two phases P, namely, sodium sulphate, $Na_2SO_4.10H_2O$, and water vapour; and two components C, namely, Na_2SO_4 and H_2O. Hence the system is bivariant ($F=2$), so that the pressure of the water vapour and the temperature can be arbitrarily within certain limits without altering the state of the system. If, however, some efflorescent salt be present, there will be three phases, and the system will be univariant ($F=1$), so that for every temperature there is one and only one vapour pressure for equilibrium. The phase rule is only concerned with the conditions of equilibrium, and has nothing to say about how that state will be obtained.

The study of copper sulphate, which is typical of numerous other hydrates, shows that the molecules of the combined water may differ in the tenacity with which they are retained by the molecule of copper sulphate. The older books on chemistry drew fine distinctions between the different combinations of water with a salt; it is now believed that the water of one hydrate does not differ in kind from that of the other hydrates. The water is sometimes conventionally styled "constitutional water," "water of crystallization," "water of hydration," or "water of combination." The actual term used does not matter very much provided it is not misunderstood. The proportion of water in the different hydrates is in accord with the law of multiple proportions—if not, the water is arbitrarily said not to be chemically combined. The mode of writing the formulæ—$CuSO_4.5H_2O$; $Na_2SO_4.10H_2O$—and the ease with which the hydrates dissociate into water, etc., might give rise to the idea that the water molecule exists in the hydrate ready-made. There is, however, no evidence how the elements of water are combined in the hydrate, and consequently, following the old adage—truth is to be found within ourselves; it takes no rise from outward things—many suggestions have been made to represent the constitution of the hydrates graphically. The application of the theory of valency to explain the composition of salts does not usually include water of crystallization; and in order to extend that theory to salts with water of crystallization, it is usually assumed that all or some of the contained oxygen atoms are quadrivalent. For instance, assuming that in copper sulphate (1) the oxygen is quadrivalent; (2) one water molecule is associated in the molecule differently from the other four molecules because it is not expelled except at a much higher temperature; (3) two of the remaining four molecules are more strongly attached than the other two as is evidenced by the step by step dehydration of the pentahydrate→trihydrate→monohydrate→anhydrous salt, one of the many formula which can be devised is:



If all four water molecules were united in the same way it is further assumed that they would be liberated together, or set free individually one after the other forming respectively penta-, tetra-, tri-, di-, and mono-hydrates. There is some evidence to show that when a double salt is formed containing the solvent, the latter is an essential constituent of the salt, for the substitution of one solvent for another may prevent the formation of a particular double salt. Thus H. W. Foote (1910)[3] found that potassium and mercuric chlorides form the following double salts with water, alcohol, C_2H_6O, and acetone, C_3H_6O:

Water.	Alcohol.	Acetone.
. . .	. . .	$KCl.5HgCl_2.C_3H_6O$
$KCl.2HgCl_2.2H_2O$	. . .	. . .
. . .	$5KCl.6HgCl_2.2C_2H_6O$	$5KCl.6HgCl_2.2C_3H_6O$
$KCl.HgCl_2.H_2O$	. . .	. . .
$2KCl.HgCl_2.H_2O$	. . .	. . .

We know very little beyond the simple facts that (1) water is a product of the dissociation of the hydrates; (2) the water of the hydrate is given off at comparatively low temperatures; (3) the water is not an essential part of the reacting unit in its most characteristic transformations; (4) the water is not generally necessary for the formation of the salt itself since the water of crystallization can generally be removed by suitable means leaving behind the anhydrous salt; and (5) the water can often be replaced by an organic solvent so that a salt crystallizing with a definite number of molecules of water at a given temperature will crystallize from one organic solvent with the same or a smaller number of molecules of the solvent.

There is much cogent evidence leading to the inference that water is a ternary substance containing molecules H_2O, $(H_2O)_2$, and $(H_2O)_3$, and A. Rosenstiehl (1911) considers that in salts containing water of crystallization, the water may be present as H_2O, $(H_2O)_2$, or $(H_2O)_3$, or a mixture of these different groups. The effect of temperature on the dehydration of the hydrated salts will show the state of the polymerization of the bound water. Salts containing 1, 2, or 3 molecules of water of crystallization usually lose water in one step. Salts with 3, 6, 9, 12 molecules of water on hydration lose water as $3H_2O$ or multiples of this; and salts with 4, 5, 7, 8, or 10 molecules of water furnish evidence that two kinds of molecules of water are involved. For instance, the dehydration of $CuSO_4.5H_2O$ behaves as if the molecule contained $CuSO_4.H_2O+2(H_2O)_2$; $MgSO_4.7H_2O$, as if it were $MgSO_4.H_2O+3(H_2O)_2$; while $Na_2CO_3.10H_2O$ behaves as if the molecules contained $Na_2CO_3.H_2O+3(H_2O)_3$.

If the term "water of crystallization" be carelessly employed it may suggest that crystallization is somehow dependent on the presence of water, and this the more, as efflorescent salts appear to lose their crystalline character when water is lost. Crystals of gypsum—$CaSO_4.2H_2O$—form a white chalky powder when the water is driven off; crystalline sodium carbonate, and Glauber's salts, likewise produce white powders when their combined water is expelled. The powdered dehydrated substances are all crystalline. Several zeolites may lose their combined water without losing their crystalline form. In fact, practically all chemical compounds can be crystallized. Crystallization is not dependent upon the presence of water. Sulphur, common salt, iodine, potassium chlorate, potassium sulphate, and numerous other crystalline substances do not contain the elements of water.

Again, crystalline calcspar does not contain the elements of water, and yet when calcined it gives a white powder. The calcspar loses carbon dioxide, not water.

Alcohol, C_2H_5OH, has a constitution similar to water, but one of the hydrogen atoms of water is replaced by the radicle C_2H_5. Alcohol, ammonia, and hydrogen peroxide can combine with certain other molecules to form complexes, and thus we speak of "alcohol of crystallization," "ammonia of crystallization," "hydrogen peroxide of crystallization," etc.

CHAPTER X

SOLUTIONS

§ 1. The Solubility of Solids in Water

> In a strictly scientific sense of the word, insolubility does not exist. Even those substances which are characterized by the most obstinate resistance to the solvent action of water should probably be regarded as extraordinarily difficult of solution, but not insoluble.—O. N. WITT (1905).

WATER is one of the most active of solvents, and, in consequence, it has been styled *the universal solvent*, but not in the same sense as the visionaries' *alcahest* (universal solvent) so often mentioned in the writings of mediæval alchemy. It is remarkable that a belief in this, Paracelsus' menstruum, was fairly prevalent towards the beginning of the eighteenth century. R. Boyle[1] said: "He that hath seen it, hath more reason to believe it, than he that hath not." J. Kunckel[2] said that some derive the term alcahest from the Latin *alkali est*, others from the German *all geist*—all spirit—and yet others from the German *alles est*—it is all. J. Kunckel also expressed his surprise that it does not seem to have occurred to the old alchemists that no vessel on earth could hold their universal solvent, because a universal solvent would also dissolve its containing vessel.

For convenience, the dissolved substance is often called the **solute,** and the liquid in which the solute is dissolved the **solvent.** When no solvent is mentioned, water is usually understood; the list of possible solvents is almost as extensive as the list of chemical compounds. If potassium chloride be added to water kept at a constant temperature the salt is gradually dissolved, and the process of solution continues until a definite amount has dissolved. Any solid in excess of this will remain an indefinite time without further change, provided the temperature remains constant, and no solvent is lost by evaporation, or gained by absorption. The solid and solution are then in equilibrium. As in the analogous case of the pressure of a liquid, the equilibrium between a saturated solution and a solid is dynamic, not static. Accordingly, with the preceding notation the equilibria with solid and liquid solutes respectively are represented:

$$\text{Solute}_{\text{solid}} \rightleftharpoons \text{Solute}_{\text{dissolved}}\ ; \quad \text{or } \text{Solute}_{\text{liquid}} \rightleftharpoons \text{Solute}_{\text{dissolved}}$$

A solution in equilibrium with its solid is said to be **saturated** with the solid at the temperature of experiment. **The weight of salt dissolved by 100 c.c. of the solvent so as to make a saturated solution at any assigned temperature is called the solubility of the salt.** Thus, 100 c.c. of water at 20° will dissolve 35 grams of potassium chloride, and accordingly, 35 is the solubility of potassium chloride in water at 20°.

J. L. Gay Lussac (1819)[3] expressed the solubility as parts of the substance in 100 parts of water. Other modes of representing solubility are more convenient in special cases—*e.g.* the percentage amount of salt in a given weight of the solution may be employed, and A. Etard (1884) represented the solubility in terms of the weight of the solvent in 100 parts of solution. With the latter mode of representation, the solubility curves are usually straighter, and very great solubilities cannot exceed 100, whereas with J. L. Gay Lussac's method they may become infinite. For example, at 310° a saturated solution of sodium hydroxide has 22,222·2 parts of the solid in 100 parts of water, and 99·45 grms. of the hydroxide in 100 parts of solution. E. Cohen and E. H. Buchner, however, have shown that A. Étard's rule (1898)—to the effect that if the solubility be defined as the weight of salt in 100 grms. of saturated solution, the solubility-temperature curves are straight lines—is not in accord with facts.

It is common in studying the physical properties of solutions, to represent the ratio in terms of the number of gram-molecules of the dissolved substance per 100 of the solvent, or of the solution; or as the *molecular fraction* as it is called, that is, the ratio of the number of gram-molecules of the solute to the number of gram-molecules of the solvent and solute. If S denotes the quantity of the substance by weight dissolved in 100 parts by weight of the *solvent*, and W the quantity by weight in 100 parts by weight of the solution; then, if S parts of the substance are contained in 100 parts of the solvent, the S parts of the substance are contained in $100+S$ of the solution; and consequently, 100 parts of the solution will contain $W=100S/(100+S)$ parts of the dissolved substance. Conversely $S=100W/(100-W)$. This gives a relation between S and W, provided no marked change in volume occurs on solution.

There are also many ways of respresenting the concentration of a solution, for example, the concentration of ordinary sulphuric acid can be represented: (1) By the specific gravity (or density) 1·161. This mode of representation must be supplemented by tables relating concentration and specific gravity. (2) By the stoichiometric proportion of H_2SO_4—(i) 22·27 per cent. by weight of H_2SO_4; (ii) 258 grms. of H_2SO_4 per litre; (iii) $258\div98=2·63$ gram-molecules per litre; or (iv) $H_2SO_4+19H_2O$. (3) By the normality of the solution $258\div49=5·26N$—that is, 5·26 equivalents of H_2SO_4 per litre. (4) Molecular fraction 0·05, meaning that 0·05 gram-molecule of H_2SO_4 is mixed with $1-0·05=0·95$ gram-molecule of water.

It is important in measuring the solubility of a salt to make sure that the solution is really saturated because some salts dissolve very slowly. Many of the older determinations are vitiated by failure to guard adequately against supersaturation,[4] and by using inadequately purified salts.

The **concentration** of a solution is determined by the relative amount of solute in solution—if but a small proportion is present, the solution is said to be *weak* or *dilute*; if a relatively large amount of solute is dissolved, the solution is said to be *strong* or *concentrated*. We can thus see with C. L. Berthollet (1803) a close analogy between the solution of a salt in water, and of water by air. In each, the quantity dissolved at a given temperature is always the same—in the case of a solution of salt in water, this constant is called *the solubility of the salt*, and in the case of a liquid in air, *the vapour pressure of the liquid*.

J. H. van't Hoff's definition (1890) [5] of a solution is one of the best yet suggested. It runs somewhat as follows: **A solution is a homogeneous mixture of two or more substances; the composition of the mixture can vary within certain limits**—the limits of its existence; or, as C. L. Berthollet expressed it in 1803: *Les sels s'unissent à l'eau en toute proportion, jusqu'au point de la saturation.* It has been conventionally agreed to call solutions mixtures because their composition can vary in the way just described and not *per saltum* as is characteristic of that mode of chemical combination defined by the laws of constant and multiple proportion. F. Wald distinguishes a chemical individual as a substance which persists as a phase of constant composition when the conditions of temperature, pressure, and composition of the other phases present, undergo continuous alteration within certain limits—the limits of existence of the substance.

Pliny commented on the limited solubility of salts in water. In his *Historia naturalis* (**31.** 34) of the first century, he said:

> It is a singular fact that if more than one sextarius of salt be put into four sextarii of water, the solvent action of the water will be overpowered, and no more will dissolve.

N. le Febure [6] in the seventeenth century stated the law of saturation very clearly:

> Digest four ounces of ordinary salt in eight ounces of water, and you will find that the water will dissolve three ounces of the salt, and that it will take up the other fourth if the water be boiled and the liquid agitated. . . . When a menstruum is fully saturated—either cold or hot—it is impossible by any art to go further, because it is charged conformably with *le poids de nature*, which cannot be transgressed.

The numbers expressing the solubility of a salt were thus regarded as natural constants—*le poids de nature.*

Speaking in terms of the phase rule, the solubility of a solid in a liquid is the saturation concentration, and at an assigned constant temperature the system is invariant; and, with liquid-liquid systems, two liquid layers are necessary for invariance; and, in dealing with gas-liquid systems, the pressure of the gas must be specified. It is also necessary to consider the formation of compounds of solute and solvent, for, at a given temperature, some compounds with the solvent may be stable, others unstable. When a compound is decomposed by water, its solubility has no more meaning than to speak of the solubility of zinc in dilute sulphuric acid. The term solubility is loosely applied to both phenomena because in each case the solid phase disappears, and the material passes into the liquid until the liquid is saturated. In a rough way the term *dissolution* is applied when the substance dissolved is decomposed by the solvent, and *solution* when it is not decomposed.

Are all substances soluble in water?—Excluding chemical action, so-called, there are three possible ways in which two substances can behave: (1) One substance may be quite *insoluble* in the other—*e.g.* platinum in water; (2) One substance may be *partially soluble* at a given temperature—*e.g.* salt in water; (3) The two substances may be *completely miscible* in all proportions—*e.g.* alcohol and water; fused cobalt and nickel. It might be argued that a substance must either be soluble or insoluble in a given menstruum—either it will be diminished in mass by the solution of a portion in the menstruum, or it will suffer no change after prolonged contact therewith. Very exact investigations have shown that few substances considered by the chemist to be *insoluble* really are so. The so-called **insoluble substances** obtained as precipitates in analysis are in reality substances with a very low solubility. It is all a question of measurement. As the methods of observation become more and more precise, so does the list of insoluble substances grow less and less. The general use of the term *insoluble* must, in consequence, give way to *sparingly soluble*. In illustration, the three precipitates obtained in the first group of the regular scheme for qualitative analysis are usually said to be insoluble, but they are not really insoluble in water because their solubilities, per 100 c.c. of water, at 20°, are represented by the following numbers: silver chloride, 0·00016 gram; mercurous chloride, 0·00031 gram; and lead chloride, 1·18 gram. In some cases the alleged solubility—*e.g.* platinum in water—cannot be proved directly, but requires involved reasoning which appears to be subtle sophistry of no substance or profit.

The influence of the grain-size of solids on the solubility.—In 1813, W. H. Wollaston noted that finely-divided substances suspended in a solvent not only dissolve more rapidly but they may have an even greater solubility than coarse-grained powders; in 1870, E. Divers also made the same observation with respect to calcium carbonate; and G. A. Hulett found that a litre of water at 25° will dissolve 2·085 grms. of gypsum when particles have an average diameter of about 0·0004 cm. and 2·476 grms. when the average diameter is about 0·00006 cm. The theory was worked out by J. W. Gibbs [7] in 1876, and by J. J. Thomson in 1888. J. W. Gibbs' theory is embodied in the expression

$$\log\frac{S_2}{S_1}=\frac{2M\sigma}{RTD}\left(\frac{1}{r_1}-\frac{1}{r_2}\right)$$

where R denotes the gas constant, *viz.* $8{\cdot}315\times10^7$ ergs per degree; T, the absolute temperature; D, the specific gravity of the solid; M, the molecular weight of the solute; σ the energy per unit area of the surface of separation between the solid and solution; and S_1 and S_2 denote the concentrations of saturated solutions in contact with spherical particles of the respective radii r_1 and r_2. If r_2 be indefinitely large, the expression reduces to that employed by G. A. Hulett, for S_2 then denotes the ordinary or normal solubility of the substance. For calcium sulphate, where $D=2{\cdot}33$; $M=136$; $\sigma=1050$ ergs per sq. cm. at 25°,

$$\log\frac{S_1}{S_2}=\frac{2M\sigma}{RTDr_1};\ \text{or}\ \log\frac{S_1}{S_2}=\frac{14{\cdot}69\times10^{-4}}{r_1T}$$

if D and σ are independent of temperature. On calculating the solubilities of gypsum for different values of r and T it is found that the solubility curve for $r = 50{\cdot}0\mu$ is virtually the same as when r is infinite. The results shown in Fig. 1 represent the solubility curves (milligram-molecules per litre) for $r=0{\cdot}5\mu$; $r=1{\cdot}0\mu$; $r=3{\cdot}0\mu$; and $r=50{\cdot}0\mu$.

A solution in equilibrium with fine-grained particles, say $0{\cdot}5\mu$, is super-saturated with respect to coarser-grained particles, say 50μ. Consequently with a mixture of coarse and fine grains, the coarse grains will grow at the expense of the fine grains. In illustration, a fine-grained precipitate, after standing some time in contact with its solution, becomes coarser-grained, so that the freshly-made precipitate readily passes through the filter paper, while the older precipitate does not pass.

E. Podszus found that certain oxides—alumina, thoria, and zirconia—usually not acted upon by the hydrochloric acid are dissolved by this reagent when they have been reduced to a fine state of subdivision so that the particles have a diameter of the order 1μ. The dissolution of the oxides in hydrochloric acid is a phenomenon different in kind from the solution of, say, gypsum in water. W. Herz calculated the molecular diameter, d, of liquids from the equation $d=2\gamma v/L$, where γ denotes the capillary constant, v the specific volume, and L the latent heat of evaporation per gram. He then examined the relation between this magnitude and the solubility of the liquids in water, and found that in general the solubility is greater the smaller the diameter. The rule can be entirely altered by specific chemical properties.

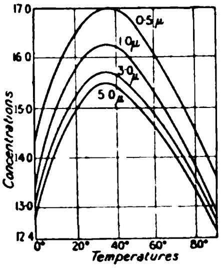

FIG. 1. — Solubility Curves of Calcium Sulphate of Different Grain-size.

The effect of grain size on solubility recalls the fact that when drops of liquid are suspended in air or other gas, the smaller drops of liquid grow smaller and disappear, so that the larger drops grow larger at the expense of the smaller drops. The vapour pressure of a liquid depends on the curvature of its surface; the greater the curvature the greater the vapour pressure, and hence the vapour from the smaller drops is distilled on to the larger drops—**1.** 9, 6. The two phenomena are not strictly analogous except in this way. The boundary-surface between a liquid and a solid is the seat of a certain amount of energy—the so-called free surface energy of the liquid. The greater the curvature of a liquid, the greater the surface energy. The greater the free surface energy of a substance, the greater the solubility—*e.g.* the allotropic forms of a substance have different solubilities, the less stable is always the more soluble. Hence, P. Curie inferred that the greater the free surface energy between a solid and its solution, the greater the solubility.

Is water in aqueous solutions identical with water alone ?—When the absorption of light by a given layer of an aqueous solution is compared with that of a layer of water of the same depth, it cannot be assumed that the water in the aqueous solution absorbs as much light as pure uncombined water; and that the difference between the light absorption of the aqueous solution and of pure water is due to the dissolved substance. The different transparency of the water in a solution as compared with water alone must be ascribed to a relation between the dissolved substance and the solvent water; part, at least, of the water must be different from water alone, and the most probable hypothesis is that the water is partly depolymerized by the solute or that part of the water present in a solution is in combination with the dissolved substance. Of the salts examined by H. C. Jones (1913) and his co-workers, those which do not form hydrates absorb practically the same amount of light as a corresponding layer of water. A difference in light absorptive power is only exhibited by solutions of those substances which form hydrates; this is taken to mean that the difference between light absorbing power of solutions of hydrated salts and the corresponding amount of the solvent is not fully explained by the depolymerization or the breaking down of associated molecules of water by the dissolved substance.

The influence of temperature on solubility.—The solubility of most substances increases with the temperature; the higher the temperature, the greater the solubility. **Graphs obtained by plotting the relation between the solubility of solids and temperature are called solubility curves.** The solubility curve presents a graphic picture which enables the relation between solubility and temperature to be seen at a glance. In illustration, the upward left-to-right slope of the solubility curve of calcium sulphate shows that the solubility of this salt *increases* with a rise of temperature up to about 40°, and the downward left-to-right slope over that temperature shows that the solubility then decreases as the temperature rises. Sodium chloride is but slightly more soluble in hot than in cold water. The solubilities of a few typical salts at 0°, 50°, and 100° are as follows:

Solubility of	0°	50°	100°
Potassium hydroxide, KOH	97·00	140·00	178·00
Sodium chloride, NaCl	35·63	36·67	39·12
Calcium hydroxide, $Ca(OH)_2$	0·14	0·10	0·06
Calcium chromate, $CaCrO_4$	4·50	1·12	0·42
Cerium sulphate, $Ce_2(SO_4)_3$	19·09	4·78	0·78

The solubility of a substance depends on so many complex factors that a satisfactory quantitative theory has not yet been established. E. Clapeyron and R. Clausius' equation can be written:

$$\frac{d\log S}{dT}=-\frac{Q}{RT^2};\text{ or }\frac{1}{S}\frac{dS}{dT}=-\frac{Q}{RT^2}\quad .\quad .\quad .\quad .\quad (1)$$

so as to show the relation between the absolute solubility, S, and the temperature coefficient, dS/dT, of the solubility—*i.e.* approximately the change in solubility per degree—and the reversible heat of solution, Q. The gas constant R is nearly 2 calories. It is usual to represent the observed data between the concentration S and the temperature $\theta°$ by an empirical formula of the type, $S=a\theta+b\theta^2+c\theta^3+. . .$, where a, b, c are constants to be evaluated from the measurements of the solubilities S at temperatures θ_1, θ_2, θ_3, . . . R. T. Hardmann and J. R. Partington[8] used the empirical expression $\log S=A-BT^{-1}-C\log T$, which contains three constants like the simpler relation, $S=a+b\theta+c\theta^2$.

Starting from F. M. Raoult's vapour pressure law, G. Bodländer calculated the solubilities of some very sparingly soluble salts from the heats of formation Q of an equivalent amount of the salt, and the electrode potentials of their ions—$E^{\bullet}$ for the cation, E' for the anion:

$$0\cdot058\left(\frac{1}{n^{\bullet}}+\frac{1}{n'}\right)\log S=E^{\bullet}+E'\frac{Q}{230}$$

where $n^{\bullet}$ and n' respectively denote the valencies of cation and anion, and the solubility S is expressed in gram-equivalents per litre. It is here assumed that the free energy of the reaction is equal to the total energy change. F. Dolezalek also calculated the solubility of gases in liquids on the assumption that Raoult's law is valid. J. H. Hildebrand deduced the following expression for the solubility N of a solid at the absolute temperature T:

$$\log\frac{n}{N}=-\frac{\lambda TT_m}{4\cdot58(T_m-T)}$$

where n/N denotes the solubility of the compound expressed in terms of the molecular fraction—n representing the number of gram-molecules of the solute in the solution, and N the total number of gram-molecules of solvent and solute; λ denotes the heat of fusion per gram-molecule assumed to be independent of the temperature; T_m, the absolute melting temperature of the solute. It follows from this conclusion that the solubility of a solid is smaller the greater the heat of fusion, and the higher the melting point over $T°$.

D. Tyrer assumes that the solubility of a given substance depends not only upon the temperature and nature of the solvent, but also on the mass of the solvent contained in unit volume of the solution. The solubility of a substance in a given solvent is always diminished when the solvent is diluted with a liquid in which the given solute is insoluble. On this assumption he deduces the relation, $S^n = a(V/v)^n - b$. which also contains three constants, n, a, and b. V represents the total volume of the solution and v the specific volume of the solute. Sufficient data have not been published to establish this relation.

The influence of pressure on solubility.—The effect of pressure on solubility in condensed systems—liquids and solids—is relatively small—one per cent. per 1000 atm.—when contrasted with the effect of temperature, and it may be either positive or negative. Pressure has but a slight influence on binary condensed systems generally. The most accurate work on the effect of pressure on solubility is that by E. Cohen and co-workers[9] on the solubility of sodium chloride and mannite; when at 24·05°, it was found:

Pressure	1	250	500	1000	1300 atm.
Solubility	26·41	26·60	26·76	27·02	27·20 per cent.

and H. F. Sill's work on sodium chloride and barium hydroxide, $Ba(OH)_2.8H_2O$, where it was found, for the latter, at 25°:

Pressure	1	25	490 atm.
Solubility	8·299	8·790	9·366 per cent.

In 1862, K. Möller stated that that pressure must exercise an influence on the solubility of a salt; and in 1863, H. C. Sorby[10] made some remarks on the subject. The solubility of a salt is increased by pressure if, during solution, a contraction occurs; and conversely, the solubility of a salt is decreased by pressure if an expansion occurs during solution. For example, the percentage changes in the volumes of solid sodium and ammonium chlorides over their volumes in a saturated solution are respectively +13·57 and −15·78; the percentages changes in solubilities per atmosphere increase of pressure are respectively +0·00419 and −0·00638, when the + signs denote increases, and the − signs decreases. In 1870, C. M. Guldberg deduced a general expression for the change of solubility S which occurs when the pressure changes by an amount dp. This is usually expressed in the form:

$$\frac{d \log S}{dp} = \frac{\delta v}{RT}; \text{ or, } \frac{1}{S} \cdot \frac{dS}{dp} = \frac{\delta v}{RT} \quad . \quad . \quad . \quad . \quad (2)$$

These expressions follow directly from Clapeyron's equation. The observed results are in agreement with these formulæ when δv denotes the change in volume which occurs during the solution of the solid, and dS/dp, the pressure coefficient of the solubility—that is, the change of solubility which occurs when the pressure changes one unit. F. Braun made a special study of the subject in 1870, and this work has crystallized in the statement: **The solubility of a salt will increase with pressure if the solution occupies a less volume than the sum of the volumes of its constituent parts; while the solubility will diminish if the solution occupies a greater volume than the sum of the volumes of its constituent parts.** This is but a specialized form of the so-called generalization of G. Robin in 1879: At constant temperature there is one definite pressure at which a system will be in equilibrium; on raising the pressure, the reaction will take place in that direction which is produced with a decrease in volume; while if the pressure be reduced, the reaction will proceed in that direction which has the greater volume. This, again, is a special case of J. H. van't Hoff's law of mobile equilibrium; which in turn is a special case of the principle of least action, foreshadowed in a vague sort of way by

Maupertius in 1747—all natural changes take place in such a way that the existing state of things will suffer the least possible change.

By division of the expression (1) for the relation between the temperature coefficient of the solubility, dS/dT, and the heat of solution Q by the above expression, (2) for the relation between the pressure coefficient of solubility, dS/dp, and volume change dv, it follows that

$$Q\frac{dS}{dp}=-\frac{dS}{dT}(v_2-v_1)T \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where v_2-v_1 represents the change in volume, in c.c., which occurs when a gram-molecule of the solid is dissolved at the temperature T in an unlimited quantity of the saturated solution; Q represents the heat of solution under these conditions. The term dp may be taken to represent the increase in pressure necessary to cause one gram more of the solute to pass into solution and dT the increase in temperature necessary to produce that result; or dS/dT, the temperature coefficient of the solubility represents the change in solubility per degree change of temperature, and ds/dp the pressure coefficient of the solubility. Values of Q for barium hydroxide calculated from this equation agree well with the observed.

Since chemical equilibrium [11] is determined only by the relative concentration of the different kinds of molecules concerned in the reaction, the equilibrium can be altered by pressure only by changing the relative concentration of the substance concerned in the reaction; but the compressibility of liquids and solids is small, and differences in the compressibility of the components in a reaction must therefore be very small. Consequently, the effect produced by changes of pressure on chemical equilibrium in condensed systems must be small. When one of the components is a gas, the case is different because gases are highly compressible, and their reactivity is almost proportional to the pressure. A compound involving a volatile component will not be formed in a reaction unless the concentration or partial pressure exceeds a certain limiting value which is mainly dependent on the temperature. For instance, liquid water will not be formed at 200° if the pressure is less than 15 atm., and at 300° if the pressure be less than 100 atm. Calcium hydroxide in an atmosphere of steam at 550° and one atm. pressure, does not dissociate into water and calcium oxide, but at 750° a pressure of 15 atms. is required to prevent dissociation.

According to G. Tammann,[12] if a solvent and a solution be subjected to a certain pressure p, it is sufficient to raise the pressure on the solvent by a certain amount of δp in order that it may behave like the solution with respect to volume, temperature, and pressure. The extra pressure δp required to make the coefficient of thermal expansion of the solvent, or the coefficient of compressibility of the solvent, equal to that of the solution under the standard pressure, depends upon the concentration and nature of the solute. G. Tammann explains the phenomenon by assuming that internal pressure is raised by the solution of a substance in the solvent, so that the solvent requires an additional external pressure to compensate the extra internal pressure of the solution. Under these circumstances the equations of state of solution and solvent are the same.

Transition temperatures.—Some solubility curves exhibit irregularities at certain temperatures. The solubility curve may change its direction, as calcium sulphate does at 35°, and barium butyrate at 45°. The solubility curve of sodium sulphate is a very trite illustration, but none the less instructive on that account. It is shown in Fig. 2.[13] The solubility of sodium sulphate, said J. L. Gay Lussac, follows *une marche très singulière* for the solubility of the salt, $Na_2SO_4.10H_2O$, *increases* rapidly with rise of temperature, as shown by the slope of the curve EO, Fig. 2. There is an abrupt change in the direction of the solubility curve at 32·383°, O, Fig. 2. Above that temperature the solubility *decreases* with rise of temperature. This, said J. L. Gay Lussac in 1819, is the second example of a body whose solubility decreases with a rise of temperature, for J. Dalton had previously shown that lime behaves in a similar manner.

The break—*point de rebroussement*—in the solubility curve of sodium sulphate, the first of its kind, was discovered by J. L. Gay Lussac in 1819, and in 1839 he recognized that the breaks in the solubility curves of some substances can be accounted for by assuming that at this point it is no longer the same substance which dissolves further. In 1840, H. Kopp showed that the solubility curves above and below the *point de rebroussement* are two distinct curves representing the solubility of two different substances. The one curve below the transition point can be represented by the formula $S_1=5{\cdot}02+0{\cdot}30594\theta-0{\cdot}000410\theta^2+0{\cdot}0009977\theta^3$; and the other by $S_2=58{\cdot}50-0{\cdot}27783\theta+0{\cdot}0006900\theta^2+0{\cdot}0000049802\theta^3$. At the transition point $S_1=S_2$, and θ then becomes 32·93°. The observed value is a little lower than this, *viz.* 32·383°. At the transition temperature, adds H. Kopp, the crystallized sodium sulphate passes into the anhydrous salt. Consequently, the curve of increasing solubility of temperature below 32·383° represents the solubility of curve of the decahydrate, $Na_2SO_4.10H_2O$; and the curve of decreasing solubility with rise of temperature represents the solubility curve of the anhydrous salt, Na_2SO_4. The decahydrate, at 32·383°, is transformed into the anhydrous salt. The decahydrate is not stable above 32·383°; the anhydrous salt is not stable below 33°. This temperature is called the *transition temperature* or *transition point*, and the change is symbolized :

$$Na_2SO_4.10H_2O \overset{32{\cdot}383^\circ}{\rightleftharpoons} Na_2SO_4+10H_2O$$

The solubility curves, it will be observed, represent the conditions of equilibrium between the solvent and salt. It makes no difference whether we start with the anhydrous sulphate or the decahydrate. When in equilibrium, the solution in contact with the solid will contain the amounts of sodium sulphate—Na_2SO_4—indicated by the solubility curves, Fig. 2. The saturated solutions, when in equilibrium, have the same concentration and are identical in every way. We cannot continue the observation of the solubility of the decahydrate beyond 32·383°, because it *immediately* splits up either into a less hydrated form—*e.g.* $Na_2SO_4.7H_2O$—or the anhydrous form, Na_2SO_4. The solubility curve of the heptahydrate meets the solubility curve of the anhydrous sulphate in the region of instability; the transition point from the heptahydrate to the anhydrous salt is 34°, or

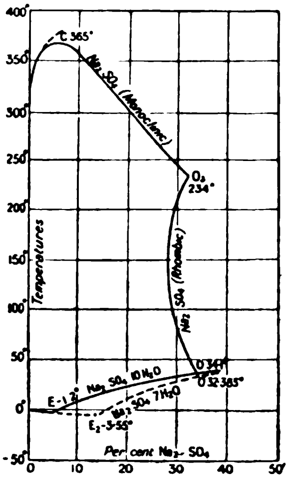

FIG. 2.—Solubility Curve of Sodium Sulphate.

$$Na_2SO_4.7H_2O \overset{34^\circ}{\rightleftharpoons} Na_2SO_4+7H_2O$$

The so-called eutectic points E and E_2 will be discussed later, but since the transformation of the anhydrous salt into the hydrate takes an appreciable time, it is possible to measure the approximate solubility of the anhydrous salt below 32·8. This is indicated by the dotted line in the diagram. In saturated solutions of hydrates, a definite hydrate is in dynamic equilibrium with the solution; if the hydrate changes as shown by E. Demarçay's study (1883) of the hydrates of thorium sulphate, the maximum amount of a salt which can enter into solution depends on its temperature and on its state of hydration; the solubilities of the different hydrates of a salt are different, and at the transition temperature, there is a break in the continuity of the solubility curve. H. W. B. Roozeboom's studies of the hydrates of a number of salts show that the solubility curves of the different hydrates of a salt indicate the limits of their stability.

The solubilities of the two sodium sulphates—anhydrous and decahydrate—are quite different. If the solid decahydrate were in contact with a saturated solution at 20°, and some of the anhydrous sulphate were added to the solution, some of the latter would dissolve and be deposited later as the decahydrate. The final result would be a transformation, through the medium of the solution, of the anhydrous salt into the decahydrate. Although 100 c.c. of water at 0° can only dissolve about 5·0 grams of the decahydrate, the same quantity of water can dissolve much more of the anhydrous sulphate. The general result of a multitude of experiments is to show that salts which crystallize in two or more different forms with different amounts of combined water, have different solubilities; and at certain temperatures a solution may be saturated with either of two different hydrates, *e.g.* $Na_2SO_4.10H_2O$, or $Na_2SO_4.7H_2O$; it is therefore necessary to specify which sodium sulphate is in question when reference is made to a saturated solution of sodium sulphate. Of two hydrates that containing the less water is usually the more soluble at any temperature below the transition temperature—H. le Chatelier's rule. For instance, sodium sulphate forms the hydrates, $Na_2SO_4.7H_2O$ and $Na_2SO_4.10H_2O$, and 100 grams of a saturated solution of the former at 10° has 23·1 grams of the former and 8·3 grams of the latter. The rule is not general; the hydrates of manganous sulphate do not fit the rule.

The solubility curve of anhydrous rhombic sodium sulphate progresses from O_3 into the metastable region. The solubility curve is at first retrograde—decreasing with rise of temperature—and it then becomes normal—increasing with rise of temperature. A. Smits explains the retrograde solubility curve of rhombic sodium sulphate by assuming a retrogression of the degree of hydration of the salt in solution with a rising temperature. At the transition point, 234°, the rhombic crystals of sodium sulphate pass into the monoclinic form:

$$Na_2SO_{4\,\text{rhombic}} \overset{234^\circ}{\rightleftharpoons} Na_2SO_{4\,\text{monoclinic}}$$

The solubility of anhydrous monoclinic sodium sulphate is wholly retrograde, and at the critical temperature (365°) the concentration of the solution is so small that the critical temperature is virtually the same as that of water. A. Smits assumes that the strongly retrograde solubility of monoclinic sodium sulphate indicates that the latent heat of liquefaction of this salt is much less than that of the rhombic salt. In the diagram, the concentration near the point C is on a much enlarged scale in order to make the relations clear, for the curve up to C represents the solubility of sodium sulphate in the vapour phase, and hence this curve virtually coincides with the H_2O axis. At the critical temperature of the solution, the liquid and vapour perhaps have the same composition, and the two curves join up with one another.

Is a heterogeneous solution to be regarded as a phase?—In heterogeneous solutions there are an infinite number of phases because every different degree of concentration can be regarded as a phase. **The phase rule is concerned with conditions of equilibrium,** and a heterogeneous solution is not in equilibrium because there is a tendency to diffusion. Hence, the phase rule is not needed to determine if such a solution is in equilibrium. If sulphur be placed in contact with iron, it might be said that, neglecting vapour, there are two components, and two phases, and therefore the system is univariant. Hence, sulphur and iron will not interact when heated. It will be noticed, however, that the mixture of sulphur and iron is not a system in equilibrium; the two elements are not phases of a prior system, or molten ferrous sulphide, FeS, on cooling would separate into particles of free sulphur and free iron. Consequently, the phase rule does not apply.

Is a solution to be regarded as a one-phase or as a two-phase system?—The decrease in the solubility of a substance with rise of temperature is due to the solute changing its nature thus, the diminishing solubility of sodium sulphate, $Na_2SO_4.10H_2O$, above 33° is referred to the passage of the decahydrate into the anhydrous salt, Na_2SO_4; with calcium hydroxide, $Ca(OH)_2$, too, the change is usually attributed to the transformation of some hydroxide into oxide, CaO. In general, **a turning point in the solubility curve shows that the solid phase in the saturated solution is changing.** From this it follows that the molecules of a substance in solution may retain their individuality and that they can undergo changes in the solution similar to those they suffer when heated alone. H. C. Jones and J. S. Guy[14] showed that water which is combined with salts in solution is far more transparent than pure water; and J. E. L. Holmes and H. C. Jones, that the rate of saponification of methyl acetate or formate is likewise faster with combined than it is with free water.

While a solution in equilibrium can be said to have the same composition in all its parts, so that it cannot be separated by mechanical or physical operations into different individual parts, yet, according to the molecular theory, there must be a limit to the subdivision beyond which the solution can no longer be regarded as homogeneous. Consequently, there is no clearly defined line of demarcation between heterogeneous and homogeneous mixtures. A so-called homogeneous solution, for instance, can sometimes be separated into its component parts by certain membranes, just as a mixture of gases can sometimes be separated into its constituent parts by atmolysis. A homogeneous solution, or a mixture of gases, however, is considered to be a homogeneous one-phase system because diffusion maintains one uniform concentration throughout its mass.

§ 2. The Freezing of Solutions

> Proof or disproof of the existence of many compounds must be sought in the physical properties and in the behaviour of mixtures at different temperatures.—L. W. Andrews (1907).

The curve *OB*, the *salt line*, Fig. 3, represents the solubility of sodium chloride at temperatures ranging from —23° to +40°; the observation cannot be continued below —23°, because the whole mass freezes at or above that temperature; the upward curve would probably stop only at the melting point of sodium chloride, 801°, if it were not for the volatilization of the water. Hence, to determine the solubility, the pressure would have to be very great at this high temperature to prevent the water leaving the salt.

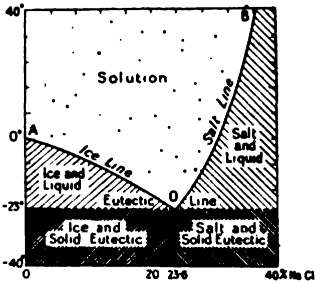

Fig 3.—Solubility and Freezing Curves of Sodium Chloride: Water Solutions.

The freezing temperature of a solution is generally lower than that of the pure solvent. More than a century ago, C. Blagden (1788)[1] cited a number of observations which led him to the belief that the lowering of the freezing point is proportional to the amount of substance in solution. In his own words: **The effect of a salt is to depress the freezing point in the simple ratio of its proportion to water.** This generalization is sometimes called **Blagden's Law.** The freezing point of an aqueous solution of sodium chloride, that is, the temperature at which *ice* begins to separate, is gradually reduced by the continued addition of small quantities of sodium chloride, and reaches its lowest value, —23°, when the solution has nearly 23·5, say 24, per cent. of sodium chloride; further additions of the salt raise the temperature at which the solid is deposited. Solid sodium chloride, not ice, separates from the solution. F. Guthrie's measurements (1875)[2] of the relation between the freezing point and the concentration of aqueous solutions of sodium chloride are shown graphically by the *ice line*, *AO*, Fig. 9, Cap. IX.

Impurities included in crystals.—It has long been known, even as far back as Aristotle's day, that drinkable water could be obtained from frozen sea-water; and that if an aqueous solution of salt be gradually cooled, comparatively pure ice first separates from the solution. The work of F. Rüdorff (1861) and of J. Fritzsche (1863)[3] on the freezing of coloured solutions clearly established this fact. Thus, magnesium cyanoplatinate forms a colourless solution from which colourless ice separates, whereas, if solid magnesium cyanoplatinate separated, the colour would be intensely red.

Faraday's experiment.—Water coloured with sulphindigotic acid is placed in a test-tube and immersed in a freezing mixture; the water on freezing near the walls of the tube drives the colouring matter to the axis of the tube. The coloured liquid is poured away, and when the cavity is rinsed out, a plug of transparent colourless ice is obtained. The trace of salt which is generally found in the ice which separates from a salt solution is merely the mother liquid or solute which is mechanically entangled in the crystals of ice.

The freezing curves of binary mixtures which do not form compounds.—A solution of sodium chloride in water may be taken as an example. It may be assumed that these substances are but partially soluble in the liquid state and insoluble in the solid state. Imagine a 5 per cent. solution of salt subjected to a gradually diminishing temperature. Start at 0°. When the temperature reaches, say, —3·4° ice separates from the solution. The mother liquid remaining has therefore more than 5 per cent. of salt in solution; as the temperature falls, more ice separates. The further concentration of the mother liquid and the separation of ice continue until the mother liquid has about 23·6 per cent. of salt, when the whole remaining liquid freezes *en bloc* at —23°. The solid now consists of crystals of ice embedded in a matrix of ice and salt. Quite an analogous sequence of changes occurs if solutions containing more than 23·6 per cent. of salt be gradually cooled. This time, however, instead of pure ice, pure salt separates until the residual liquid has 23·6 per cent. of salt. The whole solidifies *en masse* at —23°. If the cooling solution has just 23·6 per cent. of salt, neither ice nor salt separates, until the temperature has fallen to —23°, when the whole freezes to a solid mass. No other mixture of water and salt freezes at a lower temperature than this. Hence a solution containing 23·6 per cent. of salt is called a **eutectic mixture** or simply a **eutectic**; —23° is the **eutectic temperature**; and the general phenomenon is called **eutexia**—from the Greek εὐ, easily, and τήκω, I melt. Hence *eutectic* means "that which is easily melted." The word εὔτηκτος was used by Aristotle (*Problemata*, **1**. 50) in the sense of easily soluble or digestible. The nature of the cooling liquid, or of the solid of any given composition, is also shown by the shaded areas in Fig. 3. F. Guthrie used to think that this mixture—water with 23·6 per cent. of salt—corresponded with the formation of a definite compound of sodium chloride and water—$NaCl.10H_2O$—stable only at low temperatures. Hence his designation **cryohydrate** for the alleged compound. A. Ponsot (1896)[4] called the substance a **cryosel.** The term eutectic mixture is preferred in place of cryohydrate or cryosel. The eutectic temperature, —1·2°, represented at *E*, Fig. 2, corresponds with the eutectic mixture of 3·85 per cent. of Na_2SO_4 in 100 grams of solution when the decahydrate, $Na_2SO_4.10H_2O$, is the stable phase; and with the heptahydrate, $Na_2SO_4.7H_2O$, the eutectic mixture contains 12·7 per cent. of Na_2SO_4, and the eutectic temperature is —3·55°. The same type of curve is illustrated in Fig. 4—two separate branches meeting in a eutectic is characteristic of binary metal alloys which form neither compounds nor solid solutions—*e.g.* alloys of tin and bismuth, tin and zinc, cadmium and zinc, lead and antimony, etc.

Cryohydrates and eutectics.—We now know that Guthrie's cryohydrates are nothing but mechanical mixtures of ice and salt. The one is entangled with the other. The more salient characteristics of eutectics are: (1) They have a lower melting point than mixtures with a greater or less quantity of one component; (2) They freeze at a constant temperature; and (3) They have a constant composition. With these qualities, it is easy to understand how eutectic mixtures were mistaken for true chemical compounds. No matter what the original composition of the salt solution, the last fraction to solidify always has the same composition; and a constant melting point. Both these qualities are often stated to be characteristics of true chemical compounds. The inference that eutectics or cryohydrates of sodium chloride and numerous other salts are not chemical compounds is based on the following evidence: (1) The heterogeneous structure is frequently apparent under the microscope. The crystals of ice can often be seen lying in a matrix of salt, especially if a coloured salt like potassium permanganate, copper sulphate, or potassium dichromate be employed. Indeed, the eutectic sometimes forms definite patterns, with iron and carbon, the eutectic consists of alternate bands of the two components—*lamellar eutectic*; with copper and aluminium, one component forms globules embedded in a matrix of the other—*globular eutectic*; with copper and antimony, the one component appears like small polyhedral crystals arranged in matrix of the other—*polygonal eutectic.* (2) Unlike true crystalline compounds, the cryohydrates are generally opaque and ill-defined. (3) Alcohol may dissolve the solvent, leaving behind a network of salt. (4) There are no special signs of chemical change during the formation of the cryohydrate. (5) The physical properties of the cryohydrate—*e.g.* heats of solution, specific gravities—are a mean of those of the corresponding constituents. This is not usually a characteristic of chemical combination. (6) The ratio of salt to solvent is not always in molecular proportions. The agreement in some cases is merely a coincidence. (7) The composition of a cryohydrate is different when the solidification takes place under different pressures. Hence, added A. Ponsot (1896), the eutectics or " cryohydrates of F. Guthrie are not chemical compounds, they are mechanical mixtures of pure ice and the solid salt. The salt may be anhydrous like potassium nitrate, KNO_3, or hydrated like copper sulphate, $CuSO_4.5H_2O$."

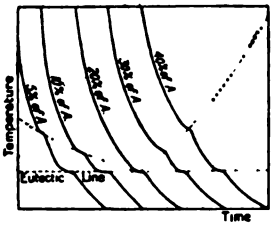

FIG. 4.—Cooling Curves of Binary Mixtures of *A* and *B* with a Eutectic.

There is another kind of eutectic which is formed in a solidified, congealed, or supercooled solution, at the time of solidification. In the case of a solidified solution; to distinguish this mixture from a true eutectic it is sometimes called a **eutectoid**. The only difference between a eutectoid and a eutectic is that the former is formed *after*, and the latter *at* the time of solidification. In the case of a solidified solution of carbon in iron, the eutectic—called pearlite—is formed after the metal has become solid. The conglomerate or impure ice formed by the freezing of a solution with less than 23·5 per cent. of sodium chloride is called a **hypo-eutectic** because it contains less than the eutectic percentage of the salt; likewise also the conglomerate formed by the freezing of a solution with more than 23·5 per cent. of salt is called a **hyper-eutectic** because it contains more salt than the eutectic proportion. The hypo-eutectic is a mixture of the eutectic with an excess of the frozen solvent; the hyper-eutectic is a mixture of the eutectic with an excess of solute.

Cooling and heating curves.—If a thermometer or thermocouple be placed in a cooling solution, and the time be plotted against the temperature, three main types of cooling curve may be obtained: (1) *Pure liquids* show a break in the continuity of the curve at the freezing point corresponding with the evolution of heat—latent heat of solidification—middle curve, Fig. 4. (2) *Mixed liquids*—binary alloys and solutions—show two breaks in the continuity of the curve: (*a*) when the solvent begins to separate and there is a change in the direction of the cooling curve, *B*, and (*b*) when the eutectic freezes *en masse*, Fig. 4. (3) *Eutectic mixtures* have a cooling curve with one break corresponding with the evolution of heat when the whole mass solidifies (20 per cent. *A*, Fig. 4). These phenomena are reversed when the corresponding solids are heated. The observation of the heat changes which occur when a metal, alloy, or other substance is cooled from an elevated temperature or raised to a higher temperature is called **thermal analysis,** and it has played a great part in studying the constitution of metals and alloys.[5]

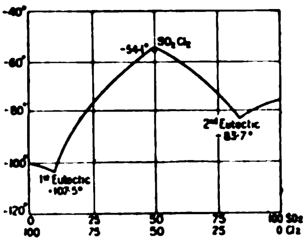

FIG. 5.—Freezing Curve of Mixtures of Chlorine and Sulphuric Dioxide showing Two Eutectics.

The freezing curves of binary mixtures which form compounds.—T. P. van der Goot (1911)[6] found that when a mixture of sulphuryl chloride, SO_2Cl_2, melting at —54·1°, and of sulphur dioxide, SO_2, melting at —75·1°, be treated as in the case of the above mixture of sodium chloride and water, a eutectic melting at —87·3° is obtained, while a mixture of sulphuryl chloride and chlorine—Cl_2, melting at —100·9°—furnishes a eutectic melting at —107·5°. A mixture of sulphur dioxide and chlorine furnishes two eutectics melting at —83·7° and —107·5° respectively with a maximum point at —54·1°, corresponding with the formation of the compound

SO_2Cl_2 from the components in question, $SO_2+Cl_2=SO_2Cl_2$, and the eutectic at −107·5° is characteristic of a mixture of sulphuryl chloride and chlorine. These results are summarized in Fig. 5.

The raising of the melting or freezing point of one substance by the addition of another often indicates that a compound is being formed. The freezing point of zinc is depressed by addition of tin, bismuth, thallium, cadmium, lead, antimony, magnesium, or aluminium; and elevated by additions of silver, copper, gold, or platinum. In general, when a pair of metals, minerals, or salts furnish a freezing curve with a number of branches dependent on the number n of compounds formed, the curve will have $2n+1$ branches and there will be $n+1$ eutectics. *E.g.* alloys of copper and antimony; nickel and tin; silver and aluminium; zinc and antimony; lead and copper; lead and aluminium; bismuth and copper; aluminium and gold; aqueous solutions of ammonia, nitric, hydrochloric, or sulphuric acid; etc. If one or more of the compounds forms a solid solution with one of the other metals, this would modify the character of the curve as indicated in the first type of freezing curve.

J. P. Cooke (1855)[7] and N. S. Kurnakoff (1912) have concluded from a study of alloys—zinc and antimony, in the former case; and thallium and bismuth in the latter—that there is a class of **indefinite compounds** which are not described by the laws of definite and multiple proportions, and they support the view of C. L. Berthollet in his controversy with J. L. Proust:

> The result of the different circumstances which modify chemical action is sometimes a combination whose proportions are constant, and sometimes, on the contrary, the proportions of the combinations which are formed are not fixed, but vary according to the conditions under which they are formed.

N. S. Kurnakoff has pointed out that the composition of a compound is determined by the position of singular points on the curve representing physical properties; these points most frequently correspond with simple formulæ, but there are exceptions. For example, a maximum occurs on the freezing-point curve of mixtures of thallium and bismuth with a mixture containing 62·8 atomic per cent. of bismuth, but solid solutions at ordinary temperatures extend from 55 to 64 atomic per cent. of bismuth, and there is a cusp in the electrical conductivity curve with 64 atomic per cent. of bismuth. N. S. Kurnakoff recommends naming compounds whose composition does not change with changes in the equilibrium conditions of a system, **daltonides**; and compounds whose composition varies with a variation in the conditions under which they are formed, **berthollides.** He considers that solid solutions, brasses and bronzes, zeolites, metal ammines, etc., are representative berthollides. This is a direct attack on constant composition as a test for chemical action, and if it were accepted as an arbitrary definition, convention would return a different answer from that previously obtained for the question: Are solutions chemical compounds?

The freezing curves of binary mixtures which either form or do not form continuous series of mixed crystals.—When two substances are reciprocally soluble in all proportions and solidify to form solid homogeneous solutions—also called mixed crystals—but not chemical compounds, a continuous curve will connect the freezing points of the pure components. The properties of the mixtures will vary in a continuous manner from one end of the series to the other. The freezing points of all possible mixtures will be represented (i) by a straight (or almost straight) line between the freezing points of the pure components as is the case with mixtures of albite and anorthite. The pyrophosphates of manganese and magnesium are miscible in all proportions and belong to Roozeboom's type I:

Manganese pyrophosphate .	100	75	50	25	0 per cent.
Magnesium pyrophosphate .	0	25	50	75	100 ,,
Melting point . . .	1196°	1242°	1286°	1340°	1383°
Refractive index (mean) .	1·70	1·67	1·65	1·63	1·60

Other examples are lead bromide and iodide ; lead and stannous chlorides ; alloys of gold and silver ; gold and platinum ; copper and nickel ; palladium and silver ; palladium and gold ; palladium and copper ; and usually, with pairs of metals of high melting points, but the further apart the melting points of the two components the less the probability of this linear relation. (ii) By a continuous curve which rises through a *maximum*, as is the case, for instance, with mixtures of organic compounds which show optical isomerism—*e.g.* *d*- and *l*-carvoxime (J. H. Adriani, 1900),[8]—but has not been otherwise verified. (iii) By a continuous curve which drops down through a *minimum* as is the case with mixtures of silver and cuprous sulphides—Ag_2S—Cu_2S ; copper and manganese sulphites, $CaSO_3$ and $MnSO_3$; iron and vanadium ; manganese and nickel ; and copper and gold. Mercuric bromide melts at 23·5° and the iodide melts at 255·4° ; the system $HgBr_2$—HgI_2 has a minimum point with 59 per cent. gram-molecules of the bromide (41 of the iodide) and melts at 216·1°. The dotted line, Fig. 6, shows the solidus curve—W. Reinders (1899).

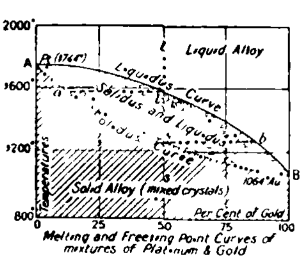

FIG. 6.—Melting and Freezing Point Curves of Mixtures of Platinum and Gold—Roozeboom's Type I.

Consider the first case. The freezing and melting point curves do not coincide, so that these two curves divide the region, Fig. 6, into three parts ; above the freezing-point curve *AlbB*—the **liquidus curve** of H. B. Roozeboom—all possible mixtures of platinum and gold are completely liquid ; below the melting point curve *AasB*—the **solidus curve** of H. B. Roozeboom—all possible mixtures are solid ; and in the part *AlbBsa*, bounded by the liquidus and solidus curves, the mixture is partly liquid and partly solid. If a molten mixture of 50 gram-atoms of each of the two metals at a temperature represented by the point *l* be allowed to cool. the temperature of the system will be represented by a point travelling down *llss*, and mixed crystals, that is a solid solution of the two metals, will begin to separate when the temperature drops to *l*. It is very unlikely that the reciprocal solubility of the two metals will be equal in the solid and liquid states ; in most cases, the solubility will be different, and be more complete in the liquid state so that mixed crystals of an alloy richer in the less fusible metal and with a composition represented by the point *a* will separate, and the mother liquid will have a composition richer in the more fusible metal and be represented by the point *b*. As the freezing continues, the composition of the mixed crystals which separate will be represented by a point travelling along the line *as*, and the composition of the mother liquid by a point travelling along the line *lb*. The process of diffusion, however, will tend to make the composition of the solid solution more and more like that of the mother liquid. With complete diffusion, the solid solution at the end of the process will be homogeneous in composition ; but since diffusion in a solid is a very slow operation, in practice, diffusion will be incomplete, and the mass will be more or less heterogeneous. If there were no diffusion, the final mass would have a composition ranging from that represented by the point *a* (in the centre of

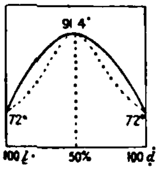

FIG. 7.—Roozeboom's Type II of mixed Crystals of Carvoxime.

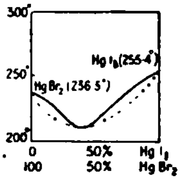

FIG. 8.—Roozoboom's Type III of mixed Crystals.

the mass) to b (on the outside). By reheating the alloy (below its melting point) diffusion may take place, and such a process—called *annealing*—is necessary to make the solid mass approximate more and more to the homogeneous condition. The alloy solidifies completely when the temperature has fallen to s, and is partly liquid and partly solid in the temperature interval ls. Hence, says H. M. Howe (1916), the liquidus traces the history of the liquid or mother liquor; the solidus, the history of the frozen or solidified part during freezing and melting.

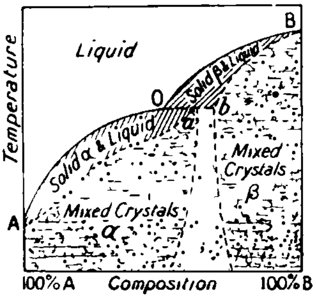

FIG. 9.—Diagrammatic—Type IV.

In addition to the three types of mixed crystal formation just considered, there are two others in which the two substances are completely soluble in the liquid state, but in one type (IV), the liquidus curve shows a transition point, O, Fig. 9, and the solidus is compounded of two disconnected curves Aa and Bb with a hiatus ab. The range of composition of mixed crystals α and β is respectively represented by the abscissæ of Aa and Bb. *A magma of composition corresponding with the transition point O is in* equilibrium with the mixed crystals α or β. Mercury and cadmium alloys investigated by H. C. Bijl (1902) illustrate the type—mercury melts at —38·8°, cadmium at 320·8°. The transition point corresponding with 61 per cent. of cadmium occurs at 188°, a corresponds with 61·7 per cent. of cadmium and b with 65·2° per cent. Fig. 9 is based on this example. Other examples are mixtures of enstatite and diopside; sodium and silver nitrates; and, according to G. Scarpa (1915), mixtures of potassium hydroxide and chloride.

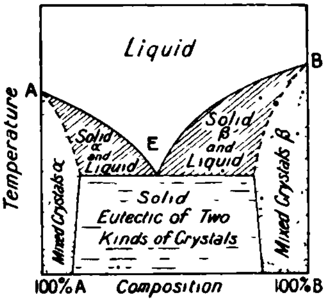

FIG. 10 —Diagrammatic—Type V.

In the next type (V), the liquidus consists of two curves meeting in a eutectic E, and the solidus likewise consists of the two dotted curves A and B, Fig. 10. Mixed crystals can exist only in the range indicated. Fig. 10 is based on C. Sandonnini's work (1911) on mixtures of silver chloride melting at 455°, and cuprous chloride melting at 422°; the eutectic is at 260°. Other examples are potassium and thallium nitrates, orthoclase and albite, cuprous and sodium chlorides, thallium chloride and iodide, calcium and lithium silicates —$CaSiO_3$ and Li_2SiO_3; mercuric chloride and iodide; aluminium and zinc, gold and nickel, etc.

To summarize the five types of mixed crystal formation, in which chemical compounds are not formed:

Liquid state.	Solid state.	Liquidus.	Figure.
Completely soluble	Completely soluble, continuous series of mixed crystals	no max. or min.	6
		maximum	7
		minimum	8
	Partially soluble limited range mixed crystals	transition point	9
		eutectic	10

Modifications of the two latter types are exhibited when the substances are only partially soluble in the liquid state, and when they are partially or wholly insoluble in the solid state. The case of salt and water, Fig. 3, illustrates the former; and copper and cuprous sulphide, iron and ferrous sulphide, and zinc and lead illustrate the latter. Very complex curves may be obtained as a result of complications introduced by the formation of chemical compounds which may or may not form mixed crystals with one another or with the pure components; the chemical compounds formed may dissociate below the freezing temperature; the solubilities in the liquids and solid states may vary; and transition points may appear in the cooling solid.

§ 3. The Solubility of Liquids in Liquids

Mixtures of liquids like benzene and water or carbon disulphide and water are mutually insoluble, and they are said to be *immiscible* or *non-miscible*. Each liquid then behaves as if it were present alone, the vapour pressure of the mixture corresponds with the sum of the saturation pressure of each. Each of the two liquids may be partially soluble in the other as in the case of ether and water, phenol and water, or aniline and water, and the liquids are then said to be *partially miscible*; or the two liquids may be miscible in all proportions—*completely miscible*—as in the case of alcohol and water. With partially miscible liquids, the composition of each solution, per unit volume, is independent of the masses of the two components—provided both are present. Thus, when ether is gradually added to water, a solution of ether in water is formed, which becomes more and more concentrated. When the aqueous solution is saturated any further addition of ether forms a saturated solution of water in ether, and with further additions of ether, the ethereal solution remains saturated with water until, finally, the ether has dissolved all the water. Any further addition of ether simply dilutes the ethereal solution of water. Consequently, partially miscible liquids have a sharply defined limiting surface furnishing a heterogeneous two-phase solution; with completely miscible liquids, a homogeneous one-phase solution is formed.

When two liquid phases are present in a system—*e.g.* ether and water—the system has the following characteristic properties: (1) The composition of each phase is constant at any assigned temperature and pressure, and is independent of the relative amounts of the two phases, and independent of the mode of preparation. (2) The composition of each phase changes with temperature changes. (3) The vapour pressure of both liquid phases are equal both as to the total pressure and to the pressure of each constituent. If in the system ether and water, the water is withdrawn continuously, the pressure will remain constant so long as both liquid phases are present. When the water disappears, the pressure of the water vapour begins to fall, and becomes zero simultaneously with the disappearance of the water phase, and the residue will be a saturated solution of water in ether. At any assigned temperature, the composition of the liquid will have one constant value, but it will vary with variations of temperature.

In 1835, M. L. Frankenheim[1] noticed that while a variety of creosote and water are only partially miscible at 0°, at 22° the two liquids are mutually soluble in all proportions; and in 1857, D. Absaheff investigated the mutual solubility of a number of pairs of liquids, and showed that the composition of partially miscible liquids changes with a rise of temperature, so that the composition of the two layers becomes more and more nearly alike until a point is reached at which the liquids become completely miscible. A few exceptions have been encountered. For example, for mixtures of water and ether E. A. Klobbie found that the solubility of ether in water *decreases* with rising temperature, while the solubility of water in ether *increases*, as indicated in Table I.

TABLE I.—MUTUAL SOLUBILITIES OF ETHER AND WATER.

Temperature.	Grams of ether per 100 grms. of aqueous solution.	Grams of water per 100 grms. of ethereal solution.
−4°	12·63	0·92
0°	12·17	1·00
10°	9·02	1·12
20°	6·48	1·23
30°	5·04	1·33

This was further investigated by W. Alexejeff [2] between 1876 and 1885; F. Guthrie in 1884, F. A. H. Schreinmakers in 1897, etc. W. Spring and S. Romanoff observed that certain pairs of molten metals presented a similar phenomenon to that observed by M. L. Frankenheim. For instance, mixtures of zinc and bismuth which, below 800°, form two layers, like mixtures of ether and water at ordinary temperatures, but are completely miscible above 900°. W. Alexejeff's data for the mutual solubilities of aniline and water are indicated in Table II.

TABLE II.—MUTUAL SOLUBILITIES OF ANILINE AND WATER.

Temperature.	Grams of aniline per 100 grms of aqueous solution.	Grams of water per 100 grms. of aniline solution.
20°	3·1	5·0
40°	3·3	5·3
60°	3·8	5·8
80°	5·5	6·5
100°	7·2	8·4
120°	9·1	11·9
140°	13·5	16·9
160°	24·9	28·8
167°	48·6	51·4

The temperature at which the two liquids become mutually soluble in all proportions is called the **critical solution temperature,** and the corresponding concentration of the solution, the **critical concentration.** Thus the critical solution temperature of aniline and water is 167°; and the critical concentration is a liquid containing 48·6 grms. of water and 51·4 grms. of aniline. The analogy between the critical solution temperature and the critical state of gases was pointed out by O. Lehmann in 1888,[3] and by O. Masson in 1891, and it is illustrated by the curves, Fig. 11. There has been some discussion as to whether the observed data lie on one continuous curve, or form two curves which intersect one another at the critical point.[4]

The determination of the critical solution temperature is effected by plotting the solubility curves of the two liquids—*A* in *B* and *B* in *A*; or by heating a mixture of the two liquids until a homogeneous solution is obtained, and noting the temperature at which a turbidity appears. The blue opalescence is due to the separation of minute drops of liquid; and their appearance is evidence that the liquid is saturated with respect to large drops, since E. Warburg[5] has shown that small drops of liquid are more readily dissolved than large ones, just as Lord Kelvin has shown that small drops of liquid appearing in vapour are absorbed by the larger one owing to the greater vapour pressure of the former.

According to C. S. Hudson[6] nicotine and water are miscible in all proportions at ordinary temperatures, but at temperatures exceeding 60°, the solution becomes turbid owing to incomplete miscibility; at 210° the two liquids again become completely miscible. The solubility curves of the binary system nicotine and water thus appear to form a closed curve with an upper and a lower temperature of complete miscibility. A similar closed curve has been observed with secondary butyl alcohol and water. According to W. Dolgolenko, the lower temperature limit of complete miscibility in the latter case is due to the presence of traces of tertiary alcohol as an impurity; if these be eliminated, the lower critical temperature does not occur. The phenomenon of a closed solubility curve is taken to be characteristic of a ternary, not a binary, system. In the case of nicotine and water, the third constituent is supposed to be a hydrate of nicotine—such a system is called a *pseudoternary system* by H. W. B. Roozeboom.[7] The hydration of nicotine is evidenced by a considerable contraction and evolution of heat when nicotine is mixed with water.

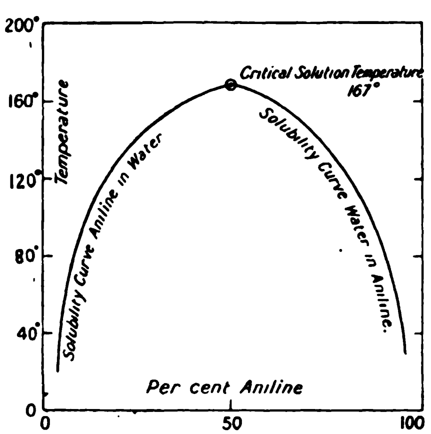

FIG. 11.—Reciprocal Solubility Curves of Aniline and Water.

The kinetic theory of the critical temperatures, and the critical solution temperature.—As the temperature of a liquid is gradually raised, the average kinetic energy of the molecules increases, and a greater and greater proportion of the molecules overcomes the cohesive forces holding the particles of liquid together, and escapes as vapour. The thermal expansion of the liquid is due to the increasing velocity of the vibrating molecules, which makes them behave *as if* they were actually repelled from one another by a force which increases in magnitude as the temperature is raised. Consequently, as the temperature is raised, the repellent forces become stronger and the cohesive forces weaker. When the two forces are just balanced, the liquid can expand indefinitely and the surface separating liquid and vapour vanishes. The properties of liquid and gas are then the same. This is the critical temperature; and the critical pressure has been taken to represent the magnitude of the quasi-repulsive force between the molecules at the critical temperature. When two liquids are in contact, molecules pass from one to the other by a process which is analogous with vaporization, except that the vibratory motions are slower owing to frictional forces. When the average speed of the molecules is great enough just to balance the physical cohesive forces between the molecules of the liquid, the surface of separation between the two liquids vanishes, and the system becomes homogeneous. Hence, in both cases, the critical temperature is due to the balancing of the cohesive forces of the liquid by the quasi-repulsive force due to the increasing velocity of its particles.[8]

Assuming that the critical pressure of a gas is that at which the repellent forces between the molecules are just equal to the forces of attraction at the critical temperature, E. C. Bingham argues that the critical pressure of a gas is a measure of the molecular attraction. Again, since Avogadro's rule applies very well for gases whose particles are so far apart that the time during which they are within the range of one another's attraction is negligible in comparison with the time the particles are independent. The closer the particles are together the more does the intermolecular attraction predominate. If the deviations of a gas from Avogadro's rule are a measure of molecular attraction, the attractive forces will be inversely proportional to the molecular volume, and consequently, the product of the molecular volume M/D and critical pressure p_c should be a constant. E. C. Bingham has worked out Table III. in confirmation of these hypotheses.

TABLE III.—INTERMOLECULAR ATTRACTION AND SOLUBILITY.

	M	D	M/D	p_c	$p_c M/D$	b	$p_c b$
H_2O .	18	1	18	197	3500	0·00150	0·295
NH_3 . .	17	0·6089	28	114	3200	0·00162	0·285
H_2S . .	34	0·91	37·4	90	3370	0·00189	0·170
HCl . .	36·4	0·835	43·6	86	3750	0·00173	0·149
SO_2 . .	64·1	1·3769	46·5	78·9	3670	0·00249	0·196
N_2O . .	44	0·758	52·6	75	3940	0·00189	0·141
CO_2 . .	44	0·8267	53·2	73	3800	0·0019	0·138
CS_2 . .	76·1	1·2922	58·9	75	4400	0·0033	0·247
Cy_2 . .	52·1	0·866	60·2	61·7	3710	0·0029	0·179
$SnCl_4$ . .	260·8	2·28	114·4	36·9	4220	0·00733	0·271
$GeCl_4$.	214·3	1·887	113·6	38	4300	0·00663	0·255
$(C_2H_5)_2O$.	76·1	0·7191	103·4	37·8	3890	0·00563	0·202
$CHCl_3$.	119·4	1·5039	79·4	54·8	4350	0·00445	0·244
C_2H_5OH .	46	0·7942	57·9	62·8	3640	0·00377	0·237
CCl_4 . .	153·8	1·5947	97·1	45	4370	0·00434	0·195

Roughly, the product of the critical pressure and molecular volume is a constant. The molecular volumes should be observed at the critical temperature, but very few data are available. The magnitude b of J. D. van der Waal's equation is proportional to the volume of the particles, and it has been compared with the quotient M/D. The agreement is not so good on account of large experimental errors.

Substances with a large molecular volume have a small intermolecular attraction —*e.g.* ether and carbon tetrachloride—and hence such substances are more likely to be miscible than if one is replaced by a substance like water with a small molecular volume and a large intermolecular attraction. Two substances with a small intermolecular attraction mix readily; no two substances are miscible when their molecular volumes differ very much, since molecular volumes are inversely as molecular attractions. V. Rothmund gives Table IV. indicating the order of solubility of a number of substances in water:

TABLE IV.—THE RELATION BETWEEN MOLECULAR VOLUME, DIELECTRIC CONSTANT, AND SOLUBILITY.

	Molecular volumes.	Dielectric constants.
Water, H_2O	18	81
Formic acid, H.COOH	37·7	57
Methyl alcohol, CH_3OH	39·5	32·5
Acetone, $CH_3CO.CH_3$	72·5	20·7
Aldehyde, $CH_3.COH$	55·6	21·1
Propionitrile, C_2H_5CN	68·8	27·7
Phenol, C_6H_5OH	90	9·7
Benzaldehyde, $C_6H_5.COH$	100	18
Ether, $(C_2H_5)_2O$	103	4·36
Carbon tetrachloride, CCl_4	97·1	1·00
Carbon disulphide, CS_2	58·9	2·64
Hexane, C_6H_{14}	129·9	1·86

Pairs of substances near each other in the list are completely miscible, and the mutual solubility is less, the greater the distance of the two liquids apart. With three or four exceptions, the order of the molecular volumes (E. C. Bingham) and the order of the dielectric constants (V. Rothmund) agree fairly well with the order of solubility. So also the work of A. Christoff shows that the solubility of a gas increases as the cohesion (or surface tension) of the solvent decreases, and that with mixtures of sulphuric acid and water, the solubility of the gases reaches a minimum as the surface tension attains a maximum. I. Traube has made analogous observations by showing that the more a solute decreases (or increases) the surface tension of a solvent, the less (or greater) the force with which it is attracted by the liquid.

The analogy between the critical solution temperature and the critical temperature led W. Alexejeff to try if L. Cailletet and E. Mathias' rule for the relation between temperature and the density of a liquid and of its saturated vapour—a straight line is obtained by joining the mid-points of the ordinates lying between two branches of the curve—is applicable to the mid-points of the line between the two branches of the curve representing the solubilities of one liquid in the other, and he did obtain an approximation to a straight line. W. Rothmund attributed the irregular deviations from a straight line to experimental errors. In cases where accurate data are available the law of rectilinear diameters applies for pairs of liquids with an upper critical solution temperature, so that if C_1 and C_2 be the two concentrations at the same temperature θ, and A and B are constants, $\frac{1}{2}(C_1+C_2)=A+B\theta$, and the concentrations at any temperature θ can be calculated from one another when the constants A and B are known. When there is a lower critical solution temperature, the line is not always straight—but then the lower solution temperature is regarded as a proof that there is some disturbing factor such as the presence of a third component as an impurity or as a compound of the two liquids, or a polymeric modification of one or both of the liquids.

J. Holmes[9] has advanced the hypothesis that the intermiscibility of liquids is a function of the molecular volume which is independent of chemical constitution, and which therefore offers a means of ascertaining the molecular weights of liquids comparable perhaps with the methods which are based on Avogadro's hypothesis for the gaseous state. The molecular volume in question, referred to water unity, is not that deduced from the regular formula. Carbon disulphide and ethyl alcohol, for instance, have the same molecular volume from this point of view, but one liquid is insoluble in water while the other liquid is miscible in all proportions. If allowance be made for the degree of association of the molecules in the liquid state, it is found that *an increase in molecular volume is attended by a decrease in miscibility with water*. Assuming that the liquid molecule consists of a nucleus of great density and an outer envelope or sphere of influence, then in the absence of chemical change, the more nearly equal the radii of the molecular spheres, the greater the miscibility of the two substances. With spheres of different sizes, then, as the ratio of the radius of the larger to that of the smaller sphere increases, the dimensions of the interspaces also necessarily change, and a point is reached when the close packing of spheres is a maximum. In an equimolecular mixture this occurs when the radii are as 1·618 to 1. It is suggested that when these conditions are fulfilled the liquids are on the border line between complete as compared with partial miscibility, and that so long as this or a smaller ratio exists, the liquids will be mutually miscible. When, however, the ratio becomes greater than this value, a complex is formed which will allow of the same close-packing, but results in the formation of two layers of liquid, in each of which the distribution of molecules depends on the further change in this ratio until it reaches 2·414, when, the smaller spheres being able to pass completely through the interspaces between the larger spheres, the liquids should be now wholly immiscible.

§ 4. The Solubility of Gases in Liquids—Henry's Law

The absorption of gases by liquids began to attract attention towards the end of the seventeenth century; and later the subject was investigated by J. Priestley and H. Cavendish. The solubility of gases in liquids depends upon the nature of the gas and of the solvent, as well as upon the temperature and pressure of the system. No common solubility has been observed, and we have no generalization of such wide applicability as Boyle's and Charles' laws. Some gases are only slightly soluble in water, others dissolve very copiously. One volume of water, at normal temperature and pressure, will dissolve 1200 volumes of ammonia, and but 0·210 volume of hydrogen.

The changes in the volume of the solvent.—There is usually a small expansion when gases are dissolved in water. The phenomenon was noticed by T. Bergmann [1] near the end of the eighteenth century; and the change was investigated by a few workers during subsequent years. Thus, T. Thomson, J. J. Mackenzie, and E. L. Nichols (1878) found that the expansion which occurred when water is saturated with carbon dioxide is almost proportional to the absorption coefficient at the specified temperature. K. Angström (1882) found the increments in the volume of a liquid following the absorption of its own volume of gas:

	N_2	Air.	CO	O_2	H_2	CO_2
Volume increment .	0·00145	0·00140	0·00127	0·00115	0·000106	0·00125

The general results show that **the specific gravity of the absorbed gas is nearly proportional to its specific gravity in the free state**; and the less compressible the gas the greater the volume increment when it is dissolved in water. Concentrated aqueous solution of some of the readily absorbed gases—*e.g.* hydrogen chloride—contract when diluted with water, showing that the volume increment on absorption cannot be proportional to the quantity of gas absorbed.

Two systems have been much employed for representing the solubility of gases in liquids. R. Bunsen (1857) [2] applied the term **absorption coefficient**, β, to the volume of a gas reduced to 0° and 760 mm. which is absorbed by unit volume of liquid when the pressure of the overlying gas on the liquid is 760 mm. and the temperature, at the time of absorption, is $\theta°$. For instance, suppose 20 c.c. of a dry gas at 10° be confined over mercury in a tube such that when the barometric pressure is 750 mm. the upper level of the mercury is 200 mm. above the lower level in the trough; further, let 2·5 c.c. of water be introduced into the tube, and, after shaking, absorption reduces the volume of the gas to 18 c.c. when the barometer remains at 750 mm., the height of the column of mercury in the tube is 204 mm. The volume of dry gas before absorption at 0° and 760 mm. is $20 \times 550/760 \times 273/283 = 13·96$ c.c.

The pressure of aqueous vapour at 10·5° is 9·5 mm. The volume of dry gas at a pressure of 536·5 mm. remaining after absorption by the water and reduced to 0° and 760 mm. is $18 \times 536{\cdot}5/760 \times 273/283{\cdot}5 = 12{\cdot}4$ c.c. Hence, the volume of gas measured at 0° and 760 mm. which is absorbed by 2·5 c.c. of water under a pressure of 536·5 mm. is 13·96 less 12·24, that is 1·72 c.c. Had the pressure at the time of absorption been 760 mm. then, by Henry's law, the 2·5 c.c. of water would have absorbed $1{\cdot}72 \times 760/536{\cdot}5 = 2{\cdot}436$ c.c. Hence, 1 c.c. of water absorbs $2{\cdot}436/2{\cdot}5 = 0{\cdot}974$ c.c. of gas; or $\beta = 0{\cdot}974$. The effect of the slight pressure due to the height of the column of water on the volume of the gas has been here neglected. To put this result in general terms, if v_0 be the initial volume of dry gas at 0° and 760 mm.; v_1, the volume of the dry gas remaining after absorption by V volumes of liquid; and p, the observed pressure of the gas remaining after the absorption, the

$$\text{Coefficient of absorption, } \beta = \frac{v_0 - v_1}{V} \cdot \frac{760}{p}$$

W. Ostwald (1888) represented the **solubility** of a gas, S, as the volume of gas absorbed by unit volume of the liquid all at the temperature of the experiment. Consequently, if S_1 volumes of gas are absorbed at a pressure p, and temperature θ, by V volumes of liquid, then the solubility $S = S_1/V$, and

$$\text{Coefficient of absorption, } \beta = \frac{S_1}{V} \cdot \frac{1}{1+\alpha\theta}; \text{ or } \beta = \frac{S_1}{V} \cdot \frac{273}{T}$$

where α denotes the coefficient of thermal expansion of the gas, approximately 0·00367; T the absolute temperature; and V is usually taken to be 100 c.c. Hence, the solubility, S, of a gas differs from Bunsen's absorption coefficient, β, in that in the former case the volume of the dissolved gas is not reduced to 0° and 760 mm. Again, $1+\alpha\theta$ times the coefficient of absorption β represents the solubility S of the gas, or, $\beta(1+\alpha\theta) = S$, and $\beta = S/(1+\alpha\theta)$, since both the solubility and the absorption coefficient are independent of the pressure. Sometimes the solubility of a gas is expressed as the weight w of the gas in grams which is absorbed by 100 grms. of pure solvent at the indicated temperature and a total pressure made up of the partial pressure of the gas plus the vapour pressure of the liquid at the temperature of the absorption. Thus for ethane at 10°, $\beta = 0{\cdot}0656$; $S = 0{\cdot}0648$; and $w = 0{\cdot}0087$. The concentration of the gases in a solvent can also be treated as in the case of solids. For example, O. F. Tower (1906) found that 27·22 c.c. of 98 per cent. sulphuric acid at 18·5° and 714·6 mm. barometric pressure absorbed 0·58 c.c. of nitrogen. The solubility of nitrogen in the acid at 18·5° is therefore $0{\cdot}58127{\cdot}22 = 0{\cdot}0213$; and the absorption coefficient is $0{\cdot}0213 \div (1 + 0{\cdot}00367 \times 18{\cdot}5) = 0{\cdot}0199$.

J. Dalton ascribed the absorption of a gas by a liquid as being due to the penetration of the particles of the gas between the molecules of the liquid, just as E. Swedenborg[3] in 1721 said that the particles of a salt which dissolve in a liquid cannot add to the bulk but only to the weight, because they occupy the spaces between the particles of water. J. Dalton, however, said that the greatest difficulty attending the mechanical hypothesis arises from the different gases observing different laws. Why does water not admit to its bulk every kind of gas alike? The fact that absorption decreases as the temperature increases and as the intermolecular spaces increase is opposed to the idea that absorption is due to a simple penetration of the gas molecules between the molecules of the solvent.

The kinetic theory of gaseous solution.—The kinetic theory of gases furnishes a mental picture of the process of solution of a gas in water. Suppose that a gas-free liquid be brought into a vessel containing a gas. The molecules of gas impinging upon the surface of the liquid will be absorbed. The dissolved molecules move about in the liquid in all directions, a small number escape back into the gas above. As the molecules of the gas crowd more and more in the liquid, the number of molecules absorbed by the liquid becomes more and more nearly equal to the number which escapes back into the superincumbent gas. If the pressure of the gas remains constant, a time will come when the number of gas molecules which leave the liquid will be equal to the number absorbed. The system is then in a state of dynamic equilibrium resembling the equilibrium of a vapour in contact with its own liquid, and the solution is saturated with the gas under the given conditions of temperature and pressure. The solution of oxygen, for example, can be symbolized: $O_{2\text{gas}} \rightleftharpoons O_{2\text{solution}}$. The surface of the liquid in contact with a dissolving gas must be very quickly saturated with the gas, and the rate of absorption of a gas by a liquid at rest is is really a measure of the rate of diffusion of the gas from the surface through the body of the liquid. The molecules of the liquid must have some attractive influence on the molecules of the dissolved gas.

It is probable that the attractive forces between the molecules of the liquid and the dissolving gas determine the solubility, otherwise we should expect the solubility of certain groups of gases to be the same. True enough, as M. Kofler (1913)[4] has shown, *the critical temperature of the gas* is a controlling factor because the solubilities of different gases in a given solvent are approximately the same at corresponding temperatures. M. Kofler assumed that the solubilities of gases in liquids is dependent upon the magnitude of the intermolecular spaces, and that the latter in turn are dependent on the *compressibility of the liquid solvent;* if so, the greater the compressibility of a liquid the greater its solvent action on gases. Similarly, assuming that a high dielectric constant is associated with small intermolecular spaces, the solubility of a gas should be related with the *dielectric constant of the liquid solvent.* On comparing these deductions with observations, it was found that some qualitative relations could be detected; but the greater variations in the solubility of different gases in the same liquid show that the properties of the gases themselves play a most important part. A. Ritzel assumed that the solubility of a gas in a liquid is proportional to the compressibility β of the solvent, and inversely proportional to the change in volume δ which accompanies the absorption of the gas; or $S=k\beta/\delta$, where k measures the solution pressure of the gas.

The influence of pressure on the solubility of gases.—With gases which are not very soluble in liquids, the greater the pressure, the more soluble the gas; that is, the greater the pressure, the greater the concentration of the gas in the solution. W. Henry (1803)[5] discovered an important relation between the pressure and the solubility of a gas. A specified quantity of liquid under a total pressure, p, of 2 atmospheres, holds in solution twice as much gas by weight, w, as under a total pressure of 1 atmosphere. Otherwise expressed, $w/p=w_1/p_1=\ldots$; or $w/p=$a constant, or, **the weight of gas absorbed by a specified volume of liquid is directly proportional to the pressure.** According to Boyle's law, the concentration of a gas, or the amount of v in an enclosed space, is proportional to the pressure or $pv=$constant; combining these two relations, $w/v=$constant. This means that a gas will distribute itself so that its concentration in the liquid is proportional to that in the space above—and this occurs whatever be the superincumbent pressure. One volume of a gas at atmospheric pressure will contract to half a volume at a pressure of two atmospheres. Under a pressure of 2 atmospheres, a saturated solution of gas holds twice as much gas in solution as it did under a pressure of 1 atmosphere, but two volumes of gas at atmospheric pressure occupy but one volume at a pressure of 2 atmospheres. Hence follows **Henry's law: under equal circumstances of temperature, water takes up in all cases the same volume of the condensed gas as it would if the gas were under ordinary pressure.** That is to say,

$$\frac{S}{p}=\frac{S_1}{p_1}=\ldots;\ \text{or}\ \frac{S}{p}=\text{Constant}$$

The proportion of gas and liquid do not matter so long as a sufficient quantity of each is present to allow the measurements to be made. The law thus describes the behaviour of the less soluble gases very well—carbon monoxide, nitrogen, hydrogen, oxygen—but not the more soluble gases like ammonia, hydrogen, chloride, sulphur dioxide. The deviation is not very great with carbon dioxide,[6] though it is appreciable:

Pressure, p . . .	1	5	10	15	20	25	30 atms.
Solubility, S . . .	1·80	8·65	16·03	21·95	26·65	30·55	33·74
Constant, S/p . . .	1·80	1·73	1·60	1·46	1·33	1·22	1·12

The graph, Fig. 12, represents the observed values of p and S; and the dotted curve in the same diagram represents what the graph would have been had carbon dioxide behaved as described by Henry's law. The value of S/p is not therefore quite constant. If the volume of absorbed gas is referred to the volume of the solution instead of the solvent alone, the constant works out better. The failure arises from the fact that carbon dioxide reacts chemically with water. For the very soluble gases S_i/p = constant, where i is a constant characteristic of the gas.

Henry's law refers to gases which do not act chemically on the solvent. When carbon dioxide dissolves in water, one portion enters into combination to produce a new substance—carbonic acid—while the other portion dissolves in the physical sense as carbon dioxide. The latter portion alone comes within the province of Henry's law. The condition of the carbon dioxide which reacts with the water is represented by $CO_2+H_2O=H_2CO_3$. With a rise of temperature the equilibrium is displaced from right to left, corresponding with the fact that the higher the temperature of observation, the more nearly does Henry's law approximate to the truth. Thus, H. E. Roscoe and W. D. Dittmar (1869) found that the law applies very well for sulphur dioxide at 40°, and for ammonia near 100°. At 100°, also, the solubility of carbon dioxide is proportional to the pressure. If the partial pressure of the hydrate $CO_2.H_2O$ is proportional to the concentration of the dissolved carbon dioxide, *the presence of the hydrate has no influence on the law of absorption*[7] provided there is no change in the gaseous molecule, resulting in the formation of molecules of the type $(CO_2)_n.H_2O$. Suppose the initial value of n is unity. If S_1 be the concentration of the gas CO_2; S_2, that of the water; and S, that of the hydrate, then the condition of equilibrium in the solution $CO_2.H_2O \rightleftharpoons CO_2+H_2O$ is, according to Gulberg and Waage's law, $S_1S_2=K_1S$. If the solubility of the gas is not great the solution will be dilute, and the water will be in so great an excess that its concentration will be virtually constant, and therefore $S_1=K_2S$, where $K_2=K_1S_2$. From Henry's rule, the partial pressure p of the gas will be $p=K_3S_1$, and therefore by substitution for S_1, $p=K_2K_3S$; or, substituting the constant $K=K_2K_3$, it follows that $p=KS$, or the concentration of the hydrated molecules is proportional to the pressure of the gas, just as is the case with the unhydrated molecules. Consequently, assuming that the partial pressure of the hydrate is proportional to the concentration S of the dissolved gas, S/p=constant, just as would be the case if the carbon dioxide were all dissolved in the form of CO_2, and none as $CO_2.H_2O$.

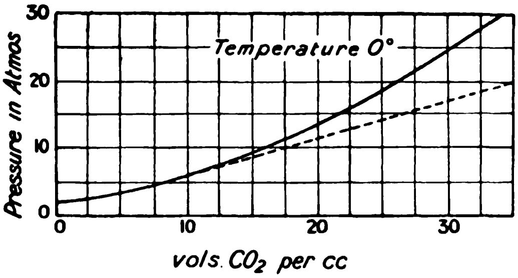

FIG. 12.—Solubility Curve of CO_2 in Water.

Henry's law also assumes that the molecular weight of the dissolved gas is the same in solution and in the gaseous state. If the gas A be polymerized in solution so that $2A_{gas}=A_{2solution}$; then, if S_1 be the concentration of the free gas, and S the concentration of the dissolved gas, by the law of mass action, $S_1^2=k_1S$, where k_1 is a constant. Accordingly, $S_1=\sqrt{k_1S}$, and Henry's law assumes the form $p=k\sqrt{S}$, where k is constant, p the pressure of the gas, and S the solubility—all expressed in proper units. Analogous remarks apply if the gas in solution is polymerized to a higher degree, say n; or if the gas is depolymerized or decomposed.

Since the concentration of a substance is understood to refer to the quantity of substance in unit volume, Henry's law means that in a closed vessel, containing gas and liquid, the gas will distribute itself so that its concentration in the liquid is proportional to that in the superincumbent space. Hence it may be inferred that **if a gas obeys Henry's law, it will have the same molecular weight in solution and in the gaseous condition.** Henry's law is therefore to be regarded as a link connecting the molecular weight of gaseous and dissolved substances with one unit of measurement. If 32 grams of oxygen depress the freezing point to the same extent as 342·2 grams of cane sugar, it would be inferred that the molecular weights of oxygen and cane sugar are related as 32 : 342·2 ; and since oxygen gas has a molecular weight of 32, it is assumed that cane sugar if it could be vaporized, and if its gas obeyed Henry's law, would have a molecular weight of 342·2, because, as indicated above, the molecular weights of a substance in solution and in the gaseous state are assumed to be the same.

It might be emphasized, in passing, that when a gas is dissolved in a liquid at a given temperature, the ratio between the concentration of the gas in the liquid and in the space above is always the same. Thus, Henry's law is a law of distribution for gases because it describes the way a gas distributes itself between the solvent and the space above. Henry's law also describes the condition of equilibrium of a gas whose molecules are physically and chemically independent of each other, and of the solvent.

EXAMPLE.—Show that the absorption coefficient is independent of pressure. If S volumes of gas at a pressure p are absorbed by unit volume of liquid, S_1 vols. by Henry's law will be absorbed at 760 mm. such that $S_1p=760S$. Again, if S_1 volumes of gas at a pressure p and temperature θ, become S_0 volumes at 760 mm. and 0° ; by Boyle's and Charles' laws, $S_1p=760S_0(1+\alpha\theta)$. Substituting for S_1 from the preceding expression and solving for S_0, it follows that $S_0=S/(1+\alpha\theta)$, which is independent of p. If V volumes of liquid have been treated, $S_0=S/V(1+\alpha\theta)$, which is Bunsen's coefficient of absorption, β.

Solids and liquids dissolve in a vacuum or in a dilute indifferent gas in accord with their vapour pressure,[8] but if the indifferent gas be strongly compressed, say at 100 atm., a specific solvent action appears. Thus, compressed oxygen has a greater solvent action on bromine vapour than oxygen under reduced pressure, and at 300 atm. pressure, the colour of the vapour is six or seven times as dense as under atmospheric pressure; while compressed hydrogen has but a smaller solvent action. Iodine imparts an intense violet colour to methane under 300 atm. pressure. Camphor and paraffin likewise dissolve in compressed methane or ethylene gas, and on removing the pressure, the iodine, camphor, or paraffin are deposited as crystals on the walls of the vessel.

The applicability of Henry's law for solvents other than water was proved by R. Bunsen[9] for alcohol; by M. Woukoloff, for chloroform and carbon disulphide; and for petroleum by S. Gniewosz and A. Walfisz. The absorption coefficients of a gas in different solvents are not proportional to one another. In order to test the applicability of Henry's law, W. Sander examined the solubility of carbon dioxide in water and in a number of organic liquids at temperatures between 20° and 100° and at pressures between 20 and 170 kgrms. per sq. cm. He found that Henry's law is the more nearly followed the higher the temperature; at the lower temperatures, the solubility of the gas in alcohol, benzene, chloro-, bromo-, and nitrobenzene, and toluene increases faster with increasing pressure than corresponds with Henry's rule, and with ethyl ether, ethyl acetate, and water, the increase is slower than Henry's law requires. The law is more nearly followed when the volume of gas absorbed is referred not to the volume of the solvent (coefficient of absorption) but to the volume of the solution (Ostwald's solubility). With carbon dioxide in ether, and ether vapour in carbon dioxide, Henry's law is not approximately valid in the neighbourhood of the critical point. O. Sackur and O. Stern have likewise examined the effect of pressure on solutions of this same gas in methyl and ethyl alcohols and acetates between —59° and 78°, and between 50 and 700 mm. pressure.

Henry's law and the kinetic theory.—The gas is in equilibrium with its own solution when the number of molecules which escape from the solution is the same as those which are captured by the solution in a given time. By, say, doubling the pressure the molecular concentration will be doubled, the gas molecules will be crowded more closely together, and the rate at which the solution captures the molecules will be increased twofold for the new state of equilibrium. Similarly the rate of escape will be doubled. Hence **variations of pressure do not alter the relative number of molecules per unit volume of solution and of gas** ; and the *volume* of gas dissolved will be independent of the pressure on the gas, while the *weight* of gas dissolved will be directly proportional to the pressure.

It will be observed that in the relation showing the influence of pressure on the solubility $(d \log S)/dp = \delta v/RT$, the magnitude δv may be interpreted to mean the change in volume which occurs during the process of solution. The volume of the gas is so great in relation to the solution that the volume v of the gas can be substituted for δv, and assuming Boyle's law is applicable $pv = RT$, and substituting for v

$$\frac{d \log S}{dp} = \frac{1}{p}$$

which, on integration, furnishes $S = kp$, that is, Henry's law.

The influence of temperature on the solubility of gases.—The solubility of a gas in a liquid is very sensitive to changes of temperature. The higher the temperature, the less the solubility of the gas. R. Bunsen's measurements agree with the assumption that the absorption coefficient of hydrogen in water and of oxygen in alcohol are not affected by changes of temperature between 0° and 20°; but W. Timofejeff found that R. Bunsen's results were not confirmed by a more sensitive method of measurement.[10] The solubility curve of helium is not much affected by changes of temperature up to 50°, but what little effect there is seems to indicate that the solubility of the gas *increases* as the temperature rises from 25° to 50°. Hydrogen was once supposed to behave in a similar way, between 0° and 25°, but later, more careful measurements show that the solubility decreases steadily from 0·0214 at 0° to 0·0171 at 26°. The solubility of carbon dioxide in nitrobenzene is nearly the same at 100° as it is at 60°.

A. Imhof represented the solubility, S, of a gas (litres of gas in a litre of water) by the expression:

$$S = e^{\frac{T}{27\cdot4}}; \text{ or } T = 27\cdot4 \log S$$

where T denotes the absolute boiling temperature in degrees reckoned from the point where $S = 1$ and $\log S = 0$, namely, $-100°$. T is positive if higher than $-100°$, and negative if below $-100°$. The results have less than a 2 per cent. error with all the gases tried excepting methane, where the error is 5·3 per cent., and hydrogen and helium where the errors are respectively 16·1 and 18·9 per cent. For oxygen, $S = 0\cdot049$; $T = -82\cdot66°$ (observed $-82\cdot5°$); for acetylene, $S = 1\cdot73$; and $T = -15\cdot02$ (observed $+16\cdot0$).

The influence of the surface tension of the solvents has been previously discussed.

§ 5. The Solubility of Mixed Gases in Liquids—Dalton's Law

When a mixture of two gases is exposed to the action of a solvent, the quantity of each gas dissolved by the liquid depends upon the amount and the solubility of each gas present. The amount of each gas determines its partial pressure, and since the partial pressure of each gas is independent of the others, it follows that **when a mixture of gases is exposed to the action of a solvent, and no chemical action intervenes, the amount of each gas which is dissolved by the solvent is proportional to the partial pressure of the gas.** Each gas behaves as if the others were absent. This is called **Dalton's law,** after its discovery by J. Dalton,[1] 1805; it is obviously a special case of Henry's law.

J. Dalton's idea was that the gases dissolved in water retain their elasticity or repulsive power among their own particular molecules the same in the water as out of it, the intervening water having no other influence in this respect than a mere vacuum. The idea that the solvent water is wholly passive cannot now be maintained. J. Dalton further showed that each gas is retained in water by the pressure of gas of its own kind incumbent on the surface; abstractedly considered, no other gas with which it may be mixed has any permanent influence. J. Dalton also had wrong ideas of the numerical relation between the gas dissolved and that incumbent on the liquid. R. Bunsen[2] studied the solubility of mixed gases, and, in his *Ueber das Gesetz der Gasabsorption,* pointed out:

Let v vols. of a mixture of gases at a pressure P, containing, per unit volume, v_1 volumes of a gas A, v_2 vols. of a gas B, v_3 vols. of a gas C, . . . with the respective coefficients of absorption $\beta_1, \beta_2, \beta_3$, . . . be agitated with V vols. of a liquid, so that there remains u vols. of the gaseous mixture containing u_1, u_2, u_3, . . . respectively of the gases A, B, C, . . . per unit volume at a pressure P_1. The temperature remains constant at 0°. The mixture contains v_1v vols. of the gas A at a pressure P, or $v_1vP/760$ vols. at a pressure 760 mm. This volume of gas is divided into x_1 vols. of gas which remain unabsorbed and y_1 vols. which are absorbed by the v vols. of liquid; but from the law of absorption, unit volume of liquid absorbs β_1 vols. of gas at 760 mm. pressure, or V vols. of liquid absorb $\beta_1 Vp_1/760$ vols. at a partial pressure p_1. The gas A_1, however, expands from x_1 to $up_1/760$ vols. when admixed with the other gases, so that the quantity absorbed by V vols. of liquid in virtue of the partial pressure $\beta_1 Vx_1/u$ is y_1, or $y_1 = \beta_1 vx_1/u$; or the volume of the component A is $x_1 + \beta_1 Vx_1/u = v_1vP{:}760$; or $x_1 = v_1vP/760(1+\beta_1 V/u)$; and generally,

$$x_1 = \frac{v_1vP}{760\left(1+\frac{\beta_1 V}{u}\right)};\quad x_2 = \frac{v_2vP}{760\left(1+\frac{\beta_2 V}{u}\right)};\quad \ldots$$

The volume of residual gases remaining when a gaseous mixture of volume $v = v_1 + v_2 + \ldots$ has been exposed to v vols. of a solvent is $u = (u_1 + u_2 + \ldots$, where

$$u_1 = \frac{x_1}{x_1+x_2+\ldots};\quad u_2 = \frac{x_2}{x_1+x_2+\ldots};\quad \ldots$$

J. Dalton believed that the influences of temperature on the amounts of various gases dissolving in the same liquid is proportional to the influence of each as separately, so that the composition of the gas dissolved by a specified liquid acting on a mixture of gases is independent of the temperature. This statement is not strictly accurate.

When air containing, say, 79 volumes of nitrogen (neglect the argon and rare gases) and 21 volumes of oxygen, and 0·04 volume of carbon dioxide, is skaken up with water, the amount of each gas absorbed by the water can be approximately computed in the following manner: The relative solubilities are: nitrogen, 0·02; oxygen, 0·04; and carbon dioxide, 1·79. The partial pressure of each gas is proportional to the relative amount of that gas present in a given volume of air. If the pressure of air be just one atmosphere, the partial pressure of the nitrogen will be proportional to 0·79 × 1; of oxygen, 0·21 × 1; and of carbon dioxide, 0·0004 × 1. Hence the relative amounts of these gases absorbed by the water will be: nitrogen, 0·79 × 0·02 = 0·0158; oxygen, 0·21 × 0·04 = 0·0082; and carbon dioxide,

$0·0004 \times 1·79 = 0·00072$. Hence 1 c.c. of water dissolves 0·0158 c.c. of nitrogen; 0·0082 c.c. of oxygen; and 0·00072 c.c. of carbon dioxide. The composition of the dissolved gases, if removed from the solution by boiling, or exposure to a vacuum, will be: nitrogen, 63·9 per cent.; oxygen, 33·2 per cent.; carbon dioxide, 2·9 per cent. The relatively large solubility of the carbon dioxide of the atmosphere is counterbalanced by its low partial pressure, otherwise we might expect a heavy rainstorm to remove a great part of the carbon dioxide from the surrounding air.

J. T. A. Mallet (1869) [3] has a proposal to separate oxygen from atmospheric air freed from carbon dioxide, which is based on the different solubilities of the oxygen and nitrogen. If the carbon dioxide be removed by passing the air through an aqueous solution of sodium hydroxide, the oxygen and nitrogen in the remaining gases after the first absorption will be nearly in the proportion: nitrogen 65·7 per cent., and oxygen 34·3 per cent. If this mixture be driven from the water by boiling, and the mixture again treated with air-free water, a gaseous mixture containing 49 per cent. of oxygen is obtained; and after the eighth absorption, a gas containing 97 per cent. of oxygen results. The relative proportions of oxygen and nitrogen in air obtained from water after successive absorptions is

TABLE V.—EFFECT OF SUCCESSIVE ABSORPTIONS BY WATER ON THE COMPOSITION OF AIR.

	Number of absorptions.								
	0	1	2	3	4	5	6	7	8
Nitrogen	79	66·7	52·5	37·5	25·0	25·0	9·0	5·0	2·7
Oxygen	21	33·3	47·5	62·5	75·0	85·0	91·0	95·0	97·3

The method is not practicable though it is an interesting application of Henry's and Dalton's laws.

EXAMPLES.—(1) The solubility of hydrogen is 0·02 and of oxygen 0·04. Show that 13·3 c.c. of each of these gases is dissolved by 1000 c.c. of water from an electrolytic mixture of hydrogen and oxygen.

(2) If 10 c.c. of an aqueous solution of carbon dioxide saturated at 0° is introduced into a vessel already containing 10 c.c. of carbon dioxide all at atmospheric pressure, show that 8·69 c.c. of carbon dioxide will remain in solution. D. I. Mendeléeff (1868) found 10 c.c. of a saturated solution at 0° contain 18 c.c. of carbon dioxide, and if x denotes the number of c.c. which remain in solution, $18-x$ will represent the number of c.c. expelled and $28-x$ will be present in the atmosphere. Hence, the partial pressure of the dissolved carbon dioxide is $(18-x)/(28-x)$. When the solution is at atmospheric pressure it contains 18 c.c. of carbon dioxide, and when the partial pressure is $(18-x)/(28-x)$, it contains $18(18-x)/(28-x)=x$ c.c. of carbon dioxide, when $x=8·69$ c.c.

The effect of saline solutions on the solubility of gases.—The behaviour of gases towards salt solutions first attracted the attention of physiologists owing to its bearing on the absorption of gases by the blood. Thus J. S. F. Pagenstecher,[4] R. F. Marchand (1846), J. von Liebig (1851), L. Meyer (1857), and E. Fernet (1858), examined the solubility of carbon dioxide in solutions of sodium phosphate. The solubility of a gas is lowered by the dissolution of a salt which does not act chemically on the gas. Thus, F. M. Raoult (1873) [5] found that the solubility of ammonia in aqueous solutions of potassium hydroxide decreased as the proportion of alkali increased from 72 with solution containing 11¼ per cent. K_2O, to 49·5, with solutions containing 25¼ per cent. of K_2O. J. Setschenoff (1889) found that the relation between the quantity of salt x and the absorption coefficient is given very nearly by the formula:

$$\text{Absorption coefficient} = \beta e^{-\frac{k}{x}}$$

where β represents the absorption coefficient of the gas for water, k is a specific constant dependent upon the nature of the dissolved salt, and e is the base of natural logarithms. Equivalent solutions of similar salts of the same acid absorb nearly the same quantities of gas. For instance, J. Setschenoff (1875) found that with calcium, strontium, and barium nitrates the absorption coefficients were respectively 0·923, 0·916, and 0·922. The effect of mixing another liquid with the water resembles that obtained by the dissolution of a salt; thus J. S. Setschenoff (1875) found the absorption coefficients of mixtures of water and sulphuric acid to be less than for either water or sulphuric acid alone, as illustrated in Fig. 13. Other physical properties of mixtures—viscosity, electrical conductivity, etc.—change in a similar manner. O. Müller (1889) obtained similar results with mixtures of alcohol and water. If the salt is acted on chemically by the gas, as is the case when carbon dioxide is dissolved in aqueous solutions of borax, sodium carbonate, or sodium phosphate, the portions of gas held chemically by the salt is almost independent of pressure, while the other portion follows Henry's law. The decrease is supposed to be due to the fixation of some of the solvent by the molecules or the ions, or both molecules and ions of the dissolved salt. On this assumption, J. C. Philip [6] calculated the degree of hydration of the salt from the decrease in the solubility of the gas from the formula :

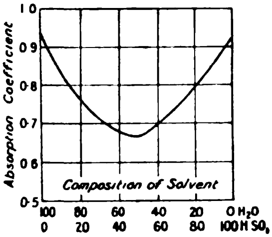

FIG. 13.—Solubility of Carbon Dioxide in Mixtures of Sulphuric Acid and Water.

$$\text{Degree of hydration} = \frac{a-b}{a}\,\frac{100-c}{c}\,\frac{M_1}{M}$$

where M_1 and M respectively denote the molecular weights of salt and water; c the per cent. of salt in solution ; a denotes the number of c.c. of oxygen dissolved by a litre of water; b the number of c.c. of oxygen in 1000 grams of water in the solution calculated from $b=a/(D-C)$, where D denotes the density of the solution, and C the number of grams of water per c.c. of solution. For example, with potassium chloride, bromide, and iodide, C. G. McArthur finds :

	KCl		KBr		KI	
Concentration	$\frac{1}{4}N-$	$2N-$	$\frac{1}{4}N-$	$2N-$	$\frac{1}{4}N-$	$2N-$
Specific gravity . . .	1·0086	1·086	1·017	1·150	1·027	1·230
Oxygen c.c. per litre . .	5·30	3·21	5·52	3·37	5·49	3·77
Degree of hydration . .	16·0	10·4	7·8	8·9	8·9	6·4

The hydration data with salts whose ionization is small were found to give results consistent with the degree of hydration calculated by other methods.

§ 6. Diffusion in Gases and in Liquids

> If a very small quantity of a salt be dissolved in a great quantity of water, the particles of the salt will not sink to the bottom though they be heavier in specific gravity than the water, but they will evenly diffuse themselves into all the water so as to make it as saline at the top as at the bottom. Does not this imply that the parts of the salt recede from one another, and endeavour to expand themselves and get as far asunder as the quantity of water in which they float will allow ? And does not this endeavour imply that they have a repulsive force by which they fly from one another, or at least, that they attract the water more strongly than they do one another ?—ISAAC NEWTON (1675).

Let a large crystal of a coloured salt—say copper sulphate or potassium dichromate—be placed at the bottom of a tall glass cylinder, and the remainder of the jar be filled with water. A coloured salt is chosen because the movements of the resulting solution can be readily seen. Let the jar stand where it will not be disturbed by evaporation, agitation, etc. The surface of separation between the solid and solvent will be gradually obliterated ; in time, the coloured salt will diffuse uniformly throughout the whole body of liquid. Similarly, if a solution of one concentration be in contact with a solution of another concentration, the dissolved substance passes from the region of greater to the region of lesser concentration, until the concentration is uniform throughout the whole mass of liquid provided the temperature is everywhere the same.[1]

The phenomenon of diffusion was known to Isaac Newton (1695), to C. Berthollet (1803), and to F. Parrot (1815). The last-named attributed the action to a special force which he called *Affinität erster Art, eine neu aufgedeckte Naturkraft*—affinity of the first degree, a newly discovered natural force—which M. L. Frankenheim (1835) styled diffusion. F. Parrot said : All miscible liquids show a tendency to wander one into the other when they are brought into contact, and this process continues until the liquids are perfectly evenly distributed. W. Nernst attributed the driving force to osmotic pressure, a phenomenon about to be described. T. Graham first obtained quantitative data about the speed of diffusion of different salts, and A. Fick then developed a theory of the process based on the hypothesis that *the quantity of a salt which diffuses through a given area in a given time is proportional to the difference between the concentration of two vertical and parallel planes indefinitely close to one another* ; or, the amount of solute dm which will pass in a given time dt between two parallel planes unit distance apart and of unit sectional area, is proportional to the difference in concentration, C_1-C_2, on the two sides of that section—**Fick's law of diffusion** —or $dm=k(C_1-C_2)dt$, where k is the coefficient or constant of diffusion. The hypothesis was tested by many investigators—F. Beilstein (1856), T. Simmler and H. Wild (1857), F. Hoppe-Seyler (1867), E. Voit (1867), and A. Johannisjanz (1877), but the results, as J. Stefan (1878) showed, were not of a sufficient degree of accuracy. Then followed the work of H. F. Weber, W. Seitz (1898), J. Schuhmeister (1879), J. H. Long (1880), R. Lenz (1882), J. D. R. Scheffer (1881), and P. de Heen (1884). The general results have established the validity of A. Fick's law based on the theory of the conduction of heat, and that just as the magnitude of the heat conduction decreases slowly with rise of temperature, so does the diffusion decrease as the concentration increases. The mathematical theory has been discussed by W. Seitz, F. Niemöller, E. Voit, T. Simmler and H. Wild, J. Stefan, O. Wiedeburg, O. Wiener, P. G. Tait, H. F. Weber, F. Neimbrodt, J. Trovert, etc. The speeds of diffusion of many salts have been investigated by T. Graham, J. D. R. Scheffer, L. W. Oeholm, J. Trovert, F. Heimbrodt, W. Scitz, O. Wiedeburg, W. Kawali, etc. T. Graham observed great differences in the rates of diffusion of two classes of substances—what he called crystalloids diffused rapidly, colloids slowly.

	HCl	NaCl	Cane sugar.	$MgSO_4$	Albumen.	Caramel.
Velocity of diffusion . .	1	2·3	7	7	49	98 units

J. H. Long noted a parallelism between the velocity of diffusion and the electrical conductivity. The diffusion of mixtures of salts has been investigated by T. Graham,

J. C. G. de Marignac, and F. Rüdorff. Each salt seems to diffuse independently of other accompanying salts. T. Graham, P. de Heen, H. F. Weber, W. Seitz, L. W. Oeholm, and others have investigated the influence of temperature on the speed diffusion, and found it to increase rapidly with a rise of temperature. W. Nernst found that with dilute solutions of neutral salts, the coefficient of diffusion k at θ° is $k_{18}\{1+0{\cdot}026(\theta-18)\}$, and for acids and bases $k_{18}\{1+0{\cdot}024(\theta-18)\}$.

T. Graham, E. Detlefsen, H. de Vries, L. Chabry, P. Nell, H. Bechhold and J. Liegler, J. Hausmann, S. Leduc, N. Pringsheim, and F. Voigtlander studied the rate of diffusion in agar-agar jelly and found the process similar to that which occurs with water. R. E. Liesegang found that the diffusion of silver nitrate in a tube of gelatine containing ammonium chromate furnishes a series of rings or laminæ—**Liesegang's rings**—at right angles to the axis of the tube. W. Ostwald suggested that it is a supersaturation phenomenon. F. Köhler found that if the ammonium chromate be too concentrated or too dilute the rings are not well developed; and if the gelatine contains the silver salt, *rhythmic precipitation* does not occur. H. W. Morse and G. W. Pierce obtained a similar result with lead nitrate diffusing into gelatine and sodium sulphate.

There seems to be some force at work driving the molecules of the solute upwards against the force of gravity. From the kinetic theory, it is inferred that the molecules of the liquid are in perpetual motion in all directions; and that the protracted time occupied by the diffusion of the molecules of the dissolved salt in the liquid is due to the close packing of the molecules of the liquid, such that the free progress of the molecules of the dissolved salt in the solvent is greatly impeded. It can be shown from the kinetic theory that the potential energy of the molecules of a mixture of gases is diminished by diffusion, and in consequence the phenomenon is due to the tendency of the molecules of the mixing gases to follow the dynamical principle: the position of stable equilibrium is the position of minimum potential energy; diffusion is motion towards a state of stable equilibrium.

The analogy between the dissolution of a substance in a solvent, and vaporization, has been emphasized by R. Hooke (1664), by J. L. Gay Lussac (1839),[2] by B. Bizio (1845), and by A. Rosenstiehl (1870). A substance in solution was regarded as an elastic vapour, and the difference between the dissolved substance and a gas was said to arise from the circumstance that "a gas does not need the presence of the molecules of a solvent, and of their affinity to sustain it in the occupied space." In 1873 A. Horstmann developed a thermodynamic theory of equilibrium between gaseous substances, and showed that the same laws applied for substances in solution. The idea gradually grew into chemistry, and proved singularly fruitful in the work of J. H. van't Hoff (1886), who widely extended the analogy between the physical and chemical behaviour of substances in dilute solution, and in the gaseous state.

Just as the molecules of a gas in a closed vessel are disseminated in a relatively large space, so are the molecules of a solid in solution scattered in a relatively large volume of solvent. It is true that the molecules of the salt in solution could not occupy the space if the solvent were absent, otherwise the analogy between a substance dissolved in a solvent and a gas scattered in space would be very close. Arguments from analogy are notoriously treacherous; and whatever conclusions might be inferred from a closer study of the analogy between the process of solution and gaseous diffusion, the fact that the molecules of the dissolved substance are comingled with the solvent, and that the molecules of the gas are not associated with such an agent, must be constantly borne in mind. As G. F. Fitzgerald[3] has said: "The dynamical condition of molecules in solution is essentially and utterly different from that of the molecules of a gas."

The **rate of solution** of a solid in a solvent depends on the surface area, and on the amount of the solid already present in solution. This latter was suspected by C. L. Berthollet[4] in 1803, and established by the experiments of A. A. Noyes and W. R. Whitney. They showed that the rate of solution of a solid is proportional to the difference between the concentration of the film in immediate contact with the solid and with the more dilute layers. Consequently, it follows that the solution of a solid involves two processes : (i) The reaction between the solvent and solid ; (ii) The rate of diffusion of the solute away from the solid. If the speed of the latter process predominates, the observed rate of solution will not depend merely on the amount of solid already on solution ; whereas if the speed of the former predominates, the observed rate of solution will be proportional to the concentration of the solution in conformity with the observations of A. A. Noyes and W. R. Whitney—see crystals.

§ 7. Solution Pressure—Osmotic Pressure

Just as a small quantity of water is able to dissolve a quantity of salt which can diffuse itself through a large quantity of water, so a quantity of air which can expand and diffuse itself through a large space may be contained within a small compass.—R. HOOKE (1664).

It has been shown that if the diffusion of gases be resisted by placing a permeable partition between two gases, a pressure will be exerted upon the partition. It is easy to show that the particles of a dissolved substance exert a similar pressure when a partition is placed between the solution and solvent so that the partition offers no obstacle to the free circulation of the molecules of the solvent, but resists the free passage of the molecules of the dissolved substance.

A piece of wet bladder is stretched and wired over the head of a wide thistle-headed funnel with a stem about 10 cm. long. When nearly dry, the bladder is removed and the hot funnel is smeared about the rim with marine glue. The bladder is immediately wired securely in position. The thistle-headed funnel is nearly filled with a concentrated solution of cane sugar and joined by means of pressure tubing or a rubber stopper with a piece of capillary tubing of ½ mm. bore bent S-shaped as indicated in Fig. 14. The funnel is immersed in a jar of water. The level of the index of coloured water in the capillary tube is marked with gummed paper, and the apparatus is allowed to stand over night. In the morning the liquid in the capillary will have risen about 10 cm. Water has obviously passed from the beaker through the membrane into the sugar solution.

The passage of water through a membrane in this manner is called **osmosis**—from the Greek ὠσμός, a push. If the osmosis be inwards, towards the solution, H. Dutrochet's term **endosmosis** can be used; if outwards, **exosmosis**. The membrane permeable to the solvent, impermeable to the dissolved substance, is called a **semipermeable membrane.** The extra hydrostatic pressure exerted upon the membrane by the sugar solution was styled, by W. F. P. Pfeffer (1877), "the **osmotic pressure** of the sugar solution." Solutions with the same osmotic pressure are said to be *iso-osmotic* or **isotonic.**

Experiments on osmosis were made by Abbé Nollet (1748).[1] He showed that if the opening of a glass vessel containing alcohol be tightly covered with a bladder and inverted in water, the contents of the vessel increase so that the bladder sometimes bursts. F. Parrot next studied the phenomenon in 1803, and N. W. Fischer in 1822. F. Parrot saw the important bearing of this subject on phenomena or processes which occur in the living organism. Then R. J. H. Dutrochet took up the subject in 1826 and subsequent years. The greatest interest centred about the changes of level which occurred when two different liquids separated by an animal membrane were kept in contact. G. Magnus (1827), E. B. Jerichau (1825), E. Brücke (1842) tried to develop a theory of the process; K. Vierordt (1845–8), P. Jolly (1849), J. von Liebig (1848), C. Ludwig (1849), A. Fick (1854), and T. Graham (1861) investigated the subject of osmosis through animal membranes.

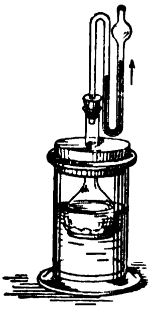

Fig. 14.—Illustration of Osmotic Pressure.

The action is curious. In the ordinary nature of things the sugar would diffuse into the solvent until the whole system had one uniform concentration. The membrane retards this. If the sugar cannot get to the solvent, the solvent goes to the sugar—a case of Mahomet and the mountain. Molecules of sugar and molecules of water attempt to pass through the membrane; the way is open for the molecules of water, but not for the molecules of sugar. Water can pass freely both ways. The extra pressure on the solution side of the membrane—the **solution pressure**—is supposed to be due to the bombarding of the membrane by the molecules of sugar. Equilibrium occurs when the number of molecules of water passing downwards through the membrane is equal to the number passing in the opposite direction. The resulting pressure is the solution pressure or the osmotic pressure of the solution.

Let us be perfectly clear about this or we may be led into error. The *fact* observed is that **the osmotic pressure is the excess of the hydrostatic pressure on the solution side of a semipermeable membrane over the pressure on the solvent side.** The *hypothesis* here suggested—often styled J. H. van't Hoff's kinetic theory of solutions (1886)—is that this pressure is due to the bombarding of the semipermeable membrane by the dissolved molecules trying to diffuse into the solvent and make solvent and solution one uniform concentration. The hypothesis was developed in a very important memoir: *The rôle of osmotic pressure in the analogy between solutions and gases* (1887).[2] The hypothesis has served as a stimulus to much valuable work; there are, however, other possible explanations of the phenomenon. The merits of rival hypotheses cannot be settled by symposia although discussion may bring fundamental issues into relief. Harsh experience alone can shatter or establish this interesting analogy—for *comparaison n'est pas raison.*

Imagine the experiment arranged a little differently. Suppose the aqueous solution of sugar in the lower part of a cylinder, Fig. 15, to be separated from the pure solvent in the upper part of the cylinder by a semipermeable membrane *A*, so fitted that it can slide freely up and down the cylinder. The upward osmotic pressure of the solution will naturally force the piston upwards, and a weight, *P*, equivalent to the osmotic pressure of the solution, will be required to keep the semipermeable membrane in one fixed position.

Many hypotheses have been suggested to explain the function of the membrane in osmotic phenomenon, ranging between the purely physical conception which refers the effect to the passage of the liquid through capillary pores, and the purely chemical conception of a combination between the membrane and the liquid passing through. M. Traube (1867), S. U. Pickering (1891), and W. Sutherland (1907) considered the semipermeable membrane acted as a kind of sieve which allowed the passage of the molecules of the solvent, but obstructed the passage of the supposed larger molecules of the solute. This hypothesis is now abandoned, for no attempt to distinguish between true pore diffusion occurring through capillary openings and the so-called true endosmosis occurring through smaller molecular interstices, has proved successful; and even in the case where collodion membranes and porcelain plates serve as partitions, S. L. Bigelow (1907) found that the same laws described the passage of liquids through both; there is no experimental evidence clearly distinguishing between the passage of a liquid through capillaries and through molecular interstices.

According to the solution hypothesis, a substance will pass through a membrane only if it is soluble therein. According to this hypothesis, if two miscible liquids, A and B, are separated by a membrane, and the membrane has the power to absorb or dissolve only one of them, say A, this liquid will be dissolved on one side of the membrane and given up on the other, and if the liquid B is in a closed cell, an hydrostatic pressure will be there developed. The magnitude of this pressure will depend on the relative attractions or solubility of A and B in the membrane. If A is soluble and B insoluble or sparingly soluble, the membrane will be saturated with A on one side and supersaturated on the other, and there will be a transfer of solvent through the membrane until hydrostatic pressure is developed sufficient to check the flow. Hints of this hypothesis were given by T. Graham, but M. l'Hermite (1855) published the first clear statement of a possible development of osmotic pressure by a selective action of the membrane, and he gave the three-liquid experiment—with chloroform, water, and ether—with the express idea of demonstrating that a substance which passes through the membrane dissolves in that membrane. Accordingly, argued M. l'Hermite, there must be a relation between solution and chemical union; osmotic phenomena are not the result of a special force, but rather the effect of forces of affinity similar to those acting in solutions. L. Kahlenberg (1906) also has sought for evidence in support of the solution theory of osmosis.

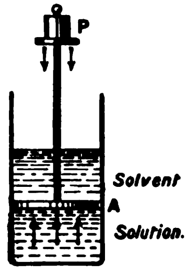

Fig. 15.—Osmotic Pressure.

The following is A. C. Brown's modification of M. l'Hermite's three-liquid layers to illustrate the development of osmotic pressure by the solvent action of the membrane. A concentrated solution of calcium nitrate is saturated with phenol and the mixture poured into a tall narrow cylinder. The excess of phenol rises and floats upon the surface of the calcium nitrate solution. The phenol should not be in larger excess than is required to give a layer a few millimetres thick. Distilled water saturated with phenol is carefully poured above the two layers of liquid in the cylinder. The water floats on the surface of the phenol. The water on both sides of the phenol can traverse the partition of phenol, but the calcium nitrate cannot pass through. Hence the layer of phenol is a semipermeable membrane. Mark the level of the layer of phenol in the cylinder by means of a piece of gummed paper. If the upward motion of the layer of phenol be marked from day to day, it will be found to rise higher and higher, and finally surmount the rest of the liquid in the cylinder.

Osmotic phenomena can be obtained by continuous and by discontinuous or porous films. With continuous films it is necessary for the solvent but not for the solute to dissolve in the membrane; with porous films it is necessary for the pure solvent to be adsorbed by pores so small that only the solvent not the solute can pass through. Benzene, toluene, and pyridine were found by L. Kahlenberg to pass through a rubber membrane while water does not. Hence rubber probably acts as a semipermeable membrane to the three first-named liquids, because these liquids dissolve in the rubber.

W. Ramsay (1894) illustrates the production of an osmotic pressure in solutions by the following analogy illustrating what has been termed the osmotic pressure of gases.

> A palladium vessel at 250° to 350° is filled, at atmospheric pressure, with nitrogen gas or with some gas not absorbed by the warm palladium. This vessel is immersed in hydrogen at a given pressure; hydrogen gas diffuses through the metal membrane until the increase of pressure inside the vessel is nearly equal to the outside pressure. In one experiment, this increase was equivalent to 733 mm. of mercury, which is "regarded as the osmotic pressure of nitrogen dissolved in hydrogen." The excess pressure is independent of the concentration of the hydrogen molecules, for the pressure of the hydrogen is the same on both sides of the septum. The (osmotic) pressure of the nitrogen is produced by the bombardment of the nitrogen molecules on the walls of the vessel, while the osmosis of the solvent hydrogen is possible in virtue of its faculty of dissolving in the metal membrane under conditions where the solute nitrogen is insoluble.

In ordinary or *positive osmosis* the direction of flow of the solvent, water, is from the less towards the more concentrated solution; in some cases the direction of flow is from the more to the less concentrated solution; the phenomenon is then styled *negative or reversed osmosis.* H. Dutrochet first described osmosis with inorganic membranes, and T. Graham attributed the phenomenon to chemical interaction between the salt and the membrane. F. E. Bertel, P. Girard, and H. Freundlich attribute the anomalous effect to the electrical endosmose; the flow of liquid is brought about by a difference in electrical potential, the two ends of the capillary pores in the membrane becoming oppositely charged. Potential differences of this kind were shown to exist in animal cells by M. Oker-Blom and W. Ostwald; in frog's muscle by A. Brünings; in vegetable skins by M. Loeb and R. Beutner; in lung tissue by R. S. Lillie and P. Girard; in copper ferrocyanide membranes by R. Beutner; and in clay by A. Brünings. According to W. D. Bancroft, the sign of the electric charge on the membrane is dependent on the absorption of anions or cations. J. Perrin ascribed the polarization to contact electrification being dependent on the preponderance of $H^{\cdot}$-ions or OH'-ions. F. E. Bartel also showed that the appearance of negative osmosis is dependent on the pore diameter, for the phenomenon occurs with solutions of magnesium chloride only when the pore diameters are less than $0{\cdot}4\mu$. J. Mathieu found negative adsorption occurs with a number of dilute solutions when adsorbed by porous plates, membranes, or capillary tubes, such that the liquid adsorbed by the capillary tubes from N-solutions was often only $\frac{1}{10}N$; and he suggests that if the capillary were fine enough only pure water would be adsorbed. Summing up the literature on the subject, W. D. Bancroft says: (1) Osmotic phenomena may occur with a porous diaphragm provided we have very marked negative adsorption and provided the diameter of the pores is so small that the adsorbed films fill practically the whole of the pores. (2) A porous diaphragm will act as a semipermeable membrane in case there is no measurable adsorption of the solute and in case the adsorbed films fill the pores completely. (3) In the usual case of a semipermeable diaphragm, we do not have a porous diaphragm and the semipermeability is due to the fact that the solvent dissolves in the diaphragm while the solute does not to any appreciable extent under the conditions of the experiment. (4) A liquid is not to be considered as a porous substance and solubility does not depend on porosity. Again, A. M. C. Chanoz found that when the two sides of the membrane differ, as with a skin, differences in the osmosis are obtained depending on whether a given side of the membrane is in contact with solution A or solution B. These differences disappear, of course, when the two sides of the membrane are alike, as with parchment paper. It seems probable that the behaviour of the membrane depends largely on its greater or less permeability.

Animal membranes are objectionable when exact measurements are required, because to a certain extent the results depend upon the nature of the membrane, which is not strong enough to withstand the great pressures developed by osmosis; and, most serious of all, the membrane is not quite semipermeable, so that an appreciable amount of, say, sugar does actually pass through. It would therefore be as profitable to measure the pressure of a gas in a leaking vessel as to try to measure the osmotic pressure of a solution with a membrane which allows part of the dissolved substance to pass through. We therefore fall back on artificially prepared membranes. No artificial membrane has been so successful as a film of copper ferrocyanide deposited between the inner and outer walls of a porous earthenware pot—prepared by M. Traube,[3] and described in 1867 in his *Experimente zur Theorie der Zellenbildung und Endosmose*. The film is made by steeping a clean porous pot in an aqueous solution of potassium ferrocyanide, rinsing in water, and then submerging the pot in an aqueous solution of copper sulphate, and subsequently washing out the soluble salts. The deposition of the copper is symbolized by the equation: $2CuSO_4+K_4FeCy_6=Cu_2FeCy_6+2K_2SO_4$. The porous pot with its semipermeable membrane is fitted with a suitable manometer to indicate the pressure. In 1877, W. F. P. Pfeffer made some measurements with cells prepared in this manner. The apparatus was immersed in a large bath of water to maintain the temperature constant during the experiment. Analogous experiments were made by H. de Vries (1878), G. Tammann (1888), P. Walden (1892), etc. Earl of Berkeley and E. G. J. Hartley (1904) placed a solution of sugar in a porous earthenware pot with a semipermeable membrane of cupric ferrocyanide, and surrounded the pot with water. The pressure on the solution was increased until it was just sufficient to prevent the passage of water into or out of the cell through the septum of the ferrocyanide. H. N. Morse (1901–9) employed an apparatus similar to that of W. F. P. Pfeffer, but he improved the quality of the membrane by depositing the cupric ferrocyanide in the pot electrolytically; and also improved the joints between the cell and the manometer; and the manometer itself.

§ 8. The Osmotic Pressure of Dilute Solutions and the Gas Laws

> Every formula obtained by the application of thermodynamical considerations alone to a mixture or solution remains the same, no matter what assumptions be made regarding the molecular condition of the substances. Consequently, thermodynamics alone cannot decide whether solution is attended by a chemical change in the molecular state of the dissolved substance or otherwise.—P. DUHEM (1894).

J. H. van't Hoff's kinetic theory of osmotic pressure (1887)[1] emphasizes the analogy between the process of vaporization and the process of solution. In a solution the dissolved substance is distributed throughout the whole bulk of the solvent, and the solvent plays the part of so much space. The vapour pressure of a liquid in space will thus be represented by the osmotic pressure of a solution. In the words of A. Rosenstiehl, the osmotic pressure is analogous to the elastic force of vapours. Just as the closed space above a liquid becomes saturated with vapour, so does a solvent in contact with the solute form a saturated solution. An increase of temperature augments the vapour pressure of a liquid, and also the osmotic pressure of a solution.

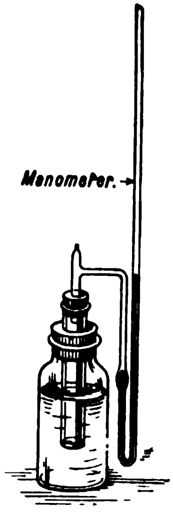

FIG. 16.—Measurement of Osmotic Pressure.

I. The relation between osmotic pressure and the concentration of the solution—Boyle's law.—W. Pfeffer in his *Osmotische Untersuchungen* (Leipzig, 1877) obtained some data with the apparatus which J. H. van't Hoff (1887) utilized, with remarkable cleverness, in developing what he called "the *rôle* of osmotic pressure in the analogy between solutions and gases." The experimental data showed that the osmotic pressure is very nearly proportional to the concentration of the solution; otherwise expressed, the osmotic pressure appears to depend upon the degree of crowding of the molecules of the dissolved substance. Instead of repeating Pfeffer's measurements, a selection from some later determinations with solutions of glucose (sugar) by H. N. Morse (1907) can be quoted (temperature nearly 0°, rounding off the decimals to the nearest tenth of a unit):

Concentration	0·1	0·2	0·3	0·4	0·5	0·6	1·0
Osmotic pressure	2·4	4·7	7·0	9·3	11·7	14·1	23·7 atm.
Equivalent gas pressure . .	2·2	4·5	6·7	8·9	11·1	13·4	22·3 atm.

In dealing with the concentration of solutions, it will be well to adopt the same unit of comparison as that employed in dealing with gases, *i.e.* the molecular weight of the solute expressed in grams per 22·3 litres of solution at normal temperature and pressure. H. N. Morse found that his direct measurements of osmotic pressure came out best when referred to a constant volume of the solvent, not to the volume of the solution.

Assume that a gram-molecule of glucose (180) were it a gas would occupy 22·3 litres. Hence, 0·1 gram-molecule will occupy 2·23 litres. By choosing the concentration so that in Boyle's relation, $PV=\text{constant}$, a solution containing a molecular weight expressed in grams, per 22·3 litres, has a concentration of 22·3 units when $P=1$, we get from Boyle's law $P\div C=22{\cdot}3$. The concentration, it will be remembered, is inversely proportional to the volume. Hence for a concentration 0·1, we get $P=2{\cdot}23$, for $C=0{\cdot}2$, $p=4{\cdot}46$, etc.

The "equivalent gas pressure" is here calculated on the assumption that a "sugar gas" obeying Boyle's law really exists. The results are plotted in Fig. 17. The deviation of the osmotic pressure curve from the dotted curve emphasizes the fact that the deviations of the osmotic from the equivalent "gas pressures" grow larger with increasing concentrations, and hence **exact proportionality occurs only when the solutions are very dilute.** For dilute solutions, the osmotic pressure is nearly proportional to the concentration, or, as W. Ostwald puts it, "the osmotic pressure of a sugar solution has the same value as the pressure the sugar would exert if it were contained, *as a gas*, in the volume occupied by the solution—of course assuming Avogadro's rule." This is another way of saying that the relation between the osmotic pressure of a solution and its concentration has the same form as Boyle's law for gases.

The analogy does not work out so well for concentrated solutions as with dilute solutions—possibly owing to the disturbing effects of overcrowding produced by: (1) molecular attraction between the molecules of the dissolved substance; (2) the volumes of the molecules themselves. The two effects for gases were discussed when dealing with Boyle's law for gases. J. D. van der Waals' corrections for the gas equation $pv=RT$, involves the introduction of terms for the mutual attraction of like molecules and for the space occupied by the molecules, and the corrected equation takes the form $(p+a/v^2)(v-b)=RT$, and by regarding v in the equation $pv=RT$ as the volume of the solvent not of the solution, H. N. Morse really corrected the equation for the space occupied by the molecules of the solute as J. D. van der Waals' did for gases. And (3) the mutual attraction between the molecules of the solute and solvent. On account of the enormous number of molecules of the solvent which are present, each molecule of the solute is probably completely surrounded by molecules of the solvent, and the resultant of all the forces due to the solvent, acting upon each molecule of the solute, is zero. The velocity of the solute molecules impinging on the semipermeable membrane is not affected provided the solution is so dilute that the difference in the concentration of the molecules of the solvent on the two sides of the membrane is negligibly small. O. Stern diminishes the factor a of J. D. van der Waals' equation by a factor $a_{12}(x_0-x)$, expressing the attraction between the molecules of solvent and solute which, so far as osmotic pressure is concerned, acts in the opposite direction to the attraction a_1 between the molecules of the solute itself, for this attraction pulls the molecules of the solute away from the solvent. The term x_0-x represents the difference between the concentration of the solvent outside the membrane and in the solution itself. The term b of J. D. van der Waals' equation is also increased by a factor $b_{12}(x_0-x)$, because the repulsive force b_{12} between the molecules of solvent and solute which makes the solute behave as if the molecular volume b_1 of the solute is smaller than it really is. O. Stern's equation is then:

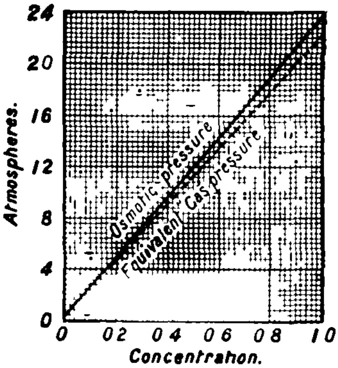

Fig. 17.—Osmotic Pressure and Concentration.

$$\left(P+\frac{a_1-a_{12}(x_0-x)}{v^2}\right)\{V-b_1+b_{12}(x_0-x)\}=RT$$

There are thus four constants in the equation, and since the new constants have to be evaluated from the experimental data, better agreement is to be expected than with an equation including two constants. If two miscible liquids with critical states not very far removed from one another be under investigation, a_{12} and b_{12} are of the same order of magnitude as a_1 and b_1. The difference between the concentrations of the pure solvent and that which it has in solution is nearly identical with the concentration of the solute, then $(x_0-x)/v$ will be nearly $1/v$, the concentration of the solute; the term x_0-x then cancels out, so also do the terms involving a and b, and the gas in solution will then obey the ideal gas law more nearly than it does in the gaseous state, as O. Stern found to be the case with solutions of carbon dioxide in methyl and ethyl alcohols.

2. The relation between osmotic pressure and temperature.—Charles' law.—W. F. P. Pfeffer's measurements on the influence of temperature also showed that the osmotic pressure is proportional to the absolute temperature, which means that the relation between the osmotic pressure and temperature of a given solution has a formal analogy with Charles' law for gases. In illustration, some results by H. N. Morse (1911) for unit concentration may be quoted:

Temperature . . .	0°	5°	10°	15°	20°	25°
Osmotic pressure . .	24·8	25·3	25·7	26·2	26·6	27·0 atm.
Equivalent gas pressure .	22·2	23·0	23·4	23·8	24·2	24·5 ,,

The "equivalent gas pressure" is here calculated on the assumption that a "sugar gas" obeying Charles' law really exists. These numbers are plotted in Fig. 18, and the graphs show the proportionality between osmotic pressure, P, and temperature; P/T=constant. The space between the two curves represents the deviation of the observed osmotic pressure, from the pressure calculated on the assumption that the dissolved substance behaves as if it were a gas. W. F. Magie has also studied the relation between osmotic pressure and temperature.

An experiment due to C. Ludwig (1856) and investigated by C. Soret (1881)[2] —Soret's phenomenon—may be cited in illustration of the applicability of the gas laws to dilute solutions. If a solution be kept at one uniform temperature, it will in time become homogeneous; on the contrary, C. Soret showed that if the two ends of a tube containing a homogeneous solution be kept at different temperatures, the concentration of the solution at the cooler end will increase, and decrease at the warmer end. The warmer solution becomes more dilute because the osmotic pressure of the warm solution is greater than that of a cold solution; and conversely. Equilibrium will be established when the osmotic pressure in all parts of the solution is the same. If the warm end of the tube be 50° hotter than the cold end, then, if Charles' law applies to solutions, the cold solution should increase in concentration $\frac{1}{273}$rd more than the warm solution per degree difference of temperature, and hence the colder solution should be $\frac{50}{273}$rd more concentrated than the warm one. N. M. Hopkins (1905) claims to have observed a difference of 14·03 per cent. in the density of a dilute solution of copper sulphate in a tube 80° at the one end and 20° at the other when the theoretical difference by Charles' law was 14·3 per cent. The phenomenon also appears to be connected with an observation made in 1799, by N. Leblanc, to the effect that if crystals of a salt are placed some at the upper and some at the lower part of a cylinder containing a saturated solution of the same salt, the lower crystals grow larger at the expense of the upper; and likewise also the upper portion of the crystals at the bottom of a liquid decreases while the lower portion increases.

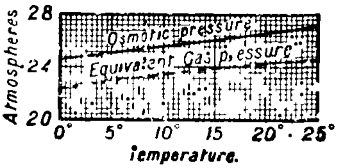

FIG. 18.—Osmotic Pressure and Temperature.

3. Avogadro's hypothesis applied to solutions.—If P denotes the osmotic pressure of a solution, and V the volume containing one gram-molecule of the solute, $PV=RT$ (where R is a constant), and for a solution of volume V containing n gram-molecules of the solute $PV=nRT$. The volume V is to be regarded as the molecular volume of the solution only when, as J. H. van't Hoff (1887) said: "the volume occupied by the molecules of the solute is negligible in comparison with the volume of the solution." Hence, at constant temperature, n molecules of a solute in unit volume of a dilute solution (for which $V=1$) have the same osmotic pressure; otherwise expressed, **equal volumes of solutions containing the same number of solute molecules have the same osmotic pressure;** and conversely, solutions, at the same temperature and the same osmotic pressure contain the same number of molecules of the dissolved substance per unit volume. There is a striking resemblance between this assumption and Avogadro's hypothesis for gases, and it harmonizes with a number of facts. The principle can be applied to measure the molecular weight of substances in solution, for the term "number of molecules" is used in the same sense as the term is used in stating Avogadro's hypothesis for gases: Equal volumes of all gases at the same temperature and pressure contain the same number of molecules; or, conversely, at any assigned temperature the pressure of a gas depends on the *number* of molecules and not on their kind. Hence van't Hoff's hypothesis assumes that *the osmotic pressure and related properties—vapour pressure, freezing point, and boiling point—of dilute solutions* (1) *depend upon the number of molecules of solute dissolved in unit volume of the solution, and are independent of* (2) *the chemical nature of the solvent and solute, and* (3) *of the relations between solvent and solute.* In contradistinction to additive properties like the specific gravity of mixtures, *colligative properties* depend merely on the relative number of molecules present and not on the kind of molecules—*e.g.* the osmotic pressure, freezing and boiling points of solutions.

Examples.—(1) An aqueous solution of 1·0047 grams of orthoboric acid per litre at 0° has an osmotic pressure of 27·3 cm. of mercury. What is the molecular weight of the acid? Since one gram-molecule of a substance in the gaseous state occupies 22·3 litres at 0° and 760 mm., we have here to find what weight of substance will occupy 22·3 litres at 0° and 760 mm., given 1·0047 gram occupy 1 litre at 0° and 273 mm. pressure. Obviously, 1·0047 gram will occupy 0·361 litre at 0° and 760 mm.; and if 0·361 litre weighs 1·0047 gram, 22·3 litres will weigh 62 grams at the same temperature and pressure. Hence the molecular weight of the given acid is 62; this agrees with the formula $B(OH)_3$ for orthoboric acid.

(2) A two per cent. solution of cane sugar has an osmotic pressure of 1016 mm. at 15°; what is the molecular weight of cane sugar? 100 c.c. at 1016 mm. pressure becomes 0·126 litres at 760 mm. pressure and 0°, and 0·126 litre corresponds with 2 grams of cane sugar. Hence 22·3 litres will have 355 grams at the same temperature and pressure. The molecular weight of cane sugar therefore approximates 355. The true number is 342 for $C_{12}H_{22}O_{11}$.

In place of using the equation $PV=RT$, K. Jellinck[3] used J. D. van der Waals' equation in his study of osmotic pressure from the kinetic point of view, and F. Tinker used C. Dieterici's equation.

There are so many experimental difficulties involved in the direct measurement of osmotic pressure that the method is rarely, if ever, employed directly for molecular weight determinations. As in the kinetic theory of gases, it can be shown, with the above assumptions, that the kinetic energy of the solute in dilute solutions is equal to that of a gas at the same temperature and pressure; and that with the same average kinetic energy, the number of impacts depends only on the concentration, and is independent of the presence of the solvent. As a corollary, too, it follows that the mutual exchange of energy at each collision, when equilibrium is established between the solvent and solute, will make the average molecular kinetic energy of solvent and solute the same. Hence, said W. Ostwald (1890),[4] the kinetic energy of the molecules of a liquid is the same as that of the molecules of a gas at the same temperature and pressure.

E. W. Washburn (1915)[5] has drawn attention to the fact that the term osmotic pressure is loosely employed to designate three quite different ideas: (1) The *osmotic pressure* of a solution is really a physical quantity and not a real pressure, and is the difference in the pressure which must be established upon solution and pure solvent in order to make the tendency of the solvent to escape as vapour the same for both; it is the difference of pressure necessary to prevent osmosis through a perfect semipermeable membrane. For dilute solutions, the osmotic pressure at the limit is equal to CRT, where C denotes the concentration of the solute. As the concentration increases, the osmotic pressure increase towards infinity, as illustrated in Fig. 19. (2) In virtue of unordered heat motions, the molecules of a solute in a solution may be considered as exerting a certain pressure, called the *thermal pressure*. For dilute solutions the thermal pressure will be equal to CRT, but as the concentration C increases, the thermal pressure increases towards a large but finite limit, as illustrated in Fig. 19. (3) The partial pressure exerted by the molecules of the solute in a solution against a membrane permeable only to the solvent is called the *diffusion pressure*. For dilute solutions the diffusion pressure is equal to CRT, and as the concentration C increases, the diffusion pressure increases to a finite definite limit whose value depends upon the temperature, pressure, and the attractive forces extended on the molecules of the solute, in the interior of the liquid. See Fig. 19.

The effect of the heat of dilution on osmotic pressure.—Describing osmosis in the language of free energy, the osmosis is attributed to the difference which exists between the free energy of the solvent and solution; and diffusion is an effect of the free energy driving the solvent from the region where the free energy is greatest to the solution where the free energy is least. The process of diffusion continues until the free energy has fallen to the value characteristic of a solution with one uniform composition. When solution and solvent are separated by a semipermeable membrane, the solvent will travel into the solution until the free energy of both is the same. The solute cannot travel through the membrane to the solvent, and therefore the system can never have one uniform composition; for equilibrium, however, the free energy of solution and solvent must be the same.

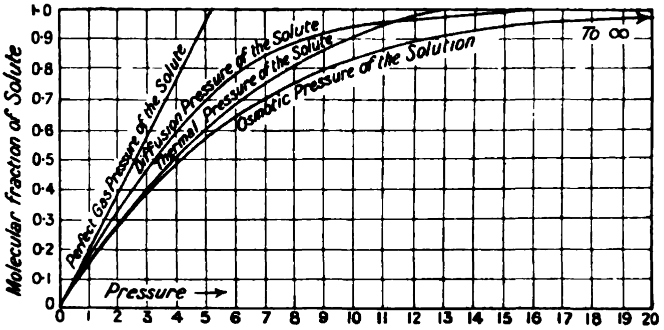

FIG. 19.—Washburn's Illustration of Solution Pressure.

The free energy of the solvent is the greater, and the free energy of the solution can be augmented only by increasing the pressure on the solution; consequently, solvent will diffuse through the membrane to the solution until the hydrostatic pressure—osmotic pressure—required to make the free energy of solvent and solution the same, is attained. The change in the free energy of an isothermal reversible process is given by the expression $W=Q+T(dW/dT)$, where Q is the heat evolved when the solution is diluted. The diminution in the free energy which occurs when a gram-molecule of the solvent passes reversibly and isothermally into a large volume of solution through a semipermeable membrane is therefore

$$PV=Q+T\frac{d(PV)}{dT}$$

where P is the osmotic pressure and V is the increase in volume. This relation represents the temperature coefficient of the osmotic pressure. If Q, the heat of dilution, is zero, the preceding expression reduces, on integration, to $PV/T=$constant, and hence $PV=RT$ is true only when the heat of dilution is zero. For all but extremely dilute solutions, Q is not constant, and the osmotic pressure cannot be calculated from $PV=RT$, but rather from $PV=RT+Q$. Before the above equation can be integrated, it is necessary to know how Q varies with temperature (say, $Q=A+BT+\ldots$). When molecular weights are calculated from the osmotic pressure or related phenomena, neglect of this factor—heat of dilution—may give quite erroneous results.

In his work on the thermodynamics of osmotic pressure, J. H. van't Hoff assumed that the solutions were so dilute that no thermal change occurred on further dilution. W. D. Bancroft (1905)[6] has shown that the osmotic pressure is abnormally high when heat is evolved on dilution, and similarly the lowering of the freezing point of such a solution will not be so great as when the heat of dilution is zero. In the case of the metals of the alkalies and alkaline earths dissolved in mercury, molecular weights equal to half the atomic weights are obtained by formulæ in which the heat of dilution is assumed to be zero; and with sulphuric acid, values ranging from 57·7 to 11·7 when the concentration of the solution ranges from 5·6 to 68·5 per cent. respectively—the anomaly of a decreasing molecular weight with increasing concentration disappears if the heats of dilution are included in the computation.

§ 9. The Relation between the Vapour Pressure of a Solution and the Molecular Weight of the Solute

> The mutual action of two liquids is observable when a mixture of say alcohol and ether is subject to experiment in the vacuum of a barometer column, for the mixture depresses the column less than either component alone.—C. L. BERTHOLLET (1803).

M. Faraday[1] knew, in 1822, that the vapour pressure of a solution is lower than the vapour pressure of the pure solvent; and C. L. Berthollet's experiment in 1803 shows that at a given temperature the vapour pressure of a solution of ether in alcohol is less than that of either ether or alcohol alone. A. Wüllner discovered the important fact experimentally, in 1858, that **the lowering of the vapour pressure of a solution is proportional to the quantity of substance in solution provided that the dissolved substance is non-volatile.** This is sometimes called **Wüllner's law.** A. Wüllner worked with aqueous solutions, but the abnormal behaviour of such solutions as a result of the extraordinary properties of water prevented him decisively demonstrating the generalization. F. M. Raoult (1887) worked with non-aqueous solutions and succeeded better than his predecessors. The phenomenon can be illustrated by introducing about 2 c.c. of water, 2 c.c. of a 2 per cent. solution of potassium iodide, and 2 c.c. of a 4 per cent. solution of the same salt into the Torricellian vacuum of each of three barometer tubes mounted within a hot jacket. The more concentrated solutions will depress the mercury most, the less concentrated solution will depress the mercury more than water alone, but less than the more concentrated solution. Some observed values[2] of the difference between the vapour pressures of water and of solutions containing *w* grams of potassium iodide, KI, in 100 grams of water are:

	10·33	30·71	54·75	71·54	111·14	134·93	169·14	200·25
w . .	15·6	47·6	91·0	21·7	191·3	231·6	283·4	321·3

W. W. Reed (1913) has an experiment to show the lowering of the vapour pressure of a solution. Three similar thermometers are arranged like the two in a wet-and-dry bulb hygrometer. The wick of one bulb dips in the given solution. The thermometer with the wick dipping in the pure solvent reads lower than the one with its wick dipping in the solution, and both read lower than the dry-bulb thermometer.

Suppose a solution *A*, Fig. 20, confined in a long-stemmed tube, as illustrated in the diagram, be separated by a semipermeable membrane *M* from the pure solvent. Let all be confined in a closed vessel. Osmotic pressure will force the solution to rise in the narrow tube to a height *h*, until the whole system is in equilibrium. Let p_s denote the vapour pressure of the solution in the narrow tube, and *p* the vapour pressure of the pure solvent in the outer vessel. The vapour pressure of the solution at the surface in the narrow tube must be equal to the vapour pressure of the solvent at the same level, otherwise distillation would take place either to or from the surface of the liquid in the narrow tube. In either case, there would be a constant flow of liquid respectively to or from the vessel *A* through the semipermeable membrane in order that *h* may have a constant value. Otherwise expressed, perpetual motion would occur. By the law of excluded perpetual motion this is not possible, hence the vapour pressure of solution and solvent at the upper level of the solution in the narrow tube must be the same. The vapour pressure of the solvent at the level *a* will be equal to the vapour pressure of the solvent at the lower level *b*, less the pressure of a column of vapour of height *h* per unit area. Hence, the hydrostatic pressure of the *liquid* column *h* measures the osmotic pressure; and the hydrostatic pressure of the *vapour* column *h*, measures the difference in the vapour pressure of solution and solvent. Since the height *h* is determined by the osmotic pressure, which, in turn, is determined by the concentration of the solution, there must be **a simple proportionality between the osmotic pressure or concentration of the solution and the lowering of the vapour pressure** $(p-p_s)$, for the vapour of the solution will be in equilibrium with the vapour of the solvent at such a height *h* above the surface of the solvent, that the hydrostatic (osmotic) pressure of the column of liquid will make the vapour pressure of the solution equal to that of the solvent, so that the height *h* measures the lowering of the vapour pressure, $p-p_s$, and also the osmotic pressure, *P*.

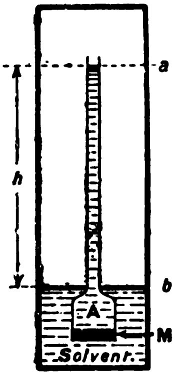

FIG. 20. — Diagrammatic.

If the tube *h* has unit sectional area, $p-p_s : P =$ Weight of column of vapour : Weight of equal column of liquid; or, if *w* and *W* respectively denote the weights of columns of solution and vapour of height *h*, and unit sectional area, then, $p-p_s : P = W : w$. Let one gram-molecule *M* of vapour occupy a volume *v*, and let *V* denote the volume of the solution also containing a gram-molecule of the solute, then $pv = PV$ for dilute solutions, and hence, $v = VP/p$, or the volume occupied by a gram-molecule of the vapour is P/p times the volume of the solution containing a gram-molecule of the solute. A volume *v* of the vapour containing a gram-molecule of the solvent will weigh *M* grams, or $W = M$. If *n* gram-molecules of the solute are dissolved in *N* gram-molecules of the solvent, a volume *V* of the solution containing one gram-molecule of the solute will weigh MN/n grams, and a volume v or VP/p of the solution will weigh $w=PMN/np$ grams. Substituting these values of w and W in the above proportion, and reducing the resulting expression to its simplest terms, there remains :

$$\frac{p-p_s}{p}=\frac{n}{N}$$

In concentrated solutions when n, the number of molecules of the solute, is equal to N, the number of molecules of the solvent, $n=N$, and p_s/p is zero, which is impossible, because the vapour pressure of a concentrated solution will always have some numerical value. F. M. Raoult therefore changed the preceding expression to

$$\frac{p-p_s}{p}=\frac{n}{N+n} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where n denotes the number of gram-molecules of the solute, and N the total number of gram-molecules of solvent. In words, the relative lowering of the vapour pressure of a dilute solution is proportional to the relative number of molecules of the solute and solvent. F. M. Raoult[3] found this rule valid for dilute solutions—**Raoult's vapour pressure law**—and for more concentrated solutions $(p-p_s)/p=kn/(N+n)$ represented the results more exactly.

Instead of starting from J. H. van't Hoff's rule applicable to dilute solutions, G. N. Lewis[4] argues that the results are incompatible with solutions of finite concentration, and he prefers to start from Raoult's law, which is the only law of dilute solutions which ever holds in concentrated solutions. He therefore defines a perfect solution as one which follows this rule : At a constant temperature the vapour pressure of the solvent is proportional to its molecular fraction $n/(N+n)$. Thus, a solution which contains $n=0{\cdot}1$ gram-molecule of the solute and $N=0{\cdot}9$ gram-molecule of solvent, $n/(N+n)=0{\cdot}9$; and the vapour pressure of the solvent p should be nine-tenths of the vapour pressure in the pure state. It is assumed that concentrated solutions which deviate very much from this rule are those in which solvent and solute form complex compounds either with themselves or with one another. From this relation it is then possible to deduce expressions for the osmotic pressure and related properties of solutions by the regular methods of thermodynamics. It will be observed that Raoult's rule reduces to Henry's law when applied to gases when the concentration is expressed as a molecular fraction $n/(N+n)$. Henry's law is symbolized $p=Kn/(N+n)$, where the constant K is the vapour pressure of the pure gas, for $p=K$, if the amount N of the solvent is zero.

The relation between the relative lowering of the vapour pressure and the osmotic pressure.—A relation between the osmotic pressure and the vapour pressure was deduced by J. H. van't Hoff in 1886, and the demonstration was improved in 1889 by S. Arrhenius.[5] Many other modifications have been suggested. Let p denote the vapour pressure of water, and p_s that of the solution. S. Arrhenius found the osmotic pressure, P, to be

$$P=\frac{sp}{u}\log\frac{p}{p_s}$$

where u is the specific volume of the solution, s the specific volume of the vapour of the solvent at the pressure p. W. Spens obtained a somewhat similar expression with u representing the increment in volume of a large mass of solution when unit mass of solvent is added ; and Earl of Berkeley and E. G. J. Hartley with u representing the specific volume of the solvent. A. W. Porter, J. E. Trevor, J. J. van Laar, H. Boldingh, G. N. Lewis, E. W. Washburn, and H. L. Callendar have also deduced expressions for the relation between the vapour pressure and osmotic pressure of solutions.

In the demonstration that $(p-p_s)/p=n/N$, the molecular weight of the solvent is assumed to be the same in vapour and in solution. If n represents the number of molecules of the solute of molecular weight m, then $n=w/m$, where w denotes the weight of the n molecules; similarly, $N=W/M$, where W denotes the weight of N molecules of the solvent. Substitute these values of n and N in $(p-p_s)/p=n/N$, and solve for m; there remains $m=wMp/W(p-p_s)$. Let $W=100$ grams, then for any given solvent the constant Mp/W can be represented by k. Consequently, if w denotes the weight of substance in grams dissolved in 100 grams of solvent, and if p' denotes the resultant lowering in the vapour pressure of the solvent $p-p_s=p'$, the molecular weight of the solute in dilute solution is:

$$\text{Molecular weight}=k\frac{w}{p'}, \quad . \quad . \quad . \quad . \quad (2)$$

where k is the so-called **vapour pressure constant** whose numerical value depends upon the particular solvent used; k therefore represents the diminution in the vapour pressure which occurs on dissolving one gram-molecule of the solute in 100 grams of the solvent.

EXAMPLES.—(1) A solution of iodine in ether showed a difference of $p'=7{\cdot}4$ cm. at 15° in the levels of the mercury in the two legs of the differential manometer. The solution contained $w=7{\cdot}139$ grms. of iodine per 100 grms. of ether. The value of k—the reduction in the vapour pressure produced by one gram of the solute in 100 grms. of solvent—for ether at 15° is 260. Hence, from formula (1), $260\times7{\cdot}139\div7{\cdot}4=250$. Theory gives $I_2=254$.

(2) A solution containing the equivalent of 7·435 grms. of sulphur per 100 grms. of carbon disulphide lowered the vapour pressure 4·9 cm. The constant for carbon disulphide at 15° is 171·5. Hence, the molecular weight of sulphur under the conditions of the experiment is 260·2. Theory for $S_8=256$.

The method for determining the molecular weight of a substance from direct measurements of the lowering of the vapour pressure is of great theoretical interest, but in practice it is seldom employed, because some of the related properties of solutions are more amenable to measurement—freezing point, boiling point, etc.

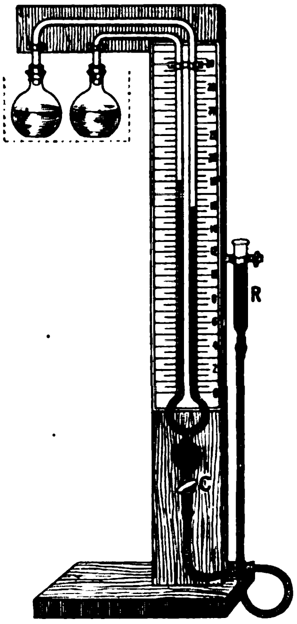

FIG. 21. — Vapour Pressure Method of estimating Molecular Weights.

The practical methods for determining the lowering of the vapour pressure of a solvent are classed as: (i) dynamical, or (ii) statical.[6] W. Ostwald's dynamical process (1891) consists in determining the lowering of the vapour pressure from the ratio of the loss of weight of the solvent to the gain in weight of an absorption bulb when a slow current of air is passed in order through solution, solvent, and absorption bulb. The barometric vacuum process—Fig. 21—is a statical process.

The following modification is one of the most convenient forms of the statical process: Two small c.c. flasks are fitted to a differential manometer, as illustrated in Fig. 21. One flask contains the pure solvent, and the other a known weight of the solute—say from 2 to 4 grms.—and three-fourths filled with solvent. Each flask is heated by placing it in a beaker containing warm water so that the vapour of the solvent can sweep air out of the system *viâ* the three-way cock C. When all the air is expelled, the stopcock is put in communication with the flask and both flasks allowed to cool to any desired temperature by placing them in a suitable bath. The difference in the levels of the mercury in the two tubes is measured. The reservoir of mercury is again adjusted until the level of the mercury in the bulb is below the stopcock; and the flask containing the solution is weighed. Other manipulation details should be obvious. The subsequent procedure can best be illustrated by example.

The methods used in hydrometry to determine the pressure of aqueous vapour in the air, and the relation between this pressure and that of saturated water vapour at the same temperature can be employed to measure the vapour pressures of solutions and solvent (G. Guglielmo, 1901); vapour pressures can also be determined from the rate of evaporation of solutions (H Kronberg, 1893).[7]

The osmotic pressure of solutions of any concentration.—Just as the attempts to adapt the relation $pv=RT$ to gases has led to about fifty more or less unsatisfactory modifications of the formula, so the attempt to adapt the gas equation $pv=RT$ to concentrated solutions has led to quite a number of tentative equations some of which are modelled after J. D. van der Waals' well-known gas equation. While the law holds good for very dilute solutions in which there is no polymerization, dissociation, or formation of complexes, yet it can be regarded only as a limiting law which is approached as the solution becomes more and more dilute, and it results from an unknown general equation by omitting certain terms which become negligibly small as dilution increases. Accordingly E. W. Washburn (1910)[8] has attempted to reconstruct this equation in the following manner. For dilute solutions, $PV_s=nRT$, where V_s denotes the volume of the solution. If N gram-molecules of the solvent have n gram-molecules of the solute in solution and the molecular volume of the solvent is V, $V_s=NV$; consequently, $NPV=nRT$. If the composition of the solution be expressed as a gram-molecular fraction of the solute such that n' represents the molecular fraction of the solute and N' that of the solvent, $n'+N'=1$; $n=n'/(N'+n')$; and $N=N'/(N'+n')$; hence, it follows that

$$P=\frac{RT}{V}\cdot\frac{n'}{N'}$$

This relation is true only at the limit to which the osmotic pressure approaches when the concentration of the solution approaches zero. Hence, by differentiation, $dn'+dN'=0$, and $dn'=-dN'$; accordingly

$$dP=\left(\frac{RT}{V}\right)\left(\frac{-dN'}{N'}\right)$$

which means that the addition of dN' molecules of a solute to a solvent raises the osmotic pressure dP. If the molecular volume of the pure solvent be V_0, under a standard pressure, and if a is the coefficient of the compressibility, $V=V_0(1+aP)$, and integration of the above equation furnishes

$$P+\left(\frac{aP^2}{2}\right)=-\frac{RT}{V_0}\log(1-N')$$

which resembles J. J. von Laar's equation, and represents the osmotic pressure of solutions for all concentrations. The relations between osmotic pressure and vapour pressure, boiling point, and freezing point can be derived from this equation in the usual way. For dilute solutions, if a be very small, the solution can be assumed to be incompressible, without committing sensible error; and if N' be small log $(1-N')$ will be virtually equivalent to N'; and consequently, $P=-N'RT/V$. A deduction from this equation has been tested, with satisfactory results, by J. von Zawidzky (1900) for concentrations ranging from zero to infinity for over a dozen different binary mixtures.

G. F. Fitzgerald (1896)[9] has pointed out that the kinetic theory of evaporation describes the lowering of the vapour pressure of a solution in this manner: The presence of non-volatile molecules of the solute at the surface of the solution hinders the egress, but does not prevent, or possibly facilitates, the return of the volatile molecules. The gas-analogy hypothesis of osmotic pressure assumes that the presence of a body in solution produces no effect or the same effect on the ingress or egress of the molecules of the solute, for the surface of a liquid with a non-volatile solute is a perfect semipermeable membrane—water molecules can pass through the surface freely, but the molecules of the solute cannot. It is a remarkable coincidence that with dilute solutions the osmotic pressure is roughly the same as that which would be produced by the molecules of the solute if it were in the gaseous state, but, as previously indicated, the dynamical theory of the two must be intrinsically different.

§ 10. Distillation

It is rather curious that the solvent can usually be evaporated from a solution of a non-volatile solid without any of the latter passing away. If the molecules of the solute are moving freely among the molecules of the solvent, it is difficult to understand clearly why the former do not escape from the surface of the solution at a rate which is comparable with the escape of the molecules of the solvent. According to the hydrate theory, the molecules of the solute are loaded with the molecules of the solvent, and this prevents the former from moving fast enough to escape from the attraction of the molecules of the liquid. Of course, most solids are not volatile at the temperature the solutions are evaporated, and the act of solution implies that the attraction of the molecules of the solute for one another is less than the attraction of the molecules of the solvent for those of the solute. It has been argued that the non-volatility of the original solid implies that its molecules are retained by the attraction of the molecules of the solvent so as to prevent the vaporization of the solute along with the free solvent. When a mixture of two liquids is boiling in a retort, their joint vapour pressure will be equal to the barometric pressure, and the boiling point of each liquid will be lower than its boiling point under atmospheric pressure because the partial pressure of each liquid must be lower than the total pressure. Consequently, each substance will behave as if it were being distilled under a reduced pressure, and will volatilize at a lower temperature than its boiling point under atmospheric pressure. In illustration, ammonium chloride or boric acid volatilizes much more rapidly in a current of steam than when alone, and hence these substances are carried off the rising vapour when aqueous solutions are evaporated. J. L. Gay Lussac (1832) [1] showed that if p_1 and d_1 respectively denote the partial pressure and vapour density of the liquid, and p_2 and d_2 the corresponding constants for the other component of the mixture to be distilled, then the relative quantities of the two liquids which distil over are related as

$$\frac{\text{Quantity of substance 2 in distillate}}{\text{Quantity of substance 1 in distillate}}=\frac{p_2d_2}{p_1d_1}$$

If this ratio be large, the distillation of the required substance will be rapid, and conversely, if this ratio be small.

EXAMPLE.—A. Naumann (1877–79) applied Gay Lussac's law to mixtures of immiscible liquids. He showed that a mixture of water and nitrobenzene boils at 99° under atmospheric pressure. The vapour pressure of water at this temperature is 733 mm. and its vapour density is 18; while the vapour density of nitrobenzene is 123. Hence, the vapour pressure of nitrobenzene at 99° is $760-733=27$ mm. Here $p_1=733$; $d_1=18$; $p_2=27$; and $d_2=123$, and the proportion of water to nitrobenzene in the distillate is as 13194 : 3328, or nearly as 4 : 1.

The composition of the vapour formed by the evaporation of the mixture of two liquids depends on the proportion in which the two components are contained in the mixture, and on the vapour pressures of these components at the temperature at which the evaporation occurs. The total vapour pressure of a mixture of completely miscible liquids depends upon (1) The relative solubilities of the vapours in the unlike components of the liquid mixtures; (2) on the relative attraction between like and unlike molecules; and consequently also on (3) the relative proportions of the components of the mixture. If the attraction of the unlike molecules of solvent and solute for one another be negligibly small, the two substances will appear to be insoluble in one another; consequently, the vapour of the one liquid will not dissolve in the other liquid. The greater the attraction of the unlike molecules for one another, the greater will be the solubility of the one in the other. In the case of two immiscible liquids, each exerts its own characteristic vapour pressure independently of the other, although, if one liquid be covered by a deep layer of the other, the lower liquid may take some time to develop its equilibrium pressure—unless the mixture is agitated so as to bring the heavy liquid to the surface and thus facilitate vaporization. In the case of consolute liquids—*i.e.* liquids which can be mixed in all proportions—if the mutual attraction of the unlike molecules be not much in excess of that needed to produce complete miscibility, the vapour pressure may be less than the sum of that of the components, but greater than either one taken singly; while if this attraction be relatively large, the vapour pressure may be less than that of either component. When the mutual attractions of the like and unlike molecules of two consolute liquids are nearly the same the relation between the vapour pressure of the mixture and its composition is comparatively simple, and can be represented by a straight line.

C. L. Speyers (1900) [2] supposed that the total pressure P of a mixture of two liquids, 1 and 2, is related to m, the percentage molecular composition, by $100P=mp_1+(100-m)p_2$, where p_1 and p_2 respectively denote the vapour pressures of the two liquids. This expression resembles one previously obtained by F. Guthrie (1884) when the percentage weights were employed in place of molecular proportions. This is probably the case with closely related compounds—*e.g.*, chloro- and bromo-benzene—where admixture is attended neither by any measurable change in volume, nor by any evolution or absorption of heat. Let a_{12} represent the attraction of unlike molecules, and a_1 and a_2 the mutual attractions of like molecules of the liquid 1 and 2. B. Galitzine (1890) assumed that the relation $a_{12}=\sqrt{a_1a_2}$ will probably obtain when there is no appreciable alteration of temperature or volume when the liquids are mixed in equimolecular proportions. C. L. Speyers' rule does not apply to many mixtures of normal liquids—*e.g.* carbon tetrachloride and benzene—but, according to J. D. van der Waals (1900), it should hold good for liquids whose critical pressures are equal, and whose molecular attractions agree with Galitzine's relation $a_{12}=\sqrt{a_1a_2}$. S. Young (1902) tested this hypothesis for mixtures of chloro- and bromo-benzene, and found that the differences between the observed and calculated pressures were within the limits of experimental error.

EXAMPLE.—The molecular proportion of a mixture of bromo-benzene mixed with chloro-benzene is 50 per cent., while the vapour pressure, p_1, of the former is 526·25 mm., and of the latter, p_2, 992·30 mm. Hence, $P=\{50\times326{\cdot}25+(100-50)992{\cdot}30\}\div100=759{\cdot}4$ mm.; the observed value was 760 mm.

P. Duhem (1887),[3] M. Margules (1895), and others have shown that the relation between the composition and the vapour pressures of the components of a mixture of two liquids, 1 and 2, can be represented by an expression equivalent to

$$\frac{d(\log p_1)}{1-x}+\frac{d(\log p_2)}{x}=0$$

where x and $1-x$ represent the respective molecular proportions of the components of the mixture, such that if n_1 and n_2 respectively denote the number of gram-molecules of the liquids 1 and 2, in the mixture, $x=n_1$ divided by n_1+n_2, and $1-x=n_2$ divided by n_1+n_2. It is assumed that the molecular weights of each liquid is the same in the gaseous and liquid state of aggregation, and that the vapours obey the ideal gas laws. The above equation—sometimes called **Duhem and Margules' equation**—can be translated into a number of different though equivalent forms, *e.g.*

$$\frac{dp_1}{dx}\left(\frac{x}{p_1}\right)=-\frac{dp_2}{dx}\left(\frac{1-x}{p_2}\right)$$

When one liquid, say 2, is present in large excess, the partial pressure p_1 of the other liquid will follow Henry's law approximately, so that $p_1/x=\text{constant}=dp_1/dx$, or $(dp_1/dx)(x/p_1)=1$, and graphically, the variations of x and p_1 will be represented by a straight line; it also follows that the partial pressure curve of the other substance will be represented by a curve of the same type. The value of p_1/x may be expected to increase or decrease continuously as x changes in value from zero to unity when it becomes equal to the vapour pressure of the pure liquid. Thus, for binary mixtures of consolute liquids the vapour pressure curve of the one component will be represented by a straight line—Type II, Fig. 22—or by a curve showing a minimum—Type I—or a maximum—Type III—value. There are no sharp lines of demarcation between the three types; representatives with every degree of curvature between the two extreme maximal and minimal curves are known, with the straight line as a special case. If the two substances are not miscible in all proportions, the partial pressure curve assumes the form Type IV shown in Fig. 22, and in the region of immiscibility, when the solution separates into two layers corresponding in composition and vapour pressure with the points a and b, each of the two layers has the same partial pressure. More complicated variations of each of these types of curve are known.

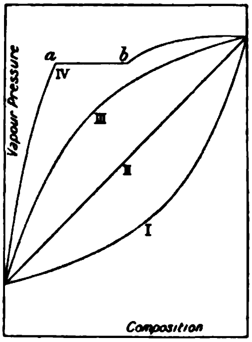

FIG. 22. — Diagrammatic Relations between the Vapour Pressure and Composition of Binary Mixtures.

The total vapour pressure P of a binary mixture is, according to Dalton's partial pressure law, $P=p_1+p_2$, and hence, by differentiation $dp_1/dx=dP/dx-dp_2/dx$. Substituting this value of dp_1/dx in equation (2), it follows that the variation of the total pressure with composition will be represented by

$$\frac{dP}{dx}=-\frac{dp_2}{dx}\left(1-\frac{p_1}{p_2}\frac{1-x}{x}\right)$$

and the vapour pressure P will be a maximum or a minimum when $dP/dx=0$, as is the case in the region between a and b, Fig. 22, or else when $p_1/p_2=x/(1-x)$. The last condition is satisfied by mixtures with a constant boiling point; and for consolute liquids it also follows that there can be one and only one maximum or minimum.

The vapour pressure curves of consolute liquids shown in Fig. 22, are related with the general phenomena of distillation. The vapour pressure curve III with a maximum vapour pressure corresponds with a curve with a minimum boiling point, while the vapour pressure curve I with a minimum corresponds with a mixture showing a maximum boiling point. In general, the distillation of a binary mixture furnishes a distillate which is richer in the more volatile constituent, and a residue in the retort which is richer in the less volatile constituent. There are, however, three cases:

During distillation, the boiling point of the liquid steadily rises. This corresponds with the curve II, Fig. 22, and is illustrated by mixtures of methyl alcohol and water, or of liquid oxygen and nitrogen. The vapour pressure of such mixtures steadily falls during the progress of the distillation, and the vapour pressures and boiling points of all possible mixtures lie between those of the two single constituents. The vapour must, therefore, be always richer than the liquid in the more volatile constituent. By repeated distillation of the distillate, an almost perfect separation of the two liquids can be effected into distillate (more volatile) and residuum (less volatile constituent)—provided, of course, that their boiling points be not too close together.

During distillation, the boiling point of the liquid rises to a maximum corresponding with the minimum vapour pressure. This is typified by curve I, Fig. 22. H. E. Roscoe (1861–2) showed that with aqueous solutions of hydrochloric, hydrobromic, hydriodic, sulphuric, nitric, or perchloric acid, there is a certain mixture which has a higher boiling point than any other mixture. The case of hydrochloric acid was studied by A. Bineau much earlier—1838. He found that if hydrochloric acid with less than about 20·24 per cent. of hydrogen chloride be distilled, water will accumulate in the distillate until the liquid in the retort has 20·24 per cent. hydrogen chloride. Such a mixture will distil over unchanged. If the concentration of the liquid being distilled be greater than about 20·24 per cent. hydrogen chloride, acid will accumulate in the distillate until the residue has 20·24 per cent. hydrogen chloride, and after that an acid of this composition will distil over unchanged. The boiling-point curves of aqueous solutions of formic acid and of hydrazine also show maxima corresponding with distillates of constant composition. The residue in the retort will always have a composition corresponding with a minimum vapour pressure, that is, with the least volatile mixture.

During distillation the boiling point of the liquid falls to a minimum corresponding with the maximum vapour pressure. This corresponds with curve III, Fig. 22. Examples occur with mixtures of propyl alcohol and water. A. A. Noyes and R. R. Warfel (1901)[4] also found a mixture of 4·43 per cent. of water with ethyl alcohol boils at 78·15°, while ethyl alcohol alone boils at 78·3° and water at 100°. The particular liquid with a maximum vapour pressure has a minimum boiling point. Whatever the concentration of the original liquid there is a tendency for the more volatile mixture with the minimum boiling point to distil first.

In neither of these two latter cases can one component be made to accumulate in distillate or in the residue in the retort so that a separation is as complete as in the first case—*e.g.* aqueous solutions of ethyl alcohol can be obtained with no more than about 96 per cent. of alcohol.

W. Ostwald (1904)[5] used the term **hylotropic mixture** (ὕλη, matter; τροπῶς, form) for a body which retains the same composition and the same properties when it changes from one phase to another—*e.g.* when a substance changes its state of aggregation. J. Wade and R. W. Merriman (1911) proposed the term **azeotropic mixtures** (α, not; ζέω, to boil; τροπῶς, form) instead of the phrase "mixture of maximum or minimum boiling point." An azeotrope resembles a chemical individual in boiling without undergoing a change in composition, but differs from it in losing this character when the pressure is altered. If the composition is independent of the pressure and therefore of the temperature, the hylotrope is a *chemical individual.* Hence, a chemical individual is a body which can form hylotropic phases within finite ranges of temperature or pressure. When these limits are exceeded, and the substance begins to dissociate, it is a chemical compound; and if there are no known limits to the range of existence, the body is an *element*.

§ 11. Other Hypotheses explaining Osmosis

The substitution of analogy for fact is the bane of chemical philosophy; the legitimate use of analogy is to connect facts together and to guide to new experiments.—H. DAVY.

Vague similarities on certain properties are never sufficient to determine a person who earnestly seeks for truth, and is not shackled by hypotheses.—T. BERGMANN (1767).

After J. H. van't Hoff[1] had established the striking analogy between the osmotic pressure of solutions of cane sugar in water, and the elastic pressure of gases, he attacked the problem on the theoretical side, and proved that if the solution be so dilute that the mutual attractions of the molecules of the solute, and the space they occupy can be neglected, and with a perfectly semipermeable membrane, the numerical value of the osmotic pressure must be equal to the elastic pressure the solute would exert if it were in the gaseous conditions at the same temperature and pressure. The method of proof depends on a reversible cycle of operations and the second law of thermodynamics. Both J. H. van't Hoff (1890) and Lord Rayleigh (1897) based their proofs on the applicability of Henry's law, and this was considered by Lord Kelvin (1897) to be an objection. Accordingly, J. Larmor (1897) devised a proof in which the laws of the solubility of gases or possible changes in the state of molecular aggregation during solution are not involved. The thermodynamic explanation of osmotic phenomena makes no assumption as to the cause of osmosis, or how the membrane does its work, and the validity of its deductions is quite independent of all hypotheses as to the cause of the phenomena it seeks to investigate. Consequently, it throws little or no light on the mechanism of the process, and the quest for an explanation of osmotic phenomena proceeds independently of thermodynamics. There are a number of explanatory hypotheses—both physical and chemical—*sur le tapis*. The chemical hypotheses will be considered later.

The gas-analogy hypothesis of osmotic pressure.—The laws associated with the names of Boyle, Charles, Dalton, and Graham, and the hypothesis of Avogadro, are but a few of the many striking analogies subsisting between the behaviour of gases confined in a given space and substances in dilute solution. We know enough about nature to believe that if two things are exactly alike, they will behave alike under the same circumstances; but when the things compared are not quite similar, we must be prepared for discrepancies. Analogy is not proof. Had Isaac Newton measured the refractory power of native cadmium sulphide—greenockite—he would no doubt have said: "greenockite is probably an unctuous substance coagulated," and he would have been wrong. As it happened, this prognostication turned out all right with the diamond. The hypothesis that the osmotic pressure of a dilute solution is produced by the bombardment of the semi-permeable membrane by the dissolved molecules gives a very plausible interpretation of the analogy between the behaviour of dissolved molecules, and the molecules of a gas brought out by J. H. van't Hoff in 1887, but the analogy appears to break down so completely with more concentrated solutions that a number of rival hypotheses have been advanced to explain the phenomena. The principle of exhaustion compels us to investigate other hypotheses.

Solvent pressure hypothesis.—According to F. Tinker,[2] osmotic pressure is primarily a solution pressure and is not a pressure produced by the solute or dissolved substance. He says: The tendency of a liquid to diffuse is measured by its diffusion pressure, which may be defined as the bombardment pressure exerted by the liquid molecules on either side of a plane of unit area placed anywhere within the liquid. Since the absolute concentration of a solvent is reduced by the introduction of a solute, it follows, therefore, that the diffusion pressure of the solvent in a solution is always less than that in the pure solvent itself, and the osmotic pressure of the solution will be proportional to the difference between the absolute concentration of the solvent on the two sides of the membrane. It is also approximately proportional to the concentration of the solute because the latter is itself approximately equal to the difference in solvent concentration on the two sides. If now there be removed from the solution side all the solvent molecules and an equal number from the pure solvent side, the residue of solvent molecules will diffuse across the membrane as before while the solute molecules will bombard the membrane. Moreover, the pressure of the solvent residue on the one side will be equal to the pressure of the solute on the other, and both will be equal to the corresponding gas pressure since the molecules are now at distances from one another comparable to gas distances. Hence to prevent the residue of solvent from flowing across the membrane, a hydrostatic pressure equal to the gas pressure will have to be applied. The phenomenon of osmotic flow is therefore due to the residue or excess of solvent molecules on the pure solvent side. The solute molecules play an indirect part only, but they do cause a strain to be placed on the membrane which tends to rupture it. The fundamental difference between osmotic phenomena in the gaseous and solution states is that whereas the active molecules have a vacuum for a medium in the case of gases they have a liquid for a medium in the case of solutions.

Vapour pressure hypothesis.—H. L. Callendar's hypothesis [3] (1908) is one of the most satisfactory of the purely physical explanations of osmotic pressure, and it is superior, in many respects, to the gas-analogy hypothesis. H. L. Callendar's hypothesis has been tested with somewhat concentrated solutions, and wherever data are available it has been eminently successful. Experiment shows that the maximum vapour pressure of a solution can be altered in three ways: (1) by altering the temperature; (2) by varying the concentration of the solution; and (3) by altering the pressure under which the liquid itself is confined. The effect of pressure on the freezing point of water (*ON*, Fig. 9, Chapter IX) is an application of the third principle. An objection might very properly be raised to the third method of altering the vapour pressure of a liquid; it has been shown to be impossible to raise the pressure on a saturated vapour, without causing some of it to liquefy. If a vertical cylinder, provided with a piston, contains nothing but water—liquid and vapour, it is quite true that the descent of the piston will result in the condensation of water vapour until all the vapour is liquefied, and as long as water vapour is present the vapour pressure remains constant. On the contrary, if air as well as water vapour be present, it is easy to see that the volume of the air decreases, or *the pressure of the air on the surface of the liquid increases* during the descent of the piston. The water vapour still supports its own share of the total pressure up to its maximum vapour pressure, and not quite so much water vapour as before will condense, consequently the liquid under a considerable external pressure can exert a greater vapour pressure than the maximum vapour pressure under atmospheric pressure.

It has been proved experimentally that **the maximum vapour pressure of a solution under very great pressures is rather greater than the maximum**

---

vapour pressure of the same solution under atmospheric pressures (see the curve *ON*, Fig. 9, Cap. IX). Again, the vapour pressure of a solution is *less* than the vapour pressure of the pure solvent, Fig. 21. Consequently, if the pressure on a solution be sufficiently augmented, the pressure of its vapour can be made equal to the vapour pressure of the pure solvent under atmospheric pressure. This is the condition necessary in order that solution and solvent can exist side by side in equilibrium. If the vapour pressure of the solution were less than that of the pure solvent, the system would not be in equilibrium, because vapour would distil from the solvent into the solution until the vapour pressure of both were the same. Conversely, when a solution under its own osmotic pressure and the pure solvent are in equilibrium, it follows that their vapour pressures must be equal. Hence, according to H. L. Callendar: **The osmotic pressure of a solution represents the external pressure which must be applied in order to make its vapour pressure equal to that of the pure solvent.** With this hypothesis, H. L. Callendar has calculated the osmotic pressures of sugar solutions of different concentration from published vapour pressure data, and the results are in close agreement with observation:

Concentration (grams per litre)	180	300	420	540
Observed osmotic pressure (atmospheres)	14·6	26·8	44·0	67·5
Calculated osmotic pressure (atmospheres)	14·1	26·8	43·7	67·6

Hence it is inferred that **osmotic equilibrium depends upon the equality of the vapour pressure of the solution and of the pure solvent.**

The semipermeable membrane has been styled a *vapour sieve*, and likened to a partition pierced by a large number of minute capillary tubes. Suppose that the capillary tubes are not wetted by either the solvent or solution, then neither the liquid solvent nor the solution can enter the capillaries—unless the pressure on one of the liquids exceeds 100 atmospheres—although vapour can diffuse through the capillary tubes. But the vapour pressure of the solution on one side of one of the capillary tubes is less than the vapour pressure of the solvent on the other side; consequently, vapour will pass through the capillary and distil from the solvent to the solution. Hence the volume of the solution will increase, and if the solution be confined in a closed vessel, the pressure must rise and continue rising until the vapour pressure of the solvent and solute are the same. This increase is the so-called osmotic pressure of the solution.

The agreement of this expression for dilute solutions with observation does not necessarily mean that the molecules of the solute can move independently of the solvent. It is difficult to believe that the molecules of solute and solvent are independent of one another, and J. Larmor (1897) assumed that each molecule of the solute forms for itself a nidus in the solvent; that is, it sensibly influences the molecules around it up to a certain minute distance so as to form a loosely connected complex in the sense, not of chemical union, but of *physical* influence; and, if the solution be dilute, each such complex is very much the greater part of its time out of the range of influence of other complexes, an application of the principles of thermodynamics then necessitating the osmotic laws. J. H. Poynting (1896)[4] has shown that the very same expression can actually be obtained by the assumption that the molecules of the solute enter into some sort of chemical combination with the solvent. Evaporation occurs when the molecules pass through the surface of the solution with a sufficient velocity to overcome the attractions of the neighbouring molecules, and if the molecules of the non-volatile solute are each loaded with molecules of the solvent, the complexes will not pass out of the solution, and the surface of the solution may be likened to a semipermeable membrane as regards solute and solvent; accordingly, the evaporation of a solution must proceed more slowly than with the pure solvent. The complex hydrates, however, are supposed to be always as effective as the solvent molecules in entangling the particles which impinge on the surface, and accordingly condensation proceeds more rapidly than evaporation until equilibrium is established. Hence, both evaporation and condensation proceed more slowly with the solution than with the solvent. A similar state of things is supposed to prevail at the surface of a semipermeable membrane, but owing to the rigidity of the latter, the excess of " condensation " over " evaporation " gives rise to a hydrostatic pressure on the solution side which is a measure of the osmotic pressure. T. M. Lowry (1897) has shown that it is not necessary to assume, with J. H. Poynting, that the molecules of the solute are hydrated, and he shows that in virtue of the mere presence of the molecules of the solute in the surface layer of the solution, evaporation must be retarded; a molecule of the solvent rising from the interior of the solution may strike a molecule of the solute in the surface layer and rebound back into the liquid without passing through the surface into the region of the vapour; condensation is more rapid because it will proceed as if no solute were present. While T. M. Lowry's hypothesis gives a similar relation between vapour pressure as that previously obtained, J. H. Poynting's hypothesis requires that if the molecules of the solute are mono-hydrated the osmotic pressure will be doubled; etc.

Surface tension hypotheses.—M. l'Hermite (1855), S. L. Bigelow (1907), I. Traube (1904), G. Jäger (1891), and B. Moore (1894)[5] tried to explain osmotic phenomena as a result of the different surface tensions of the two liquids—solution and solvent. Let T and T_s denote the respective surface tensions of the two liquids A and B contained in vessels connected by a capillary tube of radius r so that the liquids meet in the capillary. If T be greater than T_s the skin of liquid at the surface of contact with the wall of the capillary tube will move in the direction of A with a force equivalent to $(T-T_s)2\pi r$. If the radius of the capillary be small enough to bring all the contained liquid within the range of the capillary force—as is probably the case with ordinary osmotic membranes—the whole body of liquid in the tube will be driven in the direction of A. Hence, osmosis should proceed from the region of the less to that of the greater surface tension. Hence, (1) the surface tensions of solutions obeying the other solution laws should be greater than those of the pure solvents; and (2) the surface tensions of solutions of a given substance in a given solvent should be proportional to the concentrations. I. Traube (1904) compared hundreds of measurements of surface and osmotic effects, and found one and all in agreement with the hypothesis that the motive force of osmotic phenomena is determined by a difference in the surface tensions of solution and solvent. A. Battelli and A. Stefanini (1906) showed that aqueous solutions of salicine (or of ethyl alcohol) have a less surface tension than water, and yet osmosis takes place in the direction of the solution. Hence, they, like I. Traube, ascribe osmotic phenomena to differences in the surface tensions of the liquids on the two sides of the membrane; but, unlike B. Moore and I. Traube, they consider that osmosis proceeds in the direction which lends itself best to an equalization of surface tensions. If the membrane be permeable to but one liquid, it alone will pass through; but if permeable to both, osmosis will proceed in both directions until the surface tensions are equalized. If the passage of n molecules of water will increase the surface tension of a given mass of alcohol less than the passage of n molecules of alcohol would decrease the surface tension of water, water will flow to the alcohol more rapidly than alcohol will flow to the water. Solutions with the same surface tensions have the same osmotic pressure independent of their concentration. For instance, a 1·78 per cent. solution of magnesium sulphate, and a 1·11 per cent. solution of sodium sulphate have the same surface tension, and they produce no difference in osmotic pressure when placed on each side of an osmotic cell. In conclusion, no one has yet succeeded in giving an adequate account of osmotic pressure, but that facts seem to indicate that osmotic pressure and surface tension are related in some way so that the two phenomena exhibit in many cases an interesting parallelism.

§ 12. The Relation between the Boiling Point of a Solution and the Molecular Weight of the Solute

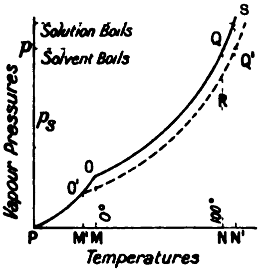

FIG. 23.—Diagrammatic.

In Fig. 23 the curve *PO* represents the vapour pressure of the solid, and *OQ* the vapour pressure of the pure liquid. The two curves intersect at the freezing point *O*. Let *Q*, Fig. 23, represent the boiling point of the solvent at 760 mm. pressure, then since the vapour pressure of a solution is less than the vapour pressure of the pure solvent, let *O'Q'* represent the vapour pressure curve of a given solution. Then *PM* will represent the freezing point of the solvent, and *PM'* the freezing point of the solution. Since *PM'* is less than *PM*, the freezing point of the solution will be less than the freezing point of the solvent ; and since *PN'* represents the boiling point of the solution and *PN* the boiling point of the solvent, the boiling point of the solution must be greater than the boiling point of the pure solvent. This agrees with experiment. For instance, with solutions of potassium iodide in 100 grams of water, G. T. Gerlach (1887)[1] found :

Boiling point . .	100°	101°	102°	103°	104°	105°
Potassium iodide .	0	15	30	45	60	74 grams.

If the solutions are very strong the relation is not quite the same, but **the raising of the boiling point of a dilute solution is directly proportional to the weight of the dissolved substance in a given weight of solvent.** Double the concentration of the solution, and the elevation of the boiling point will be doubled. An equal number of molecules of the dissolved substance in the same quantity of a solvent give the same elevation of the boiling point—F. M. Raoult (1886).[2] Hence **the rise in the boiling point of a solvent is proportional to the number of**

molecules of the dissolved substance in solution, and inversely proportional to the molecular weight of the solute.

In Fig. 23, QN and RN represent the respective vapour pressures of solvent and solution at the boiling point PN of the pure solvent; QS and RQ' represent the vapour pressure curves as the temperature rises; QQ' is parallel to the temperature axis, and represents the rise in the boiling point $NN'dT$. The solution is supposed to be dilute, and therefore there will be no sensible error if the curves be taken close together and parallel. Then $QQ'=QQ'.QS/Q'S$; or $dT=QR(Q'S/QQ')$; but $Q'R=p-p_s$; and $Q'S/QQ'=dp/dT$. Consequently, $dT=(p-p_s)dp/dT$. From Clapeyron's equation, neglecting v_2 for small differences of temperature, and putting the vapour density $D=1/v_1$ per unit mass of substance,. it follows that $dp/dT=\lambda D/T$; and from $p-p_s=PD/s$, where s denotes the specific gravity of dilute solution or solvent, and P denotes the osmotic pressure of the solution. Hence, $dT=PT/\lambda s$, where λ represents the latent heat of vaporization of the solvent. This expression shows that *the osmotic pressure is directly proportional to the rise of the boiling point.* Since P denotes the osmotic pressure of the solution containing one gram-molecule of solute in a volume V, it follows that $PV=RT$, and if the same volume of solution has n gram-molecules of the solute $PV=nRT$, or $P=nRT/V$; if the solution, of specific gravity s, contains N gram-molecules each of molecular weight M, it follows that $V=NM/s$. Remembering that R is nearly equivalent to 2 cals., substituting in $dT=PT/\lambda s$ for the values of P and V just determined; and reducing to its lowest terms, $dT=2nT^2/NM\lambda$; or, $dT=(n/N)(2T^2/M\lambda)$. As previously indicated, if $n=w/m$, and $N=100/M$, it follows that $dT=(w/m)(0{\cdot}02T^2/\lambda)$.

Let the symbol k stand for the so-called boiling constant; then, since, for any given solvent, T and λ are physical constants, the

$$\text{Boiling constant, } k=\frac{0{\cdot}02T^2}{\lambda}$$

and m, the molecular weight of the vapour of the solute, becomes $m=kw/b$, where b, the raising of the boiling point, has been put in place of dT. The meaning of k is obtained by assuming that one gram-molecule (w/m) of the solute—say 342 grams of cane sugar, $C_{12}H_{22}O_{11}$—is dissolved in 100 grams of the solvent, then $k=b$, and therefore k represents the elevation of the boiling point produced by dissolving one gram-molecule of a substance in 100 grams of solvent; k is called the **boiling constant**, or *the molecular elevation of the boiling point.* E. Beckmann and O. Liesche [3] have shown a number of other ways of computing the boiling constant; thus $100k=mp(dT/dp)$; $k=0{\cdot}0096MT$; $k=0{\cdot}0011089T^2/a^2$; $k=0{\cdot}004343MT(1-T/T_c)\div\log(P_c/p)$, when dT/dp represent the rise dT in the boiling point for a change dp in the vapour pressure; a^2 denotes P. Walden's specific cohesion of the solvent at the boiling point; and T_c and p_c respectively denote the critical temperature and pressure of the solvent.

EXAMPLE.—What is the molecular elevation of the boiling point of water boiling at 100°, when its latent heat of vaporization is 537 cals? Here $T=100+273$; and $k=0{\cdot}02\times(373)^2\div537=5{\cdot}18$, which is very near the observed value 5·2.

Each solvent has its own specific boiling constant: *e.g.* acetone, 16·7; benzene, 26·7; ether, 21·6; carbon disulphide, 23·5; ethyl alcohol, 11·5; chloroform. 35·6; pyridine, 30·1; etc. The boiling constant is determined by finding the boiling point of, say, water and of aqueous solutions containing 0·02, 0·06, 0·10 gram-molecules of cane sugar, and calculating the results per 342 grams of cane sugar. Suppose that w grams of a substance dissolved in 100 grams of water raised the boiling point of the water b°. Then, if M be used to denote the molecular weight of the substance, we have the proportion $w : M=b : 5$, or, for substance dissolved in water:

$$\text{Molecular weight}=5{\cdot}2\frac{w}{b} \quad . \quad . \quad . \quad . \quad (3)$$

This enables the molecular weight of many substances to be determined from their effect on the boiling point of water. The particular solvent to be used depends on the solubility of the substance under investigation. If ether is used in place of water, 5·2 must be altered to 21·6, etc. In no case must a solvent be employed which reacts chemically with the substance under examination.

EXAMPLES.—(1) E. Beckmann (1890) found that 2·0579 grams of iodine dissolved in 30·14 grams of ether raised the boiling point of the ether 0·566°. What is the molecular weight of iodine? Here, 2·0579 grams of iodine in 30·14 grams of ether correspond with $100 \times 2{\cdot}0579 \div 30{\cdot}14 = w = 6{\cdot}8278$ grams of iodine in 100 grams of the solvent. Hence, $M = 21{\cdot}6 \times 6{\cdot}8278 \div 0{\cdot}566 = 254{\cdot}6$. This corresponds with the formula I_2 when iodine has a molecular weight of 253·84. The numbers seldom, if ever, coincide, but there can be no mistake in the significance of the figures.

(2) E. Beckmann (1890) found that a solution of 1·4475 gram of phosphorus in 54·65 grams of carbon disulphide raised the boiling point 0·486°. What is the molecular weight of the phosphorus? Answer: Molecular weight, 129·16. The atomic weight of phosphorus is 31, hence the molecule of phosphorus is represented: P_4.

(3) A. Helff (1893) found that 0·2096 gram of sulphur in 17·79 grams of carbon disulphide raised the boiling point 0·107°. Hence show that the molecular weight of sulphur is probably S_8. Here $w = 1{\cdot}17$; and the molecular weight is 259. This is close to the theoretical value 256 for S_8.

(4) A solution of 3·164 grams of cupric chloride in 100 grams of alcohol raised the boiling point 0·308°. The boiling constant of alcohol is 11·5, what is the molecular weight of the solute? Answer: 134·5.

(5) L. Marchlewsky and J. Sachs (1892) analyzed Roussin's salt and found it to contain 38·29 per cent. of iron; 16·54 of sulphur; 16·70 of nitrogen; and 6·54 per cent. of water. When 0·1826 gram of the salt was dissolved in ether, the boiling point was raised 0·012°. Show that this agrees with the recognized formula of the salt: $Fe_4(NO)_7S_3K.H_2O$.

E. Beckmann's process for the determination of boiling points (1888–96).—This method of determining molecular weights has been much employed by F. M. Raoult, E. Beckmann, H. C. Jones, and many others.[4] The process is applicable only to solutes which do not give off an appreciable amount of vapour at the boiling point of the solution. The so-called Beckmann's thermometer has contributed largely to the successful application of the method. The modern forms of this instrument are sensitive to 0·001°. Great precautions must be taken to measure the temperatures accurately since a small error in the temperature readings has a large influence on the computed result.

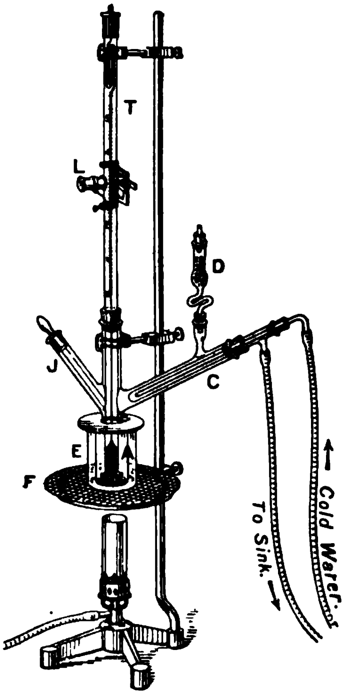

FIG. 24.—Beckmann's Apparatus for Boiling-point Determinations.

The apparatus consists of a glass boiling tube *A*, Fig. 24, with a piece of platinum wire sealed in the bottom, and packed with beads to prevent irregular boiling. A side tube with a condenser, *C*, liquefies the vapour given off during the boiling; and the exposed end of the condenser is closed with a calcium chloride tube, *D*. The boiling tube is surrounded by a jacket of some non-conducting material, *E*, to prevent the radiation of heat. The boiling tube is fitted with Beckmann's thermometer, *T*, which can be read to $\frac{1}{1000}$ of a degree, and set so that the mercury is about halfway up the stem when the solvent is boiling. Beckmann's thermometer has a reservoir of mercury at the top so that it can be set for use at any desired temperature. As indicated in text-books of laboratory processes, this avoids an inconveniently long, or an inconveniently large number of thermometers. The thermometer is always tapped before a reading to make sure the mercury is not lagging behind. The lens *L* facilitates the reading of the thermometer. The barometer should be read to make sure no appreciable change occurs during a determination.

The boiling tube has a stoppered side tube, *J*, for introducing the solutions under investigation. The whole is clamped to a stand and rests on an asbestos tray, *F*. The boiling point of the solvent is first determined. The boiling tube is weighed. The solvent is introduced and its boiling point determined when the boiling is brisk and vigorous. A known weight of the substance is then introduced, and the boiling point of the solution determined. A correction is made by subtracting 0·2 to 0·4 gram from the weight of the solvent in order to allow for the solvent condensed on to the walls of the apparatus and the condenser. The actual correction depends upon the nature of the solvent and the particular form of the apparatus used. The difficulty with this apparatus is to avoid fluctuations of temperature in the boiling tube due to the radiation of heat; dripping of the cold liquid from the condenser into the boiling solution, etc. Many other forms of apparatus for this determination have been devised.

W. Landsberger's method for the determination of boiling points (1898).—When the solution of a non-volatile solute boils, the vapour of the solvent and solution are in equilibrium, and this condition can be established by leading the vapour of the boiling solvent into the solution. When the solution is boiling, the vapour will pass through the system without condensation; if the solution is below this temperature some vapour will condense, and the latent heat of condensation will continue heating the solution until the boiling point is reached. There is virtually no danger of superheating the solution. This method of determining the boiling point of a solution has been employed with some success in molecular weight determinations.[5]

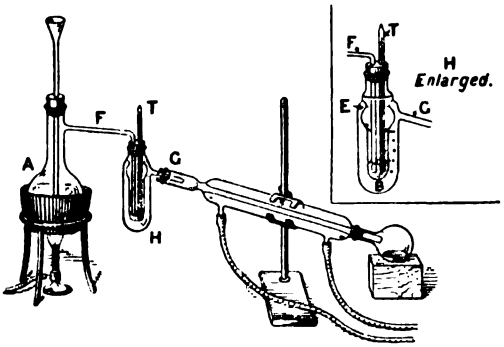

FIG. 25.—Landsberger's Apparatus for Boiling Determinations.

In W. Landsberger's apparatus, a modification of which is shown in Fig. 25, the solvent is boiled in the flask *A*, and the vapour passed into the solution *viâ* the tube *F*. The temperature of the solution is raised to its boiling point by the latent heat of condensation of the vapour of the solvent. The vapour of the solvent passes to the condenser *G* through *E* around the boiling tube, and thus the inner tube is jacketed with the vapour of the boiling solvent. This reduces radiation losses. The boiling point of the solvent is first determined, and a weighed amount of the solute is introduced into the inner tube *B*, which is graduated so that the boiling can be interrupted for a moment before more solute is added, and the volume of the solution read at a glance.

With this apparatus, **the boiling constant** for water is nearly 5·4; allowing for this, and using the preceding notation, with water as a solvent,

$$\text{Molecular weight} = 5{\cdot}4\,\frac{w}{b} \quad . \quad . \quad . \quad . \quad (4)$$

where *w* denotes the weight of the substance per 100 c.c. of the solvent, and *b* represents the elevation of the boiling point. If other solvents be used 5·4 is altered thus: for acetone (sp. gr. 1·827), 22·2; benzene (sp. gr. 0·879), 32·8; ether (sp. gr. 0·736), 30·3; carbon disulphide (sp. gr. 2·63), 26; ethyl alcohol (sp. gr. 0·80), 15·6; chloroform (sp. gr. 1·526), 26·0; aniline (sp. gr. 1·022), 38·2. If the boiling tube be weighed so that the amount of solvent is determined by weight, and not by volume, the original formula is used.

EXAMPLES.—(1) 0·8686 grm. of boric acid with 7·73 c.c. of water raised the boiling point 0·917°. What is the molecular weight of boric acid? Ansr.: 63·7. Theory for $B(OH)_3$ is 62. Show that this result is concordant with an elevation of the boiling point of 0·262° when 33·4 c.c. of water contains 1·015 grms. of the acid in question.

(2) W. Landsberger (1898) found that 0·4929 grm. of cadmium iodide with 7·30 grms. of ethyl alcohol gave a rise of 0·218° in the boiling point of the solvent. Show that this is in harmony with the theoretical molecular weight of 366 for CdI_2. The value computed from the observed data is 356.

Correction for the volatility of the solute.—The formula (3), for calculating the molecular weight of a solute from its effect on the boiling point of the solvent, is valid only when the solute does not volatilize. If the solute volatilizes along with the solvent, this formula must be replaced by

$$\text{Molecular weight}=5{\cdot}4\frac{w-w_1}{b}\text{ ; or, Molecular weight}=k(1-a)\frac{w}{b} \quad . \quad (5)$$

where w represents the number of grams of the solute in 100 grms. of the solvent, and w_1 the number of grams of the solute per 100 grms. of the vapour, and its value is obtained from the mean value of the concentration of the solute in 100 grms. of the distillate when the solution is distilled; and a represents the ratio of the concentrations of the volatile solute in the vapour and in the solution; k is the boiling constant—for water, $k=5{\cdot}4$.

EXAMPLE.—Compare the molecular weights of iodine in carbon tetrachloride and in benzene when it is found that 8·498 grms. of the distillate from iodine in carbon tetrachloride contained 0·168 grm. of iodine per 8·330 grms. of the solvent; the initial and end concentrations of the boiling solutions were 4·507 and 6·592 respectively; 0·722 grm. of iodine in 30·2 grms. of the same solvent raised the boiling point 0·315°; and the boiling constant for this solvent is 48·8. Similarly, for the solvent benzene, $a=0{\cdot}144$; boiling constant $k=25{\cdot}7$; and 1·195 grms. of iodine in 22·3 grms. of the solvent raised the boiling point 0·467°. For carbon tetrachloride, w is the mean value of 4·507, 6·592, and 5·550; w_1 is $100\times0{\cdot}168\div8{\cdot}330=2{\cdot}107$; and a is $2{\cdot}107\div5{\cdot}550=0{\cdot}36$. Again, the solution used for measuring the effect of iodine on the rise of the boiling point of carbon tetrachloride, $w=0{\cdot}722\times100\div30{\cdot}2=2{\cdot}391$, and $w/b\times48{\cdot}8=2{\cdot}391\times49{\cdot}8\div0{\cdot}315=370$. The uncorrected molecular weight of the iodine in boiling carbon tetrachloride is 370, and when corrected for the volatility of the iodine it is $370(1-a)=370\times0{\cdot}66=244$. Similarly, the uncorrected molecular weight of iodine in boiling benzene is 294, and the corrected value 252.

In the laboratory, advantage is taken of the fact that the boiling point of a solution is higher than the boiling point of the solvent to get liquids for baths, etc., boiling a few degrees higher than water, by using salt solutions in place of water. For example, a saturated solution of sodium nitrate boils at 120°, and a saturated solution of sodium chloride at about 108°.

§ 13. The Relation between the Freezing Point of a Solution and the Molecular Weight of the Solute

F. M. Raoult's method for determining the molecular weight of a substance is the most significant contribution to the list of physical processes applicable to chemical investigations since the discovery of the law of Dulong and Petit.—V. MEYER (1888).

Similar remarks apply *mutatis mutandis* to the freezing point of solutions as were made with reference to the boiling point. A study of Fig. 23 will show that if the vapour pressure of a solution is less than that of the pure solvent, the vapour pressure curve will cut the ice curve at a temperature below the freezing point of the pure solvent. This means that the freezing point of a given solution will be lower than the freezing point of the pure solvent, and experiment shows that the lowering of the freezing point will be proportional to the weight of the substance dissolved in a given weight of the solvent. This reminds us of C. Blagden's discovery (1788) that the depression in the freezing point of a solvent produced by the addition of a salt is directly proportional to the concentration of the solution; in 1861 F. Rüdorff rediscovered the law and explained certain deviations he observed by assuming that hydrates were formed; and in 1871, L. C. de Coppet found that if the quantity of salts dissolved is proportional to the molecular weight, salts of analogous constitution produced the same depression. Experiments show that an equal number of gram-molecules of different substances in the same solvent depress the freezing point to the same extent—F. M. Raoult's law (1883–84).[1] **The depression in the freezing point is proportional to the weight of the dissolved substance in a given weight of the solvent; and inversely proportional to the molecular weight of the dissolved substance.** The same law was deduced from thermodynamics by J. H. van't Hoff in 1886.[2] Solutions of sugar (342 grms.), methyl alcohol (32·03 grms.), etc., in 100 grms. of water depress the freezing point 18·5°. This is the **freezing constant** for water; Raoult called it the molecular depression of the freezing point per 100 grms. of solvent, and its numerical value for each solvent can be derived precisely like the boiling constant by substituting the latent heat of fusion for λ in place of latent heat of vaporization.

$$\text{Freezing constant } (k)=\frac{0{\cdot}02T^2}{\lambda}$$

EXAMPLES.—(1) The latent heat of fusion of water is 79 cals; hence $T=273$, and $\lambda=79$, and k is 18·9; the observed value is 18·5 (F. M. Raoult).

(2) The observed value for the freezing constant of acetic acid is 39; show that this deviates from the theoretical value by about 2 per cent. when the latent heat of fusion is 43·66 cals. The computed value is 38·2.

(3) The freezing constant or molecular lowering of the freezing point of sulphur which freezes at 119·25°, and has a latent heat of fusion 9·368, is $0{\cdot}02\times(392{\cdot}25)^2\div9{\cdot}368=328$.

Each solvent has its own specific freezing constant; *e.g.* acetic acid, 38·88°; benzene, 49°; mercury, 425°; naphthalene, 69°; phenol, 74°; etc. If *w* grms. of a substance, molecular weight *M*, dissolved in 100 grms. of solvent, lowers the freezing point $f°$, we have the proportion $w:M=f:18{\cdot}5$ for water; or, for substances dissolved in water,

$$\text{Molecular weight}=18{\cdot}5\frac{w}{f} \quad . \quad . \quad . \quad . \quad . \quad (6)$$

This enables the molecular weight of a substance to be computed from its effect on the freezing point of water. The particular solvent to be selected is of course determined by the solubility of the substance under investigation, and the number 18·5 must be replaced by another if a different solvent be used. In no case must a solvent be chosen which can enter into chemical union with the substance to be examined.

EXAMPLES.—(1) W. Tammann (1889) found that a solution of 0·022 grm. of sodium in 100 grms. of mercury lowered the freezing point of mercury 0·39°. What is the molecular weight of sodium? Here, $M=425\times0{\cdot}022\div0{\cdot}39=23{\cdot}8$. Hence the atomic and molecular weights are the same.

(2) W. R. Orndorff and J. White (1893) found that a solution of 0·2735 grm. of hydrogen peroxide in 19·86 grms. of water lowered the freezing point of water 0·746°. What is the molecular weight of hydrogen peroxide? Here $w=100\times0{\cdot}2735\div19{\cdot}86=1{\cdot}3773$; $f=0{\cdot}746$; hence, $M=34{\cdot}2$. This corresponds with the molecule H_2O_2. An earlier determination by W. Tammann (1899) gave H_4O_4, but this was afterwards found to be due to the use of an impure sample.

(3) J. Hertz (1890) found that 2·423 grms. of sulphur in 100 grms. of naphthalene lowered the freezing point of naphthalene 0·641°; hence show that the molecular weight

of sulphur under these conditions corresponds with the formula : S_8. Ansr. : The molecular weight by experiment is 262, and by calculation for S_8, 256.

(4) G. Buchbock (1897) found that a solution of 21·740 grms. of ethyl ferrocyanide in a litre of water lowered the freezing point 0·1270°; show that this corresponds with the formula $(C_2H_5)_4FeCy_6$. The theoretical molecular weight is 328, observed 323.

(5) J. L. R. Morgan and H. K. Benson (1907) find that 0·292 grm. of potassium chloride dissolved in 100 grms. of molten calcium chloride, $CaCl_2.6H_2O$, as solvent depressed the freezing point 0·181°. The freezing constant of $CaCl_2.6H_2O$ is 45·0. Hence show that these observations agree with the formula KCl.

(6) G. Marchetti (1899) found that an aqueous solution of 1·703 grms. of a hydrated molybdenum oxide in 100 grms. of water lowered the freezing point 0·072°. An analysis of the compound gave 56·9 per cent. of molybdenum. Show that these results agree with the formula $Mo_3O_8.5H_2O$.

E. Beckmann's process for the determination of freezing points.—Applications of the freezing process for the determination of molecular weights present no particular difficulty. Several different forms of apparatus have been devised by investigators who have followed Raoult, but no apparatus has proved so useful as the later forms of E. Beckmann's. Precautions have to be taken against undercooling. Satisfactory results too are only obtained with those solvents which do not separate out with the solute in form of solid solutions.

Freezing-point determinations are usually made in Beckmann's apparatus.[3] The tube *A*, Fig. 26, with a side neck, *B*, is weighed, and about 15 c.c. of the solvent are added, and the tube is weighed again. Beckmann's thermometer, reading to the 0·01° of a degree. It is set so that the mercury is near the top of the scale at the freezing point of the solvent, and it is provided with a reading lens. The thermometer *T* and a stirrer *S* are placed in the solvent, and the whole arrangement is placed in a glass tube *A*, which serves as an air jacket. This is surrounded by a vessel *D* of water or some liquid at a temperature about 5° below the freezing point of the solvent. This vessel is fitted with a thermometer T_1 and stirrer S_1. The temperature recorded by the thermometer slowly falls until the solvent begins to freeze ; it usually falls from 0·2° to 0·3° below the freezing point of the solvent, and then begins to rise to the freezing point proper. The thermometer should always be tapped before a reading is taken to make sure the mercury is not lagging behind. The highest point reached by the mercury in the thermometer is taken to be the freezing point of the solvent. Owing to undercooling, it is sometimes difficult to start the freezing of the solution. In that case, a few pieces of platinum foil, or a minute fragment of the frozen solvent, will start the freezing. It is sometimes necessary to introduce a correction for undercooling as indicated in text-books for the laboratory. Each determination should be repeated two or three times and the successive observations should agree within 0·002° to 0·003°. When the freezing point of the solvent has been determined, add a sufficient amount of the substance under investigation to give a depression of 0·3 to 0·5°. After the freezing point has been determined again, find the freezing point after adding a second and then a third portion of the substance under investigation.

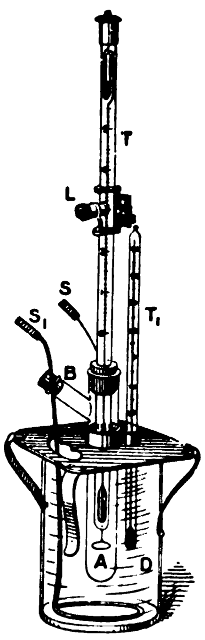

Fig. 26. — Beckmann's Apparatus for Freezing-point Determinations.

The molecular weights of volatile substances relative to the weights of the hydrogen molecule have been determined from the vapour density determinations and Avogadro's hypothesis. The osmotic pressure and related properties of solutions enable the molecular weights of *liquids* and *solids* in solution to be determined. There is an extensive choice of solvents, and it is possible to utilize such widely different substances as stearic acid, mercury, ether, fused metals, etc. Molten salts containing water of crystallization may be used—*e.g.* sodium sulphate, $Na_2SO_4.10H_2O$; calcium chloride, $CaCl_2.6H_2O$; lithium nitrate, $LiNO_3.3H_2O$; sodium chromate, $Na_4CrO_4.10H_2O$; etc.—the results agree with those obtained with other solvents. The molecular weights of a great many substances in solution are in agreement with those furnished by the vapour density method, yet there are some irregularities. F. M. Raoult found that the molecular weights of substances in solutions are sometimes greater and sometimes less than what we should expect. Organic substances, like cane sugar and alcohol in aqueous solution, gave normal values for their molecular weights, while inorganic salts like potassium and sodium chlorides gave about half the values which correspond with their normal formulæ. The results are then said to be abnormal. F. M. Raoult first assumed that organic substances must form double molecules in solution, while inorganic salts are normal. He then tried if extreme dilution would break down the supposed doubled molecules, but the experiments returned a negative answer.

The **relation between the osmotic pressure and the rise in the boiling point or depression of the freezing point.**—From the Clapeyron-Clausius equation, $\log p - \log p_s = (M\lambda/R)(dT/TT_s)$, where dT is put in place of $T_s - T$; and T denotes the temperature at which the vapour pressure is p, and T_s a slightly higher temperature where the vapour pressure is p_s. Since it has been shown that $(p-p_s)/p$ is an approximation for $\log p - \log p_s$, and $(M\lambda/R)(dT/TT_s)$ can be substituted for $(p-p_s)/p$ in equation (1), the result reduces to the relation $P = s\lambda dT/T$, which shows the relation between the osmotic pressure P and the rise dT in the boiling point. A similar relation between the depression dT of the freezing point and the osmotic pressure obtains if λ denotes the heat of fusion of the solvent in place of the heat of vaporization. The simpler form obtained by G. M. Lewis (1908),[4] $P = 12{\cdot}06f - 0{\cdot}21f^2$ atm., gives the osmotic pressure of a solution which lowers the freezing point f°.

EXAMPLE.—If an aqueous solution contains enough solute to raise the boiling point 1°, show that the osmotic pressure is nearly 47 atmospheres, $dT = 1$; $T = 373$; $s = 0{\cdot}96$; and $\lambda = 537$ cals.

§ 14. The Relation between the Solvent Power of a Solvent and the Molecular Weight of the Solute

The capacity of a pure solvent A to dissolve another liquid B is reduced when another substance C is dissolved in B. For instance, an ethereal solution of naphthalene (C) dissolves less water (B) than does pure ether (A). In following out the analogy between vaporization and solution, W. Nernst (1890)[1] argued that whatever depresses the vapour pressure of A should also depress the solubility of A. The relative lowering of the vapour pressure of A is proportional to the number of gram-molecules of non-volatile solute C in A, so the relative lowering of the solubility of B and A should also be proportional to the number of gram-molecules of the solute C in A when the solute C is not soluble in B. Let S denote the solubility of the liquid B in the pure solvent A; and S_s the solubility of the liquid B in the solution of C in A; the lowering of the solvent power of A is $S - S_s$, then, by analogy with the vapour pressure formula:

$$\frac{p-p_s}{p}=\frac{n}{N}, \quad \frac{S-S_s}{S}=\frac{n}{N}$$

where n denotes the number of gram-molecules of the solute C in N gram-molecules of the solvent A. If w grms. of C are dissolved in A, $n = w/m$, where m denotes the molecular weight of C. Then, $(S-S_s)m/w=S/N$; and since S/N is a constant, say k, whose numerical value can be determined experimentally for a particular temperature and amount of solvent, then, if S' denotes the lowering of the solubility $S-S_s$,

$$\text{Molecular weight}=k\frac{m}{S'} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

Experimental details for the application of the principle were worked out by S. Tollaczko (1895) for substances soluble in ether, and insoluble in water. The accuracy of the process does not appear to be very great even though the temperature be maintained constant for all the readings.

Example.—The constant k was found to be 536, and 0·1266 grm. of naphthalene depressed the solubility of water in ether about 0·55; accordingly, the molecular weight of naphthalene is $536 \times 0{\cdot}1266 \div 0{\cdot}55 = 123$—the theoretical value for $C_{10}H_8$ is 128.

If there is an appreciable change in the volume of the solvent on addition of the solute, a correction factor v/v_s is required—v represents the initial volume of the solvent and v_s its volume after the addition of the solute.

The **relation between osmotic pressure and the lowering of the solvent power of a solvent.**—By analogy with formula (3), above, the osmotic pressure P is related with the relative lowering of the solvent power of the solvent by

$$P=\frac{S-S_s}{S}\cdot\frac{sRT}{M}$$

The connection between the osmotic pressure and the colligative properties of a solution—the lowering of the vapour pressure, of the freezing point, and of the solvent power of a solvent, and the raising of the boiling point—has thus been established. Consequently, results obtained by these different methods cannot be regarded as independent evidence supporting any particular hypothesis, for the different processes are simply different ways of measuring one quantity, and they must necessarily lead to similar conclusions. The different methods are distinguished from one another by the degree of accuracy which can be obtained in the application of a particular process ; by convenience in the theoretical (mathematical) treatment ; and by the range of temperature over which they are applicable.

§ 15. Anomalous or Abnormal Results for the Molecular Weights of Substances in Solution

We never profit more than by those unexpected results of experiments which contradict our theories and analogies.—Guyton de Morveau.

I thank God that I was not made a dexterous manipulator, for the most important of my discoveries have been suggested to me by failures.—Humphry Davy.

The analogy between gases and solutes in dilute solution has been pursued further. If the molecules of a dissolved substance are in a similar state to what they would be if the substance were in the gaseous condition, the relation between the pressure, temperature, and concentration will be represented by the expression, $PV=iRT$; or, since the concentration C is inversely as the volume, by $P/C=iRT$. As before, if i be unity, the molecules of the substance in solution and in the gaseous condition are presumably similar ; if i be greater than unity, the analogy with similar phenomena with gases $pv=iRT$, has led to the assumption that the molecules dissociate when they pass into solution ; and if i be less than unity, the molecules polymerize. If we apply the uncorrected relation, $P/C=RT$, it is now easy to see that if i be greater than unity (dissociation), the osmotic pressure will appear too high; and if i be less than unity (polymerization), the osmotic pressure will appear too low. When we speak of the lowering of the osmotic pressure, we also imply that the vapour pressure is increased, the boiling point is lowered, and the freezing point raised; and conversely, the raising of the osmotic pressure implies that the boiling point is raised, and the vapour pressure and freezing point are lowered.

EXAMPLES.—(1) F. Vogel (1903) found that the lowering of the freezing point of a 2N-solution of barium nitrate, $Ba(NO_2)_2$, was 3·931°, and of a 0·2N-solution, 0·479°. The specific gravity of the former solution at 21° was 1·1604, and of the latter 1·0017. Calculate the value of $i=M$ (theoretical)/M_1 (observed) for each solution. Here 50 c.c. of the 2N-solution contains 11·4740 grms. of barium nitrate and 46·5456 grms. of water; and the 2*N*-solution, 1·1474 grms. of barium nitrate and 48·9358 grms. of water. The computed molecular weights of the salt in the two solutions are respectively 97·4016 and 99·7581, the theoretical value for both solutions is 229·14, hence, $i=2·54$ for the 2N-solution, and 2·48 for the 0·2N-solution.

(2) Which is the more probable equation for the action of a potassium hydroxide solution on aluminium hydroxide: $KOH+Al(OH)_3=Al(OH)_2OK+H_2O$, or $2KOH+Al_2(OH)_6=Al_2(OH)_4(OK)_2+2H_2O$, when the freezing point of solutions of potassium hydroxide are not changed by the addition of aluminium hydroxide? C. L. Speyers (1898). The former, because one molecule of aluminate is produced per molecule of potassium hydroxide, etc.

Again, from the argument based upon Fig. 23, it follows that the osmotic pressure P is to the lowering of the vapour pressure $p-p_s$ of the solvent and solution as the density s of the solution is to the density D of the vapour; or $P:p-p_s=s:D$; and since $p-p_s=pn/N$, and $p=DRT/M$, where M represents the molecular weight of the vapour, the osmotic pressure,

$$P=\frac{n}{N}\cdot\frac{s}{M}RT$$

According to J. H. van't Hoff's relation, $P=nRT$, unit volume of all solutions, with n molecules of the solute, have the same osmotic pressure. If unit volume of a solution of specific gravity s has N molecules of the solvent of molecular weight M', then $NM'/s=1$, or $N=s/M'$; and hence,

$$P=nRT\times\frac{\text{Molecular weight of solvent}}{\text{Molecular weight of solute}};\text{ or, }P=\frac{M'}{M}nRT$$

which shows that van't Hoff's relation—$P=nRT$—is valid only when the molecular weight M' or the solvent is the same as that of the vapour, M.

Abnormally high osmotic pressures—dissociation of solute, or polymerization of the solvent.—The molecules of the liquid may be more complex than the molecules of the vapour, so that the molecular weight of the liquid molecules is $M'=aM$, where a, the so-called association factor, represents the number of normal molecules of molecular weight M which combine to form one molecule of the associated liquid. The observed osmotic pressure P_1 of a solution containing n gram-molecules of the solute in unit volume of the solvent, whose molecular weight is a times that of the vapour, will be a times the osmotic pressure P of a solution in which the solvent is not so associated, or $P_1=aP$. A very considerable number of aqueous solutions of acid, bases, and salts furnishes a much greater osmotic pressure than we should naturally expect. The deviation of a gas from Avogadro's law is usually explained by assuming that the molecules of the gas are dissociated into simpler forms. Iodine molecules, I_2, at high temperatures appear to behave as symbolized: $I_2=I+I$. S. Arrhenius (1887) sought to explain deviations of the molecular weights of salts, acids, and bases in aqueous solutions by assuming that the molecules are dissociated into simpler parts. The molecules of sodium chloride, for instance, are supposed to be dissociated in aqueous solutions into two parts—Na and Cl. The idea came as a surprise, and much opposition has been raised against this interpretation of the results, because there are no signs of chemical action which might be expected if the molecule of sodium chloride were dissociated into electrically charged Na+ and Cl— atoms on solution in water. Accordingly, other hypotheses have been invented to make the first hypothesis fit the facts. In spite of this, Arrhenius' hypothesis at once explains in a seductive and plausible manner the abnormally high osmotic pressures obtained for these substances. There is a strange coincidence. Arrhenius determined the value of *i*—the number of molecules in the above equations—for ninety different substances. He noticed at once that these substances could be roughly divided into two classes: those which gave values of *i* nearly unity were either non-conductors or poor conductors of electricity; whereas those which gave values of *i* materially greater than unity were fair or good conductors of electricity. In the following table is taken to represent, within the limits of experimental error, the relative number of molecules formed when one molecule of the substance is dissolved:—

TABLE VI.—NORMAL AND ABNORMAL OSMOTIC PRESSURES.

Non-conductors.		Conductors.	
Substances in solution.	*i*	Substances in solution.	*i*
Methyl alcohol	0·94	Calcium nitrate	2·48
Mannite	0·97	Magnesium sulphate	1·25
Cane sugar	1·00	Strontium chloride	2·69
Ethyl acetate	0·96	Potassium chloride	1·81
Acetamide	0·96	Lithium chloride	1·92

We naturally inquire: What connection, if any, subsists between the alleged dissociation of the molecules of a substance in a solution and the conduction of electricity? How can one molecule of sodium chloride, one molecule of lithium chloride, each furnish what appears to be two molecules when dissolved in water? Is this dissociation hypothesis the only possible explanation which covers all the facts?

Chemical theory of osmotic pressure.—The circumstantial evidence adduced to show that in liquid water at any given temperature, it is highly probable (i) that definite relation subsisting between polymerized and simple molecules; and that (ii) the presence of salts in solution displaces the equilibrium in favour of the simpler molecules. Hence, with some differences, J. J. van der Laar (1906)[1] and H. E. Armstrong (1902–6) argue that the osmotic pressure is not a result of a pressure produced by the molecules of the dissolved substance, but rather a secondary effect of the reduction in the concentration of the more complex water molecules by the dissolved substance which causes the pure solvent, say, water, to travel towards the water of the solution. Here, osmotic pressure is a consequence of the impulse of diffusion which continues until the concentration of the complex water molecules is the same on both sides of the separating membrane. A certain proportion of the complex molecules are supposed to be continuously resolvèd into simpler molecules as the pure solvent diffuses through the partition, and conversely, a certain proportion of the simple water molecules which diffuse from the solution side of the partition are polymerized on the pure solvent side. The addition of a non-electrolyte disturbs the equilibrium $(H_2O)_n \rightleftharpoons nH_2O$ in the direction $(H_2O)_n \rightarrow nH_2O$, and the resulting molecules of hydrone, H_2O, exert an attraction on similar molecules in the region of the pure solvent or more dilute solution, so that the solvent passes through the membrane to the solution until equilibrium is re-established. Osmotic pressure is then a measure of the disturbance of the equilibrium, $(H_2O)_n = nH_2O$, produced by the continuous depolymerization of the water molecules on the solution side of the partition, and a continuous polymerization of water molecules on the pure solvent side. The greater the difference in the concentration of the more complex water molecules on the two sides of the partition, the greater is the impulse of diffusion, and the greater the osmotic pressure. Electrolytes exert an attractive influence on the solvent, which is superposed on the effect produced by dissociated water complexes, so that solutions of electrolytes exert a greater osmotic pressure than solutions of non-electrolytes of equivalent molecular concentrations. H. E. Armstrong (1909) explains the selective action of the membrane in the following manner:

> The compounds which penetrate the membrane are all substances which attract water presumably only to a minor extent and which exist to some extent in solution in an unhydrated condition; those which cannot penetrate it, on the other hand, probably all form hydrates of considerable stability in solution. I picture surfaces generally, colloidal surfaces in particular, as not merely wetted by water, but as more or less hydronated and hydrolated, that is to say, they are not merely wetted by water complexes, but associated with hydrone, the simple fundamental molecule of which water is composed. The intra-molecular passages in a colloidal membrane, if thus hydrolated, would be guarded by the attracted hydrone molecules; and the hydrolated molecules in a solution which attempted to effect an entry through such passages, would be seized upon and held back in virtue of the attraction which two hydrolated surfaces—that of the membrane and that of the solute—would exercise upon one another. The hydrolated passages. however, would be indifferent to molecules which were not hydrolated—consequently such a substance as acetic acid, of which probably only a small proportion is present in solution in the hydrolated state, would gradually pass through them.

H. E. Armstrong further assumes that the reason non-electrolytes in equivalent concentration all exert the same osmotic pressure, while, in contradistinction, electrolytes exert an excessive pressure, turns on the assumed fact that non-electrolytes dissolve in water in the form of their fundamental molecules, which exerts no appreciable attractive action (affinity) on the water molecules; and that electrolytes have the power to attract water molecules in proportion to their efficiency as electrolytes. It is inferred that the process of solution implies a strong affinity of a chemical or quasi-chemical nature in order to break up the cohesion of the crystal. The molecules of a compound like mercuric chloride which dissolves in water with difficulty probably differ from the molecules of, say, calcium chloride in exerting but a slight attractive force on molecules of water, while the so-called ionized molecules are assumed to form complex reversible systems of solvent and solute, say:

$$\text{K-Cl} + \text{O-OH} \rightleftharpoons \text{K-Cl}<^{\text{H}}_{\text{OH}}$$

The observed osmotic effects are thus assumed to be an effect of two distinct forces: (1) the *depolymerization* of the complex water molecules; and (2) the *hydration* of the solute whereby the solvent is attracted towards the solute by the same forces which cause it to dissolve in the water. The function of the electric current is to break down such systems by drawing certain groups of atoms apart. As these systems are broken down by the current new ones spontaneously form in the solution. Molecules which exhibit no tendency to form such systems are virtually non-electrolytes. Thus, in the words of M. Faraday, "the inability of a system to suffer decomposition by electricity . . . may be dependent upon the absence of that mutual relation of the particles which is the cause of aggregation." J. Larmor has also shown that the osmotic laws deduced for dilute solutions by thermodynamics are the same, even supposing that a complex between solvent and solute is formed, provided that the solution is so dilute that each such complex is for very much the greater part of the time out of the sphere of influence of other complexes.

V. A. Vilde and A. J. Bogorodsky (1915)[2] explain the abnormal depression of the freezing point of aqueous solutions by assuming with A. Hantzsch (1907) that just as ammonia may attach itself to a hydrogen atom forming ammonium, NH_4, so can a molecule of water similarly form *hydroxonium*, called for brevity *hydronium*, OH_3. When a little water is dissolved in absolute sulphuric acid, H_2SO_4, *hydronium sulphate*, $OH_3.HSO_4$, is formed: $HSO_4H+H_2O=OH_3.HSO_4$; just as ammonia under similar conditions reacts: $HSO_4H+NH_3=NH_4.HSO_4$. Assuming, however, that water is polymerized and contains, say, trihydrol molecules, $(H_2O)_3$, then, when a little acid, HR, is dissolved therein, $(H_2O)_3+HR=H_3O.R+H_3O.OH$; with a base, M.OH, the action is represented: $(H_2O)_3+M.OH=H_3O.OH+H_2MO.OH$; and with a salt, MR, similarly: $(H_2O)_3+MR=H_3O.R+H_2MO.OH$. In dilute solution, with the molecules $(H_2O)_3$ in large excess, the effect of such changes would make the solution behave as if each molecule of the solute formed two molecules on passing into solution. *The number of molecules is increased owing to the reaction between solvent and solute.* An analogous case occurs when various salts or oxides are dissolved in fused alkali hydroxides: $n\mathrm{KOH}+\mathrm{PbO}=\mathrm{Pb(OK)_2}+\mathrm{H_2O}+(n-2)\mathrm{KOH}$.

There are available at least three explanations of an abnormally high osmotic pressure: (i) Dissociation of the solute; (ii) Polymerization of the solvent; and (iii) Reaction between polymerized solvent and solute. Observations on osmotic pressures and the related phenomena—raising of the vapour pressure, raising of the boiling point, lowering of the freezing point, etc.—do not discriminate between these three explanations unless it be to decide against the hypothesis that the molecules of the electrolytes are dissociated, both on account of its revolutionary nature, and *a priori* improbability. It is therefore necessary to seek evidence from other sources. The solvent water is undoubtedly associated, and it has been shown that the degree of association is diminished by the dissolution of salts in the liquid. It has not yet been shown that the degree of association of different solutions varies concomitantly with the changes in their osmotic pressure (or related phenomena); it has, however, been shown that solutions of salts in non-associated solvents—*e.g.* hydrocarbons and their halogen derivatives, ethers, esters, most aldehydes and ketones—do not usually show abnormally high osmotic pressures; while solutions of salts in associated solvents—*e.g.* water, compounds containing hydroxyl groups like the alcohols, organic acids, oximes, some nitro-compounds, and compounds containing amidogen groups—do show phenomena corresponding with abnormally high osmotic pressures. It will probably be found in later years that the abnormal behaviour of water retarded the development of the generalizations concerning the effect of solutes on the depression of the freezing points, the elevation of the boiling points, and the lowering of the vapour pressures of solutions. F. M. Raoult's success followed as a result of his experiments with non-associated solvents where the main phenomenon was not obscured by secondary effects. If it turns out that electrolytes are salts which are in the normal or unassociated condition when dissolved in associated solvents, the so-called ionization hypothesis which has been elaborated on the assumption that electrolytes have molecules which are dissociated into electrically charged units when in solution, will be unnecessary. It is also remarkable how tenaciously the ionization hypothesis is held when it is remembered how very many properties of electrolytes, supposed to be uniquely and adequately explained by the hypothetical *dissociation of the solute* can be satisfactorily explained by the observed *association of the solvent.*

Abnormally low osmotic pressures—polymerization of solute.—If the liquid solvent and its vapour have the same molecular weight, and the solute is so associated that it has an association factor, i, then, in place of n molecules of the solute, there are in reality n/i molecules, and the observed osmotic pressure P_2 will be i times smaller than the osmotic pressure P would be if the solute were not associated, or, $P=iP_2$. F. M. Raoult (1886) noticed that the depression of the freezing point of a solution of alcohol in benzene, naphthalene, nitrobenzene, ethylene dibromide, etc.—is just about half what we should expect if the molecules of alcohol were represented by the regular formula: C_2H_5OH. This means that the molecules of alcohol—C_2H_5OH—in benzene solutions are doubled, and may be represented by $C_4H_{10}(OH)_2$ in benzene solution. This phenomenon is common with molecules possessing hydroxyl, OH, groups—*e.g.* alcohols and acids. Formic—H.CO.OH—and acetic—CH_3.CO.OH—acids, and indeed water, behave in a similar manner, and we know that if these substances be vaporized, they appear to have twice the molecular weight they would have if their molecules could be really represented by the ordinary formulæ. Otherwise expressed, the molecules are polymerized. Increasing dilution usually reduces the abnormality indicating that the association becomes smaller and smaller; W. Ramsay and J. Shields also noticed that the dilution of associated molecules has a similar effect to an increase of temperature. It is also necessary to remember that the dissolved substance may freeze out along with the solvent so as to form a kind of solid solution—for example, the ice which separates from a dilute solution of ether or alcohol in water contains appreciable quantities of the solute. The observed reduction of the freezing point of the solution may be less than that calculated from the regular molecular formula of the dissolved substance. J. H. van't Hoff (1890) demonstrated the elevation of the freezing point from this cause. In 1889, W. Ramsay[3] determined the lowering of the vapour pressure of mercury by the solution of a number of metals—lithium, sodium, barium, magnesium, zinc, aluminium, tin, lead, antimony, manganese, silver, gold, etc.—and found the results agreed with the assumption that the metals are in the atomic condition in mercurial solution. C. T. Heycock and F. H. Neville examined solutions of several metals in molten tin and sodium. There is abundant evidence of the existence of definite compounds of mercury with the metals, the alkalies, or the alkaline earths, and there is no reason to assume that these compounds break up when in mercurial solution. If there is no evidence of the formation of chemical compounds, it might be assumed that the lowering of the freezing point is an indication of the molecular state of the metals—*e.g.* zinc, cadmium. bismuth, lead, and tin, dissolved in mercury.

If both liquid solvent and solute are associated, it follows from the above discussion that the osmotic pressure P_s, will be equal to $P\alpha/\beta$; and if $\alpha=\beta$, the osmotic pressure will appear to be normal, but both solvent and solute would have polymerized. It also follows by analogous reasoning that J. H. van't Hoff's relation, $k=0{\cdot}02T^2/\lambda$ applies only to the unassociated solvent and solute; if the solvent be alone associated, this relation becomes $0{\cdot}02T^2\alpha/\lambda$; and if the solute is alone associated, $0{\cdot}02T^2/\beta\lambda$.

§ 16. The Cause of Solution

There is probably no sharp line of demarcation between chemical union and the process of solution.—S. L. BIGELOW (1907).

Clear answers to the questions: What determines the solubility of a substance? Why is cæsium chloride, CsCl, so very soluble and silver chloride so very sparingly soluble in water? are not forthcoming. The alchemists considered solution to be produced by the penetration of the particles of the solute between the particles of the solvent, or to the result of some kind of union of the two. P. Gassend,[1] following the old atomic theory, taught in 1647 that the atoms of one substance could enter the interstices between the atoms of another substance. The cubic particles of common salt, for example, filled up the water molecules, and when all such pores were filled, the water could dissolve no more salt; similarly the octohedral alum. Hence, it was supposed that water also contained octahedral pores which the alum but not the salt could enter. The ideas of solution prevailing in the seventeenth century may be gathered from R. Boyle's essay: *Of the producibleness of chymical principles* (Oxford, 1663). He says:

Dissolution depends not so much on the pretended cognation between the solvent and

> the body it is to work upon as upon the congruity, as to size and figure, between the pores of the latter and the corpuscles of the former.

A similar view of solution was advocated about the same time by N. Lemery in his *Cours de chymie* (Paris, 1675). Near the beginning of the eighteenth century Isaac Newton naturally extended the idea of attraction to the particles or atoms composing a substance; and, reasoning from the fact that the particles of a salt dissolving in water, in spite of their greater density, diffuse themselves uniformly throughout the solvent so that the particles of the salt recede from one another and endeavour to get as far asunder as the solvent will allow, Isaac Newton asked: Does not this endeavour imply that the particles of the dissolved substance exert a repulsive force on one another, or else attract the particles of the solvent more strongly than they do one another? Otherwise expressed: Does not the solute dissolve because it exerts an attraction on the solvent? H. Boerhaave (1772) took a somewhat similar view, and added:

> The particles of the solvent and those of the dissolved substance unite, after solution, to form a new homogeneous substance. . . . The cause of this must be sought for in both the solvent and the dissolved substance. It is common to them both. *Particulæ solventes et solutæ se affinitate suæ naturæ colligant in corpora homogenea.*

About this time, J. K. Wallerius (1772),[2] M. H. Klaproth (1806), and many others also regarded solution as the result of the action of chemical affinity between solvent and solute which must be stronger than the cohesion of the particles of the dissolved substance each to each.

In 1789, A. L. Lavoisier distinguished between *dissolution, a chemical process*, typified by the dissolution of zinc in dilute acid; and *solution, a physical process*, typified by the solution of salt in water. In the latter process, said A. L. Lavoisier, the salt molecules are simply torn apart from one another, but neither the solvent nor solute suffers any other change, because both can be recovered in the same quantity as before the operation. These views were adopted by A. F. de Fourcroy (1801), who regarded a solution as a physical or mechanical mixture in which the dissolved substance is in a state of fine subdivision in the solvent. With reference to purely physical hypotheses of this kind, W. A. Tilden adds:

> Such a theory, however, serves to account only for the initial stage in the process of solution, and does not explain the selective power of solvent, nor the limitation of the solvent power of a given liquid, etc.

The father of the chemical school, C. L. Berthollet (1803),[3] took the contrary view. A solution, said he, is a true chemical compound which is not very stable, and which shows the characteristics of the dissolved body. Solution must be due to a force which is great enough to overcome the cohesion of the dissolved substance. The difference between a solution and a chemical compound is to be found in the firmness of the union of the parts. In solutions the parts are the less firmly united, and the characteristic properties of the dissolved substance have not been lost. J. P. Cooke[4] expressed similar views in 1881. C. L. Berthollet, it will be remembered, did not accept the laws of definite and multiple combination; hence he could say: Chemical union and solution must therefore follow the same laws.

After the laws of combination had been generally accepted, it became necessary for those who regarded solution as a chemical process to explain the reason why chemical combination takes place in certain definite proportions, while solution occurs in any proportion up to a certain limit. This was done by J. L. Gay Lussac,[5] who assumed that the force which leads to chemical combination is more powerful than that which produces solution. He compared the process of solution with that of vaporization—both are dependent on temperature and obey its variations. The essential difference between the two processes consists in this: Gaseous molecules do not need a solvent to maintain them in a given space, their own repulsive force suffices for this purpose. On the other hand, in a solution, the particles of the dissolved substance cannot maintain themselves in the space if they are not united by affinity to the molecules of the solvent.[6]

These ideas were fairly general during the greater part of the nineteenth century, and they are typified by the views of L. Dossios,[7] who referred solution to the molecular attraction between unlike molecules exceeding the attraction between molecules of the same kind. Consider the case of two fluids A and B in contact with one another. Molecules of the one fluid A will enter among the molecules of the other B if the molecules of the latter attract the former more strongly than the attraction of either the molecules of A or B have for one another. When the number of molecules of A passing into the fluid B is equal to those passing from B in a given time is equal, the liquid B is saturated; similar considerations apply to the fluid A and the molecules of B. Finally, therefore, each liquid will be saturated with the other. The same remarks apply, *mutatis mutandis,* to the solution of a solid in a liquid. The solubility will increase with a rise of temperature, if the temperature diminishes the attraction of like molecules for one another more than it does for unlike molecules. If the solution of a salt in water is a consequence of the attraction of the molecules of water for a molecule of the salt exceeding the attraction of the molecules of a salt for one another, it follows, says W. W. J. Nicol[8]:

> As the number of dissolved salt molecules increases, the attraction of the dissimilar molecules is more and more balanced by the attraction of the similar molecules; when these two forces are in equilibrium, saturation takes place.

D. I. Mendeléeff[9] modified the views of C. L. Berthollet and J. L. Gay Lussac so as to bring the conception in accord with the law of definite proportions and the phenomena of dissociation. He supposed that the solvent and solute formed chemical compounds with so feeble an affinity that the compounds are more or less dissociated at ordinary temperatures. According to the nature of the solute one or more such compounds may be simultaneously in the solution. M. Berthelot (1879)[10] also advocated the view that a solution is a mixture of the free solvent and a compound of solvent and solute—called, in the case of aqueous solutions, a hydrate—united in definite proportions. *Les phénomènes de la dissolution normale sont en quelque sorte intermédiares entre le simple mélange et la combinaison véritable.* Definite hydrates are formed in solution by the union of the solvent water with the anhydrous salt, and they are comparable with the crystalline hydrates of the salt, but with this difference, the hydrates in solution are in *une état de dissociation partielle* which depends on the relative quantities of solute and solvent and the temperature in accord with the law of mass action. In some cases, he added, the whole mass of the solvent takes part in the action as in the case of strong acids; and in other cases, as with salts of the alkalies, only a part of the solute is combined with the solute; and lastly, there may be many hydrates, or equivalent bodies existing in the solution in equilibrium at the same time.

D. I. Mendeléeff could see no way of definitely determining the composition of the supposed hydrates, and his attempt to determine the character of the hydrates was not very successful. He plotted the specific gravities of solutions of sulphuric acid of varying concentrations against the concentrations, and assumed that the maxima in the curves represented definite hydrates. S. U. Pickering[11] also examined the physical properties of numerous aqueous solutions, and when one of these properties is plotted against the concentration he inferred that (i) abrupt changes in the curvature of the resulting curves, and (ii) the supposed points of discontinuity of the first or second differential coefficient of a function connecting the physical property of a solution with concentration, indicated the presence of certain definite hydrates.[12] Some of these discontinuities are possibly due to experimental errors, since a small error may be much magnified in the differential process. Definite breaks do exist in many curves connecting the composition with some physical property—specific heat, specific gravity, viscosity, refractive index, electrical conductivity, compressibility, surface tension, thermal expansion, heat of solution, etc.—but striking irregularities are encountered, when the attempt is made to connect these with specific hydrates. For example, Pickering's hydrates did not always correspond with those deduced by other physical methods—*e.g.* by the freezing points of the solutions.[13]

According to T. M. Lowry, the breaks observed in the density-composition curves of dilute solutions are due to distortions produced by alterations in the character of the solvent water whereby complex water molecules are depolymerized.[14] Apart from the question whether the hydrates actually assumed are those really present, the underlying hypothesis that the cause of solution is dependent on the chemical affinity between solvent and solute is very generally accepted.

In the ionic theory, to be described later, it is assumed that in dilute solutions the molecules of the salt, presumably *after* the salt has dissolved, are more or less dissociated into parts which carry electric charges, and which are called ions; and in the so-called solvate theory, the ions as well as the non-ionized molecules are supposed to be more or less hydrated, so that aqueous solutions of a salt may contain hydrated molecules, and hydrated ions.

The formation of hydrates or of complexes between solute and solvent is evidenced by the so-called abnormal effects produced by the solute upon the freezing point, boiling point, vapour pressure, and solvent power of a solvent; by the distribution of a solute between two solvents, or a solvent and a gas (Henry's law); breaks and irregularities in the solubility curves; by deviations in the physical properties—specific gravity, thermal expansion, heat of solution, specific heat, surface tension, viscosity, conductivity, compressibility, index of refraction, magnetic rotation of the plane of polarization, diffusion, ionic velocities, hydration and colour changes, etc.; effect of salts on the velocities of reactions in aqueous solutions, etc.

§ 17. The Physical Properties of Solutions

In a sense it is unfortunate that such an enormous number of observations have been made on aqueous solutions, and so few with other solvents, because water is so emphatically exceptional in its physical and chemical properties, and the mechanism of solution will never be clearly demonstrated until these observations have been supplemented by prolonged series of investigations with less complex non-aqueous normal solvents. Nearly every physical property of water is profoundly modified when it is used as a solvent for the various salts, and the evidence as to the formation of hydrates is ambiguous, in that it may be interpreted to imply that the complex molecules of this solvent are more or less depolymerized in the presence of a solute.

According to the law of mixtures, the molecular physical properties X of a mixture are additive if $X=X_1N_1+X_2N_2+\ .\ .\ .$, where X_1, X_2, . . . represent the magnitude of a molecular physical property of the components, and N_1, N_2, . . . denote the molecular fractions of the corresponding components of the mixture. Deviations from this rule are attributed to changes in one or more of the components —*e.g.* polymerization or depolymerization of one or more components of the mixture —or to the chemical union of two or more of the components of the mixture.

The specific gravity of solutions ; the molecular volumes of salts in solution. —The early observers, P. Gassend, A. Nollet, and M. Eller believed that salts dissolve in water without a change in volume, but R. Watson demonstrated that the assumption has no foundation in fact.[1] In 1840, J. Dalton discovered that a contraction occurs when some salts dissolve in water ; and in some cases, the contraction is as large as that of the volume of the anhydrous salt in solution, so that the volume of the solution is not greater than that of the solvent alone. He experimented with hydrated and anhydrous salts and concluded :

> I have tried the carbonates, the sulphates, the nitrates, the muriates or chlorides, the phosphates, the arseniates, the oxalates, the citrates, the tartrates, the acetates, etc., etc., and have been uniformly successful ; only *the water adds to the bulk, and the solid matter adds to the weight.*

J. Dalton said of this observation (1840) : " This fact is new to me and I suppose to others. It is the greatest discovery that I know of next to the atomic theory ; " but, added L. Playfair, " Dalton was here inclined to generalize much further than the observation would bear. There is, indeed, a class of salts which behaves in this manner—magnesium, copper, zinc, and iron sulphates and a few other salts like sodium borate and phosphate." Apparently unknown to J. Dalton, E. Swedenborg (1721), a century earlier, made a similar observation as is indicated in a previous citation. J. Dalton's work was followed up by S. Holker (1844), L. Playfair and J. P. Joule (1845), J. C. G. de Marignac (1846), and others. The degree of contraction varies with different salts, and in some cases—*e.g.* lime water—the volume of the solution is even less than that of the contained solvent. The contraction which occurs during the formation of a concentrated solution continues as the solution is diluted and either approaches a constant value in a dilute solution, or else becomes negative so that the volume of the solution is less than the original volume of the water used as a solvent.[2] In some cases—*e.g.* silver nitrate—the solution occupies almost as great a volume as the sum of the volumes of salt and water, whereas with solutions of sugar and water the solution occupies the same volume as the joint volume of the two components in accord with the law of mixtures. Again, solutions of organic compounds in hydrocarbons, though seldom strictly conformable to the law of mixtures, show but slight deviations.[3] P. A. Favre and C. A. Valson, I. Traube, and J. Y. Buchanan [4] showed that with lithium bromide and nitrate and the ammonium halides and nitrate, the volume of the solutions is greater than the sum of the volumes of the water and dry salt. According to G. P. Baxter and C. C. Wallace, lithium and cæsium halides also produce expansion during solution ; lithium chloride is exceptional, but it too produces an expansion if the concentration is high and the temperature over 25°.

Does the contraction which occurs when a solid is dissolved in water or when water is progressively added to its solution indicate the formation of hydrates ? The answer is in the negative. The curves shown in Fig. 27 represent the differences between observed molecular volumes and those calculated on the assumption that the law of mixtures obtains for sulphuric anhydride with up to ten molecules of water, SO_3+10H_2O ; and for sodium chloride with up to $NaCl+100H_2O$. Hence, there is no point in the curve where we should be justified in setting up a distinction between the effect due to chemical combination, and that due to other causes.[5]

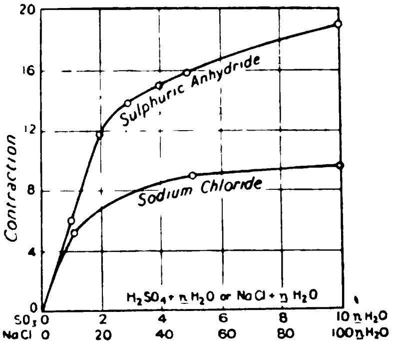

Fig. 27.—Contraction during Solution and Progressive Dilution.

Table VII, by G. P. Baxter and C. C. Wallace, shows the change in volume *a* which occurs during the formation of the solid salt from the solid or liquid elements, and the change in the molecular volume *b* of the salt during the solution of the alkali halides. The change in volume which occurs during the solution of a salt in water is a highly complex phenomenon. According to P. A. Favre and C. A. Valson, the observed change of volume during solution is the joint result of two opposing influences : (i) the contraction of the solvent under the influence of the solute, and (ii) an increase in the volume of the salt *par suite de la dissociation plus ou moins avancée de ses éléments constituents*. The observed contraction which usually occurs is taken to prove that the first effect is usually greater than the second.

Table VII.—Changes in the Molecular Volumes of the Alkali Halides during their Formation from their Elements, and during Solution.

CsI . .	259·73	4·509	96·7	57·6	−39·1	+1·77	−37·3

The contraction is usually attributed to hydration. G. Tammann[6] argues that since solutions behave in approximately the same way when subjected to changes of temperature and pressure, as the same volume of water, at a higher pressure, there must be a compression of the water by the solute owing to an increase of internal pressure which he calls the *Binnendruck*. It is not clear whether the *Binnendruck* is exerted throughout all the water or only to the portions in the vicinity of the solute molecules. This, however, is immaterial from the present point of view. G. P. Baxter argues from T. W. Richards' hypothesis of compressible atoms that under the influence of chemical affinity the atoms are more or less compressed—the greater the affinity, the greater the compression. This agrees with the observed thermal values of the reactions. For related elements, the greater the heat of formation the greater the difference between the sum of the atomic volumes and the observed molecular volume of a salt. During solution, the compression due to chemical affinity and molecular cohesion is more or less relieved. In addition to the contraction due to hydration, the expansion due to dissociation (or ionization), and the expansion due to the partial release of the compression (T. W. Richards' hypothesis), profound changes are produced in the degree of polymerization of water during the dissolution of a salt.

C. A. Valson (1874)[7] noticed the curious fact that the differences between the specific gravities of solutions containing one gram-equivalent of various salts per litre of two specific metals with one acid are equal, and therefore independent of the nature of the acid; and conversely the differences between the specific gravities of solutions of various salts of two specified acids with one metal are equal, and therefore independent of the nature of the metal. Hence, the specific gravity of a normal salt solution—that is, a solution containing one gram-equivalent of the salt per litre—is obtained by adding two numbers to the standard value—one is a characteristic or modulus of the metal, and the other is a characteristic or modulus of the acid. C. A. Valson used a solution of ammonium chloride of specific gravity 1·015 as his standard of reference, but water would have been the better standard.

TABLE VIII.—VALSON'S MODULI.

Ammonium	0·000	Manganese	0·037	Chlorine	0·000
Potassium	0·030	Iron	0·037	Bromine	0·034
Sodium	0·025	Zinc	0·041	Iodine	0·064
Calcium	0·026	Copper	0·042	Sulphate	0·020
Magnesium	0·020	Cadmium	0·061	Nitrate	0·015
Strontium	0·055	Lead	0·103	Carbonate	0 014
Barium	0·073	Silver	0·105	Bicarbonate	0·016

Thus the specific gravity of a solution of silver nitrate is 1·015+0·105+0·015=1·135. The rule is valid only for dilute solutions. The observed irregularities depend upon the regular volume changes which accompany the formation of salts in solution. It has been found that at a given concentration, within the limits of observational errors, the physical properties of dilute aqueous solutions of strong electrolytes—*e.g.* volume changes on mixing, the thermal, optical, and other properties—are purely additive functions of the constituent ions. Consequently, it is assumed that in these solutions, the electrolytic solute is completely ionized. For example, if the partial volumes of HCl, HBr, and KBr are known in $\frac{1}{10}N$-solution, the partial volume of KCl in the same concentration can be computed. C. Bender[8] tried to extend the rule to concentrated solutions by showing that the difference between the specific gravities of two substances containing an equal number of gram-equivalents per litre was proportional to the number of equivalents. This extension of C. A. Valson's moduli is made possible on account of the empirical fact that the dilution of equivalent salt solutions is attended by almost the same contraction.

In 1878, W. Ostwald[9] showed that the changes in volume observed by G. T. Gerlach (1859), C. Tissier (1859), and J. Regnauld (1865), to accompany the neutralization of solutions of ammonium and alkali hydroxides by various acids, in solutions containing a gram-equivalent of base or acid per kilogram of solution, are dependent on both the acid and the base, and that the difference in the changes in volume which accompany the neutralization of different bases by one acid is the same whatever acid is used; and conversely, the difference in the volume changes which attend the neutralization of the different acids by one base is independent of the nature of the base. W. Ostwald showed that similar additive relations hold good for many other properties of dilute salt solutions, and used the facts as an argument in support of the ionic hypothesis. These relations do not hold so well for concentrated solutions. It is argued that a negative molecular volume for the solute is impossible, and accordingly a portion of the solvent must be denser than the pure solvent. Consequently, the increase in density which occurs when salts are dissolved in water is attributed to the union of a portion of the solvent water with the solute to form a salt which is hydrated in aqueous solution, and this is supposed to be confirmed by the increased density of the water of crystallization in solid crystalline hydrates. The alternative hypothesis is that the increase in the density of solutions is due to the depolymerization of the solvent water. The attempts made to determine the formulæ of the supposed hydrates from irregularities or discontinuities in the density-composition curves have not been generally successful, for the alleged breaks in the curve have been shown in many cases to be due to experimental errors,[10] and that no reliable conclusions about the formation of hydrates can be drawn from the density-composition curves.

The thermal expansion and compressibility of salt solutions.—Some remarks on these properties have been discussed in dealing with water. Aqueous solutions of salts do not follow the mixture law.[11] In general, the thermal expansion of aqueous solutions of salts is the more uniform the more concentrated the solution; the more dilute the solution the greater the curvature of the line showing the relation between its volume and temperature; and with the more concentrated solutions, the more nearly does the volume-temperature curve approach a straight line. This is attributed to the depolymerization of the so-called ice-molecules when salt is dissolved in water. Similarly with the compressibility of salt solutions. W. C. Röntgen and J. Schneider investigated the compressibilities of 1·5 and 0·7 normal solutions of various salts of the alkalies and ammonium, and the corresponding acids, and concluded:

> The substitution of one constituent of the compound in solution by another, *e.g.* I by NO_3, Br, Cl, OH, SO_4, or CO_3, alters the compressibility of the solution to an extent which is only slightly dependent on the nature of the other constituent of the compound (H, NH_4, Li, K, Na). It appears, then, as if each constituent of a salt exerted a specific effect on the compressibility of the solution of that compound, which effect is only slightly modified by replacing the other constituents by different substances; or, in other words, it seems as if the components of the dissolved body, and not the compound in which these components are contained, had the greatest influence on the compressibility of the solution.

Water and ammonia are exceptions; and each of the exceptional solutions is found to be a relatively poor conductor of electricity.

The viscosity of solutions.—The viscosity curves of binary solutions are of three kinds: those which follow the law of mixtures, and those which exhibit maxima or minima. According to A. E. Dunstan, the minima are produced by the depolymerization of one or both the associated components of the mixture; the maxima are produced by the formation of complexes between solute and solvent. T. Graham attributed the maxima he obtained with aqueous solutions of many common acids and alcohols to the formation of definite compounds, and in this he is supported by A. E. Dunstan, D. E. Tsakalotos, O. Faust, R. B. Denison, and others.[12] As in the case of the specific gravities, the existence of numerous hydrates has been deduced from points of discontinuity in the viscosity curves. Four hydrates of acetone, six of methyl alcohol, and seven of ethyl alcohol have been reported by E. Varenne and L. Godefroy to be formed in aqueous solutions of these compounds. E. W. Washburn takes the view that the deviations of a physical property from the mixture law cannot give conclusive evidence of the existence of hydrates or other complexes; and he states that in the case of aqueous solutions of methyl alcohol, "the points of discontinuity in the viscosity curves are purely imaginary, and due to experimental errors." Probably the larger part of the abnormal effects of salts on the physical properties of water should be ascribed to changes in the complexity of the solvent.

The specific heat of solutions.—The molecular specific heat of mixtures of some organic compounds—*e.g.* carbon disulphide and chloroform—follow the mixture law, but mixtures of alcohol and water, and indeed aqueous solutions generally, do not follow this rule. This was noticed by A. A. B. Bussy and J. L. H. Buignet [13] in 1865. The thermal capacity of mixtures of alcohol and water is always greater than that calculated by the law of mixtures, but in the case of aqueous solutions the thermal capacity is usually less than that calculated by the law of mixtures. The total heat capacity of aqueous solution of salts is frequently less than that of the contained water; in illustration, J. Thomsen found that the difference between the thermal capacity of 100 parts of water and the thermal capacity of a 10 per cent. solution of sodium chloride is 2·01 cals.; a 20 per cent. solution, 0·36 cal.; and a 30 per cent. solution, —2·66 cals. J. Thomsen has also shown that the calculated molecular heat capacity of the solute in solutions of electrolytes is nearly always less than for the solute alone, and it steadily decreases on dilution, passing through zero, and finally assuming a negative value. A negative heat capacity has no physical meaning; consequently, the heat capacity of the water as a whole, or of a certain portion of the water is lowered by the presence of a solute. M. Berthollet believed that the formation of hydrates with a smaller heat capacity than water explains the phenomenon satisfactorily. The depolymerization of the solvent water is the alternative hypothesis.

The heat of solution.—The heat developed or absorbed during the formation of a solution may be expressed in different ways. The magnitude measured in the calorimeter usually refers to the thermal change which occurs when a gram of the substance is dissolved in so large a quantity of the solvent, that any further dilution of the resulting solution is not attended by any thermal change; or when a gram of the substance is dissolved in *w* grams of water; or when a gram of the substance is dissolved in sufficient water to form a saturated solution; or when a small quantity of the substance is added to a saturated solution containing a gram of the substance—this is, the reversible heat of saturated solution; the heat evolved or absorbed when a small quantity of water is added to a saturated solution containing a gram of the solute; etc. These magnitudes can all be represented in terms of the gram-molecule instead of the gram.

In the solution of a solid, work must be performed in the separation of the molecules against intermolecular attraction, *this* is equivalent to the latent heat of sublimation or to the heat of fusion plus the heat of vaporization. This exerts a cooling effect. In the solution of a liquid, work equivalent to the heat of vaporization must be expended against intermolecular attraction. Thermal phenomena of greater or less magnitude may also accompany a reaction between solvent and solute, the formation of complexes, depolymerization of the solvent, etc. The observed heat of solutions is a resultant of these several effects. The heat of solution of gases includes the external work—pv or RT—performed in compressing the gas, and this magnitude must be subtracted from the observed heat of solution. The external work associated with the solution of solids and liquids is negligibly small. All known gases have a positive heat of solution; and this is usually the case with liquids; solids also may have a positive heat of solution, but more usually the heat of solution of solids is negative, for they dissolve with an absorption of heat. If the heat of vaporization of a liquid exceeds the heat of solution, it will dissolve with an evolution of heat, and with an absorption of heat if the heat of vaporization is less than the heat of solution. Similarly with solids, the nature of the thermal change is conditioned by the difference in the heats of solution and sublimation. Consequently, the heat of solution of a gas is usually greater than the heat of vaporization; and the heat of solution of a solid is usually less than the heat of sublimation. As a rule, the heat of solution of a substance is smaller the less its solubility.[14]

Does the evolution of heat which occurs when a solid is dissolved in water, or when a concentrated solution of the salt is diluted indicate the formation of hydrates? J. Thomsen [15] returns a negative answer. The progressive addition of water to sulphuric anhydride, SO_3, gave him the curve indicated in Fig. 28, and it is asked: At what point in such a curve should we be justified in setting up a distinction between the effect due to chemical combination and that due to other causes? The volume of the solution obtained when anhydrous salts are dissolved in water is always less than the sum of the volume of solvent and solute, and the subsequent dilution of the solution is likewise followed by a contraction. P. A. Favre and C. A. Valson[16] calculated the amount of heat required for the contraction which occurs when sulphuric acid, H_2SO_4, is diluted with a gram-molecule of water from the specific heat and coefficient of thermal expansion, and found it to be 179 calories less than that actually observed. Hence, the hypothesis that the observed change in volume is merely due to such a change in the mean distances and motions of the molecules as would be produced by a change of temperature is not tenable. The effect must be complicated either by the formation of hydrates, or to a polymerization or depolymerization of the solvent. Analogous results are obtained with sodium chloride, only that the heats of solution and dilution are negative.

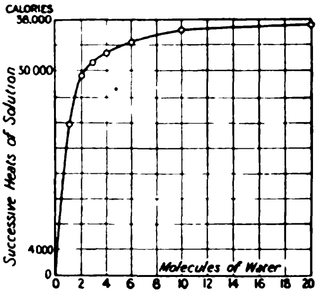

FIG. 28.—Heat of Solution and Dilution of Aqueous Solutions of Sulphuric Anhydride.

There is a parallelism between the heat of solution and the degree of hydration when the process of solution is attended by the formation of one or more hydrates. This is shown when the heats of hydration of salts with a common ion are compared with abnormal freezing points or vapour pressures. The magnitude of the depression corresponds with the order of the hydrates of these salts, which is that indicated in Table IX.

TABLE IX.—HEATS OF SOLUTION (CALORIES).

—	Nitrate NO_3	Thiocyanate SCy	Cyanide Cy	Chloride Cl	Bromide Br	Iodide I
Potassium . .	−8·64	−6·00	−3·12	− 3·12	− 5·04	−5·04
Ammonium . .	−6·24	—	—	− 4·08	− 0·24	−3·60
Sodium . . .	−5 04	—	—	− 1·20	− 0·24	+1·20
Lithium . .	+0·24	—	—	+ 8·40	—	—
Barium . . .	—	—	—	+ 2·16	+ 5·04	—
Strontium . .	—	—	—	+11·04	+16·08	—
Calcium . .	—	—	—	+17·52	+24·48	—
Magnesium . .	—	—	—	+24·00	—	—

J. Thomsen found that of thirty-five salts he examined:

The chlorides of *sodium*, *ammonium*, calcium, magnesium, zinc, nickel, and copper; *potassium bromide*, *potassium cyanide*; the nitrates of *sodium*, *ammonium*, *strontium*, *lead*, magnesium, manganese, zinc, and copper; the acetates of potassium, sodium, ammonium, and zinc; the sulphates of *ammonium*, magnesium, manganese, zinc, and copper; sodium hydrogen sulphate; *ammonium tartrate*, and *bicarbonate*,

eighteen salts which evolve heat when the anhydrous salt dissolves in water also evolve more heat on dilution; and eleven salts (italicized in the list) which absorb heat on solution also absorb still more heat on dilution. All those salts which form definite crystallizable hydrates evolve heat, the other salts do not. The six exceptions included:

Ammonium and potassium bisulphates, sodium sulphate, sodium iodide, and the carbonates of potassium and sodium.

J. Thomsen's opinion is that

> There is no doubt that the salts which dissolve in water with the evolution of much heat, and form crystallizable hydrates, are present also in solution as hydrated compounds; but a determination of the number of water molecules contained in such compounds must be very difficult.

In 1858, G. R. Kirchhoff[18] obtained thermodynamically an expression between the vapour pressure and the heat of solution of a solid or the thermal change which occurs when a gram of the substance is dissolved in sufficient water to form a saturated solution. G. R. Kirchhoff also deduced an equation for the heat of dilution of a saturated solution, and his formulæ have been verified by F. Jüttner (1901) and R. Scholz (1892), and improved by N. N. Schiller. Assuming that the variation in the heat of dilution dl of a solution with change of temperature $d\theta$ is equal to the rate at which the thermal capacity dC of the solution changes with concentration dm—that is, $dl/d\theta=dC/dm$—provided the thermal capacity of the solution does not change with respect to temperature, H. Teudt has shown that the change in the heat capacity of a salt solution with temperature is in general less than that of water; and F. R. Pratt, that the ratio dC/dm or $dl/d\theta$ decreases considerably with an increase of temperature.

It has been shown[19] that the solubility S—gram-molecules per litre—at the absolute temperature T, is related with the heat of solution Q by the expression:

$$\frac{d\log S}{dT}=-\frac{Q}{RT^2};\text{ or }\log\frac{S_2}{S_1}=-\frac{Q}{2}\left(\frac{1}{T_1}-\frac{1}{T_2}\right)$$

when S_1 denotes the solubility of a compound in water at the absolute temperature T_1, and S_2 the solubility at a temperature T_2; and Q denotes the heat of solution on the assumption that the heat of solution Q does not vary with temperature. If the heat of solution does vary with temperature—say $Q=a+bT+cT^2+\ldots$—changes corresponding with those previously indicated must be made. The heat of solution here refers to the solution of a gram-molecule in its own saturated solution. This fictitious quantity may differ considerably from the observed heat of solution in a large quantity of water, and it may even be of opposite sign, as L. T. Reicher and C. M. van Deventer observed with copper chloride, $CuCl_22H_2O$, which evolves heat when dissolved in a large quantity of water, but absorbs heat if "dissolved" in its own saturated solution. With sparingly soluble substances, the difference between the two heats of solution is negligibly small.

EXAMPLE.—Boric acid has a solubility 1·95 at 0°, and 2·92 at 12°. Accordingly, by substituting $T_1=273$, $S_1=1{\cdot}95$; and $S=2{\cdot}92$ and $T=285$ in the preceding expression, and using natural logarithms, $Q=5{\cdot}2$, the observed value is 5·6.

For solutions of substances which dissociate so as to increase the number of molecules in the solution to i per molecule of solute during solution, J. H. van't Hoff introduces the factor i; and J. J. van Laar the factor a, where a denotes the degree of dissociation such that $1+a=i$. The respective equations are:

$$\frac{d\log S}{dT}=-\frac{Q}{2iT^2};\quad\frac{d\log S}{dT}=-\frac{Q}{2T^2}\cdot\frac{2-a}{2}$$

Equations (1) and (2) show that the change of the solubility of a compound with temperature is of opposite sign to the heat of solution—if the solubility increases with a rise of temperature, heat will be absorbed when the substance dissolves in its own saturated solution—this phenomenon occurs with most substances: cupric chloride, $CuCl_2.2H_2O$, etc.; if the solubility decreases with a rise of temperature, heat will be evolved—examples, gases, ether, carbon disulphide, bromine, etc.; and if the solubility is a maximum or a minimum, the solubility does not change appreciably with a small variation of temperature, and the heat of solution will be zero—examples, the solubilities of isobutyl alcohol (W. Alexejeff),[20] calcium sulphate (H. le Chatelier), and of sodium chloride (C. M. van Deventer and H. J. van de Stadt) in water; the heat of solution of two liquids at their critical solution temperature is also zero.

The effect of chemical composition on solubility.—It has been empirically observed[21] that while there is a marked tendency for unlike substances to react chemically, there is a strong disposition for like substances to dissolve in like, for *when there is a close connection in chemical constitution between a liquid and a solid, the solid will usually dissolve readily in the liquid.* In illustration, nearly all salts which contain water of crystallization are soluble in water—calcium sulphate is one of the least soluble, while magnesium phosphate and arsenates, and some natural silicates, are exceptional in being insoluble. Insoluble salts are almost always anhydrous and rarely contain the elements of water. The solubility and capacity for uniting with water of crystallization of a series of salts containing nearly allied metals generally diminishes as the atomic weight increases—*e.g.* the sulphates of magnesium, calcium, strontium, and barium; the chlorides or nitrates of calcium, strontium, barium, and lead. These facts have been taken to imply that the salts which readily crystallize with water of crystallization also dissolve readily in water, because they are likewise readily hydrated in the solvent. Anhydrous copper sulphate is white, and its hydrated crystals as well as its aqueous solutions are blue. It has also been demonstrated by P. Vaillant and by G. N. Lewis[22] that the colour changes produced in aqueous solutions of copper and cobalt salts are due to hydration. Hence, there is here direct evidence of the formation of hydrates in solution. Chemical composition, however, is not a sufficient criterion to determine whether a solid will be soluble or insoluble in a given menstruum.

W. Herz[23] has tried to show that the solubility of a number of organic liquids in water is greater the smaller the diameter of the molecule; but the relationship between molecular diameter and solubility is still largely conditioned by the specific chemical properties of the substance concerned.

The relation between the solubility and the melting point of a solid.—A. L. Lavoisier (1793)[24] expressed the opinion that the solubility of a solid must be related with its fusibility. He stated that the solubility of a salt in cold and hot water is greater the more readily it fuses. T. Carnelley, W. A. Tilden and W. A. Shenstone have shown that there appears to be some connection between the two constants in that the more fusible a substance, the more readily does it dissolve in a given liquid. In illustration, the solubilities and fusibilities of the alkali chlorides may be cited:

	$LiCl$	$NaCl$	KCl	$RbCl$	$CsCl$
Melting point . .	602°	801°	790°	726°	646°
Solubility (15°) . .	80	36	33·4	80	179

Fusibility, however, is not sufficient in itself to determine whether a solid shall be soluble or insoluble in a given menstruum. Silver chloride, $AgCl$, for instance, is more fusible than any of the alkali chlorides—its melting point is 490°—but it is very sparingly soluble—almost insoluble.

According to I. Schröder, if s denotes the molecular fraction of the dissolved molecules to the total number in a given solution, s will be proportional to the osmotic pressure, and J. H. van't Hoff's well-known equation, $dp/p=QdT/RT^2$, becomes $ds/s=QdT/RT^2$, as indicated above. Consequently, the integral $\log s=Q/RT$ plus the constant of integration. This result was obtained independently by H. le Chatelier in 1894. To evaluate the integration constant, it will be observed that when the absolute temperature T rises, the concentration of the solution increases until at the melting point T_m, $s=$unity, and Q is then identical with λ the latent heat of fusion of the solvent. Since $\log 1=0$, the integration constant $=-Q/RT$; and therefore the relation between the melting point

T_m, and the solubility of the solid at a temperature T, can be represented by the expression:

$$\log s=\frac{1}{R}\left(\frac{Q}{T}-\frac{\lambda}{T_m}\right); \quad \text{or, } \log s=\frac{M\lambda}{2}\cdot\frac{T_m-T}{TT_m}$$

if T_m be the melting point of the solution and T that of the pure solvent when $M\lambda$ is the molecular latent heat of fusion of the solvent (a negative quantity). I. Schröder found the approximation $\lambda=Q$ to be applicable for a number of organic compounds.

The above expression contains no term relating to the dissolved substance, so that when the solubility is expressed by the number of molecules of the solvent present in one gram-molecule of the solution, it is found to be independent of the nature of the dissolved substance, and one and the same solubility curve records the behaviour of a given solvent towards all the compounds which it may be capable of dissolving. The term solvent here refers to the substance which crystallizes first from the liquid mixture on cooling, or the substance whose melting point is being lowered—*e.g.* if salt crystallizes out on cooling an aqueous solution, then the salt is here regarded as the solvent. H. Crompton adds that since $M\lambda=1{\cdot}38T\Sigma v$, where Σv denotes the sum of the valency bonds, it follows by substitution for $M\lambda$, and solving for T_m, that $T_m=-0{\cdot}7T\Sigma v/(\log s-0{\cdot}7\Sigma v)$, from which it follows that, knowing nothing more than the chemical constitution and melting point of a given compound, it should be possible to deduce its solubility curve, and its general behaviour as a solvent.

If a mixture of two substances be in question, the preceding expression will apply to the one, and $T_m'=-0{\cdot}7T'\Sigma v/\{\log(1-s)-0{\cdot}7\Sigma v'\}$ will apply to the other. At the eutectic temperature $T_m=T_m'$, and therefore

$$\frac{T\Sigma v}{T'\Sigma v'}=\frac{\log s-0{\cdot}7\Sigma v}{\log(1-s)-0{\cdot}7\Sigma v'}$$

which shows that if T be greater than T', s will be less than $1-s$, or, in a eutectic mixture, the substance with the lower melting point will be present in the greater proportion. A. Miolati was the first to show that *the eutectic point always lies nearest to the melting point of the lower melting constituent of the mixture; and the eutectic mixture always contains the larger proportion of the lower melting constituent.* With a mixture of potassium and sodium nitrates, for instance, $\Sigma v=\Sigma v'$, and since T differs by about 3 per cent. from T', s should be nearly equal to $1-s$; or, more exactly, the eutectic mixture contains 47 gram-molecules of KNO_3, 53 of $NaNO_3$, and melts at 217°. H. Crompton and M. A. Whiteley also showed that the above relations hold for a number of pairs of organic compounds. The observed melting points are higher than the calculated values in cases where the solvent does not crystallize out alone but forms a solid solution with the solute.

CHAPTER XI

CRYSTALS AND CRYSTALLIZATION

1. The Crystallization of Salts from Solutions

> The world is not a meaningless medley. We do not believe that blind chance reigns supreme. On the contrary, we see order everywhere, and law is the regulating principle in all things and processes.—P. Carus.

If a saturated solution of a salt be allowed to evaporate at a given temperature, crystals of the salt separate when the concentration of the solution becomes greater than that represented by a point on the solubility curve. The phenomenon becomes a little more complex when the solution contains two or more salts which do not act upon one another; and more complex still if the salts react with one another forming double salts or with the solvent forming hydrates.

The solubility of a mixture of sodium and potassium chlorides in water at 25° is represented by the curves shown in Fig. 1. These salts form neither hydrates nor double salts at this temperature. The ordinates represent quantities of sodium chloride, NaCl; the abscissæ, quantities of potassium chloride, KCl. The concentration of a saturated solution of sodium chloride at 25° is represented by a point *A*, and of a saturated solution of potassium chloride by a point *B*. The line *AC* represents the composition of solutions of sodium chloride saturated in presence of the proportions of potassium chloride indicated by the abscissæ of the curve *AC*; and the line *CB*, the composition of solutions of potassium chloride saturated in presence of the proportions of sodium chloride represented by the ordinates of *CB*. The point *C* represents the composition of a solution saturated with both salts. The composition of all possible solutions of these two salts can be represented by a point inside the surface *AQBO*, points outside this area can only represent super-saturated solutions not in a state of equilibrium. Hence, when a solution containing equal molecular proportions of both salts—say 50 gram-molecules per 1000 molecules of water—is evaporated, the relative proportions of the two salts will not alter; water alone is removed and the solution becomes more and more concentrated, so that the abscissa and ordinate, representing the composition of the solution, change from those of the point *P* to those of the point *Q*—when *P* is left of *Q*. At *Q* the solution will be saturated with respect to the less soluble potassium chloride, and this salt will accordingly crystallize from the solution; as evaporation proceeds, potassium chloride continues to separate; the successive states of the solution are represented by points passing from *Q* in the direction *BQ*.

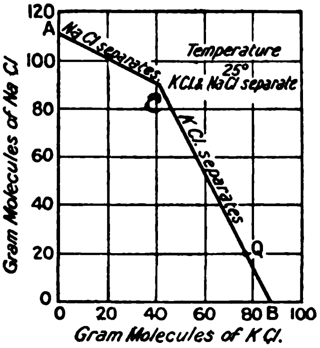

Fig. 1. — Solubility Curves of Mixed Solutions of Sodium and Potassium Chlorides.

The phenomenon is really wonderful. The molecules of both sodium and potassium chlorides are uniformly diffused throughout the original solution; but, as soon as the evaporating liquid has attained a certain concentration, the molecules of the potassium chloride alone commence crystal-building; and ordered cosmos grows out of a chaotic mixture of molecules; the molecules of the solute appear to be dominated by some occult power, for they withdraw from the solution in harmonious order, which is followed as rigorously as the bricklayer, when building a mansion, places brick upon brick, according to the plan predetermined by the architect. The operation continues until the solution has the composition represented by the point of intersection, *C*, of the lines of *A* and *B*. At *C* the solution is saturated with respect to both salts. Any further concentration of the solution will result in the deposition of sodium and potassium chlorides side by side, and at rates which are proportional to the concentration of the solution. A solution which has the composition represented by the point *C* continues to deposit a mixture of crystals of a constant composition until it has been evaporated to dryness. J. H. van't Hoff (1905) calls the point *C* **the end-point of crystallization,** and he draws attention to the fact that when a solution of the two salts is depositing crystals of one of them, the composition of the solution changes further and further away from the composition of a saturated solution of that salt until the end-point of crystallization is reached. Similar remarks would have been applicable for a solution with, say, 90 gram-molecules of sodium chloride and 20 of potassium chloride. Sodium chloride would separate along the curve *AC* until the end-point *C* was attained. Here the molecules of both salts are simultaneously building crystals side by side.

§ 2. Fractional Crystallization

> What chemist who has watched under the microscope the beautiful symmetrical manner in which minute particles of a substance separating in solid form from solution, arrange themselves in geometrical figures obeying well-established mathematical laws, can pretend to explain the cause of the astounding behaviour of inert lifeless matter ?—H. C. Bolton.

The molecules of a substance in solution appear to be distinct individuals before crystallization, while **in a crystallizing solution each molecule appears to exert some specific attraction on its fellow molecules** to enable them to separate from the solution in a definite orderly way so as to form crystals whose architectural symmetry has been called "a miracle of beauty and delight." The alignment of the molecules in a growing crystal can proceed so rapidly that a few seconds of our time must appear a long era in the molecular world. Thus, if concentrated solutions of aluminium and potassium sulphates be mixed, and constantly stirred, a mass of transparent sparkling crystals of alum is immediately precipitated. The molecule of alum is represented in its simplest form by $KAl(SO_4)_2.12H_2O$; and accordingly, in these few seconds, the atoms have had ample time to arrange themselves in molecular groups each containing at least 48 atoms; and the molecules, in turn, have had time to align themselves in a precise methodical way to form an indefinitely large number of regular octahedral crystals. Each tiny crystal contains more molecules than could be enumerated by continuous counting for myriads of years.

G. la Valle noted in 1853 that under suitable conditions crystals grow in directions in which growth is opposed by an external force; this was denied by H. Kopp, but the fact has been abundantly confirmed by O. Lehmann and others. Still further, the force—*crystallizing force*—exerted by a growing crystal as it builds up its structure, molecule by molecule, must be comparatively great. Sodium sulphate or thiosulphate crystallizing in the pores of earthenware will shatter the body into small fragments.[1] G. F. Becker and A. L. Day (1905)[2] placed a plate of glass, supporting a kilogram weight over a growing crystal of alum about one centimetre in diameter, and found that it raised the weight several tenths of a millimetre. The disintegration of rocks, etc., by the growth of ice crystals; the bursting of a test-tube when plaster of Paris is allowed to set therein; and the disintegration of porous bricks and tiles by crystallizing sodium sulphate, are illustrations of a definite and powerful crystallizing force. F. E. Wright and J. C. Hostetter found that when crystals are grown under pressure, the results agree with an hypothesis made by J. Thomson, namely, that during crystallization each particle—atom or radicle—enters into the crystalline state in the condition of the crystal at the point to which it becomes affixed; and that if the crystal be under a state of strain, the freshly deposited particle enters into the same state of strain.

The separation of a mixture of potassium chloride, chlorate, and perchlorate.—When a solution of two (or more) salts is slowly evaporated, if the solubilities of the salts differ appreciably, one salt may pass more or less completely out of solution before the other commences to separate; provided, at the temperature of separation, the solubilities are independent of one another so that the salts exhibit no tendency to unite chemically or physically.

Warm 50 grams of potassium chlorate, just above its melting point, in a new porcelain dish, and keep the mass at that temperature until it becomes viscid and almost solid. This will occupy from ten to fifteen minutes. Let the mass cool. It contains undecomposed potassium chlorate, some potassium chloride, and potassium perchlorate. Add 50 c.c. of hot water, say at 50°, and when all has disintegrated and the solution cooled, the crop of crystals of potassium perchlorate can be filtered off. Evaporate the filtrate until a drop crystallizes when rubbed on a cold surface. The first crop of crystals which separates as the solution cools is mainly potassium perchlorate, because this salt is so very much less soluble than the other two; 100 c.c. of water, at 15°, holds in solution about 36 grams of potassium chloride, 6·6 gram of the chlorate, and 1·5 gram of the perchlorate. The solubility curves of these three salts are shown in Fig. 2. If the evaporation be carried too far, crystals of potassium chlorate will separate. The first crop of crystals is redissolved and again allowed to crystallize by cooling the hot solution; potassium perchlorate can thus be obtained almost free from the other two salts; and by repeated recrystallization it is possible to isolate the salt in a high degree of purity. Recrystallization is needed to get a more pure product, because the crystallizing salt often carries down with it some of the mother liquid, or some of the other salts dissolved in the mother liquid. Indeed, it is perhaps impossible to prepare crystals quite free from the imprisoned solvent. If the evaporation be continued after the separation of the perchlorate, potassium chlorate will eventually separate, and the product must be recrystallized in order to isolate a purer salt. The remaining mother liquid contains potassium chloride contaminated with the chlorate.

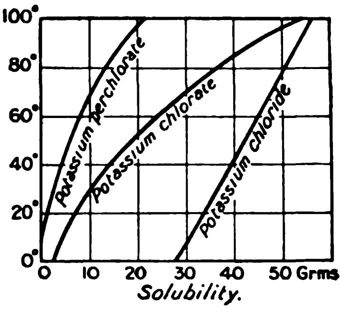

FIG. 2.—Solubility Curves of Potassium Chloride, Chlorate, and Perchlorate.

This operation—**fractional crystallization**—is sometimes a useful method of separating salts which differ appreciably in solubility. In some cases it is the only method of separation available, even though the salts in solution do not differ very much in solubility. The process of fractional crystallization is then very laborious, involving, maybe, scores of crystallizations and recrystallizations. In other cases it is impossible to separate the salts in this way, because double salts separate.

As a rule, the slower the process of crystallization, the larger and more perfect the crystals. The chemist must learn from the mineralogist many facts concerning the slow growth of crystals because some natural phenomena cannot be imitated in the time at man's disposal, for, said J. W. Judd in his work, *The Rejuvenescence of Crystals* [3]:

> Nature is unstinting in the expenditure of time upon her handiwork, and her slow elaboration of crystals during millions of years accounts for the presentation of some natural products of curious phenomena that are not reproducible in test-tubes and crucibles.

Crystals are usually more or less distorted because, owing to local differences in concentration, the crystallizing solution, in the vicinity of some faces of the crystal, may be more concentrated than the others. Perfect crystals are rarely found in nature or in the laboratory.[4]

The purification of salts by recrystallization is a well-known process. The Latin Geber frequently alludes to the purification of salts by recrystallization, and the process was recommended by R. J. Haüy [5] in 1801 for the purification of nitre. The operation, however, was the subject of a controversy in 1814. Thus, F. Clément and J. B. Désormes [6] in their *De l'épuration des corps par la cristallisation,* cited many experiments which demonstrated the fact, and remarked that chemists who did not believe in the process should cease to purify their salts in this manner. The operation of fractional crystallization has been compared with fractional distillation; the former is determined by the solubility of a body at a given temperature, the latter by the temperature of vaporization.

Inclusions in crystals.—Ideal crystals are homogeneous, but crystals are sometimes coloured with pigments—*e.g. smoky quartz*—and they may also have other inclusions discernible under the microscope. There may be cavities in the crystal containing gases of various kinds—*e.g.* air, carbon dioxide, hydrocarbons, sulphur dioxide, etc.—or the cavities may be wholly or partially filled with liquid —*e.g.* water, liquid carbon dioxide, salt solutions, etc. Fig. 3 shows a photograph of quartz (from Cornish granite) with four cavities containing a liquid, each liquid inclusion has a bubble of air or gas. If the liquid be condensed carbon dioxide, the crystal was probably formed under great pressure. Similar cavities are found in natural crystals of rock salt, calcite, fluorspar, topaz, beryl, barytes, etc. A cavity formed at an elevated temperature may be filled with liquid; as the temperature falls the liquid contracts faster than the solid, and a space containing a vapour bubble results. The cavities may also contain crystals which have separated from the solution. Then again, crystals of a totally different substance may be embedded (included) in the larger crystal—*e.g.* in the so-called *sagenitic quartz* (*σαγήνη*, a net)—needle-like crystals of rutile cross one another, giving a reticulated or net-like appearance to the quartz; and in the variety poetically called *veneris crinis* or *Venus' hair*, or *flèches d'amour* (love's darts), the quartz encloses bunches of reddish-yellow rutile needles; this variety of quartz is probably the *chrysothrix* (golden hair) of the Orphic poem. *Aventurine quartz* has imprisoned golden or brassy-yellow spangles of, presumably, mica. H. C. Sorby (1858) [7] has shown that crystals deposited from solutions usually contain cavities enclosing small quantities of the mother liquid, and this the more the quicker the rate of crystallization.

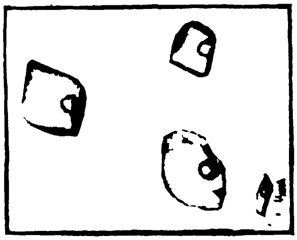

FIG. 3.— Quartz in Cornish Granite showing Four Cavities with Liquid Inclusions and Gas Bubbles (× 1000).

Experiments on this subject can be made conveniently by allowing a solution of potassium chloride to evaporate slowly; the crystals which form are more or less opaque towards the centre, and clear and transparent elsewhere. Under a high magnification (50 to 400 diameters) in a shallow glass cell containing a cold saturated solution of the salt itself, the opacity appears to be produced by vast numbers of minute cavities arranged in bands parallel to the sides of the crystals. The cavities are full of liquid. This is demonstrated by allowing sodium chloride to crystallize from a solution tinted with potassium dichromate, the crystals of sodium chloride appear yellow to the naked eye; and on magnification, this coloration is evidently an effect due to a large number of cavities in the colourless crystals filled with yellow liquid.

The decrepitation of common salt on heating is due to the vaporization of the included water; similarly, the decrepitation of some varieties of quartz just over 1000° is due to the release of imprisoned gases. So important is this imprisoned solvent in the preparation of pure material for exact work that, according to T. W. Richards (1903), many records of painstaking determinations of atomic weights can be safely ignored because the contamination of the materials from this cause has been entirely overlooked, or inadequate means have been taken to counteract the effects.

§ 3. Crystals

> In whatever manner, or under whatever circumstances, a crystal may have been formed, whether in the laboratory of the chemist or in the workshop of nature, in the bodies of animals or in the tissue of plants, up in the sky or in the depths of the earth, whether so rapidly that we may literally see its growth, or by the slow aggregation of its molecules during perhaps hundreds, perhaps thousands of years, we always find that the arrangement of the faces of the crystal, and therefore its other physical properties, are subject to fixed and definite laws.—H. P. GURNEY.

When homogeneous substances solidify from a state of vapour, fusion, or solution, their particles often cohere so as to form solid figures—**crystals**—with regular symmetrical shapes bounded by plane faces. The solids are then said to be crystallized. M. A. Capellar's *Prodromus crystallographiæ*, published at Lucerne in 1723, was the first book devoted to crystallography; and in an essay on the crystal forms of calcspar, in 1773, T. O. Bergmann[1] made what may be regarded as a first approximation to a definition of crystals. He said: "Crystals are bodies which, though destitute of organic structure, yet externally resemble geometrical figures more or less regular." The term crystal originally referred to the ice-like appearance of rock crystal or quartz, but the angular shape of this substance, as well as that of garnet, beryl, and other minerals, seems to have been regarded by the ancients as an accidental and not an essential characteristic. The alchemists must have studied many salts and noticed that on evaporation of their solutions, definite and regular crystals were obtained which were to some extent characteristic of particular salts. Thus, at the end of the sixteenth century, A. Libavius, in his *Ars probandi mineralia* (Francofurti, 1597), stated that the nature of the saline components of mineral waters could be ascertained by an examination of the crystalline deposit left on evaporating the water to dryness; and in his *Chemical Lectures* (London, 1712), J. Freind said:

> Let these salts be never so divided, and reduced into minute particles, yet when they are formed into crystals, they each of them reassume their proper shape; so that one might as easily divest and deprive them of their saltness, as of their figure. This being an immutable and perpetual Law, by knowing the figure of the crystals, we may understand what the texture of the particles ought to be, which can form those crystals.

The constancy of interfacial angles.—In 1669, N. Steno,[2] in an essay *De solido intra solidum* (Florentiæ, 1669), showed that in spite of numberless variations in the size and shape of crystals of different specimens of rock crystal, he could detect no variation in the angles between the faces. Thus, by cutting a series of specimens at right angles to the faces of the prism, he obtained six-sided sections with sides of varying length, and apparently different figures, but the angles were all equal, each to each—Fig. 4. Soon afterwards, D. Guglielmini, in his *Riflessioni filosofiche dedotte delle figure de' sali* (Bononeæ, 1688), and in his dissertation *De salibus* (Venetiæ, 1688), generalized N. Steno's observation, and asserted that the crystals of every salt have their own peculiar shape which never changes, and that even in imperfect and broken crystals, the interfacial angles are always constant. As a result of an examination of over four hundred crystal forms, J. B. L. Romé de l'Isle confirmed the earlier generalization of D. Guglielmini, and developed the idea further in his *Essai de cristallographie* (Paris, 1772). **Every crystalline substance of definite chemical composition has a specific form characteristic of that substance.** This is sometimes called **Haüy's law,** because R. J. Haüy (1801) may be said to have "erected the science of mineralogy on a crystallographic basis which was in turn founded on this principle." The faces of crystals of the same substance may vary in size and shape; but if the crystals possess the same chemical composition, and are at the same temperature, the interfacial angles have the same numerical value. In other words, **the angles between similar faces of crystals of the same substance are precisely the same, and are characteristic of that substance.** As indicated above, this generalization was first announced by D. Guglielmini (1688). This means that the crystalline form of a substance is not determined by the absolute position nor by the sizes of the faces of the crystal, but rather by the dimensions of the interfacial angles. The primary dominant faces, so to speak, may persist, but the angles and edges of some of the crystals may or may not be truncated and bevelled (*cf.* Fig. 4), giving rise to new facets, or secondary faces. As a general rule, when crystals are formed rapidly the faces are simple, while the faces of crystals which have grown slowly may be more complex. The dominant form of the crystals of a given substance "persists in spite of these variations; although the primitive fundamental form can sometimes be recognized, the crystal can be interpreted only after careful study." The doctrine of the identity of the primitive form of the crystals of a substance was not at first generally accepted; and even so late as 1783, G. L. L. de Buffon, in his *Histoire naturelle des minéraux* (Paris, 1783–88), combated the idea. He said:

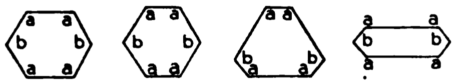

FIG. 4.—N. Steno's Demonstration of the Equality of the Angles of Quartz Crystals of Different Sizes.

> No crystallization will ever afford a specific character, for the variety is infinite; not only are there forms of crystallization common to several substances of a different nature, but, on the contrary, there are few substances of the same nature which do not present different forms on crystallization. It would thus be more than precarious to establish differences or resemblances, real and essential, by means of this variable and almost accidental character. . . . Our crystallographers thus propose . . . to substitute ideal combinations for the real facts of Nature.

This is a remarkable testimony to the difficulties which the contemporaries of D. Guglielmini and R. J. Haüy encountered in seeing order among the diverse forms of the crystals of a substance.

In 1767, C. F. G. H. Westfeld,[3] and in 1773, T. O. Bergmann, stated their opinion that the different forms of crystals could be regarded as variations of a very small number of primitive forms, and J. B. L. Romé de l'Isle (1783) followed up the idea, using the method employed by geometers—*e.g.* W. Janitzer (1568) and J. Kepler (1619). J. B. L. Romé de l'Isle derived all the different forms of crystals from six primitive forms by replacing similar edges and corners by one or more planes. The idea was still further developed by R. J. Haüy (1782) in a remarkable *Essai d'une théorie sur la structure des crystaux* (Paris, 1784); it was extended by F. Mohs (1820) and others;[4] and finally culminated in the seven systems now in general use. Some emendations must be made to the law of the constancy of crystalline form.

Crystal mimicry.—At first sight there appears to be a kind of mimicry among the crystals of some minerals. for a mineral sometimes has the external crystalline form characteristic of a totally different mineral species. Such crystals are said to be **pseudomorphs,** and they appear to have been formed by secondary chemical processes whereby the original mineral has been decomposed, and its place taken by another. As a result of some such process of infiltration, quartz crystals are sometimes found with the external form characteristic of calcite or fluorspar, or barytes ; tin-stone in the form of felspar ; galena (cubic) in the form of pyromorphite (hexagonal) ; etc. The apparent mimicry is confined to the external form of the crystals, the internal structure is that peculiar to the normal crystals. A crystalline substance with its own characteristic outlines is said to be **idiomorphic.**

The twinning of crystals.—It appears as if, during the building of some crystals, the structural units instead of continuing to deposit in layers with units oriented all in the same direction, suddenly commence to deposit in layers turned through an angle—sometimes 180°—about an axis perpendicular to those previously laid down. As a result, two individual crystals appear to be united in a common plane, or to penetrate one another symmetrically. The phenomenon is called *twinning* ; and the double crystal is called a **twin.** Twinned crystals of selenite often have the appearance of an arrow-head, Fig. 5 ; tinstone similarly forms twinned crystals. Sometimes too, after a number of layers of the crystal units have been laid in the new direction, there is an abrupt reversion to the original form. The result is a kind of twinning band which has different texture from the material on either side.[5] Sometimes, too, a series of parallel bands are formed in this way. R. J. Haüy was interested in twinning. He pointed out that the phenomenon is subject to certain laws, so that "instead of precipitating themselves tumultuously on one another, the crystals have in a prearranged manner prearranged their disposition." There is a plane of juncture "so that the two structures follow their regular development, each in its sphere, towards their common plane, which forms their respective limits." Fig. 6 is a photograph of a twinned crystal of pyrite from Minden (Prussia). The twinned crystals may not only be juxtaposed but they may also be interpenetrant. The interpenetration may be so complete as to form a single crystal, which may then appear to have a higher degree of symmetry than it really possesses. Thus a rhombic crystal may be so twinned that externally it cannot be distinguished from a tetragonal crystal. Crystals so twinned are pseudo-symmetric, and this form of mimicry is called **mimetic twinning**—*e.g.* rhombic aragonite may be so twinned as to form a pseudo-hexagonal prism.

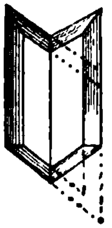

Fig. 5.—Twinned Selenite Crystal.

Fig. 6.—Twinned Crystal of Pyrite.

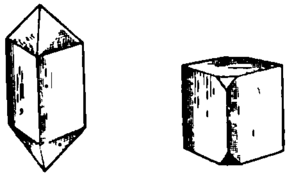

Fig. 7.—Dimorphic Forms of Alkali Diphosphate.

Substances with crystals of more than one form.—Crystals of different substances usually have different forms ; crystals of the same substance developed under the same conditions have the same form ; but crystals of the same substance developed under different conditions may or may not have the same form. For instance, crystals of sulphur formed above and below 94·5° are different ; there are two differently shaped crystals of sodium phosphate—Fig. 7. These are cases of *polymorphism*. The *habit* of crystals of sodium chloride is octahedral, if grown in alkaline solutions; and cubical, in neutral solutions; and conversely, crystals of alum are usually octahedral, but cubical if grown in alkaline solutions. The two phenomena, change of habit and polymorphism, are quite different. Change of habit does not mean a change of phase, while polymorphic modifications represent different phases. There is no change of properties in crystals with a different habit, but the transformation from one polymorphic form to another usually involves a discontinuous change of scalar and vectorial properties, and it takes place within a definite range of temperature, or at a definite temperature, the so-called transition point.

A. G. Werner mistook aragonite from Spain, described by J. B. L. Romé de l'Isle,[6] for apatite, but M. H. Klaproth showed that the composition is the same as that of calcspar, and he said that aragonite must be regarded as ordinary calcspar, which while retaining the same constituents has been altered by a change in the disposition of its constituent parts. If this be the correct interpretation, it was recognized that R. J. Haüy's law required revision. In consequence, a great many new analyses were made by French and German chemists—A. F. de Fourcroy and L. N. Vauquelin, L. J. Thénard and J. B. Biot, L. J. Proust, C. F. Bucholz, J. B. Trommsdorff, etc. A. F. de Fourcroy and L. N. Vauquelin said that their analyses rendered it necessary for mineralogists to inquire if it is not possible for the same substance to assume different forms; and L. J. Thénard and J. B. Biot added that aragonite and calcspar are compounded from the same elements (*principes chimiques*) united in the same proportions; and that the same elements uniting in the same proportions can form compounds with different physical properties, because the molecules of the constituent elements can combine in many different ways. The analyses showed that impurities are present in the native minerals. In 1801, L. N. Vauquelin and M. A. Klaproth showed that anatase and rutile consisted of titanic oxide along with some impurities; while A. Laurent and P. Dejussieu found that marcasite and pyrite were modifications of iron disulphide—*comme l'analogue de l'arragonite*. A. Stromeyer, in his *De arragonite ejusque differentia a spatho calcareo rhomboidali chemica* (Göttingen, 1813), recorded the presence of strontium in aragonite, and that this had been overlooked in previous analyses. This lent support to R. J. Haüy's contention that small quantities of a foreign agent with a great power of crystallization may cause a compound to change its crystalline form. A. Laugier found no difference in strontian-free and strontianiferous aragonite. The question was not decided until E. Mitscherlich's work on polymorphism of sulphur and sodium dihydrogen phosphate, $NaH_2PO_4.H_2O$, had been accepted.

Each kind of crystal is stable only within a limiting range of temperature, so that the amended form of Haüy's law is: **Every crystalline substance of definite chemical composition has one specific stable form within certain definite limits of temperature.** Substances which crystallize in two different forms are said to be **dimorphous.** Fig. 7; and substances which crystallize in three different forms are said to be **trimorphous.** Titanic oxide, TiO_2, for example, is known in three forms—rutile, anatase, and brookite. Two of these forms will probably be found to be in a metastable condition at ordinary temperatures. Magnesium metasilicate, $MgSiO_3$, exists in four different crystal forms, and it is **tetramorphous. Polymorphism** is the general term applied to the phenomenon when a substance crystallizes in more than one form. When the crystals are similar and yet so fashioned that one is the mirror image of the other, the crystals are said to be **enantiomorphic**—*e.g.* *d*- and *l*- quartz, *d*- and *l*- tartaric acid, etc. Enantiomorphic crystals are not usually regarded as polymorphic forms.

One or more faces of a crystal may be abnormally developed or stunted in growth. During the growth of a crystal, the concentration of the mother liquid is rarely so evenly balanced on all sides as to allow the growth to proceed with the same rapidity in all directions. The crystal will grow fastest where the solution is most concentrated. If a crystal grows on the bottom of a liquid at rest, flat plates, almost parallel with the bottom of the vessel, may be formed; while if the solution be agitated during crystallization, a more uniform growth in all directions may prevail. This is not all the story, for a crystal may habitually grow more rapidly in *one* direction so as to form a prismatic crystal—**prismatic habit**—*A*, Fig. 8. This may take the form of needle-like or **acicular crystals**; hair-like or **trichitic crystals**; arborescent, branching, or **dendritic crystals** (δένδρον, a tree); or fibrous masses; or the crystals may grow in *two* directions so as to form a tabular or plate-like crystal—**tabular habit**—*B*, Fig. 8, this may take the form of groups of thin separate plates, fan-like more or less divergent plates, feather or branching aggregates (*e.g.* the six-rayed snow crystals); or again the crystals may grow uniformly in all *three* directions, and the ideal cube—*C*, Fig. 8—will be produced. In the well-known *en tremies* or hopper-shaped crystals of bismuth, quartz, or of sodium chloride—*D*, Fig. 8—growth has been fastest along the edges and corners of the cube, and the crystals assume the form of hollow cubes—*hopper salt*. These crystals can be obtained by the addition of a little alum to the salt. In every case of distorted cubical crystals, the angles between the faces, however, will remain unchanged—90°. Similar remarks apply to the different forms of crystal other than the cubes.

The most suitable condition for uniform growth in all directions occurs when the growing crystal is suspended in the middle of the given solution by means of a thread. The crystal then sometimes approximates more or less closely to the ideal form. If the crystallization of a solution be rapid, the crystals are usually much smaller than if the process be slow. O. Lehmann laid down the empirical rule:

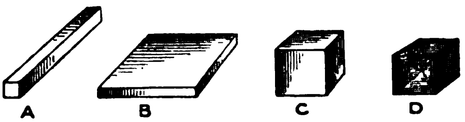

FIG. 8.—Ideal and Distorted Cubic Crystals.

> When a substance crystallizes from a solution owing to the withdrawal of the solvent, the crystals are the more irregular in shape (i) in proportion as the separation occurs with greater rapidity; (ii) in proportion as the solvent is the more viscid; and (iii) in proportion as the substance is less soluble.

The minute crystals precipitated by alcohol from solutions of barium chloride, copper sulphate, lead nitrate, etc., were found by P. Gaubert to be almost perfect in form.[7]

As a rule, needle-shaped (*acicular*), fibrous, hair-like (*trichitic*), or branching fern-like, moss-like, or tree-like forms (*dendritic*) grow in labile solutions where crystallization is rapid, while well-formed characteristic crystals grow in metastable solutions where growth is slow and uniform. The dendritic forms are also common with highly viscous solutions, and with crystals grown in the presence of colloidal suspensions. Ammonium chloride, calcium sulphate (Fig. 10), copper sulphate (Fig. 9), or potassium dichromate (Fig. 11) can be used in illustration. When, say, the last-named salt is deposited slowly from metastable solutions, well-developed crystals are formed, while if crystallized from labile solutions feather-like aggregates are developed. This is illustrated by Fig. 11, which shows that the first crystals deposited have arborescent branches, while the later crystals have the regular crystalline form.

Again, the *habit* of a crystal may change when grown from liquids containing other salts in solution. This fact was noted by Robert Boyle[8] in 1666, in the words: "Notwithstanding the regular and exquisite figures of some salts, they may by the addition of other bodies, be brought to constitute crystals of very differing, yet curious shapes." Again, J. B. L. Romé de l'Isle (1783)[9] showed that the crystals of *sodium chloride* which separate from an aqueous solution containing fresh urine are octahedral, and not cubical. Urea or carbamide can be used provided, as J. W. Retgers emphasizes, not too small a quantity of urea is present. The presence of colloids in a solution usually inhibits or modifies crystallization; thus, sodium chloride crystallizing from a solution containing a trace of gum arabic forms tree-like or dendritic-masses. Again, *ammonium chloride* crystallizing from cold aqueous solutions forms dendritic masses, but if the saturated solution is tinted yellow with ferric chloride, and a few crystals of ammonium acetate are dissolved in the solution, well-formed cubic crystals of ammonium chloride separate out. Further, if a few grains of octahedral alum crystals be added to a supersaturated solution of potash alum, octahedral crystals are formed; whereas, if potassium carbonate be added to a boiling solution, the liquid, on cooling, deposits cubic crystals. Z. Weyberg has studied the effect of hydrochloric acid on the habit of the crystals of alum; and H. Gerhardt the effect of foreign salts on the crystals of barytes. Potassium chlorate gives *prismatic crystals* when grown in aqueous solutions; but if much calcium chloride be present, small needle-like crystals are obtained, and if some potassium iodate be present long plate-like crystals separate from the solution—the crystal angles, however, are the same in each case; or else the different sets of planes which bound the crystals are all derived from the same internal structure by the suppression of certain planes, and the abnormal development of others. Near the beginning of the nineteenth century R. J. Haüy [10] showed that the crystals of axinite which are coloured violet by manganese show additional faces not found on the crystals of axinite coloured green by chlorite, and that the green-tinted crystals are more regularly shaped and do not present the striated surface observed on the violet-tinted crystals. He said:

FIG. 9.—Copper Sulphate grown in a Labile Solution.

FIG. 10.—Calcium Sulphate grown in a Labile Solution.

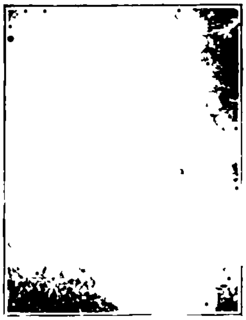

FIG. 11.—Potassium Dichromate grown in a Labile Solution.

> The molecules of a substance in a solution and disposed to unite in the formation of a crystal, are at the same time attracted towards each other and even by the molecules of the solvent itself; and it is because their mutual affinity exceeds that of the solvent that crystallization operates. . . . If there are foreign substances in the solution, they will modify the action of the liquid upon the coalescing molecules.

The general shape of a crystal, or, as it is usually called, the **habit of a crystal,** thus depends upon the character of the distortion it has suffered during growth, and the distortion is often a characteristic feature of the crystals of a given substance. Calcite occurs as rhombohedra, scalenohedra, or hexagonal prisms, but all can be referred to one fundamental form. However much the crystals may be distorted, the angles between like faces have the same value, and in consequence, similar faces can be imagined at the same distance from the centre of the crystal. In this way, the **ideal form of a crystal** can be derived from that of a distorted crystal. The term **distortion,** as distinct from habit, is also applied to certain crystals which appear as if they had been mechanically deformed—*e.g.* twisted crystals of topaz.

If a layer of gelatine containing a solution of salt be allowed to dry slowly at the temperature of the room, the water is lost quickest at the edges, and as the solution approaches a state of supersaturation, crystals of the salt begin to separate.

There are three ways in which the crystals may appear: (i) single crystals irregularly distributed are formed—*e.g.* sodium chloride; (ii) dendritic lines or branches of crystals may extend from the edges towards the middle of the gelatin—*e.g.* potassium chromate; or (iii) a number of strips, concentric lines, or bands of crystals separated by zones free or almost free from crystals may be formed—*e.g.* trisodium phosphate or ferrous sulphate. E. Liesegang's explanation of the phenomenon of **rhythmic or periodic crystallization** is as follows:

> Before the first crystals are formed at the outermost edge there is present at this place a zone of supersaturated salt solution. As the degree of concentration increases a spontaneous deposit of the salt necessarily occurs. These rows of crystals act as a nucleus upon the supersaturated solution in their vicinity, *i.e.* the solute diffuses towards the crystals and increases the size of the latter. In this manner an area poor in salt content is produced. As the loss of water proceeds this area becomes supersaturated in its turn. Accordingly the impoverishment in salt content becomes still more marked through the solute travelling towards the nuclei. Finally, however, the migration in this area ceases entirely because of the fact that the solution is entirely dried up. In the mean time, at a certain distance from the first row of crystals, the salt solution reaches such a degree of supersaturation, that the separating out of the salt begins spontaneously to occur once more. This row of crystals grows just as the first one did, and the process is repeated indefinitely. The more abrupt the precipitation, the closer together the bands of crystals. Since the first spontaneous deposit of crystals occurs very suddenly, while their increase in size through diffusion takes place more slowly, each band may exhibit a very different aspect as regards its inner side respectively, *i.e.* dense aggregates of small crystals on the outer side and larger crystals on the inner side.

The phenomenon of rhythmic crystallization is analogous with that of rhythmic precipitation.[11]

Cleavage.—Crystals can usually be readily split along certain definite planes. Thus, a fragment of calcite when struck sharply and lightly will split into a number of fragments of variable size but similar form—rhombohedrons; a crystal of rock salt similarly treated splits into little cubes; while mica splits into thin plates. Fluorspar, selenite, galena, and hornblende also illustrate the property very well. Orthoclase—normal potash felspar—splits in two directions with an angle of 90° between them, whereas the two cleavages of albite—ordinary soda felspar—are inclined at an angle of about 86°. Galena, like rock salt, splits in three directions, fluorspar in four. This property is termed *cleavage.* The cleavage of calcite into six-faced rhombohedra was noticed by T. O. Bergmann in 1773; and this suggested to R. J. Haüy that the ultimate components of crystals are irreducible formative nuclei, so that J. Herschel could say:

> From the moment that the genius of Haüy discovered the general fact that the crystals could be cloven or split in such directions as to lay bare their peculiar primitive or formative forms, from that moment, mineralogy ceased to be an unmeaning list of names, a mere laborious cataloguing of stones and rubbish.

Fracture is different from cleavage, for it is irregular and has no definite relation with the crystalline form. Cleavage is obviously a structural weakness related to the mode of aggregation of the particles which build up the crystal, and it will be obvious that once a crack is started in a crystal, it will follow the line of least resistance, that is, where the structural units exert least cohesion. If a number of spheres or ellipsoids be packed together in a regular way, the cleavage will naturally follow the direction where the number of contacts per unit area is least. If a layer of spheres be formed so that each sphere touches six others, and a second layer be laid directly over the interstices of the first one; and a third layer over the interstices of the second; a pyramid is eventually obtained representing the half of a cubical crystal. In such a configuration, the number of sphere contacts per unit area parallel to the base is $2\sqrt{3}/d^2$, where d denotes the diameter of each sphere; and $4/d^2$ sphere contacts per unit area parallel to the front face. Hence, such a crystal will break more easily along a direction parallel to one of the cubic faces of the crystal since $2\sqrt{3}$ is less than 4. This corresponds with the fact that the cubic crystals usually have an octahedral cleavage.[12]

Cleavage is an important factor in the identification of some of the commoner minerals in rocks. The possible cleavage forms given by A. J. Moses, *The Characters of Crystals* (New York, 1899), in the cubic system the chief cleavages are *cube*—*e.g.* galena ; *octahedron*—*e.g.* fluorspar, diamond ; *rhombic dodecahedron*—*e.g.* sphalerite. In the hexagonal system, *basal pinacoid*—*e.g.* beryl, pyrosmalite ; *hexagonal prism*—*e.g.* nephelite, apatite ; *rhombohedron*—*e.g.* calcite, siderite ; *hexagonal pyramid* (rare)—*e.g.* pyromorphite. In the tetragonal system, *basal pinacoid*—*e.g.* apophyllite ; *tetragonal prism*—*e.g.* rutile, wernerite ; *tetragonal pyramid* (rare)—*e.g.* scheelite. In the rhombic system, *pinacoid*—*e.g.* topaz, anhydrite ; *prisms or domes*—*e.g.* barytes ; *pyramid*—*e.g.* sulphur. In the monoclinic system, *clinopinacoid*—*e.g.* orthoclase, gypsum ; *basal pinacoid*—*e.g.* muscovite, orthoclase ; *orthopinacoid*—*e.g.* epidote ; *orthodome*—*e.g.* epidote ; *prism*—*e.g.* pyroxene, amphibole ; *pyramid* (rare)—*e.g.* gypsum. *Triclinic crystals* usually admit of equally easy cleavages parallel to any principal plane.

It has been known for a long time that many substances in the act of crystallization in the dark exhibit a bright sparkling light. G. Pickel (1787),[13] for example, noted the phenomenon with potassium sulphate crystallizing from an aqueous solution; C. G. Schönwald, with a mixture of sodium sulphate and potassium sulphate crystallizing from aqueous solution, and he noted that the crystals also became luminous when rubbed. E. Wiedemann applied the term **tribo-luminescence** to the property exhibited by many crystalline substances of emitting a characteristic phosphorescent light when rubbed or crushed, while the emission of a phosphorescent light during crystallization is called **crystallo-luminescence**. The phenomenon was also observed by J. A. Giobert, and he said that if the potassium sulphate contains magnesium sulphate as impurity, the phenomenon does not occur, and he adds that previous exposure to sunlight strengthens the effect, although this observation has not been confirmed. K. S. L. Hermann observed the light during the crystallization of cobalt sulphate at —12°. The phenomenon with potassium sulphate has also been the subject of comment by J. J. Berzelius, F. Wöhler, and M. Sager; with strontium nitrate by C. H. Pfaff and E. Stieren; with potassium acetate by J. A. Büchner; with potassium chromate, selenate, sulphate, and chloride, and arsenious oxide by H. Rose. Numerous other salts have been added to the list by E. Brandrowsky, M. Trautz, J. Guinchant, D. Gernez, W. J. Pope, E. F. Farnan, etc. H. Rose thought the phenomenon with arsenious oxide was due to the change from an amorphous to a crystalline state; O. Lehmann said from one crystalline form to another—rhombic to cubic (octahedral). E. Brandrowsky disproved both these suggestions, and he tried to show that it was an electrical effect of the union of charged ions in the act of crystallizing from aqueous solution. He thought that the light was white, but H. B. Weiser showed that with sodium chloride the light is blue. The general cause of crystallo-luminescence is now attributed to chemical action due to the union of ions—*e.g.* $Na'+Cl'=NaCl$—but it is not at all clear what is really the nature of the reaction, if one such does occur. The light also has been spectroscopically examined, and so has the varying effects of the nature and concentration of the precipitant; of agitating the precipitating solution; of adding a colloid; of increasing the viscosity of the solution; and of variations of temperature. J. Plotnikoff has described a *triboluminiscope* for exhibiting the phenomenon.

The Florentine Academicians (1660) were the first to note the tribo-luminescence of many substances—flint, sugar, salt, agate, jasper, and quartz—when rubbed in darkness.[14] R. Boyle (1663) noted that diamonds exhibited the phenomenon; C. Mentzel (1675), W. Homberg (1730), J. Bernoulli and J. Cassini (1707), F. Hauksbee (1709), C. F. du Fay (1723), and many others, made analogous observations in the eighteenth century. A great many observations were afterwards recorded showing that the phenomenon is fairly general. L. Tschugaeff, for instance, tried over five hundred substances and found that about 25 per cent. showed tribo-luminescence, and he found some cyclic carbon compounds exhibited the phenomenon to a marked degree. The early observers thought tribo-luminescence is due to small particles of the solid becoming heated to incandescence by friction, but T. de Saussure demonstrated that this explanation is very improbable when he was able to obtain the effect by stroking a mass of calcium phosphate with a quill. J. P. Dessaignes[15] tried to demonstrate that the luminescence is an electrical effect, but J. Schneider showed that neither electrification nor heating are adequate explanations of the phenomenon. After an examination of the main hypotheses propounded to explain the phenomenon, H. B. Weiser concluded that tribo-luminescence is caused by chemical action, and photographic observations are in agreement with the same hypothesis. The colour of the light is specific in that it depends on the nature of the chemical reaction by which it is produced. All crystallo-luminescent substances are tribo-luminescent, but converse of this does not obtain.

The emission of light in luminescence has been explained, in part, in terms of the electronic hypothesis. In electro-luminescence, where the effects are produced by cathode rays, X-rays, Becquerel rays, or canal rays, the result is connected with the displacement or separation of electrons from the constituent atoms of a substance; in tribo-luminescence, where the effects are produced by friction or by crushing, frictional electricity is likewise involved in the displacement or separation of electrons; in chemi-luminescence, where the effects are produced by chemical action, the result is attributed to the rupture of a chemical bond which in turn is effected by the rupture of a valency electron; and finally, in photo-luminescence whether it be transient (fluorescence) or persistent (phosphorescence), where the effect is due to the action of light, it is also supposed that the partial or complete separation of electrons from the constituent atoms is directly concerned in the emission of light.

§ 4. The Crystallization of Solids en masse

In crystals, we see one of the many ways of judging the internal world of molecules and atoms, and one of the weapons for conquering the invisible world of molecular mechanics which forms the main object of physical chemistry.—D. I. MENDELÉEFF.

When a supercooled liquid commences to solidify, rays of the solid grow into the liquid with a definite velocity,[1] and H. A. Wilson has shown that the relation between the velocity of solidification and the supercooling of some liquids fits the hypothesis that solidification is due to the difference between the internal pressure in liquid and solid, and that the molecules at the surface of a liquid are urged from liquid to solid by this difference in internal pressure. Modifying J. H. van't Hoff's method for calculating the osmotic pressure of a salt in solution from the lowering of the vapour pressure, he obtained the formula: Velocity of solidification$=k(T_m-T)/V$, where T_m represents the melting point of the solid on the absolute scale; T, the temperature at the surface separating liquid and solid, so that T_m-T measures the supercooling of the liquid; V, denotes the viscosity of the liquid; and k is a constant. Hence, the velocity of solidification of a pure substance is directly proportional to the actual supercooling of the solidifying liquid, and inversely as the viscosity. The results obtained with a number of substances agree with this hypothesis, although there is a disturbance due to the production of heat which accompanies solidification, and which raises the temperature at the surface of solidification.

Metals, during solidification, have a characteristic tendency to assume dendritic forms rather than simpler crystals. Even in the natural state, crystals of native gold, silver, and copper—all in the cubic system—frequently appear as dendritic growths. E. S. Dana, in a paper on the *Crystallization of native copper,*[2] has indicated a variety of these forms. The idealized representation, Fig. 12, illustrates a common method of growth.

It seems as if the nuclei of a crystallizing metal first stretch out long branching lines, each nucleus secures for its own crystal a large share of territory,[3] and then proceeds "in a leisurely manner to fill up the gaps." Under high magnification, it appears as if the branches radiating from adjacent crystals stop growing before they actually meet, and so form a kind of neutral territory between the tips of the branches. When the growth of all the radiating branches has been arrested in this way, the effect is almost the same as if each nucleus was enclosed by a cell-like boundary. As shown by D. K. Tschernoff and others, the crystal grains of ordinary cast metals thus appear to be produced by the mutual interference of adjacent dendrites, as illustrated diagrammatically in Fig. 13.

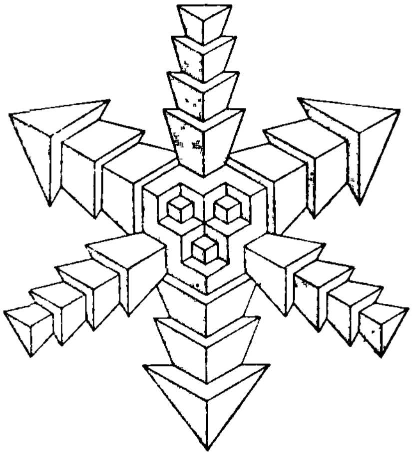

Fig. 12.—Idealized Dendrite of Copper.

O. Lehmann,[4] in his *Molekularphysik,* gives a satisfactory explanation of the phenomenon of dendritic growth in the case of supersaturated solutions: In the immediate vicinity of a growing crystal, a zone of liquid no longer supersaturated is formed owing to the removal of the solute, by the crystal. Further growth can occur only when the concentration of the solution in the immediate neighbourhood of the growing crystal is increased by diffusion or convection. The growth of the crystal thus depends upon the rate of supply of dissolved material from the surrounding supersaturated solution. The concentration currents—*Diffusionsströme*— thus set up are stronger where the difference of concentration is greatest, and this must be at the sharp angles of the growing crystal, because the crystal there presents the greatest surface to the liquid. Growth is thus accelerated with increasing velocity in the vicinity of the crystal angles. As a result, the crystal extends most rapidly in the direction of the concentration currents or supply columns bringing the food, so to speak, necessary for further growth. When the supersaturation is so reduced that the crystal can grow but slowly, the concentration currents will virtually cease, and the spaces between the branchlets will be gradually filled up.

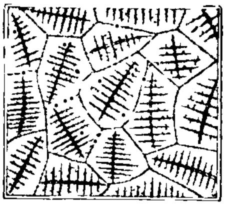

Fig. 13.—Diagrammatic Illustration of the Crystallization of Pure Metals.

O. Lehmann's explanation can be extended to the case of a cooling metal, where a certain amount of heat (latent heat of fusion) must be locally developed about each crystallizing centre; and the crystal must cool down to the crystallizing point before further growth can occur. Local currents of undercooled liquid will flow quickest from the surrounding liquid in the direction of the sharpest angles of each growing crystal, because there the temperature gradient is steepest. Hence, growth will be fastest in the direction of the currents of undercooled liquid.

G. Quincke's hypothesis of the cellular structure of metals.—When two partially miscible liquids—*e.g.* benzene with a little concentrated potash lye; or paraffin with one per cent. of a one per cent. soap solution—are shaken together, an *emulsion* is formed; and when one of the liquids is in large excess, the other may be distributed throughout the mass in such a way as to form what G. Quincke[5] called *foam cells—Schlaumkammern*—consisting of thin cell-walls of the liquid present in small quantity, enclosing drops of the other liquid. In G. Quincke's study of the formation of the emulsoidal structure, he showed how a similar structure might be obtained with solutions in which the cell-wall differed from the contents only in the concentration of the solute. He also suggested the hypothesis that the first stage in crystallization is the separation of the liquid into two immiscible phases, one of which is in relatively small quantity, and that the two liquids assume the foam-cell structure. He said that the purest of liquids still contains enough impurity to produce an eutectic which forms the cell-walls separating the primary metal. Crystallization then takes place within the foam cells, and the cell-walls are represented in the solid mass by the boundaries of the crystal grains. The arrangement of the crystalline particles, when actual solidification begins, is determined by the size and shape of the foam cells. This attempt to explain the cellular structure of metals does not appear to be satisfactory, since, although a homogeneous liquid at a certain temperature may separate into two immiscible liquids on cooling, there is nothing at all to show the phenomenon is so general as is required by G. Quincke's hypothesis. In those cases where crystallization has been observed under the microscope, the nuclei first formed control the ultimate structure, and there is no sign of a pre-existing foam-cell form. C. H. Desch has sought evidence of the assumed phenomenon and concluded that the grains of a solidifying metal have a tendency to assume the shape of foam cells, but he was not able to decide if foam cells are actually formed, or if the solidification of the metal proceeds from nuclei.

A cellular or tesselated structure is sometimes observed on the surface of cooling liquids. E. H. Weber (1855)[6] has recorded the formation of polygonal areas during the slow evaporation of a mixture of alcohol, water, and gamboge on a microscopic slide; and L. Frankenheim (1860) noticed a similar phenomenon during the evaporation of a solution of sulphur in turpentine. J. Thomson (1882) obtained a similar structure on the surface of soapy water; and C. Dauzere on the surface of mixtures of beeswax and paraffin or salol. According to H. Benard (1901), the best results can be obtained by exposing a layer of spermaceti, 0·4 to 2·0 mm. thick, in a metal trough 15 cm. diameter. The lower surface must be uniformly heated, and great care taken to eliminate disturbing influences. The partitioning approximates to an arrangement of regular hexagons. According to J. Thomson, the upper surface of the liquid is cooler than the portion below. Convection currents are set up, and the warmer liquid below ascends in vertical columns, spread out, and descends vertically downwards. The polygonal areas are the boundaries where the descending currents meet. The currents can be rendered visible, and photographed, by using fine particles of gamboge, lycopodium, graphite, etc., in suspension in the liquid. The surface polygonal areas are thus the upper surfaces of a series of prismatic columns produced by convection currents—*tourbillions cellulaires*—their axes are always vertical, never horizontal, and therefore the phenomenon is not the same in kind as that which gives rise to the cellular structure of metals. The phenomenon was studied mathematically by Lord Rayleigh in 1916.

Pure metals are aggregates of crystals which have been prevented from assuming a regular geometrical form by the crowding which occurs during the growth of neighbouring crystals. The crystals have grown more or less simultaneously and independently from a number of independent centres of crystallization. The facts must have been known to Robert Hooke[7] in 1665, and to R. A. F. de Réaumer in 1722; but H. C. Sorby was the first to show, in 1864, that a polished and etched surface of a metal is cut up into a number of polyhedral parts suggesting that the metal has a kind of cellular structure when examined under a suitable magnification and illumination. Under the microscope, also, the crystal boundaries appear as dark lines which are developed by the etching liquid attacking the surfaces of the various crystals at different rates. Although the internal structure of opaque crystals cannot be established so readily as would be the case if the crystals were transparent and could be examined under polarized light, yet, by etching the surface with suitable liquids, or by casting metals like cadmium or tin against a smooth glass surface, the evidence of an internal oriented structure is unmistakable. Thus, J. A. Ewing [8] has shown that—

> The surface of each grain consists of a multitude of geometrically similar pieces, parallel to one another so that their corresponding facets are all oriented one way. They are oriented in different ways as we pass from grain to grain, but in any one grain they face one way, and in consequence of that the light which falls on the grain is reflected in a perfectly uniform manner over the whole expanse of that grain, although it is reflected in a very different manner from the surface of any other grain. Over each grain the brightness is uniform, because the little surfaces are acting equally as regards the reflection of light.

The idea is well shown by the photograph by J. E. Stead, Fig. 14, from a specimen of iron with 4·5 per cent. of silicon in solid solution, and deeply etched. Cubic crystals of iron and octahedral crystals of copper have been obtained in an analogous form.

Although the cohesion of the molecules of a homogeneous liquid or amorphous solid can be explained by intermolecular attractions, auxiliary hypotheses must be invented to explain the stability of crystals, for the orientation of the structural units makes it appear as if the attractive forces are to some extent polar, because they act most favourably in certain directions. With aggregates of crystals, the distance between the surface molecules in two different systems of adjacent crystals must be much greater than between the molecules within each of the crystals; and consequently, it would appear as if the attraction of crystals for crystals should be less than the molecular attraction within the crystals themselves; or as if intracrystalline cohesion should be greater than intercrystalline cohesion. The intercrystalline boundaries or joints of a piece of metal of normal purity might therefore be expected to be a surface of weakness. W. Rosenhain [9] has emphasized the fact that the converse is usually the case. J. A. Ewing and W. Rosenhain have shown that the fracture of a piece of Swedish iron under a tensile load does not usually follow the intercrystalline boundaries, but rather cuts across the crystals themselves; otherwise expressed, **the intercrystalline boundaries of normally pure metals are not surfaces of special weakness, but are rather surfaces of special mechanical strength.**

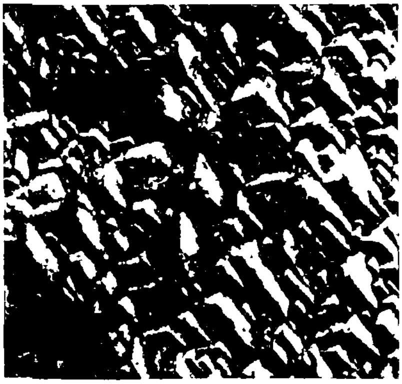

Fig. 14.—Surface of Silicon Steel. (J. E. Stead.)

The attempt has been made to explain the greater strength of the intercrystalline boundaries by assuming that the crystals grow, not by accretion layer by layer, but rather by the shooting out of dendritic branches which continue to grow until they meet one another, and finally interpenetrate one another so that the crystals are bound together by the interlacing of dendritic branches. W. Rosenhain and D. Ewen, however, reported that the "study of a large number of crystal boundaries does not seem to show sufficient evidence that the process is universal enough to account for the whole of the phenomena," and they favour the hypothesis that **there is a cementing medium between adjacent crystals in the intercrystalline boundaries which makes the crystals adhere together with special firmness.**

Although J. O. Arnold [10] has shown that a deleterious impurity may considerably weaken intercrystalline boundaries, for the presence of 0·1 per cent. of bismuth in gold was sufficient to surround the ductile crystals of the latter metal with a brittle envelope which readily fractured under a blow, yet many metals are known to be of sufficient purity to render highly improbable the assumption that the intercrystalline cement consists of impurities, more fusible metals, or eutectics. Consequently, Rosenhain concludes that the cement, if it exists at all, must be chemically the same material as the crystals themselves, and it is accordingly inferred that **the crystals of a metal of normal purity are surrounded by a thin layer of metal in an amorphous condition which acts as a cement, and which determines the mechanical strength of the metal itself.**

It is assumed that the forces at work during crystallization are such as to prevent the last vestiges of mother liquid from crystallizing, and that this liquid retains the amorphous condition while the metal cools down to the ordinary temperature. If the formation of a crystal requires not only the orderly arrangement of the structural units in the crystal, but also a grouping together of the molecules into aggregates to form the structural units, the liquid residue in the interstices when the growing crystals are nearly in contact will be unable to crystallize because there is not sufficient space for the aggregation of the molecules into the structural units.

The mechanical strength of a metal is determined by the strength of the intercrystalline cement; and if this cement be weakened or destroyed, the metal will show intercrystalline weakness. An intercrystalline cement was postulated by M. Brillouin, J. E. Sears, C. D. Bengough, and others [11] to explain the behaviour of metals when subjected to deformation under various conditions. For example, the effect of temperature on the tensile and elastic properties of metals is explained by assuming that at low temperatures the cement will accommodate itself to stresses in virtue of its elasticity while the crystals accommodate themselves to stresses by plastic deformation ; as the temperature rises, the cement weakens, and its elasticity diminishes ; when the cement has weakened sufficiently, the fracture under stress will be intercrystalline, and permanent elongation will occur under very small stresses because the cement does not prevent the crystals from sliding over one another.

§ 5. The Internal Structure of Crystals

Imagine two hundred brilliant violin players playing the same piece with perfectly tuned instruments, but commencing at different places selected at random. The effect would not be pleasing, and even the finest ear could not recognize what was being played. Such music is made for us by the molecules of gases, liquids, and ordinary solids. They may be highly gifted molecules with a marvellous internal structure, but in their activity, each disturbs the others. A crystal, on the other hand, corresponds with the orchestra led by a vigorous conductor when all eyes intently follow his nod, and all hands follow the exact beat. This picture enables us to understand how crystals can exhibit whole ranges of phenomena quite wanting in other bodies. To me, the music of physical law sounds forth in no other department in such full and rich accord as in crystal physics.—W. VOIGT.

Crystals are not only peculiar in the regularity of their external shape, but they also possess a definite internal structure.—In illustration, E. Bartholinas (1669) noticed that if a rhombohedral crystal of Iceland spar be placed over a black spot on a strip of white paper, Fig. 15, the spot appears to be doubled and one of the two spots appears clearer than the other. If the rhombohedron be rotated, the spot which seems to be nearest to the eye appears to rotate about the other. There is, however, one direction in which the dots viewed through the crystal seem to coincide. It is readily demonstrated that the beam of light in passing through the prism (in all but one direction) is split into two rays, for if a single beam of light be passed through the crystal, two beams of light will emerge. This property of splitting the ray of light into two different rays is called **double refraction,** and the crystal of Iceland spar is said to be *doubly refracting*—while the crystal is *singly refracting* in the one direction in which the image of the two spots is not doubled. One of the two rays obtained by double refraction is called the **extraordinary ray**—R. H. Haüy's *rayon d'abèrration*—and the other the **ordinary ray**—R. J. Haüy's *rayon ordinaire.* In 1690, C. Huyghens discovered that each of these rays has certain peculiar properties different from those of an ordinary ray of light. Each ray is said to be *polarized.* The splitting of a ray of light into two rays by double refraction is called **polarization of light.** The effect of polarization on a beam of light can be illustrated as follows : The ray of light is supposed to be vibrating in all possible directions perpendicular to the path of the ray ; ✱ ; on passing through the prism these vibrations are resolved into vibrations in two planes at right angles to one another : + ; and are at the same time separated into two rays, — and |, vibrating in different planes at right angles to one another. The resolution of the heterogeneous mixture of vibrations into linear vibrations in one direction is called the **plane polarization of light.** If a crystal of tourmaline, also doubly refracting, be placed between the eye and the crystal of Iceland spar, Fig. 15, and then rotated, the two spots will alternately appear and disappear.

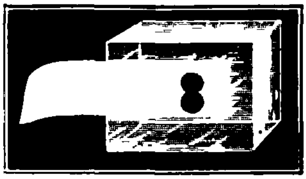

FIG. 15.—Illustration of the Double Refraction of Iceland Spar.

That direction in the crystal of Iceland spar in which light is singly refracted is called the optic axis of the crystal, and generally the directions parallel to which there is no double refraction are called the **optic axes** of a crystal. Crystals which have one optic axis—or one axis of no double refraction—are said to be **uniaxial crystals** in contrast with crystals with two optic axes—or two axes of no double refraction—which are said to be **biaxial crystals.** Examples of uniaxial crystals are calcite, quartz, borax, sugar, sodium nitrate, potassium thiosulphate, potassium or ammonium phosphate, etc. Examples of biaxial crystals are potassium nitrate, sodium sulphate (glauberite), cerussite, aragonite, gypsum, etc.

Polarizing microscope.—In the polarizing microscope, a prism of Iceland spar—called a **Nicol's prism** or simply a **nicol**—is so arranged that the ordinary ray from a parallel ray of light is reflected to one side, and the extraordinary ray alone passes through the prism. The extraordinary ray of polarized light can then be passed through a second Nicol's prism which can be turned about its axis. When the nicols are crossed, the field will appear dark in spite of the fact that there is nothing but two transparent prisms between the eye and the source of light. The first Nicol's prism is called the *polarizer* and the second the *analyzer*. When the two prisms are at right angles to the position where the field has its maximum darkness, the nicols are said to be parallel. When the nicols are parallel, the field appears of maximum brightness, and the extraordinary ray passes through both prisms.

If a doubly refracting crystal be placed between crossed nicols, instead of complete darkness, the crystal appears to be more or less illuminated on a dark background (double refraction). D. Brewster (1821) showed that the behaviour of crystals in polarized light (between crossed nicols) is an important means of distinguishing doubly refracting crystals from cubic crystals. Very few crystals fail to show light between crossed nicols when examined in a suitable instrument, the polarizing microscope; and crystals can be classified into families according to their peculiar action on polarized light, because each system interferes with polarized light in a characteristic way. Let a crystal be laid flat on a glass plate on the stage of a microscope and the eyepiece, with cross wires, so fixed that an edge of the crystal is parallel to one of the cross wires; let the polarizer and analyzer be placed perpendicular to each other. The angle through which the crystal must be rotated in order to produce darkness is called the **angle of optical extinction**. If the crystal extinguishes or disappears when the edge of reference is parallel with the cross hairs of the eyepiece, and is brightest midway between, the crystal is said to have **parallel or straight extinction** with respect to that edge; and if the position of extinction is inclined or oblique to the cross-hairs, the crystal has **oblique extinction.** Tetragonal, hexagonal, trigonal, and rhombic crystals show parallel extinction, while monoclinic and triclinic crystals give oblique extinction.

A pencil of parallel polarized light.—If the direction of vibration of the plane polarized light is continuously rotated as it passes through the crystal, the phenomenon is called **rotatory polarization,** and the crystal is said to be **optically active.** Optically active crystals rotate the plane of polarization of light even in sections perpendicular to the optic axes. In 1811, D. F. Arago discovered the optical activity of quartz. Sodium chlorate also exhihits the phenomenon. When a pencil of parallel light rays is passing through the polarizer, the interposition of a plate of glass or of an isotropic crystal between the crossed nicols will not affect the field of vision which will remain dark; on the contrary, with plates of certain other crystals—quartz, sodium chlorate, cinnabar, etc.—cut perpendicular to the optic axis, the field of vision becomes more or less clear according to the thickness of the plate interposed, and this in spite of the fact that the nicols are crossed. The plates should be not less than 0·2 mm. thick. In order to re-establish the original darkness, the analyzer must be rotated through a certain angle, showing that the interposed plate of, say, quartz rotated the plane of vibration of the polarized rays from the first nicol. If the analyzer be turned through a certain angle clockwise (viewed from the front) in order to restore darkness, the crystal is said to be **dextro-rotatory,** because the crystal rotates the plane of polarization from the left to the right of an observer receiving the light and not towards the right in the direction the wave of light progresses. The converse of this applies for **lævo-rotatory** crystals. Since the angle of rotation is proportional to the thickness of the crystalline plate under examination, it is conventionally referred to a plate 1 mm. thick. The angle of rotation is also dependent on the wave-length of the light used, and therefore the character of the light should be specified—yellow sodium light, designated after Fraunhofer's *D*-line in the solar spectrum, is commonly employed, and the angle of rotation is symbolized a_D. Examples: The angle of rotation a_D for sodium bromate, $NaBrO_3$, is 2·17°; for sodium thioantimoniate, $Na_3SbS_3.9H_2O$, 2·37°; for sodium chlorate, $NaClO_3$, 3·14°; potassium lithium sulphate, $KLiSO_4$, 3·44°; potassium dithionate, $K_2S_2O_6$, 8·39°; quartz, 21·723°; and for sodium periodate, $NaIO_4.3H_2O$, 23·3°. When these substances are dissolved, or fused, the rotatory power is lost; and it is accordingly inferred that the cause of the rotatory power must reside in the way the molecules are structurally grouped in the crystals. On the other hand, a great many compounds of carbon possess this rotatory power when in the liquid state, in solution, and sometimes even in the state of vapour, *e.g.* camphor, etc. Consequently, it is inferred that with these substances the rotatory power is not due to the structure of the crystal, but is produced by arrangement of the atoms in the molecule itself, and is concealed by the orientation of the molecules in the crystal. Strychnine sulphate is optically active in solution and still more so in the solid state, so that the optical activity is determined by the orientation of the molecules in the crystal, as well as by the arrangement of the atoms in the molecule.

It is not possible to calculate the rotatory power of a substance with certainty from the rotatory power of its aqueous solution. In 1838, J. B. Biot [1] noticed that the rotatory power of tartaric acid in aqueous solution increased with increasing dilution, but R. Pribram failed to obtain constant values for the rotatory power even with very great dilutions. The decrease in the specific rotatory power of dilute solutions of the alkali tartrates with increasing dilution was attributed by R. von Sonnenthal to ionization. G. H. Schneider found that concentrated solutions of malic acid were dextro-rotatory; dilute solutions, lævo-rotatory; and that 34 per cent. solutions appeared inactive. Hence, it is highly probable that the so-called inactive solvent does exert some kind of action on the solute—maybe by breaking down molecular aggregates; forming unstable hydrates; changing the configuration of the atoms in the molecules, or by ionizing the salt in solution.

In 1817, J. B. Biot showed that the magnitude of the angle of rotation of solutions of optically active substances depends upon (i) the thickness of the layer of solution observed; (ii) the concentration—*i.e.* the mass per unit volume; (iii) the temperature; and (iv) the wave-length of the light employed. The **specific rotatory power** or the specific rotation of a substance at a particular temperature for a particular wave-length of light is the rotation produced by a decimetre of solution which contains one gram of the active substance per cubic centimetre. If w grams of an optically active substance are dissolved in v c.c. of a solvent, and the observed angle of rotation a with a column of liquid l decimetres long, the specific rotatory power, $[a]$, of the solution will be $[a]=av/lw$, on the assumption that the solvent is without influence on the result. This assumption is usually justifiable in the case of aqueous solutions, but not with other solvents. The change in the rotatory power of certain substances when dissolved in solvents upon which they exert no apparent chemical action, is explained by assuming that the solvent either unites with the solute, or else exerts a specific attraction so that the motions of the molecules of the solute are modified. A temperature of 20° is often taken as a standard of reference.

EXAMPLE.—If 20·2 grms. of a substance is dissolved in 79·8 grms. of water and the solution has a specific gravity of 1·0842; and when a layer 2 d.m. thick has an angle of rotation $a_D=29°$, what is the specific rotation? Here, $l=2$; $w=20{\cdot}2$; v=weight÷specific gravity$=(79{\cdot}8+20{\cdot}2)\div1{\cdot}0842$; $a=29$; hence, $[a]_D=66{\cdot}21°$.

The product of the specific rotatory power and the molecular weight of a substance is called the **molecular rotatory power.** The numbers so obtained are often divided by 100 in order that smaller numbers may be used. Special instruments called *polarimeters* are used to measure the rotatory power of optically active solutions, for they do this more accurately than is possible in the ordinary polarizing microscope.

A converging cone of light.—A thin plate of a doubly refracting uniaxial crystal, cut at right angles to the optic axis, and placed between crossed nicols with a cone of convergent light incident on the polarizer, furnishes a series of circular, coloured, and concentric rings traversed by a dark cross, Fig. 16; and a biaxial crystal treated in a similar manner exhibits a double series of elliptical (lemniscate) rings traversed by a narrow bar, and separated by a broad bar, Fig. 17. These figures are called **interference figures.** When the analyzer is rotated, the distribution of the colours varies, and the interference figures change in a characteristic way in crystals of different mineral species. The black cross of uniaxial crystals changes into a white one, Fig. 16, and the colour of the rings changes to the complementary tints when the nicols are parallel. Similarly, with biaxial crystals, Fig. 17, rotating the analyzer breaks up the cross and develops two dark brushes, Fig. 17, each of which traverses one of the systems of rings. The crystals of some substances require the analyzer to be rotated to the right, and other crystals to the left in order to develop a given succession of colours—*e.g.* different specimens of quartz, for example, may show what J. Herschel called right- and left-handedness, and some samples again, principally the purple crystals of quartz (amethysts), may show both right- and left-handedness in one specimen.

The properties of crystals are not always the same in different directions.—The hardness, elasticity, crushing strength, rate of solution in acids, optical, thermal, and electrical properties, are generally different in different directions. This means that different results are usually obtained when the elasticity, refraction of light, thermal expansion, etc., of a crystal are measured in different directions. Thus, the coefficients of thermal expansion of quartz along the axes designated *a* and *c* are respectively 1515×10^{-8} and 807×10^{-8}—so that one is nearly twice as large as the other; with adularia (felspar) the coefficients along the three axes are respectively 1569×10^{-8}, $65{\cdot}9\times10^{-8}$, and 291×10^{-8}—corresponding nearly with the ratio 24 : 1 : 4. A substance, apparently homogeneous, may therefore exhibit *privileged directions* for the propagation of any particular form of energy—thermal, electrical, optical, magnetic, or elastic. Any medium in which any natural phenomenon is not produced with the same intensity in every direction is said to be **anisotropic** (ἄνισος, unequal; τρέπειν, to turn) or **æolotropic** (αἰόλος, changeful) for that phenomenon, for the body is dissymmetrical with regard to that phenomenon. A body whose optical, magnetic, thermal, electrical, elastic, or other property depends upon direction, is anisotropic. All these forms of anisotropy can exist simultaneously in a body. When the properties of a substance are the same in all directions, it is said to be an **isotropic** substance (ἴσος, equal)—*e.g.* gases, most liquids, unstrained glass, and, so far as the optical, thermal, and electrical properties are concerned, unstrained crystals belonging to the cubic system.

FIG. 17.—Interference Figures—Biaxial Potassium Nitrate.

In *H. de Sénarmont's experiment* (1847),[2] a slice of quartz is cut perpendicular to the long axis and another slice is cut perpendicular to this; each slice is covered with wax, and pierced at the centre so that a hot wire can be inserted. The wax naturally melts about the hot wire. In the former case, the molten wax will form a circle—*A*, Fig. 18;

and in the latter case, an ellipse—*B*, Fig. 18. This shows that the *thermal conductivity* of the crystals is different in different directions. In H. L. Bowman's experiment one end of a heated wire in contact with a face of a crystal of gypsum gave a white, opaque, elliptical area owing to dehydration. The ratio and direction of the axes of the ellipsoid varied for different faces—on the cleavage face, the ratio was 1·129.

If a crystal of calcite be hung in a beaker of dilute hydrochloric acid by means of a platinum wire, solution does not occur at a uniform rate over the whole surface, but the *rate of solution* of the crystal is faster in one direction than in another. Plates have been cut parallel to the different faces of different crystals, and the edges protected with wax, and measurements made of the amount dissolved after the plates had been immersed in the selected solvent for a given time. The velocity of the attack by hydrochloric acid is about 1·15 times greater when the surface exposed to the action is perpendicular to the principal axis than when the surface is parallel therewith.[3] A. Wolff found all the faces of crystals of Mohr's salt dissolve at the same rate; and A. Körbs noticed very little difference in the rates of solution of the different faces of crystals of sodium chloride, alum, and potassium nitrate, but with copper sulphate and potassium ferrocyanide wide differences were observed—in the former case, 37 per cent.; and in the latter, 86 per cent. Still further, the velocity of propagation of *light* through crystals of the cubic system is the same in all directions, but not with members of the other systems.

The attack of a crystal face by a reagent does not necessarily commence at the same time at all points, but proceeds more rapidly in some parts than in others. If the attack be stopped at the right time, the attacked face will be pitted with little angular cavities, many of microscopic size, called **etch figures**, or **corrosion figures.** Passing a moist cloth rapidly over the surface of an octahedral crystal of alum will suffice to develop triangular cavities with sloping sides, and similar to those sometimes found naturally on the octahedral faces of the diamond. With the right conditions—solvent, time, and temperature—the etch figures will be in parallel positions plane for plane. The etch figures on similar faces will be all alike, but unlike on dissimilar faces. The etch figures conform to the symmetry of the class to which the crystal belongs, and they therefore serve as an important clue in determining the symmetry of a crystal. The etch figures on cubes of galena are symmetrical to the nine planes of symmetry, while those on cubes of sylvite are symmetrical only to the axes. The etched pits are bounded by a number of minute faces with complicated indices which are generally known as *vicinal faces.*

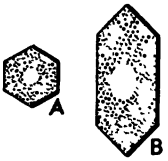

Fig. 18.—H. de Sénarmont's Experiment.

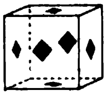

Fig. 19.—Etch Figures of Galena (diagrammatic).

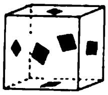

Fig. 20.—Etch Figures of Sylvite (diagrammatic).

Experiments on the rates of solution of crystal faces must always be affected by errors owing to modifications in the surface area by (i) the pitting of the faces; and (ii) the rounding of the edges. V. Goldschmidt[4] has studied the etch-figures of crystal faces and of the successive forms assumed by a sphere of calcite when subjected to the action of phosphoric, hydrochloric, nitric, formic, or acetic acid. The sphere is first etched in tracts which correspond with the natural faces most prone to attack; the etch-figures then disappear; the entire surface is then affected so that the poles of the faces most prone to attack become most sharply pronounced corners of curved faces. Consequently, growth and dissolution are inversely related This relation is called **V. Goldschmidt and F. E. Wright's law of polarity**: *the corners of a dissolving crystal become the poles of the faces of a growing crystal.*

The inversion corners shift slightly as the crystal dissolves, until at last a final form is reached which dissolves without change of shape. This final form depends on the original form of a natural crystal and on the nature and concentration of the acid. P. Hochschild obtained similar results with zinc blende; and A. E. Fersmann and V. Goldschmidt have shown the relation between these results and the corrosion forms shown by natural crystals of the diamond. W. Schnorr also studied the alteration of form brought about by a reversal of the growth process of crystals of rock salt by the solvent action of slightly unsaturated solutions of sodium chloride with a little carbamide. The first action is to bevel the cube edges—the final form is the icositetrahedron. The final form obeys V. Goldschmidt and F. E. Wright's law of polarity.

The essential difference between crystalline and amorphous substances is one of internal structure, not necessarily external shape.—The external form of crystals is their most obtrusive characteristic, and it was naturally the first to arrest attention; but the geometrical shape is by no means the most characteristic property of crystals, because the external geometrical form may be destroyed, and yet the fragments do not cease to be crystals, for they behave in polarized light like perfect crystals. On the contrary, the most perfect glass model of a crystal is not a crystal, because it lacks the characteristic internal properties of crystals. According to L. Vegard,[5] crystals of thorite show nearly perfect tetragonal forms and internally they appear to be amorphous. The shapes of gems cut and polished to accentuate the ornamental value of the gem must not be confounded with crystal structure; similarly, the term "crystal" applied to cut glass has a different meaning from the special use of the word crystal in the text. Transparent glass is not crystalline; some varieties of opaque glass are microcrystalline. In the case of granite, the crystals of felspar, quartz, and mica have been so crowded during their growth that they have had no chance to develop their characteristic external shape. The internal structure of each mineral, however, is characteristic. A crystal has therefore been defined as "a solid body bounded by plane surfaces arranged according to definite laws, and possessed of definite physical properties. Both the external form and the physical properties result from a definite and unique internal structure." Amorphous substances show no signs of the definite structure characteristic of crystals. The term "amorphous" is applied, somewhat vaguely—often wrongly—to the pulverulent substances, *i.e.* to substances occurring as fine-grained powders particularly when the powders have not the definite external shape characteristic of crystals, or when the grains are opaque and do not permit the application of the usual optical tests to find if they have the internal structure characteristic of crystals. P. P. von Weimarn has raised the question whether the finest precipitates are ever amorphous; he is right in saying that many precipitates usually classed as amorphous are really crystalline, but there is no doubt that many precipitates are really analogous with supercooled liquids, like glass. P. P. von Weimarn, however, says that a "super-cooled glass" is crystalline, and he even says that liquids and gases are crystalline; this makes it obvious that his definition of a crystalline substance is different from that usually employed, and need not here be considered.

An amorphous substance is one which, during solidification, has not taken the definite external shape characteristic of crystals, the properties when measured in any one direction are the same as when measured in any other direction, and there are no signs of a definite orientation of the molecules. In this case it is assumed that the constituent molecules are arranged haphazardly or in a chaotic manner. In crystals, on the contrary, where the properties along parallel directions are the same, but different in directions that are not parallel, it is assumed that the ultimate molecules, or their motions, are oriented or arranged in a definite regular manner. W. Voigt (1906) aptly illustrates this idea by the metaphor cited above.

The words "haphazard," "chance," and "chaotic," applied to the arrangement of atoms or molecules in amorphous substances, are not intended to imply that there is such a thing in nature as a "fortuitous concourse of atoms." The man of science believes, by faith, that the irregular path described by a mote dancing in a beam of sunlight is determined as certainly as the orbit of the planet about its sun. Words like these are conventional modes of expressing our ignorance of the great design. If this be ever discovered, we believe, by faith, that what is now regarded as a chance coincidence will be part of an everlasting harmony.

§ 6. The Seven Styles of Crystal Architecture

> In crystallography there is a beautiful instance of successful classification connected with a nearly perfect physical hypothesis.—W. S. JEVONS.
>
> A symmetrical shape is one which consists of parts exactly similar, repeated a certain number of times, and placed so as to correspond with each other. The symmetrical parts of a crystal are, under like circumstances, alike affected.—W. WHEWELL.

Crystal faces usually occur in sets so arranged as to preserve the symmetry of the crystal with respect to certain imaginary points, axes, or planes which are characteristic of certain groups or families of crystals. J. B. L. Romé de l'Isle expressed the idea in 1783 by stating: "Every crystal face has a similar face parallel to it," and the symmetry of the faces and angles of crystals has been emphasized by calling it the **law of crystal symmetry: In normally formed crystals, every face has a similar face in all positions consonant with the symmetry of the particular class to which the crystal belongs.** When a crystal shows the highest grade of symmetry pertaining to its system—that is, when a crystal possesses all the faces required by the law of symmetry—the crystal is said to be holosymmetrical or **holohedral**—from ὅλος, whole; ἕδρα, base or face. An unsymmetrical crystal may be derived from a holohedral crystal by the suppression of half its faces, when it is termed **hemihedral,** from ἡμι, half—the tetrahedron, for instance, is the hemihedral form of the octahedron; or by the suppression of three-quarters of its faces, when it is termed **tetartohedral**—from τέταρτος, a quarter.

G. D. Liveing[1] assumes that if a solid be bounded by plane faces, the surface tensions at the edges will have a resultant which tends to compress the mass; and, for equilibrium, there must be an opposing pressure on the opposite side of the crystal, or else there will be internal stresses. Hence, a reason for the law of crystal symmetry can be seen, for if *one* face of the crystal be developed, the *opposite* face will also be developed; and if one edge or angle be truncated, all the corresponding edges or angles will be truncated; if otherwise, there would be a stress in the interior tending to deform the crystals. The surface tension, which produces this stress, depends on the nature of the surfaces in contact, on their temperature, electrical condition, etc. If therefore the surface tension on one face be balanced by inequalities of temperature, etc., unsymmetrical faces may be developed, and when the stress produced by, say, an inequality of temperature is relieved, an internal stress due to unequal surface tensions would persist. Such crystals would exhibit signs of internal stresses. Crystals with unsymmetrical faces generally do exhibit signs of internal stresses by developing electrifications of opposite signs at the two ends when heated or cooled—*pyro-electrification*—or they may affect polarized light differently. In illustration, symmetrical crystals of tourmaline do not usually exhibit pyro-electrification, while the unsymmetrical crystals do. Likewise, substances which show rotatory power in solution develop unsymmetrical crystals—*e.g.* the tartrates.

A crystal is said to possess a **centre of symmetry** when to every face of the crystal there is a corresponding parallel face at the opposite side of the crystal.

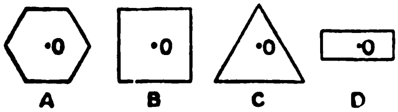

FIG. 21.—Axes of Symmetry.

A **plane of symmetry** is an imaginary plane which divides the crystal into two parts such that one part is the exact but inverse counterpart of the other. In other words, the two parts bear to one another the same relation that the image in a mirror bears to its object. The mirror is the equivalent of a plane of symmetry. A crystal of potassium iodide, for example, has nine planes of symmetry indicated in Fig. 24. The crystal of gypsum, Fig. 44, has only one plane of symmetry; and a crystal of barium sulphate has three planes of symmetry, Fig. 41. Crystals can be classified into groups, according to the disposition and number of their planes of symmetry.

Then again, a crystal may be rotated about a definite axis through an angle, which is a simple fraction—$\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, or $\frac{1}{6}$ of the angle of complete rotation, 360°—such that the faces, edges, and corners are brought into similar or symmetrical positions, and the aspect of the crystal is the same as before rotation. The axes of rotation are then called **axes of symmetry.** Thus we speak of dyad, triad, tetrad, hexad axes of symmetry according as there are 2, 3, 4, or 6 positions of symmetry during a complete rotation. These positions correspond with rotations of 180°, 120°, 90°, and 60°. Thus, Fig. 21, *A*, represents a horizontal cross-section of a crystal with one hexad axis of symmetry, because during the rotation of the crystal about the axis *O*, there are six positions—60°, 120°, 180°, 240°, 300°, and 360°—where the original aspect of the crystal is the same. In Fig. 21, *B, C, D*, respectively, denote tetrad, triad, and dyad axes of symmetry. P. H. R. von Groth (1876)[2] has shown that other grades of symmetry—pentad, heptad, octad, etc.—are not possible in crystals, and J. W. Evans proved that the only possible axes of symmetry are those with cyclic numbers 2, 3, 4, or 6, provided that the crystals have a homogeneous cellular structure. In the subjoined outline discussion of the crystal systems, the maximum symmetry is alone indicated.

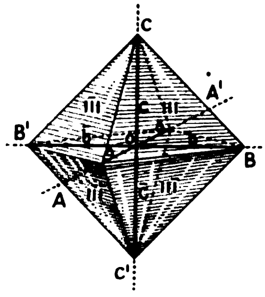

FIG. 22.—Crystallographic Constants.

Miller's system of crystal notation.—Under ordinary conditions the earth is the standard of reference for both position and direction. This is merely for convenience; other standards are used in astronomy. In analytical geometry, position and direction are referred to a set of arbitrary lines called *axes*. Similarly, in the geometrical description of a crystal, it is convenient to refer the position of the faces or bounding planes of the crystal to a set of imaginary coordinate axes within the crystal, and which are called the **crystallographic axes.** There are generally three, sometimes four, of these axes. The comparative length and mutual inclination of the axes depend upon the symmetry of the ideal crystal. The axes are chosen so as to furnish the simplest expression to describe the faces of the crystals, and to allow similar faces to be described by similar terms. In

Fig. 22, let AOA', BOB', COC' represent the three axes of a crystal, and call them respectively the a-, b-, and the c-axis. The virtual axis is called the c-axis; that passing forwards and backwards is the a-axis, and that passing right and left the b-axis. The form and nature of the crystal is supposed to be determined by the length and mutual inclination of these axes. The angles between the axes are called the **axial angles.** The axial angle BOC is symbolized α, the axial angle COA, by β; and AOB, by γ. The axial angles with the axial ratios $a:b:c$ are a characteristic for the crystals of each individual substance, and are called the **crystallographic constants** of the crystals. Each of the crystallographic axes can be drawn from the intersection or origin O in two directions; one direction is arbitrarily called the *positive* and the other the *negative* direction. A bar over the letters A, B, C represents conventionally the negative direction, the opposite directions are called positive. Mark off the equal lengths a and $\bar{a}$ on the $AO\bar{A}$ axis, b and $\bar{b}$ on the $BO\bar{B}$ axis, and c and $\bar{c}$ on the $CO\bar{C}$ axis. Suppose a set of planes to lie in such a position that the extremities meet the AOA' axis at a distance a, the $O\bar{C}$ axis at $\bar{c}$, and OB axis at b, and so on. The lengths a, b, c and $\bar{a}$, $\bar{b}$, $\bar{c}$ are called **parameters.** In the diagram, Fig. 22, the plane ABC with the parameters abc is called the abc-plane; the plane ABC' is the $ab\bar{c}$-plane; $AB'C'$ is the $a\bar{b}\bar{c}$-plane, etc.

The faces can be fixed when the directions of the a-, b-, and c-axis and the parameters a, b, c, are known. Suppose a plane to cut the axis a at half the length of a, b at $\frac{1}{3}$ the length of b, and c at $\frac{1}{4}$ the length of c, then the position of this plane about the given axes would be fixed by $\frac{1}{2}a$, $\frac{1}{3}b$, $\frac{1}{4}c$. Such a notation is considered clumsy, and the reciprocals of the fractional values alone are used in describing the plane, which would then be called the 234-plane. Similarly, a 123-plane is one which passes through points corresponding with a, $\frac{1}{2}b$, $\frac{1}{3}c$. Similar remarks apply to the other planes, allowing for the negative values as just indicated; the plane $\overline{abc}$, for instance, becomes the 111-plane. Each number is called an **index,** and conventionally, the first index always refers to the a-axis, the second to the b-axis, and the third to the c-axis. Suppose that a plane corresponded with $\frac{1}{1000}a$, $\frac{1}{1000}b$, c, it would be described as the 1000, 1000, 1-plane; this is true, however small the fractions be taken. The smaller the parameter, the steeper the plane, until finally the plane ∞a, ∞b, c is written 001, is parallel to the axes in question. The cyphers thus represent planes parallel to the a- and b-axes respectively. The three indices of a plane may be multiplied or divided by any desired number without altering their relations one to another. Thus the plane 222 must be parallel to the 111-plane, and also to the 333-plane, etc. Hence, it is usual to reduce the ratios to their simplest form. This system of notation was adopted by W. H. Miller in a classical work entitled *Treatise on Crystallography* (Cambridge, 1829). There are several other systems in use, but Miller's promises to oust them in the course of time.

R. J. Haüy's law of rational indices.—It might be supposed that the angles between the planes of crystals could have any indices, and the planes any inclination. Observations show that this is not the case. R. J. Haüy noticed that the indices can be generally represented by simple whole numbers, but never by what mathematicians call irrational numbers.[3] Thus the indices of a plane might be 123, 457, etc., but never $1\sqrt{23}$, $45\sqrt{7}$, etc. The fact that **the indices of all crystal planes can be expressed by rational whole numbers** is called R. J. Haüy's law of rational indices. The simplicity of the indices of course is largely determined on the happy though arbitrary choice of the axial directions AA', BB', and CC'. Like most other so-called laws, the rationality is seldom fulfilled with strict accuracy, but it comes so near the truth that it is regarded as an outward and visible symbol of the internal structural simplicity of crystals

Sometimes the symbols hkl, $\bar{h}\bar{k}\bar{l}$, etc., are used in a general way to express any set of rational numbers. If the symmetry of a crystal and one face of a crystal form are known, the other similar faces can be derived from the known face. A group of similar faces is called the **form of a crystal**, and the form of a crystal can be represented by the same symbol as that used for one of the faces. In that case the symbol for the face is enclosed in brackets, thus, (*hkl*) represents all the faces included in the groups of faces similar in every respect to the face *hkl*.

The seven systems of crystal architecture.—The study of the physical properties and forms of crystals *quâ* crystals is a special branch of chemical physics—**crystallography**—and the study of the forms of the different varieties of crystals is called the *morphology* of crystals. It is assumed that crystals are built of similar molecules which are either similarly related to all the adjoining molecules, or else similarly related to the adjoining molecules which are in the same plane, but differently related to those in different planes. In the one case the arrangement of the molecules is rectangular, and in the other case, oblique. All the physical properties of crystals are closely correlated with the form of the crystal; and the form of a crystal is determined by the relative length, and the mutual inclinations of the crystallographic axes.

It is supposed that the imaginary axes of all except hexagonal crystals can be varied with respect to *length* in three ways, for they may be (1) all equal; (2) all unequal; and (3) one may be unequal and two equal. The axes can conceivably be varied in *direction* or slope in four ways: (*a*) All may be at right angles to one another; (*b*) two axes may be at right angles, and the third perpendicular to one of them and oblique to the other; or (*c*) the third axis may be oblique to both; and (*d*) all three axes may be oblique to one another. There is also an additional type which has three axes lying in one plane and a fourth axis perpendicular to these three. Every known crystal can be referred, on the basis of its symmetry, to one of the following seven systems:

				SYSTEM.
Axes	Three	All rectangular	All equal	Cubic
			Two equal, one unequal	Tetragonal (uniaxial)
			All unequal	Rhombic (biaxial)
		One perpendicular to two mutually oblique, all unequal		Monoclinic (biaxial)
		All oblique and	Unequal	Triclinic (biaxial)
			Equal (with angles equal but not 90°)	Trigonal (uniaxial)
	Four	One rectangular, to three oblique and equal		Hexagonal (uniaxial)

These seven systems are further subdivided into classes, each of which has its own characteristic symmetry—described in standard works—*e.g.* A. E. H. Tutton's *Crystallography and Practical Crystal Measurement* (London, 1911).

With the exception of the members of the cubic system, the crystals of no two compounds are exactly alike; but crystals of the same compound have their faces inclined at the same angles. Consequently, it is possible to identify crystals quickly from measurements of the angles between similar faces of one or two crystals by reference to tables containing measurements of all those crystalline substances whose angles have been measured. This mode of identifying crystalline substances is called **Fedoroff's crystallochemical analysis.**[4]

I. Cubic system.—The first class of crystals possesses three axes—*a*, *b*, *c*—of equal length, and they make equal angles—α, β, γ—with one another, as illustrated in Fig. 23. The axes are interchangeable, so also are the angles, so that what is true of one axis or angle is true also of the other two. This is expressed in symbols: $a=b=c$, and $\alpha=\beta=\gamma$. The crystals have nine planes of symmetry as illustrated in Fig. 24, three of the planes of symmetry are principal planes, and six are secondary. There are six dyad, three tetrad; and four triad axes of symmetry. The primary or simplest representative form is the cube—hence the name cubic system. By cutting off the corners of the primary cube by planes variously inclined to the axes, the octahedron, dodecahedron, and various secondary forms are derived. Since each of the three crystallographic axes is exactly like the other two, every facet formed on one corner of a crystal must be repeated symmetrically with regard to the other axes; hence the forms produced are symmetrical or regular, and in place of the cubic system, the term *regular system* is synonymously employed. In addition to the terms cubic or regular system, this class of crystals has also been called the *isometric*, *monometric*, *tesseral*, *tessural*, and *octahedral* system.

Typical crystals for examination are cuprite and garnet. These cubic crystals are defined by the numerical values of the indices of the component forms. For example, *cuprite*, Fig. 25, has *a*(100), *d*(110). This particular crystal, described by A. E. H. Tutton, is apparently holohedral; but H. E. Miers has shown that in general cuprite is hemihedral. *Garnet*, Fig. 26, has *d*(110), *i*(211). Potassium iodide, barium nitrate, chrome alum, potash alum, sodium chlorate, and arsenic trioxide also furnish good crystals for examination.

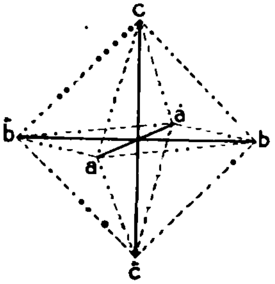

FIG. 23.—Crystallographic Axes of the Cubic System.

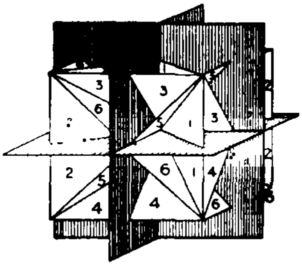

FIG. 24.—Planes of Symmetry in the Cubic System—3 Principal and 6 Secondary Planes.

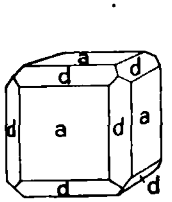

FIG. 25.—Cuprite.

EXAMPLES.—Diamond; potassium chloride; sodium chloride; alum; fluorspar; iron pyrites; lead nitrate; magnetic oxide of iron; barium nitrate; arsenic trioxide; galena; garnet; ammonium chloroplatinate; silver chloride; boracite; indium; aluminium; iron; platinum; lead; phosphorus; gold; copper; silver; nickel; arsenic; metacinnabarite; cerargyrite; ammonium chloride; amalgam—HgAg; nitrous oxide; carbon dioxide; ammonia; potassium thio-stannate—$K_2SnS_3.3H_2O$; beryllium sulphate—$BeSO_4.6H_2O$; uranyl sodium acetate; stannic iodide; bismuth; fahlerz; spinel: argentite; leucite; franklinite; nosean; tetrahedrite; tennantite; allmannite—NiSbS; barium nitrate; analcite; cobaltite: cuprite; sodalite; sodium chlorate; sodium bromate; zinc blende; mercury.

The equality and symmetry of the three axes in the members of the cubic system is a mathematical expression of the fact that the vectorial properties of the crystals belonging to this system are alike in all direction—*e.g.* the optical properties. When light or heat rays enter one of these crystals, the rays spread with equal rapidity in all directions just as they do in homogeneous gases, liquids, and unstrained amorphous solids—*e.g.* glass. The crystals are not doubly refracting unless the elasticity is modified by compression. Otherwise expressed, the crystals are optically isotropic, with an index of refraction which is the same in all directions; there is no change between crossed nicols; and there are no interference figures. When the crystals are heated, they expand equally in all directions. Consequently, the mere statement that a crystal belongs to the cubic system, is a sufficient indication that it possesses these qualities in common with other members of its class.

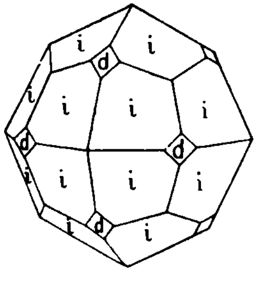

FIG. 26.—Garnet.

II. Hexagonal system.—The system is so named because a horizontal section is usually hexagonal—from ἑξάγωνια, having six angles or corners. Here the crystals have four axes—a_1, a_2, a_3, c—of which the three—a_1, a_2, a_3,—lying in one plane are of equal length, $a_1=a_2=a_3$, and meet one another at angles of 60°, Fig. 27; the fourth or *c*-axis is perpendicular to the *a*-axis, and is called the principal axis.

These facts are symbolized $a_1=a_2=a_3\lesseqgtr c$; $\alpha_1=\alpha_2=\alpha_3=90^\circ$, $\gamma=60^\circ$. The crystals have seven planes of symmetry, Fig. 28; and one hexad, and maybe six dyad axes of symmetry. The crystals are uniaxial; the interference figure is a symmetrical black cross with concentric spectrum coloured rings; there are two principal indices of refraction.

Typical crystals for examination are beryl and apatite. The crystals are defined by the form development and the values of the interfacial angles from which the axial ratios can be calculated. For instance, *apatite* has $a:c=1:0·7346$ and $m(10\bar{1}0)$, $x(1011)$; *beryl* has the angle $a:c=1·0499$, and $a(1010)$, $r(1121)$, $c(0001)$. Lead iodide, and cadmium iodide also, furnish good examples for examination.

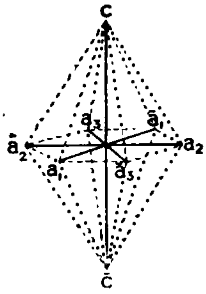

Fig. 27.—Crystallographic Axes of the Hexagonal System.

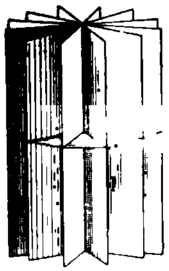

Fig. 28.—Seven Planes of Symmetry of the Hexagonal System.

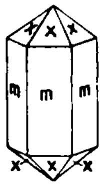

Fig. 29.—Apatite.

EXAMPLES.—Beryl; apatite; copper sulphide; lead iodide; magnesium; beryllium; zinc: cadmium; calcium; pyrrhotite; proustite; pyrargyrite; silver iodide; strontium and lead antimonyl tartrates; pyromorphite; mimetite; vanadinite; iodyrite; nephelite; etc.

Owing to the disposition of the axes in the tetragonal, trigonal, and hexagonal systems, the physical properties are alike in all directions perpendicular to the principal axes, but are different in other directions. The crystals are not doubly refracting in the direction of the principal axis, but they are doubly refracting in other directions. Thus, a crystal of beryl does not exhibit double refraction in the direction of the principal axis, but light is doubly refracted in every other direction. Accordingly, these crystals are uniaxial. Heat is conducted at the same speed in directions parallel to the principal axis, but with different speeds in directions perpendicular to this axis.

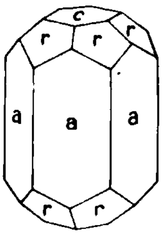

Fig. 30.—Beryl.

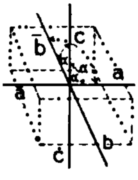

Fig. 31.—Crystallographic Axes of the Trigonal System.

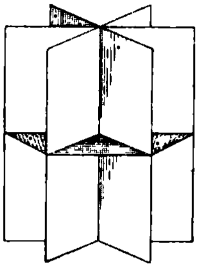

Fig. 32.—Trigonal Planes of Symmetry.

III. Trigonal system.—The name comes from τρίγωνον, having three angles or corners. The crystals of this system have three axes $a=b=c$, all equal and equally included at an angle which is not a right angle, so that $\alpha=\beta=\gamma$, Fig. 31. The crystals have three planes of symmetry, Fig. 32, one triad, and maybe three dyad axes of symmetry. The crystallographic axes are not axes of symmetry, but are lines parallel with the edges of the fundamental rhombohedron. This system is sometimes called the *rhombohedral* system, and it is sometimes regarded as a special development of the hexagonal system. The crystals are uniaxial; the interference figure is a symmetrical black cross with concentric spectrum coloured rings; there are two principal indices of refraction.

Typical crystals for examination are calcite and quartz. The crystals are defined by the form development, and the values of the interfacial angles from which the axial ratios are calculated. For example, calcite (Figs. 36 and 37) has $\alpha=101° 54'$; and $m(2\bar{1}1)$, $r100$, $v(201)$, $e(110)$; quartz (Fig. 3) has $\alpha=93° 57'$; and $m(211)$, $r(100)$, $r'(122)$, $s(4\bar{2}1)$, $x(4\bar{2}1)$. Sodium orthophosphate, $Na_3PO_4.12H_2O$, strontium chloride, $SrCl_3.6H_2O$, sodium nitrate, $NaNO_3$, furnish examples for examination.

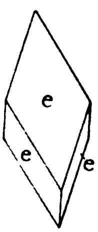

FIG. 33.—Rhombohedral Calcite.

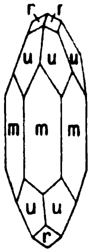

FIG. 34.—Calcite (Dog's Tooth Spar).

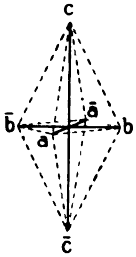

FIG. 35.—Crystallographic Axes of the Tetragonal System.

EXAMPLES.—Sodium periodate—$NaIO_4.3H_2O$; quartz; tourmaline; antimony; bismuth; calcite; ice; graphite; sodium nitrate; arsenic; tellurium; nickel sulphide—millerite; cinnabar; calcium chloride—$CaCl_2.6H_2O$; corundum; cadmium carbonate; bismuth iodide; ferrous carbonate; zinc carbonate; manganese carbonate; chabazite; brucite; corundum; lead, barium. strontium, and calcium dithionates; calamine; dolomite; dioptase—$CuSiO_3.H_2O$; benitoite—$BaO.TiO_2.3SiO_2$; ilmenite; phenacite; etc.

IV. Tetragonal system.—The name comes from τετραγωνία, having four angles or corners. The members of this system have three axes, two of which, a and b, are equal to one another $a=b\lessgtr c$; the axes intersect at right angles, Fig. 35, so that $\alpha=\beta=\gamma=90°$. The crystals may have five planes of symmetry, Fig. 36, one tetrad, and maybe four dyad axes of symmetry. The crystals are uniaxial; the interference figure is a symmetrical cross with concentric rings; the crystals are isotropic in one position, and the optical extinction is parallel in the other two; there are two principal indices of refraction. This system is sometimes called the *pyramidal*, *quadratic*, or the *quaternary dimetric* system.

Typical crystals for examination are nickel sulphate, $NiSO_4.6H_2O$, and cassiterite. The crystals are defined by the form development, and the values of the interfacial angles from which the axial ratio is calculated. For example, *nickel sulphate* (Fig. 39) crystallized from a warm solution has $a:c=1:1·912$; and $o(111)$, $x(112)$, $c(001)$, $a(100)$, $r(101)$, $s(203)$. *Cassiterite* (Fig. 38) has $a:c=1:0·673$, and $m(110)$, $a(100)$, $r(101)$, $s(431)$. Potassium cupric chloride, mercuric cyanide, and potassium arsenite also furnish good crystals for examination.

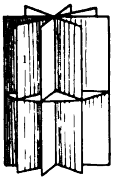

FIG. 36.—Planes of Symmetry of the Tetragonal System.

EXAMPLES.—Rutile; cassiterite; zircon; mercurous chloride; nickel sulphate; potassium hydrogen phosphate—KH_2PO_4; native lead molybdate or wulfenite—$PbMoO_4$; sodium meta-antimonite—$NaSbO_2$; potassium hydrogen arsenate—KH_2AsO_4; scheelite; tin; strychnine sulphate; anatase; lead tungstate—$PbWO_4$; stolzite; yttrium niobate or fergusonite; pinnonite; vesuvianite; urea; wernerite; mercury chloride, iodide, and cyanide; barium antimonyl tartrate; phosgenite; idocrase; apophyllite; scapolite; braunite; etc.

V. Rhombic system.—Here the crystals have three unequal axes all inclined at right angles, so that $\alpha=\beta=\gamma=90°$; and $a<b\leqq c$, Fig. 39—b is conventionally taken as unity. The larger of the two lateral axes is called the *macrodiagonal*—μακρός, long—and the smaller the *brachydiagonal*—βραχύς, short. The crystals may have three planes of symmetry, Fig. 40; and three dyad axes of symmetry. The crystals are biaxial; optical extinction is parallel in all three main positions of the crystal; and there are three principal indices of refraction—the smallest index is in the direction of greatest elasticity, and *vice versa*. This system is sometimes called the *orthorhombic*, *trimetric*, or the *prismatic* system.

Typical crystals for examination are barytes (Fig. 41) and topaz (Fig. 42). The crystals are defined by the development forms and the values of the interfacial angles from which the axial ratios can be calculated. Thus, barytes has $a:b:c=0·815:1:1·314$; and $c(001)$, $o(011)$, and $d(102)$. Topaz has $a:b:c=0·529:1:0·954$; and $c(001)$, $m(110)$, $n(140)$, $i(223)$, $l(120)$, $f(021)$, $y(041)$, $u(111)$. Ammonium sulphate, potassium nitrate, potassium sulphate, zinc sulphate, sodium nitroprusside, and mercuric chloride also furnish good crystals for examination.

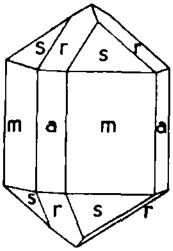

FIG. 37.—Cassiterite.

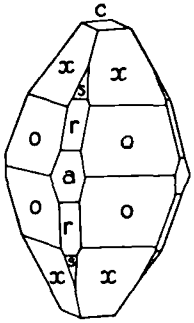

FIG. 38.—Nickel Sulphate Hexahydrate.

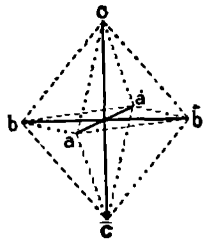

FIG. 39.—Crystallographic Axes of the Rhombic System.

EXAMPLES.—Zinc sulphate—$ZnSO_4.7H_2O$; magnesium sulphate—$MgSO_4.7H_2O$; ammonium magnesium phosphate—$NH_4MgPO_4.6H_2O$; potassium sulphate; aragonite; anhydrous sodium or silver sulphate; sulphur from solution; barium, strontium, and ammonium sulphates; sodium arsenate; sodium phosphate—$NaH_2PO_4H_2O$; iodine; potassium nitrate; tartar emetic; potassium perchlorate; potassium permanganate; topaz; marcasite; tridymite; silver nitrate; lead carbonate; silver sulphide; prehnite; calamine; atacamite; goslarite; stephanite; chrysoberyl; topaz; andalusite; chalcocite; acanthite; hypersthene: struvite; tartaric acid; manganese peroxide; barium chloride; mercuric chloride; orpiment; antimonic oxide; ammonium nitrate; Rochelle salt; citric acid: iodine; selenium; olivine; cerussite; strontianite; redruthite; bournonite; hemimorphite; stibnite; etc.

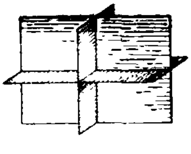

FIG. 40.—Planes of Symmetry in the Rhombic System.

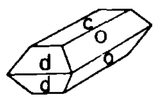

FIG. 41.—Barytes.

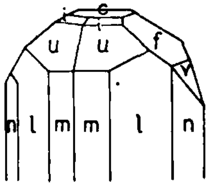

FIG. 42.—One end of a Topaz Crystal.

The physical properties of members of the triclinic, monoclinic, and rhombic systems vary in all three directions; for example, heat is conducted at different rates in all three directions; again, in the mineral iolite, $Al(F_2OH)SiO_4$, crystallizing in the rhombic system, light transmitted in the direction of the principal axes often appears blue, greyish-blue when viewed through the 100 face, and yellow through the 010 face. This phenomenon is known as pleochröism. Light is singly refracted in two directions, and doubly refracted in all other directions, hence the crystals are optically biaxial.

VI. Monoclinic system.—The name is derived from *μόνος*, one, and *κλίνειν*, to incline—having one oblique intersection in allusion to the fact that the members of this system can be referred to three unequal axes, of which two, c (the vertical axis) and a, are inclined to form one oblique angle β, and third lateral axis, b, is at right angles—to the other two—Fig. 43. The inclined lateral or a-axis is called the *clino-axis* or *clino-diagonal*—*κλίνειν*, to incline—and the rectangular lateral or b-axis is called the *ortho-axis* or the *ortho-diagonal*—*ὀρθός*, straight. Hence, $\alpha=\gamma=90°$, and $\beta \lesseqgtr 90°$, and $a \lesseqgtr b \lesseqgtr c$, and there are no closed symmetrical forms, and accordingly, the crystal must be a combination of different forms. These crystals may have one plane of symmetry, Fig. 46, and there may be one dyad axis of symmetry. The crystals are biaxial; optical extinction is parallel in two positions and oblique in the third; and there are three principal indices of refraction. This system has also been styled the *mono-symmetric*, *clino-rhombic*, or the *oblique* system.

Typical examples for examination are gypsum (Fig. 44) and ammonium magnesium sulphate (Fig. 45)—the crystals by the development forms, and the values of the interfacial angles from which the axial ratios can be calculated. Thus *gypsum* (Fig. 44) has $a:b:c=0·690:1:0·412$; $\beta=80°\ 42'$; and $l(111)$, $m(110)$, $b(010)$.

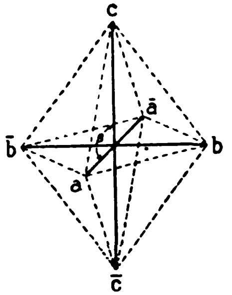

FIG. 43.—Crystallographic Axes of the Monoclinic System.

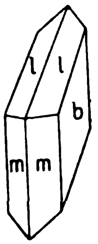

FIG. 44.—Gypsum.

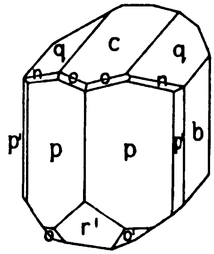

FIG. 45.—Ammonium Magnesium Sulphate.

Ammonium magnesium sulphate $(NH_4)_2SO_4.MgSO_6.6H_2O$ (Fig. 45), has $a:b:c=0·740:1:0·492=107°\ 6'$; and $b(010)$, $c(001)$, $p(110)$, $p'(130)$, $q(011)$, $r'(201)$, $o(111)$, $o'(111)$, $n(121)$. Potassium chlorate, potassium ferrocyanide, potassium chloride, barium chloride, and nickel chloride also furnish good crystals for examination.

EXAMPLES.—Borax—$Na_2B_4O_7.10H_2O$; gypsum; ferrous sulphate—$FeSO_4.7H_2O$; potassium and sodium carbonates; felspar—orthoclase; sodium sulphate—$Na_2SO_4.10H_2O$; ammonium magnesium sulphate—$(NH_4)_2SO_4.MgSO_4.6H_2O$; potassium chlorate; potassium tetrathionate—$K_2S_4O_6$; tartaric acid; sulphur—from fusion; potassium sulphate; cane sugar; arsenic disulphide—realgar; ammonium dichromate; rubidium magnesium sulphate; acid mercuric fluoride; clinohedrite; scolecite; lead chromate; oxalic acid; sodium acetate; augite; hornblende; vivianite; epidote; etc.

VII. Triclinic system.—Crystals of this system can be referred to three oblique axes, Fig. 46. There are no closed symmetrical forms, and hence each crystal must be a combination of different forms. The crystals have no axes nor planes of symmetry, but they may have a centre of symmetry; $a \lesseqgtr b \lesseqgtr c$, and $\alpha \lesseqgtr \beta \lesseqgtr \gamma$. The crystals are biaxial; the optical extinction is oblique in all three positions; and there are three indices of refraction. This system has also been designated the *anorthic*, *clino-rhomboidal*, *asymmetric*, or the *double oblique*.

Typical examples for examination are crystals of copper sulphate (Fig. 48) and of potassium dichromate (Fig. 47). The crystals are defined by the development forms, and the values of the interfacial angles from which the axial ratios can be computed. For instance, potassium dichromate (Fig. 47) has $a:b:c = 0{\cdot}558:1:0{\cdot}551$; $\alpha:\beta:\gamma = 82°\ 0' : 90°\ 51' : 83°\ 47'$; $a(100)$, $b(010)$, $c(001)$, $q(011)$, $p(110)$; *copper sulphate*, $CuSO_4.5H_2O$ (Fig. 49), has $a:b:c = 0{\cdot}5715:1:0{\cdot}5575$; $\alpha:\beta:\gamma = 82°\ 16'$; $107°\ 26'$; $102°\ 40'$; and $q(011)$, $q'(011)$, $t(021)$, $t'(021)$, $s(\bar{1}21)$, $s'(\overline{121})$, $o(111)$. Potassium persulphate, manganese sulphate, and boric acid furnish good crystals for examination.

EXAMPLES.—Potassium dichromate; copper sulphate—$CuSO_4.5H_2O$; calcium thiosulphate—$CaS_2O_3.6H_2O$; boric acid; potassium ferricyanide; anhydrous manganese sulphate; copper selenate; anorthite—lime felspar; cryolite; chromic phosphate—$CrPO_4.6H_2O$; labradorite; chalcanthite; rhodonite; albite; oligoclase; axinite; bismuth nitrate; etc.

The relation between crystal form and molecular complexity.—J. W. Retgers (1894) noticed a general relation between the molecular complexity of over nine hundred substances and their crystalline form. Table I shows the approximate percentage distribution of compounds of different molecular complexity in the different crystal systems. The hexagonal system here includes the trigonal and hexagonal systems.

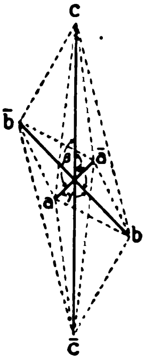

FIG. 46.—Crystallographic Axes of the Triclinic System.

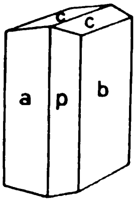

FIG. 47.—Potassium Dichromate.

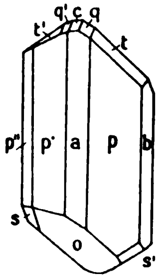

FIG. 48.—Copper Sulphate Pentahydrate.

TABLE I.—PROPORTION OF SUBSTANCES OF DIFFERENT MOLECULAR COMPLEXITY CRYSTALLIZING IN THE DIFFERENT SYSTEMS.

Complexity of molecules.	Number of substances considered.	Per cent.					
		Cubic.	Hexagonal.	Tetragonal.	Rhombic.	Monoclinic.	Triclinic.
Elements .	40	50	35	5	5	5	0
2-atoms .	67	68·5	19·5	4·5	3·0	4·5	0
3-atoms .	63	42	11	19	23·5	3	1·5
4-atoms .	20	5	35	5	50	5	0
5-atoms .	50	12	38	6	36	6	2
6-atoms or more	673	5·8	4·6	7·0	27·3	37·3	8

The results indicated in Table II can be expressed differently by including the cubic and hexagonal systems in one group, and the remaining systems in another group. From this it follows that substances with complex molecules are more inclined to crystallize in systems with a low order of symmetry; and the simpler the molecules of a substance, the greater the probability of its crystallizing in the hexagonal or cubic systems with a high order of symmetry. G. Tschermak[5] has shown that when 2, 3, or 6 atoms are present in the molecular formula, the compound usually crystallizes in the rhombohedral or hexagonal system, and the crystals are characterized by axes of two-, three-, or six-fold symmetry—*e.g.* Fe_2O_3, $FeCl_3$, Ag_3SbS_3, PI_3, $SrCl_2.6H_2O$, etc.—those compounds which have the number 4, but not 6, in their molecular formulæ, usually crystallize in the tetragonal system, and they possess a two- or four-fold, but not a six-fold, symmetry—*e.g.* $ZrSiO_4.4H_2O$, etc. Compounds in which the numbers 3 and 4 occur in the molecular formulæ, have a tendency to crystallize in the cubic system the axes of which possess a three- and four-fold symmetry—*e.g.* $2KF.ZrF_4$, Ag_3PO_4, As_4O_6, etc.

§ 7. The Growth of Crystals

The very molecules appear inspired with a desire for union and growth.—J. TYNDALL.

We do not understand the phenomenon of crystallization, nor do we know how crystals grow. The facts indicated in the preceding sections have made it almost certain that the space occupied by a crystal is not all matter; that their structure is discontinuous; and that crystals grow by accretion, molecule by molecule, like bricks in the hands of the builder, and in accord with "an architectural plan more elaborate and exact than that of any human architect." We are quite ignorant of the shape of the structural units. C. Huyghens saw that the regularity of crystals depends on the arrangement of the smallest particles from which they are built, and he assumed the structural units of calcspar to be rotational ellipsoids. For convenience, they are usually taken to be spherical, as Robert Hooke did in his *Micrographia* (London, 1665), when he said:

> All these regular figures that are so conspicuously various and curious, arise only from three or four several positions or postures of globular particles. . . . And this I have *ad oculum* demonstrated with a company of bullets and some few other very simple bodies; so that there was not any regular figure which I have met withal of any of these bodies and I could not with the composition of bullets or globules . . . imitate even almost by shaking them together.

C. F. G. H. Westfeld (1767) and T. Bergmann (1773),[1] in his *Variæ cristallorum formæ a spato ortæ*, also held the view that many crystal forms could be obtained by laying together little rhombohedra; and in 1772, J. B. L. Romé de l'Isle pointed out that the various shapes of natural crystals can be derived from a fundamental figure or *primitive form*, and that the variety of form which is found in natural crystals is due to the variety of the secondary faces. About 1801, R. J. Haüy[2] developed the idea, that all crystal forms, other than the primary ones, could be exactly imitated by building on the faces of the primary forms, successive layers of what he called integrant molecules—*molécules intégrantes*— each successive layer being regularly diminished by the abstraction of one or more rows either parallel to each edge, or to the diagonals of the faces of the primitive form or in some other way. R. J. Haüy's integrant molecules were of three shapes—the parallelopiped, tetrahedron, and the trigonal prism. R. J. Haüy deduced the shapes of his crystal units from the shapes of the cleavage fragments. W. H. Wollaston,[3] like R. Hooke, suggested the presence of *cleavage molecules* in crystals, but he also remarked that, in place of spheres, mathematical points endowed with forces of attraction and repulsion can be postulated with equal success. In 1831, J. F. C. Hessel[4] showed in his book, *Krystallometrie oder Krystallonomie und Krystallographie* (Leipzig, 1831), that only thirty-two types of symmetry are possible with a solid bounded by plane faces conforming to R. J. Haüy's law of rational indices. At that time comparatively few of these thirty-two types were known. In 1865, A. Gadolin independently made the same discovery as J. F. C. Hessel, and during the next three years V. von Lang established the external geometry, so to speak, or the symmetry of the thirty-two classes of crystals.

Speculations were gradually diverted away from the external form of the crystals, and attention focused more on to the internal orientation of the centres of the particles; L. A. Seeber (1824) and G. Delafosse (1843)[5] regarded the crystal structure as a kind of network of molecular points repeated as identical units throughout space without regard to their shape or constitution, and thus arose the idea that the arrangement of the middle points of the structural units resembles a parallelopipedal network or **space-lattice**—German, *Raumgitter*; French, *réseau.* Thus, said G. Delafosse (1843):

> The molecules of the crystal must be situated in a uniform and symmetrical manner, having their centres of gravity at the points of intersection of a series of parallel planes, and thus present the picture of a lattice with parallel-figured meshes.

The idea of a space-lattice can be gathered from Figs. 49 to 68; it has been likened to a kind of three dimensional net, in which the particles are situated at the corners of parallel and equal parallelopipeda, so that the strings of the net represent the lines of intersection of the planes, and the knots, nodes, or points, their points of intersection. M. L. Frankenheim[6] examined the different kinds of networks of points and compared them with the various types of symmetry presented by crystals; and M. L. Frankenheim's geometrical investigation was supplemented with elegant proofs by A. Bravais[7] in 1848. Whatever be the actual size and shape of the structural unit, it is equally certain that all phenomena peculiar to crystals depend upon the structure or upon the orientation of the constituent molecules of the crystals. The possibility of assigning imaginary crystallographic axes to all known crystals shows that the molecules must be so related to one another that (1) the structural units or molecules of crystals of the same chemical substance, under similar conditions, must be alike in size, and in the distribution of their attractive forces; and (2) the relative position of any one molecule must be symmetrical with that of every other molecule. No other arrangement can be regarded as possible in a crystal. Hence the study of crystal structure, the orientation of the structural units, is reduced to the purely geometrical investigation of the possible arrangements in space of networks of structural units which satisfy these conditions.

Among the problems concerned in elucidating the structure of crystals are: (1) What is the nature of the structural units? (2) How are these units arranged or oriented in space? and (3) What is the nature and character of the vectorial or directed forces which fix the relative positions and determine the orientation of the structural units which make up the crystals? Great success has been attained with the second problem, which has been studied geometrically quite independently of the nature of the material. Geometricians have investigated: **the nature of the symmetrical arrangement of particles in space which will confer on matter the symmetry shown by crystals.** As a result, the theory of the homogeneous partitioning of space, *i.e.* of the homogeneous repetition of identical parts in a uniform structure, has probably reached its final form.

The history of the development of this theory is interesting because it shows how the testing of the deductions of the mathematician's definitions of homogeneity by comparison with the morphological properties of crystals from time to time, compelled the mathematicians to make the definition of homogeneity wider and wider until it included all known forms of crystals. A. Bravais, for instance, based his geometrical treatment of the homogeneous partitioning of space on the assumption that if the properties of crystals depend upon the nature and arrangement of the crystal units, their properties are alike in *parallel* directions, and that fourteen types of space-lattice are possible with a symmetry, corresponding with the maximum symmetry of one or other of the seven systems of crystal architecture.

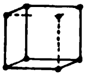

FIG. 49.—Simple Cubic Lattice.

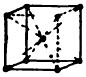

FIG. 50.—Body-centred Cubic Lattice.

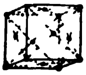

FIG. 51.—Face-centred Cubic Lattice.

The fourteen space-lattices are illustrated in Figs. 49–68, where the dots are supposed to represent the positions of the centre of gravity of the atoms. The lattices belonging to the cubic system are indicated in Figs. 49 to 51. There is: I. *The simple cubic lattice*, Fig. 49, with a particle at each corner of a cube. If the atoms are all nearly equal in size, the symmetry is apparently cubic holohedral—*e.g.* sodium chloride, NaCl; galena, PbS, etc. If two sizes of atoms are present, the symmetry is plagihedral—*e.g.* sylvine, KCl; potassium bromide, KBr; etc. II. *The body-centred cubic lattice*. Here the cube has a particle at each corner and one at its centre. The symmetry when the atoms are all alike is cubic holohedral, Fig. 50, *e.g.* iron, nickel (in part), and sodium. III. *The face-centred cubic lattice*. Here the cube has a particle at each of its corners and one at the centre of each of its faces. The symmetry is cubic holohedral when the atoms are all alike, Fig. 51, *e.g.* copper, silver, gold, lead, aluminium, nickel (in part), etc. The space lattice may consist of two or more mutually penetrating lattices. For example, two interpenetrating face-centred cubic lattices furnish the *double face-centred lattice* of the diamond and zinc blende types illustrated in Fig. 52. The atoms may be all alike when the symmetry is cubic-tetrahedral in some respects, but holohedral by compensation—*e.g.* diamond, silicon, etc. If the atoms are all alike and more than quadrivalent, the symmetry is hexagonal—trigonal, or rhombohedral—*e.g.* antimony, bismuth, arsenic, tellurium. If two kinds of atoms are present, the symmetry will be cubic tetrahedral—*e.g.* sphalerite, ZnS. If three or more kinds of atoms are present, and the atoms are numbered 1, 2, 3, then reading from the top layer downwards, 1, 2, 3, 2, 1. For instance, in chalcopyrite with Cu, 1; S, 2; and Fe, 3, alternate layers taken vertically consist exclusively of each kind in turn. The symmetry is scalenohedral– *e.g.* chalcopyrite, $CuFeS_2$; stannite, Cu_2FeSnS_4. If the atoms be supposed in contact, the shapes of the spaces available for them are illustrated in Figs. 53 to 56, when the constituent atoms are all equal in size. Atoms of one kind may form a simple cubic lattice with an interpenetrating symmetrical face-centred cubic lattice containing atoms of another kind. The symmetry is cubic-holohedral—*e.g.* calcium fluoride, CaF_2. In

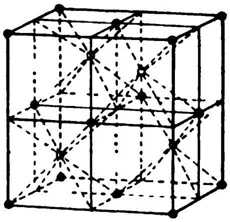

FIG. 52.—Double Face-centred Cubic Lattice.

hauerite, MnS_2, and pyrite, FeS_2, the symmetry is cubic-pyritohedral, and the space-lattice is similar to the former, excepting that the simple lattice is distorted. In cobaltite, CoSAs, the atoms on the distorted simple cubic lattice are of two kinds, and the symmetry is cubic tetartohedral. In cuprite, atoms of copper are on a body-centred cubic lattice, and the atoms of oxygen are on an interpenetrating distorted face-centred lattice; and the symmetry is cubic-gyrohedral.

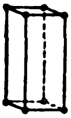

FIG. 62.—The Rhombic Lattice.

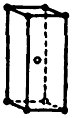

FIG. 63.—The Body-centred Rhombic Prism Lattice.

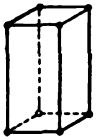

FIG. 64.—The Rectangular Prism Lattice—Rhombic.

The hexagonal prism, Fig. 61, may be regarded as a combination of three 120° prisms, each with a structure like the sixth lattice.

The rhombic system is represented by VIII. *The rhombic prism lattice*, Fig. 62; IX. *The body-centred rhombic prism lattice*, Fig. 63; X. *The rectangular prism lattice*, Fig. 64; and XI. *The body-centred rectangular prism lattice*, Fig. 65. The monoclinic system is represented by XII. *The clinorhombic prism lattice*, Fig. 66; and XIII. *The monoclinic parallelopiped lattice*, Fig. 67. The triclinic system is represented by XIV. *The triclinic prism lattice*, Fig. 68.

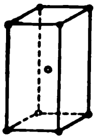

FIG. 65.—The Body-centred Prism Lattice—Rhombic.

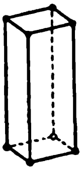

FIG. 66.—The Monoclinic Prism Lattice.

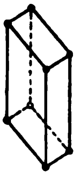

FIG. 67.—The Monoclinic Parallelopiped Lattice.

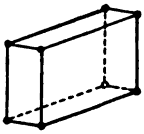

FIG. 68.—The Triclinic Prism Lattice.

In 1869, C. Wiener [8] and C. Jordan extended A. Bravais' assumption by laying down the principle that "regularity in the arrangement of identical atoms is presented when every atom has the remaining atoms arranged about it in the same manner; thus making homogeneity depend primarily on the continued repetition through space of the same relation between a unit and the entire structure as unlimited, instead of laying stress on orientation." L. Sohncke, in his *Entwicklung einer Theorie der Krystallstructur* (Leipzig, 1879), followed up the subject, and assumed that in a homogeneous structure the arrangement about any one point is the same as that about every other point, so that the aspect from any one point is the same as that viewed from any other point. He fulfilled this condition, by selecting one of A. Bravais' fourteen lattices, with one or more lattices identical with it, and thrusting the lattices into one another so as to satisfy the condition for homogeneity. This furnished L. Sohncke with 65 systems of points in place of A. Bravais' 14; and these fall into the 32 classes into which observation has classified all crystals known to exist. In 1887, L. Wulff and F. Haag showed that there is no provision in L. Sohncke's system for the crystals of the rare mineral dioptase, nor for the polar or hemimorphic forms of tartaric acid. L. Sohncke then modified his early theory, which assumed that the units were all of one kind and identically related to the structure as a whole. *A crystal consists of a finite number of interpenetrating, regular systems of points; each separate point system is occupied by similar material particles, which may be the same or different for the interpenetrating partial systems which form the complex system.* Each partial system of units taken by itself is homogeneously arranged, and all the different units are supposed to possess identical systems of axes, and to have the same set of translations common to them; but L. Sohncke did not stick to the purely geometrical problem, for he introduced hypotheses as to the physical character of the structural units, which he said can be rejected "only if they are held to be improbable."

In 1884, P. Curie [9] drew attention to the fact that crystals display not only identity of parts, but they also exhibit enantiomorphous similarity, and he deduced L. Sohncke's 32 varieties of external form, but did not pursue the subject further. Between 1891 and 1894, E. S. von Federoff,[10] A. Schönflies, and W. Barlow, working by three different methods, and in the order named, showed that L. Sohncke's definition provided for each unit being surrounded by all the other molecules in *like* manner where like referred only to identity and not to the resemblance which obtains between an object and its image in a mirror. In L. Sohncke's system two identical sets are superposable; in the extended theory, they are not necessarily superposable. H. A. Miers [11] illustrated this by showing that a point in the centre of a right-hand glove has precisely the same environment as a point in the centre of a left-hand glove, and yet the two are not superposable, for the one is as it were the reflection of the other. A. Schönflies admits the principle of reflection across a plane, inversion about a centre, or a combination of the two as an additional mode of repetition applicable to a system without changing its aspect. There are 230 possible ways of partitioning space into systems of points as types of homogeneous structures; and of these, Sohncke's 65 point-systems and A. Bravais' 14 space-lattices are special cases. Each of these 230 types of structure can be referred to one of the 32 classes into which all known crystals can be arranged, and these 32 classes can still further be grouped into the seven-systems of crystal architecture. "With the establishment of these 230 types of crystal structure," says A. E. H. Tutton, "the geometrical theory of crystal structure has attained what in all probability will prove to be finality." However, directly the space units or cells are invested with special shapes—the *parallelohedra* of E. von Federoff and Lord Kelvin, the *Fundamentalbereich* of A. Schönflies, or the *spheres of influence* of W. Barlow—complications are introduced, and controversial questions arise.

The birth of crystals.—As previously indicated, G. Quincke [12] assumed that the first stage in the crystallization of a liquid involves the separation of the solution into two immiscible liquids, one of which is formed in a relatively small quantity, so as to form a kind of emulsion; and H. F. Link (1839) thought that he could detect such globules at the moment of separation by using a magnification of 600 diameters. If the nuclear masses of the separating liquid are isotropic, with their physical characters alike in all directions, the nuclei would form spherical globules. The spherical globules would afterwards either (i) solidify and serve as nuclei for the subsequent growth of crystalline particles, or (ii) they would form particles in the act of solidification. H. Vogelsang (1875) inclined to the former hypothesis because he and C. Brame (1853) had observed what they considered embryonic sulphur crystals to separate as globular solids from solutions of sulphur in viscous solvents. H. Vogelsang called these embryonic crystals *globulites*.

The term **crystallite** is applied in several different ways—*e.g.* it has been employed for the structural units of crystals; for abnormally elongated and branched forms—crystal skeletons—in which the normal faces and angles are not developed; and for abnormally developed crystal nuclei which have received various names according to their shape or appearance—*globulites, longulites, margarites, belonites, cumulites*, etc.

The belief that small isotropic globulites first appear as nuclei during crystallization, and that only after these globulites have attained a certain size do they assume the crystalline state, has led W. Ostwald, G. Quincke, and others to believe that in the development of crystals, the crystal embryos are at first in the state of droplets of undercooled liquid, and only later become solid as they enlarge into crystals. This means that the molecules of the primary crystals are not vectorially oriented, a statement which has not yet been demonstrated.

H. Vogelsang's hypothesis is discredited, because C. Brauns (1899) showed that what are thought to be solid globules are in reality minute globular masses of undercooled solutions of high viscosity, as E. Weiss (1871) had previously supposed. If the second alternative be true the particles must be sub-microscopic, because T. W. Richards and E. H. Archibald (1901) found that instantaneous photographs of crystallizing barium chloride and potassium iodide showed that crystals have a definite character from the moment they are able to affect a photographic plate.

In his great work *On the equilibrium of heterogeneous substances* (1878), J. W. Gibbs showed that the stable form of a crystal is that for which, as a result of capillary forces, the total surface energy is a minimum. The same conclusion was drawn by P. Curie in 1885 and called **Curie's capillarity theory.** Each crystal face has a specific capillary constant which is measured by the work involved in increasing its surface face by unit area. Let the areas of the various faces be denoted by $s_1, s_2, s_3, \ldots$, and the respective capillary constants by $\sigma_1, \sigma_2, \sigma_3, \ldots$, then, adds J. W. Gibbs,[13]

On the whole it seems not improbable that the form of very minute crystals in equilibrium with solvents is principally determined by the condition that $\Sigma(\sigma_1 s_1 + \sigma_2 s_2 + \sigma_3 s_3 + \ldots)$ shall be a minimum for the volume of the crystal—except so far as the case is modified by gravity or the contact of other bodies—but as they grow (in a solvent no more supersaturated than is necessary to make them grow at all), the deposition of new matter on the different faces will be determined more by the nature (orientation) of the surfaces and less by their size and relations to the surrounding surfaces. As a result, a large crystal thus formed will generally be bounded by those surfaces alone on which the deposit of new matter takes place least readily, with small, perhaps insensible truncations.

Crystals take the habit which gives them the minimum surface energy, so that the relative areas of the faces depend on their capillary constants. While the principle probably operates with microscopic crystals it does not seem to be valid for large crystals. Droplets of liquid usually assume a spherical shape, corresponding with a minimum surface area per unit volume. A few crystals bounded wholly or partially by curved faces are known, and others are so richly faceted that they approximate to a spherical form. The most frequent styles of development are then plates or fine needles, shapes which approach a maximum area per unit volume. P. Curie assumed that plane faces are developed in preference to curved faces because the capillary constants of the former are the lower.

T. V. Barker has pointed out that if J. W. Gibbs' theorem be valid, a knowledge of the capillary constants would enable a prediction to be made of the form of a crystal. For example, in the case of a cubic crystal of common salt, in which both octahedral and cubic faces are observed, the crystal could develop only cubic or octahedron faces according as $s(100) : S(111)$ is less than $1 : \sqrt{3}$, or greater than $\sqrt{3} : 1$. S. Berent measured the capillary constant for water and a solution of carbamide where in the one case cubic faces are developed and in the other octahedron faces. The results demonstrated the existence of capillary differences, but they were unfavourably criticized by F. Pockels. Another deduction from the theory is that large crystals in favourable circumstances must grow at the expense of small ones, and this was verified by the work of G. A. Hulett on very minute crystals.

The theory of J. W. Gibbs also leads to the assumption that different faces have different solubilities. For a crystal departing from the equilibrium shape when placed in a solution of suitable strength should dissolve from some faces while others grow. M. le Blanc and G. Elissafoff showed that the only satisfactory way of testing the deduction is to find if a solution can be obtained of such a concentration that one face grows while another dissolves; and J. J. P. Valeton proved that it was not possible to obtain conditions at which the cubic or dodecahedron faces of alum dissolve while octahedron faces grow, but he did obtain a solution of such concentration that a variation of temperature even so small as 0·003° sufficed to transform unmistakable growth into unmistakable solution.. G. Wulff also measured the relative velocities of growth of the crystal faces of monoclinic Mohr's salt reckoned from the centre of the crystal. He found the relative rates of growth to be (110), 1·96; (001), 2·25; (111), 2·50; $(\bar{1}11)$, 2·64; (011), 2·77, when the rate for the $(\bar{2}01)$ face was taken as unity. S. Tolloczko also found the velocity of solution of gypsum on the (010), (110), and (111) faces were respectively 1, 1·76, and 1·88; and A. Ritzel found that water dissolved the octahedron faces of a crystal of sodium chloride faster than the cube faces, but with a dilute solution of carbamide this relation was reversed. G. Wulff and H. Liebmann also argued that the relative velocities of growth of the crystal faces are proportional to the capillary constants, but H. Hilton, G. Friedel, and C. Fastert have shown that the conclusion is faulty; and A. Berthoud has shown that the differences in the solubilities of the different faces of a crystal are so minute in comparison with the difference in the rates along different axes as to be without influence on the crystalline habit.

L. Sohncke (1888) also attempted to establish a relation between the surface energy of a crystal face and what he called its face-density, meaning by that the number of mass-points (crystal units) existing in unit area of a crystal face. He showed that in a face of maximum face-density, the particles can come no nearer together, and therefore the minimum amount of work remains for the molecular forces to perform. This means that the surface energy of such a face is a minimum. Hence, the crystalline face which is most thickly studded with mass-points will occur most frequently. The density of such points on a face is known as the *reticular density* (A. Bravais). L. Sohncke also attempted to find a relation between the principal cleavage form and the structure of a crystal.

The main factors which determine the crystalline habit are (1) the internal structure of the crystals; (2) the degree of supersaturation; and (3) the nature of concentration (diffusion) currents in the solution during deposition. A. A. Noyes and W. R. Whitney (1897) showed that the dissolution of a crystal is governed by the rate of diffusion of the dissolved molecules across the zone of falling concentration which, being replenished instantaneously from the crystal, remains saturated. M. le Blanc applied the theory to the reverse process of crystallization, but C. L. Wagner and A. Berthoud have pointed out that M. le Blanc's hypothesis takes no account of the varying rates of crystal growth on different faces. C. L. Wagner postulated that the thickness δ of the diffusion zone varies from face to face, but, as L. Brunner showed, even with the most violent agitation δ is at least 0·03 mm., and the thickness δ is not likely to be appreciably influenced by forces of molecular magnitude at the crystal surface. A. Berthoud showed that the rate V at which equilibrium tends to establish itself between a given area s of crystal surface and the solution is proportional to the difference between the concentration C_0 of the saturated solution and the concentration C_1 in contact with the crystal. If k denotes the velocity constant of crystallization of the given surface; K, the diffusion constant; and C, the mean concentration in the diffusion zone, the velocity, $V=ks(C_1-C_0)$; or velocity, $V=sK(C-C_0)/(\delta+K/k)$. When K/k is very small in comparison with δ, which occurs when the solution is quite still, the formula reduces to A. A. Noyes and W. R. Whitney's expression. The more nearly this condition is attained in practice, the more nearly do the crystal faces approximate to equal rates of growth, and facets appear which are not seen when the solution is agitated. A. Ritzel also found the rate of solution of sodium chloride varied with the degree of under-saturation of the solution.

When a crystal is growing, curiously enough, the liquid in the immediate vicinity of the growing face is more concentrated, for it contains more of the dissolved substance per unit volume than the liquid a short distance away from the growing face. At first sight, it seems as if **the growing crystal exerts some kind of attraction on the molecules of the dissolved substance a short distance away.** For instance, if a saturated solution of zinc silicate in molten lead borosilicate tinted with cobalt silicate be allowed to crystallize, the crystals of willemite which separate will also abstract the cobalt silicate from the solution, and form patches of beautiful " azure blue " crystals in a colourless matrix. If no crystallization occurs, the matrix will be uniformly coloured an intense blue. Presumably, the concentration of the colouring agent at the crystal face is maintained by diffusion from the body of the liquid. These facts, as well as the phenomenon exhibited by liquid crystals, lend support to the view that as a liquid nears its crystallizing point, there is a marshalling of the molecules of a liquid about to crystallize which culminates at the moment of separation of the solid crystalline nucleus.

Growing crystals of hydrated strontium nitrate take up colouring matter from a solution coloured with logwood. P. Gaubert[14] showed that the different faces of a crystal have not the same power to absorb colouring matter, *e.g.* certain faces of the crystals of lead nitrate or urea nitrate growing in solutions coloured with methylene blue do not take up the dye; and picric acid crystals growing in solutions containing the same colouring agent, have some faces stained blue, while others remain yellow. R. Marc attributes the power possessed by crystallizing salts to take up organic dyestuffs to adsorption. It must not be supposed that crystals usually gather up impurities from the mother liquid (except by mechanically entangling the mother liquid with the crystal); the converse is often the case. The thrusting aside of impurities by the tip of a growing crystal can be readily observed under the microscope. The shape of growing crystals and the movements of the molecules in the solvent against the resistance exerted by the liquid are controlled by molecular forces which are not alike in all directions. It also follows that the physical character of the mother liquid must modify the rate at which the molecules are supplied to the growing crystal and determined to some extent its habit and form.

The kinetic theory of crystal growth.—The kinetic theory has taught us that during crystallization, it is probable that a series of exchanges between the molecules of the crystal and the molecules of the solution are going on all over the surface of the growing crystal. Molecules of the dissolved substance are attracted to the surface of the growing crystal, the molecules of the crystal continually pass into solution again. If the crystal is growing, more molecules are deposited on the crystal than are lost in unit time; and if the crystal is dissolving, less molecules are deposited on the crystal than are lost in a unit of time.

Let Fig. 69 represent, diagrammatically, a growing crystal, one face of which is incomplete; and assume that the structural units are spherical molecules. If a sphere lodges against a completed face, it can touch *three* other spheres, and whether or not the molecule leaves the growing crystal will depend upon the force of attraction exerted upon it by the three contiguous molecules. Again, suppose that a sphere lodges on the little ledge formed by the top layer of the incomplete face. It will then touch *five* instead of *three* spheres; and it will be held in place by the attraction of five contiguous spheres. Obviously, therefore, (1) during the exchange of molecules between the growing crystal and the solution, those molecules which have been deposited on the **growing face** will be retained more tenaciously than those deposited on a **completed face**; (2) as soon as a few molecules happen to be deposited in juxtaposition on the face of a crystal, subsequent growth on that face will be more rapid than the sporadic growth elsewhere; (3) an incompleted layer will rapidly extend until it covers the entire face of the crystal, etc. These deductions are in harmony with known facts.

G. D. Liveing's explanation of the phenomena is as follows: The surface tension at the boundary between a crystallizing solid renders a supply of energy necessary to generate a surface in the interior of the fluid; and the supersaturation of air with water vapour, and the supersaturation of solutions of salts, show that the generation of a free surface in the interior of a gaseous or liquid fluid is not easy. Similarly, if a surface is already formed in a fluid, as when a supersaturated solution meets the air, or the sides of the containing vessel, if the surface energy of either boundary be less than that at the boundary surface of the crystalline solid and the solution, energy will have to be supplied in order to produce a new surface—but not so much as if there were no such surface. Hence, crystals generally form on the top, or on the sides of the containing vessel. Part of the energy of the change of state from liquid to solid is generally available for producing a new surface; but when the mass deposited is small, the energy available will be correspondingly small—for *mass* varies as the cube of the diameter, while *surface* varies as the square of the diameter of a solid. Consequently, the first solid nucleus which separates from a solution is liable to be squeezed back into a liquid by its own surface tension, so as to form a supersaturated solution. A deposit will form most easily on a surface with the same energy as that of the deposit, because the additional energy required is only needed for the extension of the surface. This explains the seeding of supersaturated solutions by particles of the same salt as is in solution; and also how big crystals grow faster than little ones, for the ratio of the increase of surface to that of the volume decreases as the crystal grows.

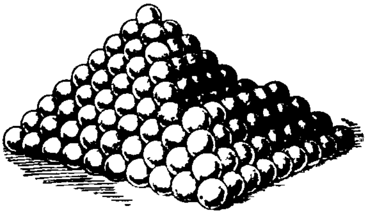

FIG. 69.—Imaginary Diagram of Growing Crystal.

If one part of a crystal be mutilated or damaged, the injured part may grow more rapidly than the other parts of a crystal until the injury disappears, and the perfect crystal is restored.[15] In his study *Die Regeneration der Krystalle* (Leipzig, 1895–6), G. Rauber was so impressed by the inherent power of a mutilated crystal to heal itself that he was led to propound the hypothesis that crystals are controlled by vital forces. D. N. Artemíeeff checked the healing process by exact measurements with the goniometer. According to T. V. Barker, he found:

> In the first period of growth the sphere exhibits a number of glittering spots corresponding with the most important faces. The rest of the surface remains matt, but later becomes covered with tiny crystals in parallel positions, each of which contributes a part to sharp goniometer reflections of the important forms: simultaneously, reflections corresponding with the less important forms appearing as glittering points. As growth proceeds, the less important faces disappear, the tiny parallel crystals coalesce, and the final result is a hemi-crystal bounded by common faces.

Further, if a crystal be removed from a solution in which it is growing, it does not lose its power of growth, for if the crystal be placed in a suitable environment at any future time, it will continue growing as if there had been no interruption. These two statements are demonstrated by the so-called *capped quartz* in which there is an overgrowth of transparent quartz on an old crystal covered with a film of clay or other material which has prevented the new growth adhering to the old so that the capping layer can be sometimes readily detached from the inner kernel. In *ghost quartz*, the film of "dust" has not been thick enough to prevent adhesion, but is sufficient to enable the outlines of the kernel crystal to be readily seen. In the remarkable photograph, Fig. 70, some quartz crystals, grown during some former geological period, have lost their external crystalline form by attrition as they "knocked about the world"—blown about as sand in the deserts, washed down the hillsides in streams of water, etc.—and they were finally deposited as rounded sand grains along with the mountain limestone from some prehistoric sea. There, the damaged crystals—sand grains—met a suitable environment in later years—probably water percolating through the limestone rocks, and carrying silicic acid in solution. The damaged crystals were repaired. Each sand grain, now embedded in each repaired crystal, served as a foundation for rebuilding the damaged quartz crystals on the original architectural plan. In the photograph it was impossible to get all the crystals in focus at the same time. Here, again, we can gaze only in ignorant wonder while the molecules of the solute deploy their mysterious forces in crystal building,

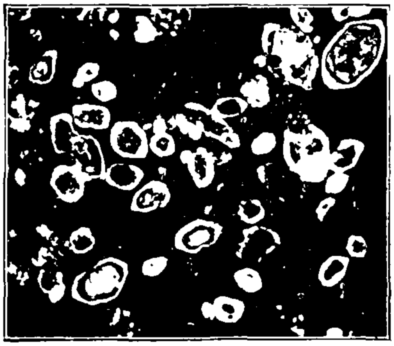

FIG. 70.—Growth of Quartz Crystals about Old Sand Grains.

§ 8. Analysis of the Structure of Crystals by X-rays

All effects are exactly proportional to their causes, therefore, unless their mutual relations be examined by accurate trials, theory must be lame and imperfect.—T. BERGMANN.

The works of nature which seem most desirous to escape our scrutiny are sometimes those which have most to show us.—R. J. HAÜY (1801).

It is shown in the text-books on physics that when a beam of light strikes against a series of very fine lines regularly ruled on the surface of a metal or glass plate, each line acts as a fresh centre from which a secondary train of light waves is diffracted. The diffracted waves enhance some of the normal light waves and damp down others, with the result that the beam of light is analyzed into a series of spectra ; the diffracted waves quench the coloured waves of normal light in the order and proportion of their wave-lengths.

B. Walter and R. Pohl found that the diffraction effects produced by the passage of X-rays through fine slits indicate that the wave-length of these rays is of the order 10^{-9} cm., a value but little less than the estimated distance between contiguous molecules in a crystal. In a paper *On the diffraction of short electromagnetic waves by crystals* (1912),[1] M. von Laue argued that a crystal must form a natural kind of grating on account of the regular disposition of the structural units. The units of a crystal are, however, so small in comparison with the wave-length of ordinary light that the crystal behaves as if it were a continuous medium when exposed to a ray of ordinary light ; on the other hand, the wave-length of the X-rays is so short —about $\frac{1}{10,000}$th of that of light—that the structural units of the crystal form a series of widely separated and regularly arranged particles each of which should diffract a small proportion of the energy of the incident X-rays ; each structural unit should be a centre of diffraction from which a secondary pulse of wavelets is diffracted producing interference effects somewhat analogous with the effect of a diffraction grating on ordinary light.

W. Friedrich and P. Knipping (1912) tested M. von Laue's hypothesis by allowing a primary pencil of X-rays to pass through a crystal, and afterwards impinge on a photographic plate. When the plate was developed the result with a crystal of zinc blende, ZnS, when the X-rays were parallel to the diagonal axis through the centre of the cubic crystal, was remarkable, four series of spots were formed symmetrically grouped about a central image, as illustrated by half a photograph, Fig. 71, also called a *röntgenogram* or *X-rayogram*, or a *radiogram*. Several hours' exposure were needed to produce good results because the greater proportion of the rays are not deflected by the crystal. The dark central spot represents the undeflected pencil of rays, while the smaller dark spots—called **Laue's spots**—symmetrically ranged about the central spot, represent secondary deviated beams due to diffraction or reflection effects of the internal planes of the crystal. The X-rays have presumably been diffracted by the structural units of the crystal *en route*, so that the secondary wavelets passed along and produced interference maxima.

M. von Laue supposed that the X-rays are electromagnetic radiations which set up vibrations in their passage through the crystal so that each structural unit becomes the centre of a wave disturbance. The resulting waves undergo interference, and a spot is produced in the diagram where a set of vibrations are so close in phase as mutually to reinforce each other. When a crystal is placed in the path of a beam of X-rays, the rays are partially reflected from the planes of the crystal which contain a relatively large number of atoms, but not from planes taken at random which do not contain many atoms. Each spot represents a partial reflection of the primary beam of X-rays by a plane rich in atoms. The general equations governing the interference of a three-dimensional grating have been developed. W. Friedrich and E. Wagner showed that the radiograms are the result of a continuous spectrum, and not of a monochromatic beam. It thus appears as if the diffracted rays should cause a general darkening of the whole of the photographic plate, and not produce well-defined spots. P. Debye got over the difficulty by assuming that the structural units at ordinary temperatures are not stationary, but possess some vibratory or oscillatory movement; and he showed that, in consequence, the intensity of the diffracted rays from most of the planes must be reduced to very low values, and only in the planes characterized by a fairly dense packing of particles will the effect survive this weakening. In support of P. Debye's assumption that the atomic vibrations are accelerated with a rise of temperature, M. von Laue and J. S. van der Lingen found that with mica, secondary spots are faintly visible at ordinary temperature under conditions where at 400° they do not appear; there is no trace of spots with rock salt at 620°; the reflected rays are weakened in intensity with a rise of temperature; and the mean distance apart of the atomic planes is augmented by the expansion of the crystal as indicated by a decrease in the glancing angle of the reflected rays. G. Friedel showed that the 32 classes of crystal symmetry can yield a total of eleven types of radiogram; and that the radiogram will not decide whether or not a crystal is endowed with a centre of symmetry. In the cubic system, for example, the holohedral, holoaxial, and tetrahedral classes all yield holohedral patterns, but the tetartohedral and pyritohedral classes give pyritohedral patterns.

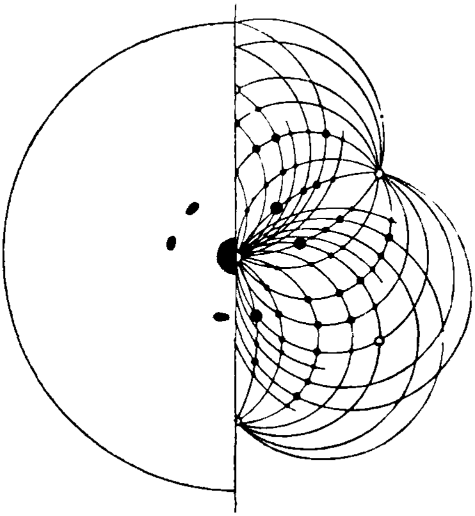

Fig. 71.—M. von Laue's Spots for Zinc Blende with W. L. Bragg's Projection.

J. Stark tried to explain Laue's spots by assuming that the X-rays are corpuscular, and that the corpuscles travel most easily in certain avenues in the crystal, each set of avenues giving rise to a spot. G. Wulff showed that this view is not tenable since there are many wide avenues not represented by spots in the radiogram. L. Mandelstam and H. Rohman suggested that the spots are due to reflections at the surface of cleavage cracks, which must be so fine as to escape detection by ordinary optical means, but M. von Laue showed that this view is untenable.

W. H. Bragg[2] (1912) found that when an incident beam of X-rays falls on a crystal face, the beam is reflected from the face itself; he further showed that the law of equality of the angles of incidence and reflection applies to the beam of X-rays. As a matter of fact, the reflecting plane is not merely the geometrical surface of the crystal, because the rays probably pass through a whole series of planes of molecules parallel to the face before an appreciable absorption occurs, and a small amount of energy must therefore be reflected by each of these planes. Thus E. Hupka roughened the surfaces of quartz and gypsum so that they scattered ordinary light completely, and found that the intensity of the reflected beams of X-rays was not appreciably influenced.

Let V_2, V_3, . . . be planes of atoms (or molecules) parallel to the crystal face V_1. Suppose a parallel beam of X-rays L_1L_2 falls on a crystal face V_1. The incident beam will be reflected by each atom, and the various atoms on the face will be centres of propagation of the reflected beam $L_1'L'_2$. The same will be true for the succeeding planes V_2, V_3, . . . If bS (Fig. 72) be perpendicular to the incident beam L_1L_2, and aS perpendicular to the reflected beam L_1L_2, the difference in the path travelled by a ray reflected from the plane V_1, and that reflected from the plane V_2, will be $bP+Pa$, but $bP=Pa$, and this is a projection of the distance l between the two consecutive planes V_1 and V_2 upon the direction of the incident and emergent beam. If θ denotes the glancing angles of the reflected beam, bP or $Pa=l \sin \theta$; and the whole difference of phase will be $2l \sin \theta$, that is, the trains of wavelets from each plane of the crystal will follow one another at intervals $2l \sin \theta$, and an interference maximum can occur only when this distance is equal to the wave-length λ or to a multiple of λ, say 2λ, 3λ, . . . Consequently, if the wave-length λ is such that $n\lambda=2l \sin \theta$, where n is an integral number, the waves will augment one another and produce a maximum interference. Consequently, if the incident beam contains rays of every possible wave-length, the crystal will appear to select the rays with those particular wave-lengths which follow the $2l \sin \theta$ rule, and produce maximum interference. The angles of reflection can be measured, and by using rays of the same wave-length, the distance l can be compared in different crystals, and with different faces of the same crystal.

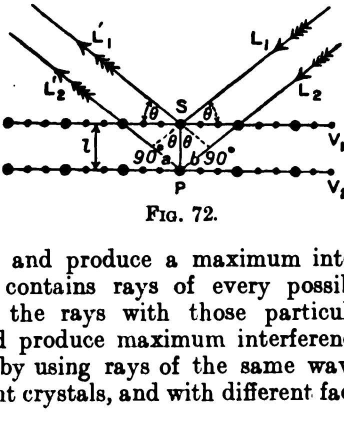

FIG. 72.

A diagrammatic representation of Bragg's apparatus—called an **X-ray spectrometer**—is shown in Fig. 74, and a perspective drawing in Fig. 73 with corresponding lettering.[3] The X-ray tube is placed in a lead box fitted with slits *A* and *B*, about a millimetre wide, to allow a fine pencil of X-rays to pass on to the crystal *C* placed on a little table with its axis passing through the crystal face and which can be rotated by the vernier *V* and scale *SS*; the ionization chamber *I* with its electrode *E* turns about the same axis. A second vernier V_2 indicates the angle at which the chamber *I* has been set in order that the beam of X-rays reflected by the crystal may fall upon and be admitted by the adjustable slit *D*. The ionization current of the chamber *I* with the electroscope *E* and reading microscope *M*, indicates the strength of the reflected beam of X-rays for each angle of incidence.

P. P. Ewald has shown that although apparently so different, M. von Laue's and W. H. Bragg's interpretations really amount to the same thing. M. von Laue worked with transmitted rays, W. H. Bragg with reflected rays. Bragg's method gives a rapid survey of the general structure of a crystal, and in the simpler cases it may furnish all that is required, but the more complex cases may require to be supplemented by Laue's radiograms, which introduce greater precision in the finer details. Laue's radiograms, if used alone, may be inconclusive and give erroneous results.

In P. Debye and P. Scherrer's method,[4] a narrow beam of X-rays is allowed to traverse an aggregate of small crystals, and the resulting diffraction pattern is photographed. The disposition of the crystals is assumed to be perfectly irregular, and A. W. Hull insures this by reducing the substance to a fine powder, and rotating the glass tube containing the powder while it is being exposed. In the latter case, the diffracted rays fall on photographic plates for some hours, and concentric bands are obtained which represent the X-rays reflected from all the important layers of atoms instead of from one at a time. M. de Broglie mounted the crystal, to be exposed in the path of the X-ray pencil, upon a rotating stage.

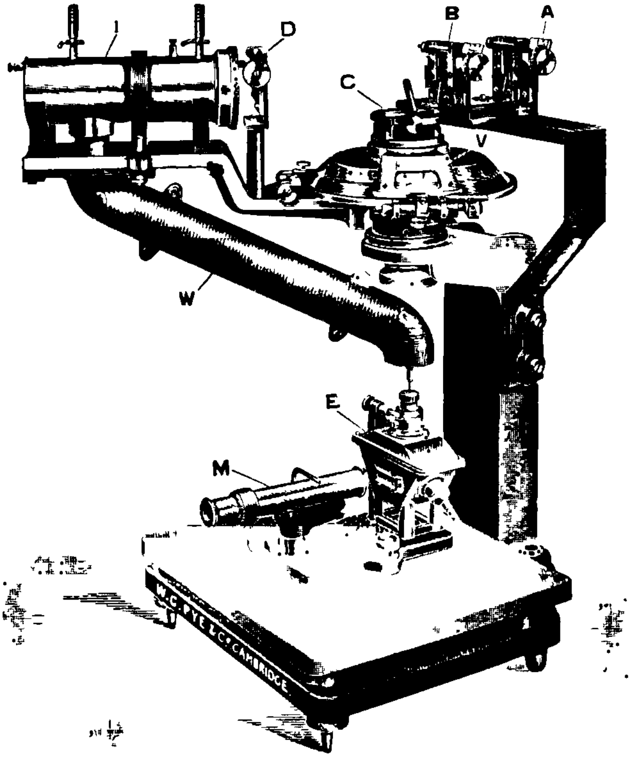

FIG. 73.—X-ray Spectrometer.

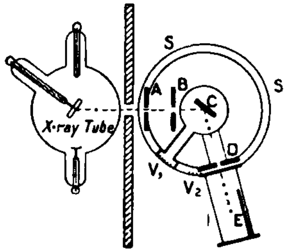

FIG. 74.—Diagrammatic Plan of Bragg's X-ray Spectrometer.

The measurements of the ionization current are usually plotted vertically while the angles of incidence are plotted horizontally. The curve is called an **X-ray spectrum.** This is done for *potassium chloride* and *sodium chloride* crystals in Fig. 75. There is a comparatively small reflection of the rays for all angles of incidence, but a very much larger reflection for special angles. This is shown by the peaks in the curves, Fig. 75. These peaks recur again for angles whose sines are twice those of the former angles, they recur again at triple these values, and so on. Since the wave-length λ and spacing l of the crystal planes parallel to a given face are connected by the equation $n\lambda=2l\sin\theta$, the second peak of the curve gives respectively for potassium and sodium chlorides $2l_1\sin\frac{1}{2}(10{\cdot}43^\circ)=\lambda$, and $2l_2\sin\frac{1}{2}(11{\cdot}8^\circ)=\lambda$, where l_1 and l_2 respectively denote the spacings for the (100)-plane of the crystals of potassium and sodium chlorides. Hence, $l_1=5{\cdot}48\lambda$ and $l_2=4{\cdot}85\lambda$. This shows that while the crystals of the two salts probably have a similar structure, the molecule of potassium chloride is more voluminous than that of sodium chloride, This agrees with the observed molecular volumes, for obviously, if M_1 and M_2 denotes the respective molecular weights of potassium chloride (37·8), and sodium chloride (27·8), and D_1 and D_2 the corresponding densities, then $l_1^3 : l_2^3$=Mol. vol. KCl : Mol. vol. NaCl$=M_1/D_1 : M_2/D_2$; and hence $l\sqrt[3]{D/M}$ should be a constant for different members of this series of salts. The computed value for potassium chloride is $5{\cdot}48\sqrt[3]{(1{\cdot}97 \div 75{\cdot}5)}\lambda = 1{\cdot}63\lambda$; for sodium chloride, $1{\cdot}62\lambda$; and for potassium bromide, $1{\cdot}63\lambda$. This is taken to mean that the structure of these salts is analogous.

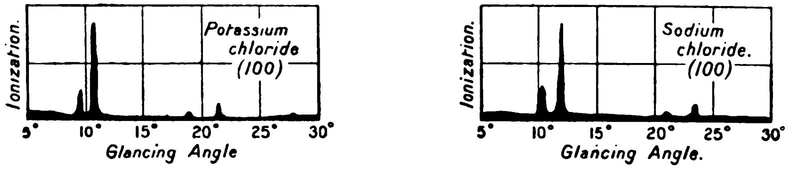

FIG. 75.—X-ray Spectra of Crystals of Potassium and Sodium Chlorides.

The curve in which the intensity is plotted against the glancing angle of incidence with the (100)-face of rock salt exhibits three peaks A_1, B_1, and C_1 at glancing angles 13° 48′, 11° 30′, and 10° respectively. These three peaks are produced with a platinum anticathode in the X-ray tube, and they have been found to correspond with three monochromatic beams of X-rays with wave-lengths $\lambda_A=1{\cdot}316\times10^{-8}$ cm.; $\lambda_B=1{\cdot}095\times10^{-8}$ cm.; and $\lambda_C=0{\cdot}96\times10^{-8}$ cm. The A_1, B_1, C_1 peaks are repeated by a less pronounced system of peaks A_2, B_2, and C_2 with glancing angles respectively 27° 36′, 23° 30′, and 20°; and these again by a third system B_3, and C_3 of still smaller intensity and with the respective angles 35° 50′ and 30° 48′. For the A-peaks, therefore, sin 13° 48′ : sin 27° 36′=0·238 : 0·463; for the B-peaks sin 11° 30′ : sin 23° 30′ : sin 35° 50′=0·199 : 0·399 : 0·585; and for the C-peaks, sin 10° : sin 20° : sin 30° 48′=0·173 : 0·342 : 0·512. These ratios correspond closely with 1 : 2 : 3. For corresponding maxima on the (100), (110), and the (111) planes for sylvine, KCl, the angles are respectively 5° 13′, 7° 18′, and 9° 3′, and their sines are in the proportion $1 : \sqrt{2} : \sqrt{3}$. The same ratios occur with the sines of the angles for corresponding maxima on these faces with rock salt, although their absolute values are different. Let $OBFAEGBC$, Fig. 76, represent a simple cubic space lattice, the (100)-planes are parallel to $OBDC$, and their distance apart $l_{100}=OA$; the (110)-planes are parallel to $CBFE$, and their distance apart is $l_{(110)}=OP$; and finally, the (111)-planes are parallel to ABC, and their distance apart is $l_{(111)}=OQ$. Geometrically, therefore,

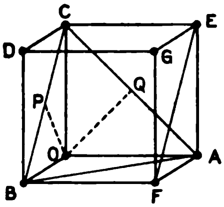

FIG. 76.

$$\frac{1}{l_{(100)}} : \frac{1}{l_{(110)}} : \frac{1}{l_{(111)}} = \frac{1}{OA} : \frac{1}{OP} : \frac{1}{OQ}; \text{ or } 1 : \sqrt{2} : \sqrt{3}$$

Experiment shows that for the crystals of sylvine

$$\frac{1}{l_{(100)}} : \frac{1}{l_{(110)}} : \frac{1}{l_{(111)}} = \sin 5^\circ\, 13' : \sin 7^\circ\, 18' : \sin 9^\circ\, 3'$$

which is very nearly that required for the simple cube lattice $1 : \sqrt{2} : \sqrt{3}$. These ratios with the three types of cubic space lattice (Figs. 49, 50, and 51) are

	$\frac{1}{l_{(100)}} : \frac{1}{l_{(110)}} : \frac{1}{l_{(111)}}$
Simple cubic lattice	$1 : \sqrt{2} : \sqrt{3}$
Body-centred cubic lattice	$1 : \frac{1}{2}\sqrt{2} : \sqrt{3}$
Face-centred cubic lattice	$1 : \sqrt{2} : \frac{1}{2}\sqrt{3}$

The measurements for both sodium and potassium chlorides are thus in agreement with the measurements for the simple cubic lattice.

Thus, the various glancing angles θ_1, θ_2, θ_3, at which a plane of crystal units serve as efficient reflectors, are determined. The wave-lengths of the rays emitted by anticathodes of platinum, rhodium, tungsten, or palladium are known. The results are then interpreted by means of the equation $n\lambda=2l \sin \theta$. The term n is unity with a reflection produced by the mutual reinforcement of pulses provided by successive chemically and crystallographically identical planes—first order reflection at angle θ_1; similarly, the co-operation of the second plane gives a second order reflection at an angle θ_2; likewise also with the co-operation of the third plane, the third order reflection at an angle θ_3 is obtained; and so on. The intensity of the reflection diminishes regularly in passing up the orders excepting in cases where successive planes of crystal units differ as to composition, or distances apart, so that the even orders may appear stronger than the odd orders, while certain orders may vanish altogether. With rock salt, the relative intensities of the reflections from the cubic and octahedron planes are:

	1st order.	2nd order.	3rd order.	4th order.
Cube planes, face (100)	100	18·7	6·25	—
Octohedral planes, face (111)	16·5	24·4	3·10	4·2

The regular decrease of intensity on ascending the scale of orders is interpreted to mean that the units are chemically identical, and the spacing of the successive cube planes is the same; on the other hand, the periodic rise and fall of intensity on the octahedral planes indicates some structural peculiarity; otherwise expressed, the reflecting units in successive cube planes are identical in all respect; but, assuming that the individual atoms, and not the molecules, are reflectors, it follows that the reflecting units in the octahedral (111) planes are alternate layers of sodium and chlorine atoms. This gives the arrangement shown in Fig. 77, where the solid circles represent chlorine atoms and the open circles sodium atoms.

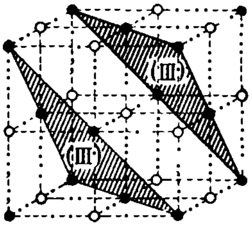

Fig. 77.—Space Lattice for Crystals of the Alkali Halides.

The patterns of the Laue spots for sodium and potassium chlorides, potassium bromide and potassium iodide are not identical. Potassium chloride gives the pattern characteristic of a simple cube lattice with points at each of the four corners; potassium bromide and iodide give patterns characteristic of the face-centred lattice; while sodium chloride gives a pattern which seems to be intermediate between the other types. It is known that the intensity of amplitude of the waves of the secondary radiation produced by X-ray impulses is nearly proportional to the masses of the atoms. It was therefore inferred that while in potassium chloride crystals the atomic weights of the potassium and chlorine are sufficiently close to make the two atoms almost equally active as centres of diffraction, the difference between the atomic weights of sodium and chlorine is sufficient to complicate the simpler potassium chloride pattern; while with *potassium bromide* or *iodide*, the difference between the atomic weights of the respective elements is so great that the effect produced by the lighter atom is overpowered by the heavier one. If the atoms of sodium be represented by open circles and the chlorine atoms by solid circles—Fig. 77—the space lattice must have an equal number of both kinds of spots, and the arrangement of the black and white points at the corners of the elementary cube will represent the effects produced by sodium chloride; while if the black spots are alone considered, the effective centres of diffraction will appear to be located at the corners and face centres of an elementary cube. In fine, the space lattice of sodium chloride may be regarded as being composed of two interpenetrating face-centred cubic lattices with the sodium atoms arranged on the one, and the chlorine atoms on the other. The structure of potassium chloride is much the same, the two interpenetrating space lattices—one chlorine and one alkali metal—are so intercalated that the chlorine space lattice is shifted over a distance of half the edge of the cube of the metal space lattice, so that each chlorine atom falls midway between two consecutive metal atoms, and similarly one metal atom falls between two consecutive chlorine atoms.

According to the kinetic theory, there are $6{\cdot}06 \times 10^{23}$ molecules per gram. The density of sodium chloride is 2·167; and therefore there are $2{\cdot}167 \times 6{\cdot}06 \times 10^{23} \div 58{\cdot}46 = 2{\cdot}3 \times 10^{23}$ molecules or $4{\cdot}6 \times 10^{23}$ atoms per c.c. The atoms of sodium are arranged cubically, and consequently the average distance apart of these molecules is the cube root of the reciprocal of $4{\cdot}6 \times 10^{23}$, or $3{\cdot}5 \times 10^{-8}$ cm.—very nearly one hundred-millionth of an inch.' This means that along the edge of a crystal of sodium chloride there are nearly a hundred million atoms per inch. The absolute dimensions of a space lattice can be calculated from the glancing angle θ—the angle of reflection of X-rays from crystals—which can be measured with great accuracy, and the known wave-length λ, by Bragg's equation $n\lambda = 2d \sin \theta$, where d denotes the spacing of the crystal planes parallel to the crystal face. If v denotes the volume of the elementary cell; M, the molecular weight; D, the density; n, the number of molecules in the cell; and N the number of molecules in a gram-molecule ($6{\cdot}06 \times 10^{23}$), $nM = NvD$. Consequently, the atomic weight of an element can be calculated from the observed data when the atomic weight of the other elements in combination with it are known.

These experiments give direct proof that the structural units of crystals are arranged in space-lattices. There is little indication of the way these units are united to form the so-called chemical molecule. Indeed, the crystal molecule as a structural unit seems to have lost its significance. (1) There is no evidence of chemical combination; (2) a sodium atom is no more closely attached to one chlorine atom than it is to any other; (3) there is no sign of a molecular structure in the chemical meaning of the term; and (4) each atom is an integral part of the whole crystal, and is not connected with any particular group of atoms which form its chemical molecule. The whole crystal endlessly extended in all directions seems to form one gigantic crystal molecule. It must be added that the scattering of X-rays is a purely atomic effect, consequently, although the exploration of crystal structure by these rays may reveal the mean positions of the atoms, yet, from the very nature of the case, it cannot throw direct light on the existence or non-existence of molecules in the crystalline condition.

The view that the radiograms demonstrate that no chemical molecules exist in crystals is not generally accepted. F. Rinne[5] claims that groups corresponding with molecules can be often recognized. A. L. W. E. van der Veen, and A. Smits and F. E. C. Scheffer claim that since the distances between the atoms in the solid state are small compared with their diameters, the atoms belonging to the same molecule can be but slightly closer than those belonging to different ones, and that the difference cannot be detected by the X-rays. A. Fock adds that even though the radiograms of sodium chloride show that six chlorine atoms surround one sodium atom this does not prove that one chlorine atom is not combined with one sodium atom. Isomorphism, electrical conductivity, and the fact that crystals and solutions of the same substance give the same molecular weight is taken by A. Fock to demonstrate the continued existence of molecules. P. Groth also claims that interatomic connections must remain even though the chemical molecule as such has lost much of its significance from a crystallographic point of view. The special nature of the symmetry elements in some crystals is closely related to the atomic structure of the chemical molecule itself, so that this cannot have any significance if there are no chemical molecules in the crystal. J. Beckenkamp holds that the ultimate structures of crystals are triclinic, and by submicroscopic twinning systems of higher symmetry are produced; and that the radiograms merely give the average positions of the atoms. A. C. Crehore mathematically investigated the mechanical forces between the atoms in a space lattice, and states that the essential difference between crystal and molecular structures is that in the former, the atoms, under certain mutual restrictions, may revolve about non-parallel axes, while in the latter, all atomic rotations are necessarily parallel.

W. L. Bragg found the results with zinc blende, ZnS; fluorspar, CaF_2; and calcite, $CaCO_3$, to be almost identical when the X-rays are taken diagonally through the centre of the cube. Each point in a space lattice is situated with respect to its neighbours like every other point; and, in the case of the three compounds just indicated, it is possible to satisfy the conditions only by assuming that each molecule acts as a single point in that it contains one atom heavier than the others which is responsible for the observed diffraction pattern. Hence, it is probable that single atoms are associated with each diffracting unit.

Still further, the value $l(D/M)^{\frac{1}{3}}$ is nearly constant for crystals of potassium chloride, KCl; sodium chloride, NaCl; zinc blende, ZnS; fluorspar, CaF_2; and pyrite, FeS_2. Hence, it is inferred that the number of molecules associated with each diffraction centre is the same; and since the crystals are so differently constituted, it is probable that one and only one molecule is associated with each diffracting centre. The volume of unit parallelopided of the space lattice for potassium chloride is about one-eighth that of the other crystals, because both its atoms, having nearly the same atomic weights, are equally effective as centres of diffraction, whereas with the others, only the heavier atom is effective.

W. H. and W. L. Bragg[6] found that in the double face-centred space lattice of the *diamond*, each carbon atom (black and shaded spots, Fig. 78) is surrounded by four other carbon atoms at equal distances away, and which are related to it like the four apices of a tetrahedron are related to the centre. If series of adjacent space lattices be examined, it will be found that the atoms appear to be arranged in a series of rings of six (heavy dotted lines, Fig. 78). This recalls the benzene, C_6H_6, ring. The diamond has also been investigated by L. Föppl, W. Barlow, A. L. W. E. van der Veen, and P. P. Ewald. W. L. Bragg found the space lattice of *zinc blende*, ZnS, to be similar to that of the diamond, if sulphur atoms (circles, Fig. 78) and zinc atoms (black spots, Fig. 78) be alternately substituted for carbon atoms. The zinc atoms now occupy the corners and face-centres of a cube with a sulphur atom in the centres of the alternate small cubes so that each sulphur atom is surrounded by four symmetrically placed zinc atoms; and each zinc atom is surrounded by four symmetrically placed sulphur atoms. The structures of zinc blende and of the diamond are thus based on the so-called double face-centred cubic lattice formed by the interpenetration of two face-centred cubic lattices. The space lattice for *fluorspar*, CaF_2, resembles that of zinc blende with the calcium atoms occupying the corners and face-centres of a cube, and fluorine atoms in the centres of all the small cubes, instead of in alternate cubes as was the case with the sulphur atoms of zinc blende. Each fluorine atom is now surrounded by four symmetrically placed calcium atoms, but each calcium atom has eight fluorine atoms arranged around it and related to the central calcium atoms as the eight corners of a cube are related to the centre. The crystals of *magnetite*, Fe_3O_4, show that the space lattice is fundamentally the same as the diamond with groups Fe_3O_4 taking the place of carbon atoms. Two out of the three atoms of iron are surrounded by four oxygen atoms arranged at the corners of an imaginary tetrahedron about each atom of iron as centre. The other atom of iron is arranged so that it is surrounded by six oxygen atoms belonging to the oxygen tetrahedra. It is therefore thought that the two iron atoms are probably bivalent, and one iron atom is tervalent representing a structural formula $Fe_2^{II}Fe^{III}O_4$. Quite similar results are obtained with spinel,

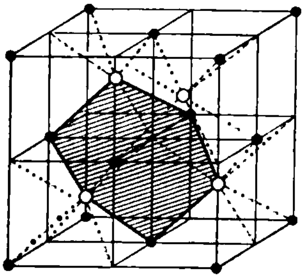

FIG. 78.—Space Lattice of Zinc Blende (and the Diamond).

Mg_2AlO_4, in which magnesium takes the place of bivalent iron in magnetite, and aluminium the place of ferric iron. L. Vegard reported that in *zircon*, $ZrSiO_4$, the atoms of zirconium and silicon are arranged alternately in a space lattice of the face-centred tetragonal type; each silicon and zirconium atom appears to be associated with two oxygen atoms forming SiO_2- and ZrO_2-groups as structural units of the space lattice. The oxygen atoms appear to be closer to the silicon atoms than to those of zirconium, probably because of the greater affinity of silicon for oxygen. Space lattices of crystals of *rutile*, TiO_2, and of *cassiterite*, SnO_2, resemble those of zircon, in which silicon and zirconium atoms are replaced by identical atoms of titanium or tin.

The space lattices of crystals of *copper*, *silver*, *gold*, and *lead* show that the structural units are arranged like a face-centred cube, Fig. 51. Each unit is surrounded by twelve equidistant units. W. L. Bragg found the space lattice of *pyrites*, FeS_2, is rather complex; it shows that the atoms of iron are arranged at the corners of a face-centred cube (circles, Fig. 79), and each iron atom has four equidistant sulphur atoms (black spots, Fig. 79) around it, and others at a slightly greater distance away. Each sulphur atom has three iron atoms arranged around it, with other iron atoms at a slightly greater distance away. W. L. Bragg also found that *hauerite*, MnS_2, *ullmannite*, NiSbS, and *cobaltite*, CoAsS, have a similar structure. *Cuprite*, Cu_2O, belongs to a similar class.

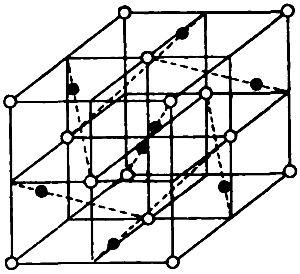

FIG. 79.—Space Lattice of Pyrites.

W. H. and W. L. Bragg found that the space lattice of *calcite*, $CaCO_3$, Fig. 80, shows that the carbon and oxygen atoms occur on triangular planes perpendicular to the crystal axis. The calcium atoms lie in planes just above and below the carbon and oxygen planes, so that each carbon atom is surrounded by six equidistant oxygen atoms. In Fig. 80, the large black dots represent carbon atoms, the small black dots oxygen atoms, and the circles calcium atoms. For the sake of clearness, the oxygen atoms are omitted from the upper part of Fig. 80, and the arrangement of the oxygen atoms is shown in the lower part of the diagram as a series of layers perpendicular to the trigonal axis. The position of the different planes is obvious from the lettering. Each carbon atom is associated with three oxygen atoms, while the latter are only associated with one carbon atom, and the distance between the calcium and carbon atoms is greater than the distance between the oxygen and carbon, or the oxygen and calcium. Each CO_3 group thus appears as a unit equidistant from the six calcium atoms. The space lattices of *rhodochrosite*, $MnCO_3$, *siderite*, $FeCO_3$, and *sodium nitrate*, $NaNO_3$, are similar to that of calcite. The change in the valency of the sodium and nitrogen in sodium nitrate from the basic element and carbon in the carbonates is noteworthy since it appears to make no difference in the general arrangement of the atoms in the crystals. In *dolomite*, $MgCO_3.CaCO_3$, the structure is similar to that of the carbonates with alternate atoms of calcium

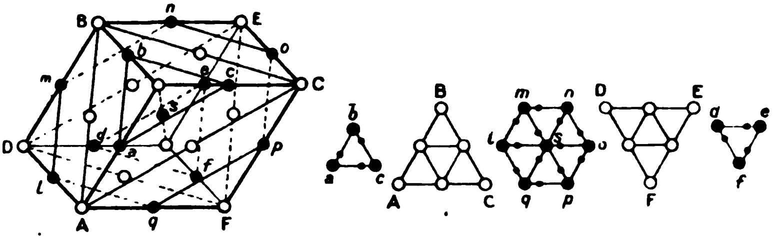

FIG. 80.—Space Lattice of Calcite.

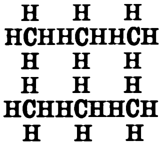
and magnesium in place of calcium. The structure of *hæmatite*, Fe_2O_3, belongs to the calcite class with the carbon atoms removed and each calcium atom replaced by two iron atoms arranged like a dumb-bell parallel to the *c*-axis.

J. Herwig [7] investigated the space lattice of *gypsum* ; S. Nishikawa investigated the *spinel* minerals—magnetite, Fe_3O_4 ; ruby-spinel, $MgAl_2O_4$; W. L. Bragg investigated magnetite ; F. M. Jäger and H. Haga have examined *d*- and *l*-sodium chlorate ; ammonium-iron and potassium-chromium alums ; *d*- and *l*-triethylenediamine cobaltic bromide ; beryl, apatite, ethylsulphates of the rare earths, nephelene, calcite, dolomite, phenacite, tourmaline, quartz, cinnabar, aragonite, topaz, anhydrite, cordierite, hambergite, hemimorphite, struvite, sodium ammonium *d*-tartrate, *l*-asparagine, zinc sulphate, and benitoite ; F. Rinne has examined cyanite, diopside, epidote, scolecite, sucrose, anhydrite, aragonite, calcite, dolomite, quartz, carborundum, beryl, and cuprite. L. Vegard has studied silver, gold, lead, anatase, ammonium iodide, tetramethyl ammonium iodide, rutile, cassiterite, zircon, xenotime, and thorite. C. M. Williams has also studied the rutile group, and his results are not always in agreement with those of L. Vegard. Copper was examined by W. L. Bragg ; scheelite and wulfenite by R. G. Dickinson; iron, silicon, aluminium, sodium, lithium, nickel, magnesium, graphite, and the diamond by A. W. Hull; chalcopyrite, by C. L. Burdick and J. H. Ellis; barium, strontium, and lead nitrates, by S. Nishikawa and K. Hudinuki; garnet, by S. Nishikawa; different forms of silica, by S. Kyropoulos; and white and grey tin, by A. J. Bijl and N. H. Kolkmeijer.

I. Langmuir's theory of solids and liquids.—I. Langmuir believes that the work of W. H. and W. L. Bragg shows that in all probability crystals are not built of molecular units in the ordinary sense of the term. With potassium chloride, for instance, each atom of potassium is surrounded by six equidistant atoms of chlorine arranged as if they were placed at the corners of an octahedron ; each chlorine atom is similarly surrounded by six equidistant potassium atoms. The identity of the molecules of potassium chloride, KCl, thus appears to be lost, unless the whole crystal itself be regarded as itself forming one molecule. Each atom is united chemically with all the adjacent atoms, and these in turn are similarly united with those beyond. Consequently, the ordinary conception of valency no longer holds good, each atom appears to be united with far more atoms than corresponds with the normal valency. The valency of potassium, for instance, equally divided between six chlorine atoms, and the valency of chlorine between six potassium atoms. Considerations like these led I. Langmuir [8] (1916) to elaborate the definition of a molecule. A *molecule*, said he, is a group of atoms held together by atomic forces ; the *gas molecule* is defined in terms of Avogadro's hypothesis, while a continuous liquid or solid mass is called a *solid or liquid molecule.*

No structural formula consistent with the primary valency of the constituent atoms can be employed to represent the structure of crystalline solids like potassium chloride. I. Langmuir (1916), assuming that the primary valencies hold good for gaseous molecules of potassium or sodium chloride ; and that if there were no residual affinity or secondary valencies developed when the temperature is lowered or the pressure raised, these molecules could not condense to form a liquid or solid, supposes that in the solid state, what Werner calls the secondary valencies, altogether supplant the effects of primary valency. He also bases a similar assumption for molecules formed from bivalent and tervalent atoms upon Bragg's space lattices for zinc blende, ZnS ; fluorite, CaF_2 ; pyrites, FeS_2 ; hauerite, MnS_2 ; magnetite, Fe_3O_4 ; and spinel, $MgAl_2O_4$. In the case of the diamond, each carbon atom appears to be surrounded by four others equidistant from and arranged around the central atom much as the four corners of a regular tetrahedron are related to the centre. Consequently, the primary valencies of the quadrivalent carbon atom seem to exert some influence on the formation of the solid crystal. In cubic crystals of methane, CH_4, the carbon atom is probably surrounded by four hydrogen atoms held by primary valencies, and the crystal is held together by secondary valencies, so weak indeed that methane melts and boils at very low temperatures. Langmuir represents the constitution of a methane crystal diagrammatically as in Fig. 81, where each hydrogen atom is associated with a particular carbon atom ; each carbon atom is associated with four hydrogen atoms; and all other hydrogen atoms besides these four are combined with a different carbon atom. Langmuir calls aggregates



$$\begin{array}{c} \mathrm{H\quad H\quad H} \\ \mathrm{HCHHCHHCH} \\ \mathrm{H\quad H\quad H} \\ \mathrm{H\quad H\quad H} \\ \mathrm{HCHHCHHCH} \\ \mathrm{H\quad H\quad H} \end{array}$$

FIG. 81.

of atoms of this kind *group molecules*, because the atoms in the group may be distinguished from those outside the group. A crystal of zircon, $ZrSiO_4$, likewise contains group molecules ZrO_2 and SiO_2. Similar remarks apply to the quadrivalent atoms of titanium and zirconium in zircon, ZrO_2, rutile, TiO_2, and cassiterite, SnO_2, where röntgenograms by L. Vegard (1916) show that the molecular groups ZrO_2, TiO_2, or SnO_2 form the structural elements in the space lattices.

When the vapour of potassium chloride is condensed to a solid and re-vaporized, it is probable that when a potassium atom escapes from the surface of the solid, it takes away one of the four adjacent chlorine atoms to form a gaseous molecule of potassium chloride, and judging from röntgenograms of the crystals, the chances are against the two partners being the same as were previously united before the condensation of the vapour. On the other hand, it is probable that if methane were treated similarly, the same four atoms of hydrogen would remain united to the same carbon atom in both the solid and gaseous states. I. Langmuir calls the largest aggregates of atoms which may pass from the gaseous to the solid or liquid phase and back again to the gaseous phase without exchanging atoms with other aggregates, a *fixed molecule*.

Still following I. Langmuir, since the secondary valencies of inorganic solids usually supplant the primary valencies exhibited by the substances in the gaseous state, (i) the composition of a solid should give little or no information about the primary valencies; and (ii) it should be possible to make more solid compounds than accord with the rules for primary valencies. If the arrangements of the atoms are regular so as to form a space lattice, the resulting solid should satisfy the tests for a chemical compound, even though it exhibits no relationship with the primary valencies of the constituent atoms. A large number of compounds are known in the solid state which do not accord with the ordinary doctrine of valency. For example, G. Tammann (1906–7)[9] obtained compounds corresponding with $AgMg_3$, $AgMg$, $AuZn$, Au_3Zn_5, Cu_3Al, $CuAl$, $CuAl_2$, Mg_4Al_3, $AlSb$, Zn_7Fe, $NaZn_{12}$, $NaCd_5$, etc., and he found that about 26 per cent. of the binary metal compounds which he investigated have formulæ in accord with those based on the primary valencies of the elements. In the case of minerals, and particularly the silicates, the number of exceptions to the valency doctrine is greater than with alloys. In these compounds, as also with potassium chloride, the atoms are held together by secondary valencies, and they have a definite composition because the constituent atoms are arranged as a space lattice. The reason solids so frequently accord with the ordinary rules for valency is that they are usually formed from solutions or from gaseous phases. Even in the case of alloys formed by solidification from a fused mixture, certain restrictions are necessarily imposed by the very method of formation. Hence, I. Langmuir argues that if methods for the preparation of solid compounds at sufficiently low temperatures could be devised, there is no conceivable limit to the number of possible compounds formed by secondary valencies.

If the units A and B in a space lattice could be replaced in an irregular manner by another unit C, the resulting crystal would not have a definite composition, and would not therefore be recognized as a chemical compound, but would rather be said to have formed a *solid solution* or *mixed crystals*. There is no reason to suppose that the forces holding the structural units together are any different in kind in the two cases; nor is there any reason, other than mere definition, to suppose that if one combination is a chemical compound the other is not a chemical compound. Again, a solid body built up from units—either atoms or group molecules—arranged irregularly in space would not form a space lattice, but it would be called an amorphous substance or a glass. The case of thorite is curious. L. Vegard[10] found that tetragonal crystals of thorite, $ThSiO_4$, are isotropic in polarized light, and show no indications of an optic axis; and Röntgen ray analyses show that while the crystal preserves the outward form of a tetragonal crystal, the original lattice resembling zircon has in the course of time been completely broken down and only the outer frame remains to indicate the original orientation of the atoms. The evidence thus seems to indicate that the internal structure is the same as that of an amorphous solid, and this in spite of its external crystalline form.

It is very doubtful if the nature of the forces holding together the units of amorphous substances or glasses are any different in kind from those in crystals. This recalls F. Wald's assumption that the composition of chemical compounds is variable, and out of all the possible variations which actually occur, chemistry reserves the term compounds for those of constant definite composition. This, says F. Wald, is quite an arbitrary choice. F. Wald also argues that the law of multiple proportions as well as the other stöchiometrical laws are really founded on similar conventions.[11]

§ 9. Liquid Crystals; Crystalline Liquids; or Anisotropic Liquids

> The very name seems to be a self-contradiction. How can a liquid be a crystal, and how can a crystal be a liquid?—H. A. Miers (1896).

In 1876, O. Lehmann [1] found that at temperatures above 146°, silver iodide can flow like a viscous solid, and that although it is actually in the liquid condition, it still exhibits several properties characteristic of crystals. Further investigations, by F. Reinitzer (1888), on cholesteryl benzoate; by L. Gattermann (1890), on *p*-azoxyanisole and *p*-azoxyphenetole; and by O. Lehmann himself on ammonium oleate, etc., have shown that the phenomenon is not uncommon; rigid solidity is not an essential characteristic of crystals. If the temperature of these substances be gradually raised, while they are on the stage of a microscope—called a *crystallization microscope*—it will be observed that double refraction indicates that the molecules have a definite alignment at temperatures above their melting point when the crystals, if touched with a needle, wobble like jellies, for they are then soft, compressible, elastic, more or less viscid, turbid, anisotropic liquids. The term **liquid crystals**—*flüssige Kristalle*—was therefore proposed by O. Lehmann for substances which have the characteristic properties of crystals—excepting solidity and geometrical form. In order to avoid the hypothesis implied in the cognomen liquid crystals, some prefer the term **anisotropic liquids**, or *birefringent liquids*.

The molecules of a crystalline solid are arranged quite regularly, and they are retained more or less rigidly in position by elastic forces. Liquid crystals have the usual properties of liquids, but unlike ordinary liquids they also show: (i) double refraction; and (ii) interference colours in polarized light. It seems as if the directive cohesive forces which bring the molecules together, at the softening temperature, are not sufficient to fix them so rigidly about their centre of gravity as to prevent the mass wobbling. In consequence, the optical properties of liquid crystals show that (i) they have an internal structure which in some respects is characteristic of crystals, but that (ii) their external faces are more or less indistinct and mobile. I. F. Homfray [2] found the solubility of carbon dioxide in the liquid crystals is 18, and in the isotropic liquid, 26. The optical properties of liquid crystals have been studied by O. Lehmann, D. Vorländer, E. Dorn, and F. Wallerant.

C. Mauguin found that the liquid crystals of *p*-azoxyanisole take up a definite orientation on a fresh cleavage surface of muscovite mica; and F. Grandjean found the same result obtains, in ninety cases out of a hundred, with a number of such liquids on fresh cleavage faces of talc, muscovite, phlogopite, brucite, blende, orpiment, pyrophyllite, rock-salt, sylvine, and leadhillite. The orientation is sometimes independent of temperature, and in other cases it changes continuously or discontinuously with temperature. The continuous variation with temperature is taken to show that this property is not necessarily due to the alignment of the molecular axes of the liquid on a row of structural particles in a space lattice, but is an equilibrium property dependent on capillarity.

The surface tension of a liquid tends to make the surface occupy the smallest possible area; and a growing crystal likewise tends in the same direction, *viz.* minimum surface area. The molecules, however, during crystallization are also under the influence of opposing directive forces which make the crystal assume its characteristic geometrical form. If the surface tension were the stronger force, the crystal would assume a spheroidal form. The smaller the volume of a given mass, the greater the relative effect of surface tension, and conversely. With thin films, the effect of surface tension is very pronounced, and in 1857, M. Faraday [3] showed that when thin films of gold or silver on glass are heated, the mirror loses its reflecting power; the metal, under the influence of surface forces, and in spite of the directive crystalline forces, collects itself into globular aggregates just as occurs when a thin film of oil on the surface of water collects itself into globular aggregates.[4] The surface tension of the gold prevents the crystalline forces developing a characteristic geometrical shape.

When the temperature of a small portion of a crystalline solid is raised, the internal molecular motions are presumably augmented, and this weakens the directive forces which produce crystallization; surface tension is acting the whole time; ultimately, the directive forces yield to surface tension, and the crystals assume a more or less globular form. The solid is then said to have melted. It is claimed that in liquid crystals, the directive forces of crystallization are not completely overpowered by surface tension, although the two are almost balanced, for the fluid crystals are more or less rounded as illustrated in Figs. 82 and 83. The effects of surface tension are also seen when two round liquid crystals are brought into contact; union takes place, and a single rounded crystal is formed—the surface area of the single crystal is less than the sum of the surface areas of the two parent crystals. The elongated liquid crystals of potassium oleate unite only when the long axis of the one is nearly parallel with that of the other, and not if the two are in contact with their long axes at right angles to one another.[5]

Fig. 82.—Liquid Crystals of Ammonium Oleate.

Fig. 83.—Parazoxyanisole—crossed Nicols (O. Lehmann).

G. Friedel and F. Grandjean here show that the shapes of the liquid crystals of ammonium oleate have no similarity with the crystal forms, but are figures of revolution of great complexity; and C. Mauguin found that in some of the more mobile liquid crystals there is no definite shape, but a continuous internal movement in the smallest globule that can be isolated for observation. The movement increases in intensity as the temperature rises, but no definite regularity could be detected. O. Lehmann frequently emphasized his opinion that the globules are not liquid crystals but rather aggregates of such crystals.

Under certain conditions, some crystals can be so affected by heat, pressure, etc., that they pass suddenly into a new system more stable under the altered conditions—much as a half-opened pocket-knife closes with a snap. There are many examples of substances which pass abruptly from one solid modification to another without any transitional liquid state. For instance, H. A. Miers has shown that a section of boracite under the polarizing microscope appears to be traversed by doubly refracting lamellæ, and when the section is warmed to 265°, a cloud seems to pass over the crystal and it becomes dark—the twin lamellæ reappear on cooling down below the same temperature; and W. J. Pope has shown that molten chloral hydrate on a microscope slide cools to a film of uniaxial needle-like crystals, and these on standing gradually pass into biaxial lamellar crystals.

There is a temperature at which a crystalline solid loses its elasticity and becomes a turbid anisotropic liquid, which at a higher temperature loses its turbidity, clears and forms an isotropic liquid. With *p*-azoxyanisole, for example, there are two transition temperatures corresponding with these changes: Solid crystals→liquid crystals→ordinary liquids; and L. Gattermann found

$$p\text{-Azoxyanisole}_{\text{solid crystals}} \overset{116^\circ}{\rightleftharpoons} p\text{-Azoxyanisole}_{\text{liquid crystals}} \overset{134^\circ}{\rightleftharpoons} p\text{-Azoxyanisole}_{\text{liquid}}$$

A comparison of H. B. Roozeboom's diagram (1900),[6] Fig. 84, with the corresponding diagram for water, will show the conditions under which H. B. Roozeboom thinks that the liquid crystals are related on the one hand to the solid crystals, and on the other to the liquid and vapour. There are two triple or transition points instead of one. At one triple point *O*, solid, liquid crystals, and vapour are in equilibrium, and at the other triple point *O'*, liquid crystals, liquid and vapour are in equilibrium.

The change from an anisotropic to an isotropic liquid is characterized by a small heat absorption. E. Bose and F. Courat found the energy change to be very small in passing from the liquid to the liquid crystal phase, in comparison with that which obtains in passing from the liquid crystal to the solid phase; with anisaldazine, the former was about one calorie, the latter 20 cals. C. de Kock and R. Schenck found the molecular latent heat of *p*-azoxyanisole to be 0·68 cal. C. Tubandt and E. Lorenz also found that purified silver iodide forms no plastic or liquid phase at 550°, two degrees below its melting point. Similar remarks apply to the chloride and bromide of silver, and the three thallium halides which H. Stoltzenberg and M. E. Huth once believed to form liquid crystals. All these substances therefore must be definitely deleted from the list of liquid crystals. The point involved is not whether these crystals are so soft that it would be a misnomer to call it a solid, but rather whether the turbid double refracting liquids are restricted to organic compounds of some complexity, or whether representatives are to be found among the simple binary compounds. P. N. Pawloff, G. Wulff, and W. Voigt have also discussed the nature of liquid crystals.

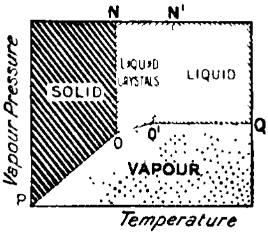

FIG. 84.—Vapour Pressure Curves showing Liquid Crystals (Hypothetical).

G. Quincke (1894) suggested that the effects obtained by O. Lehmann were produced by a trace of oil in the substance he examined; and G. Tammann (1905)[7] argued that the turbidity of liquid crystals in contrast with the clearness of solid crystals shows that the former are emulsions or suspensions and not homogeneous substances, but O. Lehmann replied that the turbidity of liquid crystals is not in evidence when they are examined under the microscope, and that the apparent turbidity is a secondary effect due to the aggregation of a large number of crystals differently oriented, just as marble appears opaque when observed *en masse*, even though it is really composed of a mass of transparent crystals of calcite. All attempts to separate the alleged emulsion into its constituent parts by G. Bredig and G. von Schukowsky and A. Cöhn by electrostatic or centrifugal processes have been futile. No clear proof of heterogeneity has been obtained. The temperature of liquefaction is constant, and is affected by pressure and admixture with foreign substances just as it is in the case with ordinary crystals. O. Lehmann (1910) studied the segregation of impurities during the formation of liquid crystals. Attempts have been made to explain some of the phenomena which occur in the vicinity of the melting point of metals by the existence of a liquid crystal phase.[8] Some metals assume a plastic condition at some distance below their recognized melting points.

The cause of the anisotropy of crystals is referred by A. Bravais [9] to the arrangement of molecules in parallel planes—that is, in certain privileged directions ; more usually it is referred to the orientation of dissymmetrical molecules. For example, the theory suggested by W. Weber in 1850 to explain magnetization assumes that the molecules are dissymmetrical in having two magnetic poles—one positive and one negative—and a body is magnetic only when a larger proportion of the constituent magnetic molecules are disposed with like poles in one direction. When the molecules of a body occupy random positions, so that the positive or negative charges are averaged in all directions alike, the body appears neutral. If an external stress comes into play and the molecules possess a certain degree of mobility, they will gradually turn in the same direction, and, little by little, one side will become positive and the other negative. The greater the controlling stress the more marked is the change. If the controlling force be withdrawn, the molecules gradually return more or less to their former position and the body remains more or less magnetized accordingly. Glass and many liquids were found by J. Kerr to become optically anisotropic or temporarily doubly refracting when acted upon by the poles of a high voltage electric machine—*J. Kerr's phenomenon.* A parallel phenomenon is produced by magnetic forces. Q. Majorana found that colloidal solutions of iron salts exhibited this phenomenon, and A. Cotton and H. Mouton obtained similar results. The explanation of the phenomena turns on the assumption that electric charges are accumulated on the molecules which, in consequence, possess electric poles so that the electric or magnetic field produces a slight change in the direction of the molecules, and the optical effect is the secondary result of the orientation of the molecules.

Again, when certain crystals are heated or cooled they exhibit positive and negative electrical charges—**pyro-electricity**—and the strength of the charge is proportional to the variation in temperature. R. J. Haüy was much impressed with the far-reaching consequences of this phenomenon. He said :

> I do not know whether there is anything better calculated to excite the interest of physicists than these minute electrical instruments built up by crystallization and confined within the compass of a crystal not more than 2 mm. in thickness.

Similarly when certain crystals are compressed or expanded, they undergo a change of form, and also exhibit positive and negative electrical charges—**piezo-electricity**—and the strength of the charge is proportional to the degree of elastic deformation. It is here assumed that a variation in the distance apart of the molecules caused by changes of temperature or pressure disturbs the orientation of the polar molecules, and the slight mobility of the molecules enables a small excess of them to orient themselves temporarily in a particular direction. If the temperature be raised sufficiently high, the resulting increase in the movements of the molecules stirs them up, so to speak, and tends to destroy the temporarily established order. Thus, a magnetized body may be demagnetized, and piezo- and pyro-electricity may disappear. In P. Lenard's opinion, also, the film next to the free surface of a liquid is a double layer of positive and negative charges which he explains by assuming that all the molecules in the surface present their electrical poles of the same kind towards the exterior, like, adds A. Perrier, the quills of a porcupine. The hypothesis here assumed is that the constituent particles of a body are dissymetrical in possessing electrical and magnetic poles, and that these particles are capable of revolving in such a way that they can occupy more or less parallel positions in particular directions ; as a result, the body acquires special properties in these privileged directions. Dissymmetry, said P. Curie, is necessary for the production of the phenomenon. *Si cette dissymétrie n'existe pas, le phénomène est impossible.*

In conformity with the above, O. Lehmann's liquid crystals can be regarded as microscopic systems in which the optical and magnetic properties show that certain groups of the constituent molecules have oriented themselves spontaneously in certain definite directions. According to **E. Bose's swarm theory**,[10] if two or more elongated molecules approach so closely that the mean distances of their centres of gravity are less than half the length of the molecule, all free rotation must cease except about the direction of elongation, and the molecules will tend to orient themselves in parallel formations. A swarm of such molecules disposed in a parallel direction, and in a perfectly fluid condition, without any suspicion of a space-lattice arrangement, will possess the symmetry of a figure of rotation and behave as a uniaxial crystal. Each swarm of such molecules will appear as a clear transparent liquid-crystal; and the turbidity of a large mass of liquid is simply due to the reflection and diffusion of light at the mutual boundaries of the swarms. The average size of the swarms will decrease on heating, and the point at which the swarms become smaller than the wave-length of light will be the clearing point; above this temperature the liquid will appear singly refracting. The idea is illustrated by Figs. 85 and 86. D. Vorländer prepared a number of complex organic compounds which when melted on a glass slide yielded a clear mass of a doubly refracting liquid which in converging light gave a normal uniaxial interference figure, Fig. 87, and, if the substance has an enantiomorphous molecular configuration, the interference figure shows rotatory polarization. If thicker than 0·3 mm. the masses may become turbid. The indices of refraction for the ordinary and extraordinary rays have also been determined for ethylbenzylideneamine α-methyl- and α-ethyl- cinnamates by E. Dorn and W. Lohmann. The change from a solid crystal to an anisotropic liquid is regarded by H. W. B. Roozeboom as a polymorphous transition point, and the clearing point as a true melting point; if the liquid crystals are merely liquids with groups or swarms of molecules aligned in parallel, H. W. B. Roozeboom's transition point must be regarded as a true melting point; and his melting point as the temperature at which the average size of the swarms becomes smaller than the wave-length of light.

FIG. 85.—Molecules disposed in all Directions.

FIG. 86.—Molecules swarming into Parallel Groups.

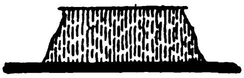

FIG. 87.—Molecular Arrangement for D. Vorländer's Uniaxial Interference Figures.

L. Pucciante and R. Schenck found the viscosity of the crystalline liquid to be usually less than that of the isotropic liquid. E. Bose found that the viscosity of an anisotropic liquid increases quite normally with a fall of temperature down to the point where the turbidity appears, and then decreases very sharply to a minimum at 2° below the clearing point. The viscosity then begins to suffer the normal increase with a fall of temperature, but not to the extent of the isotropic liquid. The lower value of the viscosity of an anisotropic liquid as compared with that of an isotropic liquid has been called the viscosity anomaly. E. Bose and F. Courat showed that if the form of the molecule be that of an elongated ellipsoid of rotation, the viscosity of a swarm can theoretically fall to two-thirds the value of the same substance in an isotropic condition, the ratio of the two viscosities for anisaldazine is anisotropic : isotropic=0·65. The change from an isotropic to an anisotropic is always attended by a moderate increase in density, corresponding with the closer packing possible with elongated molecules.

It will thus be observed that the question whether liquid crystals really have a crystalline structure turns on the definition of a crystal. O. Lehmann, in his *Ueber die Definition des Begriffes Krystall* (1890), regards the regular arrangement of the particles into a homogeneous anisotropic solid to be an accidental and not an essential feature. It is highly probable that the molecules of liquid crystals are grouped in swarms in each of which there is a definite alignment; but if a *crystal* is a homogeneous mass of material, arranged on a space-lattice pattern, the term *liquid crystal* is probably a misnomer. Hence, wrote H. A. Miers:

> It will be wise to retain the names crystal and crystalline in their old signification, rather than to extend them so as to include the birefringent liquids whose existence has been established by Lehmann.

Several of the characteristic tests for a crystalline structure are quite inapplicable —*e.g.* elasticity and cleavage. D. Vörlander says that no biaxial liquid crystals are known, while some fifty are definitely known to be uniaxial, and these are all complex organic compounds. Nearly all compounds with a complex molecular structure crystallize in a biaxial systems. These facts, said T. V. Barker, are of superlative importance inasmuch as they present a statistical proof that the structure of the so-called liquid crystals is not crystalline.

> The whole of the firmly established properties—dichroism, and the invariable straight extinction when the "crystal" is resting on a "prism" face, the apparent absence of double refraction in parallel light, and the perfect uniaxial figure in convergent light when the "crystal" is resting on its base—are in complete harmony with a structure analogous to that of an even-grained piece of wood.

The effect of an electromagnetic field on liquid crystals is said by W. Nernst[11] to furnish a decisive proof of the correctness of the swarm theory. O. Lehmann first noted that a magnetic field clears the droplets of *p*-azoxyanisole; and E. Bose noted that the effect can be perceived with the application of 600 Gauss units of force, and with a few thousand units, the layers of liquid 4 mm. thick are immediately cleared when the liquid is viewed along the lines of force; if the current be cut off, the liquid again becomes turbid. The phenomenon thus interpreted recalls Weber's theory of magnetization. H. von Wartenberg and C. Mauguin extended the work, and found that when a homogeneous film is exposed to a transverse magnetic field, the optic axis is gradually deflected in the plane containing the lines of force, but on releasing the force, the optic axis immediately returns to its normal position.

§ 10. Isomorphism—Mitscherlich's Isomorphic Law

The laws of nature represent design; they are embodied design.—P. CARUS.

Dans les substances cristallisés, la forme des molécules intégrantes, et, par suite, des cristaux, dépènd du nombre et de la position respective des atomes dont les molécules sont composées.—A. M. AMPÈRE (1814).

According to E. Wohlwill,[1] Basil Valentine prepared mixed crystals of the vitriols, and the mixed crystals were mentioned about the middle of the eighteenth century by J. F. Henkel and by A. G. Monnet. In 1772, J. B. L. Romé de l'Isle noticed that a mixture of copper and iron sulphates furnishes crystals in the form characteristic of iron not copper sulphate, and in 1787, N. Leblanc [2] made the same observation. This appeared to be an exception to D. Guglielmini's generalization or Haüy's law—that the angles between similar faces of the crystals of a given substance are characteristic of one definite compound. Analogous results were observed with crystals from mixed solutions of iron and aluminium potash and ammonia alums; many minerals also are almost identical in crystalline form through possessing a different chemical composition. In 1801, N. Leblanc confirmed J. B. L. Romé de l'Isle's observation and found many other examples. He noted that the aluminium of alum could be replaced by iron without altering the crystalline form. In 1797, L. N. Vauquelin also noted that the potassium in alum could be replaced by ammonium, without changing the crystalline form; and in 1816, J. L. Gay Lussac found that crystals of very different composition could be obtained from mixed solutions of different alums. A. Bernhardi (1809) investigated mixed crystals, and found that different substances can have the same crystalline form—*e.g.* magnesium and zinc vitriols, and he observed that in crystallizing a mixture of copper and iron vitriols the one can so influence the other that the two salts crystallize in the same form, and C. F. Bucholz proved by analysis that there must be at least 13 parts of copper vitriol to 87 of zinc vitriol in order to give to the mixed crystals the peculiar form of the former salt. F. S. Beudant made important contributions to the subject about 1817. W. H. Wollaston investigated the mixed crystals of zinc and copper vitriols in 1818, and a year later, B. de Villiers, in his *De la cristallisation* (Strasbourg, 1819), also discussed this question.

The analyses of M. H. Klaproth, L. N. Vauquelin, P. Berthier, and others showed that the variable composition of mixed crystals applies not only to laboratory preparations but also to numerous minerals. J. N. von Fuchs (1815) also showed that certain constituents of a compound can be replaced by other so-called *vicarious constituents*—*vicariende Beständtheile*—without altering its general character; for example, gehlenite is essentially calcium aluminium silicate, $3CaO.Al_2O_3.2SiO_2$, and yet the calcium can be more or less replaced by magnesium or ferrous iron, and the aluminium by ferric iron, without changing the general physical properties of the mineral. In the Berthollet-Proust controversy, C. L. Berthollet argued from such examples that chemical compounds may have a variable composition, while J. L. Proust argued that these crystals are really mechanical mixtures; R. J. Haüy maintained that when two substances crystallize together in this manner the dominant crystalline form will be characteristic of the component which is in excess. R. J. Haüy explained the results by postulating that one constituent might determine the crystal-form of a substance even though present in very small amounts, while the other constituent remained without influence on the crystal form.

E. Mitscherlich's investigations opened up the subject in a most interesting manner. His work is recorded in memoirs: *On the relations between chemical composition and crystalline form,* published in Sweden between 1818–1821.[3] While making preparations of the arsenates and phosphates of potassium and ammonium, he noticed that the crystals were so like each other as to be indistinguishable by simple inspection; and a closer examination led E. Mitscherlich to conclude: (1) That bodies of different chemical composition may have the same crystalline form; (2) substances of similar constitution have the same crystalline form. E. Mitscherlich wrote:

> The same number of atoms combined in the same manner produce the same crystalline form; the crystalline form is independent of the chemical nature of the atoms, and is determined solely by their number and mode of combination.

This relation is now known as **Mitscherlich's law.** He noticed that the acid arsenates and phosphates of potassium, sodium, or ammonium crystallize in similar tetragonal forms, Fig. 7 (left), that one element or groups of elements may be exchanged for another which appears to act in an analogous manner. Thus arsenic may be exchanged for phosphorus, and potassium for ammonium without affecting the form of the crystal. In Mitscherlich's words:

> Every arsenate has its corresponding phosphate, composed according to the same proportions, combined with the same amount of water of crystallization, and endowed with the same physical properties: in fact, the two series of salts differ in no respect, except that the radicle of the acid in the one series is phosphorus, while in the other it is arsenic.

It is not difficult to understand how atoms of different elements may be so related that they can be mutually interchanged without altering the crystalline form and general character of the compound. The idea is illustrated by an old simile: the lines of a tesselated pavement are not altered if the blue tiles are replaced partly by red or by green ones, so long as the different-coloured tiles retain the original size and shape of those they replace.

Besides the phosphates and arsenates, Mitscherlich observed that a certain group of mineral carbonates—calcite, $CaCO_3$; dolomite, $CaMg(CO_3)_2$; siderite or chalybite, $FeCO_3$; calamine or smithsonite, $ZnCO_3$; and dialogite or rhodocrosite, $MnCO_3$—all form isomorphous crystals in the trigonal system (Fig. 88), and an application of the X-ray spectrum has enabled W. L. Bragg (1914) to demonstrate the structural similarity of rhodochrosite, chalybite, and dolomite. Again, the mineral sulphates—barytes, $BaSO_4$; celestine, $SrSO_4$; and anglesite, $PbSO_4$—all form similar rhombic crystals; while aragonite, $CaCO_3$; witherite, $BaCO_3$; strontianite, $SrCO_3$; and cerussite, $PbCO_3$, form isomorphous rhombic crystals. Numerous other examples could be quoted. E. Mitscherlich applied the term **isomorphism**—from ἴσος, equal; μορφή, shape—to connote the fact that analogous elements can replace one another without affecting the apparent shape of the crystals. It is therefore inferred that **in a crystalline solid, each constituent atom occupies a certain domain or portion of the space occupied by the whole molecule.**

E. Mitscherlich's law of isomorphism, as well as the phenomena of polymorphism, appear to contradict R. J. Haüy's law, and there was some reluctance in France to accept E. Mitscherlich's conclusions. For instance, in some *Reflexions sur le mémoire de M. Mitscherlich qu'on était recueillies dans une conversation avec M. Haüy par un de ses éléves,*[4] it is said that Haüy considered : *Si la théorie de M. Mitscherlich était juste, la minéralogie serait la plus pitoyable des sciences.* R. J. Haüy,[5] however, specially remarked on the crystallographic resemblances between certain minerals like barytes and strontianite by saying :

> There is almost an identical primitive form—*noyau*—in each, and the crystals themselves furnish ocular resemblances, so that they may be compared with what botanists term family resemblances—*air de famille.*

E. Mitscherlich, no doubt, had in mind absolute identity of crystal form as the basal principle of isomorphism, but later investigations have shown that the crystals of isomorphous substances are nearly but not absolutely identical, but only similar in form ; and thus confirmed the earlier observations of W. H. Wollaston (1812) [6] that the rhombohedral cleavage angles of the native carbonates of the calcite series are nearly but not quite the same ; and E. L. Malus that :

> Des recherches posterieures des nous enseigneront comment cette loi générale sera modifiée par la petite différence qui se trouve quelquefois dans les angles des combinaisons isomorphes.

There are small but real differences in similar interfacial angles of the members of an isomorphous series of compounds. For example, the corresponding angles *P* (Fig. 88) of the following isomorphous carbonates of the calcite series are far from identical, even if they are approximately similar :

	Calcite, $CaCO_3$	Dialogite, $MnCO_3$	Chalybite, $FeCO_3$	Magnesite, $MgCO_3$	Smithsonite, $ZnCO_3$
Angle . . .	105° 5′	106° 51′	107° 0′	107° 20′	107° 40′

The idea will perhaps be clear from Fig. 88, where the change in the interfacial angle *P* in passing from calcite to smithsonite is shown in section. With the carbonates of the aragonite series, the angles between the prism faces are :

	Aragonite, $CaCO_3$	Strontianite, $SrCO_3$	Witherite, $BaCO_3$	Cerussite, $PbCO_3$
Angle . . .	116° 10′	117° 18′	117° 48′	117° 18′
Axial ratio $a : b : c$	0·623 : 1 : 0·721	0·609 : 1 : 0·724	0·595 : 1 : 0·741	0·610 : 1 : 0·723
Specific gravity .	2·95	3·74	4·32	6·60
Specific heat .	0·1992	0·1445	0·1078	0·0814
Molecular heat .	19·66–20·18	21·31	21·34	21·73

and for the isomorphous sulphates of the barytes series, the angle of the rhombic prisms are respectively 101° 46′, 103° 48′, and 104° 11′ with barytes, $BaSO_4$, anglesite, $PbSO_4$, and celestine, $SrSO_4$. With the isomorphous sulphates, $ZnSO_4.7H_2O$, $MgSO_4.7H_2O$, and $NiSO_4.7H_2O$, the angles are respectively 89° 22′, 89° 26′, and 89° 56′; and with the trigonal series: potassium platinate, $K_2Pt(OH)_6$, stannate, $K_2Sn(OH)_6$, and plumbate, $K_2Pb(OH)_6$, the angles are respectively 74° 18′, 75° 14′ and 75° 19′.

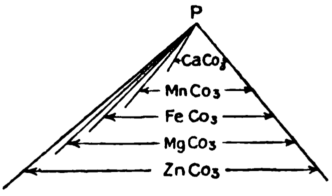

FIG. 88.—Diagramatic Representation of the Variation in the Angle *P* of the Isomorphous Carbonates.

A. E. H. Tutton [7] found that in the isomorphous selenates and sulphates of potassium, rubidium, and cæsium, specific chemical replacements are accompanied by clearly defined changes in the crystal structure along specific directions. Thus, when the basic element, say, potassium, in an alkaline sulphate or selenate is replaced by another of the same alkali family group, rubidium or cæsium, the greatest alteration occurs in the crystal angles corresponding with an elongation of the vertical axis; and when the acid-forming element sulphur is replaced by selenium, its family analogue, the greatest expansion takes place along the horizontal axes of the crystals. A. E. H. Tutton's diagram, Fig. 89, shows in an exaggerated manner, the effect of replacing potassium in potassium sulphate or selenate by the basic elements rubidium and cæsium.

Eutropic series.—According to A. E. H. Tutton, *in a strictly isomorphous series, where the interchangeable elements belong to the same family group of the periodic classification, the whole of the properties of the crystals—morphological, optical, thermal, and physical—are, in general, functions of the atomic weights of these elements*, and for the purpose of emphasizing the closeness of the relations connecting the several members, it is called a eutropic series—εὔτροπας, well nourished. Thus, thallium sulphate and selenate, and ammonium sulphate are isomorphous with the potassium, rubidium, and cæsium sulphates and selenates, because the radicle thallium or ammonium can replace the alkali metal without causing angular or structural changes greater than those produced by an interchange of the same family of elements. All the salts bear some definite chemical analogy, and crystallize in the rhombic system in forms whose angles rarely differ by more than 3°. In addition, the members of a eutropic series are not only isomorphous, but the interchangeable radicles belong to the same family group—*e.g.* the thallium, ammonium, potassium, rubidium, and cæsium sulphates from an isomorphous series, but the two former are not included in the eutropic series formed by the three latter; aragonite, strontianite, witherite, and cerussite form an isomorphous series, but the last is excluded from the eutropic series.

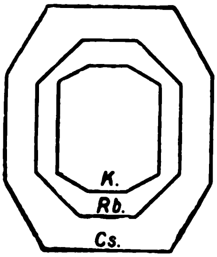

FIG. 89.

F. M. Jäger[8] similarly investigated the hexagonal crystals of the isomorphous rare earth ethyl sulphates of the type $R'''(EtSO_4)_3.9H_2O$, in which R''' denotes yttrium, lanthanum, cerium, praseodymium, neodymium, samarium, europium, gadolinium, dysprosium, erbium, thulium, and neo-ytterbium. The variation in passing from one member of the series to another is but a few minutes, so that the probable value of $c:a$ for the whole series is $c:a=0{\cdot}5062 \pm 0{\cdot}0012$. The molecular volumes are distinctive. A. E. H. Tutton has shown that F. M. Jäger's results might have been anticipated if the factors operating towards the extreme closeness of the angular values be considered: (i) Small variations in the atomic weights of the elements concerned; (ii) the mass effect of the remainder of the molecule; and (iii) the high symmetry of the hexagonal system.

The ratios in an isomorphous series whose members are not related eutropically, do not stand as an arithmetical or harmonic series of integral numbers. G. Linck[9] found empirically that if V denotes the crystal volume, D the specific gravity, and M the molecular weight, the quotients VD/M of the members of a eutropic series are related with one another as an arithmetical or harmonic series. This is illustrated in Table III.

Morphotropic series.—According to the structural theories of E. von Federoff, A. Schönflies, and W. Barlow space is partitioned into *space units*, *space lattices*, or *elementary cells*, Fig. 90, which E. von Federoff called *polyhedra*, A. Schönflies, *Fundamentalbereich*, and W. Barlow, *spheres of influence*. Further, following H. A. Miers, analogous portions of matter are supposed to be distributed in each space unit. No hypothesis is made as to the characteristics of these portions of matter; nor of the arrangement of the atoms in the molecules. Each space lattice is considered to be made up of units or points which represent either the centres of gravity of the constituent molecules, or the centres of rest about which those centres of gravity oscillate. The physical properties of crystals make it clear that whatever be the nature of the vibratory motions of the molecules, the movement does not take place outside a certain imaginary ellipsoidal domain or sphere of influence. Consequently, the molecules can then be discussed as if they were arranged like a system of points at rest. On this view, crystals are regarded as aggregates of ellipsoids or spheres, piled up in such a way that the corresponding axes are arranged in accord with some definite geometrical plan. Each molecule then appropriates to itself a space equal to one space unit—illustrated by the heavier lines in Fig. 90. It can then be assumed that the volume of each space unit can be represented by the quotient of the molecular weight by the molecular volume. W. Muthmann,[10] F. Becke, and A. E. H. Tutton attempted to determine the structure or rather the relative distances between homologous points in the space lattices of known crystals by measuring the relative distances of the crystal molecules from each other along different directions in a series of isomorphous crystals. P. Groth had previously emphasized the fact that on substituting a univalent atom or radicle in place of hydrogen, a change in the form of the crystal may take place in a particular direction, and he called the phenomenon **morphotropy.** A related phenomenon was noticed by A. Laurent (1840), and by F. de la Provostaye (1870), when chlorine was substituted for hydrogen in certain organic compounds—*e.g.* naphthalene, etc. The subject also received the attention of L. J. Wallmark, W. G. Hankel, L. Bodart, J. Nicklès, T. von Alth, L. Pasteur, etc. Numbers representing the relative dimensions of the space units can be derived from measurements of the crystallographic axes, etc. The axial ratios $a:b:c$ are used in describing the form of a crystalline substance, and they usually change, more or less, in passing from one substance to another; but since the axial ratios of a substance represent ratios of the actual dimensions of the corresponding homogeneous structure, they do not indicate the change in dimensions which occurs on passing from one substance to the other. It has therefore been found convenient to link up the axial ratios $a:b:c$ with the molecular volume V of the substance so as to furnish ratios χ, ψ, ω, which are proportional to the ratios $a:b:c$, and

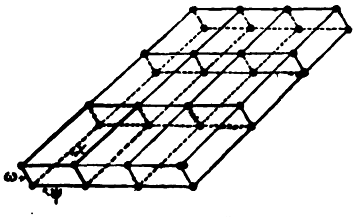

FIG. 90.—Space Lattice.

which represent the linear dimensions of the elementary cell, Fig. 90. Let χ, ψ, and ω represent the lengths of the sides of a unit cell; and V its molecular volume; further, for the sake of simplicity, suppose the cell be rectangular, and let the directions of the sides coincide with the crystallographic axes. Then $V=\chi\psi\omega=M/D$, where M denotes the molecular weight of the substance, and D its specific gravity. Hence χ, ψ, and ω may be taken to represent molecular intervals along the edges of the cell. Let a, b, and c represent the crystallographic axes coincident with the edges of the rectangular cell, then, by a well-known theorem in trigonometry,

$$\frac{\chi}{a}=\frac{\psi}{b}=\frac{\omega}{c}=\mu\,;\quad V=abc\mu^3\,;\ \text{or}\ \mu=\sqrt[3]{\frac{V}{abc}}$$

Consequently,

$$\chi=\sqrt[3]{\frac{a^2V}{bc}}\,;\quad \psi=\sqrt[3]{\frac{b^2V}{ac}}\,;\quad \omega=\sqrt[3]{\frac{c^2V}{ab}}$$

Consequently, the relative dimensions of the space units in a series of related crystals can be calculated from measurements of the crystallographic axes, etc. The values χ, ψ, ω so determined are called the **topic parameters,** or **topic axes,** or *molecular distance ratios*, and for a series of related substances, they represent the changes in the molecular magnitude of corresponding translations of the homogeneous structure common to the substances which occur in passing from one member of the series to another.[11]

The topic characters are calculated in an analogous way for crystals belonging to other systems. If the angle between the lines ω and ψ be α; between ω and χ be β; and between χ and ψ be γ, then, for a *triclinic* crystal, $V=\chi\psi\omega\sin\alpha\sin\beta\sin\gamma$; for a *cubic* crystal, $a=b=c$, and $\alpha=\beta=\gamma=90°$ and sin 90° is unity, therefore $\chi=\psi=\omega=\sqrt[3]{V}$; and for a *monoclinic* crystal, $\alpha=\gamma=90°$, so that $V=\chi\psi\omega\sin\beta$.

It is sometimes convenient to represent the cubic capacity—**crystal volume**—of a solid calculated from the axes ratios a, b, c and the angles α, β, γ of a crystal. In the *cubic system*, where $a=b=c$, and $\alpha=\beta=\gamma=90°$, the crystal volume is unity; in the *rhombic system*, where $a<b\lesseqgtr c$, and $\alpha=\beta=\gamma=90°$, the crystal volume is ac if $b=1$; ab if $c=1$; and bc if $a=1$; in the *tetragonal system*, where $a=b\lesseqgtr c$, and $\alpha=\beta=\gamma=90°$, the crystal volume is a^2, if $c=1$, and c if $a=1$; in the *hexagonal system*, where $a=b\lesseqgtr c$, and $\alpha=\beta=90°$, and $\gamma=60°$, the crystal volume is $\frac{1}{2}a^2\sqrt{3}$, if $c=1$; and $\frac{1}{2}c\sqrt{3}$, if $a=1$; in the *monoclinic system*, where $a\lesseqgtr b\lesseqgtr c$, and $\alpha=\gamma=90°$, and $\beta\lesseqgtr 90°$; the crystal volume is $ac\sin\beta$, if $b=1$; $ab\sin\beta$, if $c=1$; and $bc\sin\beta$, if $a=1$; and in the *triclinic system*, where $a\lesseqgtr b\lesseqgtr c$, and $\alpha\lesseqgtr\beta\lesseqgtr\gamma$, the crystal volume is $2ac\sqrt{\mu}$, if $b=1$; $2ab\sqrt{\mu}$, if $c=1$; and $2bc\sqrt{\mu}$, if $a=1$, where μ is put in place of $\sin s.\sin(s-\alpha).\sin(s-\beta).\sin(s-\gamma)$.

In his *Beiträge sur Volumetheorie der kristallisierten Körper*, W. Muthmann (1894)[12] calculated the topic axes of the acid phosphates and arsenates of potassium and ammonium, and also of the alkali permanganates. The relation between the axial ratios and the molecular distance ratios of the latter are:

	$a:b:c$	M	$\chi:\psi:\omega$
$KMnO_4$	0·7972 : 1 : 0·6491	58·526	3·8554 : 4·8360 : 3·1390
$RbMnO_4$	0·8311 : 1 : 0·6662	63·228	4·0322 : 4·8517 : 3·2312
$CsMnO_4$	0·8683 : 1 : 0·6853	70·042	4·2555 : 4·9009 : 3·3584
NH_4MnO_4	0·8164 : 1 : 0·6584	62·126	3·9767 : 4·8711 : 3·2071

Hence, while the axial ratios measure only the relative distances of translations, in homogeneous structure in the case of one substance, because one axial dimension, b, is taken as unity, the topic axes indicate the relative dimensions of corresponding translations in the several members of an isomorphous series; W. Muthmann concluded that with the alkali permanganates the differences between corresponding molecular distance ratios of the various salts indicate that the unit of crystalline structure is composed of four chemical molecules; but T. V. Barker's results with the alkali perchlorates, isomorphous with the permanganates, did not agree with

W. Muthmann's conclusions. A. E. H. Tutton likewise calculated the topic parameters of the alkali sulphates and selenates; J. A. le Bel and A. Ries, of the substituted ammonium chloroplatinates; G. Mez, of the derivatives of carbamide; etc.

If χ_1, ψ_1, ω_1; χ_2, ψ_2, ω_2; . . . be the topic axes of an isomorphous series in which it is assumed that the molecules are similar, that the arrangement of the molecules is similar, and that the crystals have the same elementary parallelopipedal cells which vary slightly in dimensions in passing from one series to the other, then, χ_1, ψ_1, ω_1 give the relative molecular intervals along three directions in the crystals of the one substance; χ_2, ψ_2, ω_2, the molecular intervals along three corresponding directions in the second substance. The ratio $\psi_1 : \psi_2$ represents the relative increased or decreased separation along the given direction in molecules of the two different substances, owing to the replacement of one element or radicle by another in the series. In illustration, W. Muthmann found that the molecules of the tetragonal phosphates separate almost uniformly in all directions when the atom *P* is replaced by an atom of As. When the K atom is replaced by the NH_4 radicle in either the tetragonal phosphate or arsenates, the molecules are again separated, but almost entirely in the direction of the principal axis. Hence, concludes W. Muthmann, the metallic elements occupy such a position in the molecule that the line uniting them to the acid radicles are parallel to the point axis.

If the symmetry of the crystal molecules be tetragonal like that of the crystal each physical molecule will be a complex cluster of at least eight chemical molecules, say KH_2PO_4, and he assumes that in this complex, eight $PO(OH)_2$ radicles are arranged at the corners of two superposed horizontal squares and a KO radicle is attached above or below each $PO(OH)_2$ radicle. A. E. H. Tutton employed analogous reasoning for the rhombic crystals of the alkali sulphates, and he considered the accord justifies the assumption that the crystal elements of the alkali sulphates are situated at the corners of a rectangular rhombic prism so that each cluster consists of four chemical molecules arranged in a definite symmetrical manner. The molecule of a crystal may thus include several chemical molecules, and G. J. Stoney[13] proposed to call the former *macromolecules* to distinguish them from the latter. W. Muthmann predicted that thallium and rubidium sulphates would have almost identical forms, and this prediction was later verified by A. E. H. Tutton. F. Slavik[14] has calculated the topic axes of the morphotropic series ammonium iodide, NH_4I, tetramethyl ammonium iodide, $N(CH_3)_4I$, tetraethyl ammonium iodide, $N(C_2H_5)_4I$; and tetrapropyl-ammonium iodide, $N(C_3H_7)_4I$, and found on writing Me for CH_3; Et for C_2H_5; and Pr for C_3H_7:

	Mol. vol.	$a:b:c$	$\chi:\psi:\omega$
NH_4I (cubic)	57·51	1 : 1 : 1	3·860 : 3·860 : 3·860
NMe_4I (tetragonal) . . .	108·70	1 : 1 : 0·7223	5·319 : 5·319 : 3·842
NEt_4I (tetragonal) . . .	162·91	1 : 1 : 0·5344	6·648 : 6·648 : 3·686
NPr_4I (rhombic) . . .	235·95	0·776 : 1 : 0·6283	6·093 : 7·851 : 4·933

Hence, while the value of ω is almost the same in the first three cases, the values of χ and ψ are increased by substituting four-methyl groups in place of hydrogen, and still more if four of the heavier ethyl-groups be introduced; with the still heavier propyl-groups more drastic changes take place in the spatial arrangement of the atoms, and a very marked change in the molecular volume is that the propyl-compound no longer possesses the same crystal symmetry.

C. A. Kenngott,[15] A. Schrauf, and F. Pfaff measured the relation between the *hardness* and *specific gravity* of isomorphous bodies, and found the mean hardness of the crystal faces to be related less definitely with the chemical composition than other physical properties. K. R. Koch measured the *elastic constants* of the two main alkali chlorides.

The *cleavage* of crystals is connected with their internal cohesion, and G. Tschermak[16] and A. Sadenbeck have given a number of examples showing the analogy in the cleavages of isomorphous substances. H. Baumbauer, G. Tschermak, and F. Becke [17] have examined the *corrosion figures* of isomorphous compounds. E. Jannettaz [18] has investigated the *thermal conductivity* of isomorphous crystals, and he concludes that:

> Les clivages les plus faciles ou leurs résultantes sont parallèles aux axes les plus grands de conductibilité thérmique, et inversement, même, dans les cas de trois clivages.

The *thermal expansion* of some isomorphous substances has been measured by H. Fizeau and F. Pfaff.[19] The *magnetic properties* of isomorphous substances have been studied by J. Grailich and V. von Lang,[20] and some analogies were observed.

Isomorphous bodies show close resemblances in their *optical properties*, although there are some irregularities; they have been compared with respect to the position and length of their optical elasticity axes; the index of refraction; double refraction, and dispersion. The pioneer work was done by H. de Sénarmont,[21] J. Grailich, V. von Lang, and H. Topsöe and C. Christiansen. In spite of the fact that H. de Sénarmont found

> The mechanical causes which determine the geometrical form are of a different order from those which determine the optical properties, inasmuch as the form remains the same in an entire series of isomorphous substances, whereas the optical properties show not only fundamental variations, but a complete inversion in their relative magnitude;

and J. Grailich and V. von Lang

> Different substances cannot enter into the molecule without changing the form of the crystal, but the optical qualities are more deeply affected the greater the change in the constitution of the molecule. . . . There is no direct relation between the optical properties and such properties as cleavage, hardness, and magnetic susceptibility which rest on the different arrangement of the molecules;

there are, however, many analogies between the optical properties—double refraction, index of refraction, etc.—of isomorphous bodies. The similarity in external form is one sign that there is an analogy of structure, so that isomorphous substances usually exhibit not only close chemical analogies but also close analogies in their physical properties. It is, however, possible that compounds of very different chemical composition have the same structure, and there is a risk in using isomorphism in the attempt to establish chemical relations where none exist.

The law of mixed crystals.—Extended observations have multiplied examples of substances which possess a similar chemical constitution and a similar crystalline form; but at the same time the observations have also brought into prominence the fact that substances which crystallize in similar or identical forms—particularly in the cubic system—may exhibit wide divergencies in chemical constitution. The converse of E. Mitscherlich's law does not, therefore, hold good. Similarity of chemical composition or similarity in crystalline form are not adequate tests for isomorphism. E. Mitscherlich also stated that "while substances of different crystalline form cannot combine other than in fixed proportions, substances of the same crystalline form can crystallize together in all proportions." F. S. Beudant [22] was the first to suggest that "mixed crystals" are *mélanges chimiques ou associations non mécaniques en proportion indéfinie.* He said:

> I have adopted the expression *mélange chimique* in order to distinguish by a specific term a chemical association of bodies which has characteristics different from other chemical associations to which the name *combinaisons chimiques* is applied. I do not, however, seek to imply that the components which can be associated in the *mélanges chimiques* in an infinitude of proportions, are really united chemically or simply mixed. The *mélanges chimiques* could be designated *combinaisons indéfinies* in which the product always possesses, more or less, the properties of one or other of the components.

Homogeneous crystals containing two salts mixed in indefinite proportions, and formed in solutions containing a mixture of both salts, were called ***Mischkrystalle***—*i.e.* **mixed crystals**—by H. W. B. Roozeboom in 1899; they have also been called **isomorphous mixtures,** but both terms are liable to misconception because the mixed crystals are mixtures only in the sense that ordinary homogeneous solutions are mixtures, and hence some prefer the older term **solid solution**, used by J. H. van't Hoff [23] in 1890, and regard crystals as homogeneous phases and not an aggregate of two or more phases. L. de Boisbaudran claims that he first applied the idea of solid solutions, *dissolvents solides*, in papers on fluorescence between 1886 and 1890, and that in an unpublished note—on supersaturation—before the *Académie des Sciences* in Paris in 1866, he stated:

> I do not hesitate to attribute the same cause, (i) to the solution obtained by dissolving one solid in another (isomorphisme de Mitscherlich); (ii) to the solution of liquids in another one; and (iii) to the solution of vapours in one another.

The formation of apparently homogeneous crystals is not accepted by chemists as a decisive test of the individuality of a chemical species, since, in crystals, certain elements may replace one another indefinitely without altering the form of the crystals. When mixed crystals of lead and barium nitrate are treated with a saturated solution of barium nitrate, the lead nitrate is dissolved out and a skeleton of barium nitrate remains which is not doubly refracting although the original mixed crystals exhibit this quality. The failure of mixed crystals to satisfy the law of constant composition has led chemists to agree *arbitrarily* that mixed crystals are mixtures and not definite compounds, although the phase rule regards mixed crystals as homogeneous single phases.

The colour of mixed crystals is usually intermediate between the colour of their component salts—thus, yellow cæsium chloroplumbate, Cs_2PbCl_6, and deep blue cæsium chloroantimoniate, Cs_2SbCl_6, give mixed crystals of a green colour; on the other hand, the two yellow salts, cæsium chloroplumbate, Cs_2PbCl_6, and cæsium chlorotellurate, Cs_2TeCl_6, give mixed crystals of an orange-red colour.

J. W. Retgers' colour test for mixed crystals.—Saturated solutions of the two salts which differ in colour are placed side by side on a microscopic slide and brought together with a glass rod. The crystals which form on evaporation are examined under a microscope. If the salts are isomorphous, the colour of the crystals varies gradually from one side to the other, the crystals of the pure compounds being visible on the extreme edges. If the two salts are not isomorphous, they do not mix, and near the centre, where the two solutions have been brought together, distinct crystals of each compound can be seen owing to their difference in colour. If the two salts have the same colour, J. W. Retgers uses a third salt of a different colour from the other two. If both the same coloured salts form mixed crystals with the salt of a different colour, the two salts under examination are isomorphous.

J. W. Retgers (1889) considers all important the property of forming mixed crystals in all proportions such that "if the percentages of one constituent of the mixture be plotted as abscissæ, and the corresponding magnitudes of the physical properties be plotted as ordinates, the different points lie in a continuous line." Two substances are really isomorphous only when the physical properties of their mixed crystals are continuous functions of their chemical composition; or **the physical properties of isomorphous mixtures are continuous functions of the percentage composition—Retgers' law.** Physical properties here include geometrical, optical, thermal, elastic, and electrical properties. This agrees with F. W. Küster's statement that all the physical properties of isomorphous mixtures which have been hitherto investigated are purely additive, and are continuous functions of their percentage composition. For instance, the refractive index curve of isomorphous mixtures of potassium and thallium alums lies on a straight line. H. de Sénarmont, A. des Cloizeaux, H. Dufet, G. Wyrouboff, E. Mallard, R. Brauns, A. Fock, T. Hiortdahl, etc., have shown that "the difference between the indices of refraction of a mixture of two isomorphous salts and those of the components is inversely as the number of the equivalents of the two salts in the mixtures," so that if μ be the index of refraction of the mixtures, μ_1 and μ_2 the indices of refraction of the component salts of molecular weight M_1 and M_2 respectively, then:

$$\mu=\frac{M_1\mu_1+M_2\mu_2}{M_1+M_2}$$

G. Bodländer also obtained analogous results with the circular polarization of mixed crystals of lead and strontium dithionates. The solubilities of isomorphous mixtures have been investigated by C. F. Rammelsberg, C. von Hauer, and F. Rüdorff. H. W. B. Roozeboom's work is indicated in the chapter on solutions, and he adds that if the osmotic pressure of a saturated solution of mixed crystals with an increasing content of one of the constituents, increases or diminishes, so is the proportion of this constituent in the solution greater or less than in the mixed crystal. Again, the melting points of isomorphous mixtures of albite and anorthite furnish a series which is almost a straight line representing albite by Ab and anorthite by An:

	An	$AbAn_5$	$AbAn_2$	AbAn	Ab_2An	Ab_3An	Ab
Melting point .	1532°	1500°	1465°	1419°	1367°	1340°	—

The melting point of albite has not been determined accurately within 150°. These results are in agreement with the much-discussed generalization of F. W. Kuster (1891) from observations on the melting points of mixtures of organic compounds. He found a simple linear relation, sometimes called **Kuster's rule : The solidifying point of an isomorphous mixture lies on a straight line connecting the melting points of the individual components, and it can be calculated from the percentage composition of the mixture.** This simple linear relation is supposed to represent perfect isomorphism. Imperfect isomorphism is assumed to be the cause of the slight concavity or convexity usually observed with these curves. On practical grounds, J. W. Retgers considers specific gravity, or the reciprocal of specific gravity—the specific volume—to be the most suitable property for investigation. This property was found by G. Tschermak, O. Pettersson, R. Brauns, J. W. Retgers, etc., to be a function of the specific gravity of the components such that if D and v respectively denote the specific gravity and specific volume of the mixture, D_1 and D_2, and v_1 and v_2, the specific gravities and specific volumes of the components when α denotes the volume percentage and β the weight percentage of the second component of the mixture, then:

$$D=D_1+\frac{\alpha(D_2-D_1)}{100}; \quad v=v_1+\frac{\beta(v_2-v_1)}{100}$$

An example by J. W. Retgers is indicated in Fig. 91, where the specific volume of mixed crystals of potassium and ammonium aluminium sulphates are plotted. The continuity of the curve shows that the specific gravity or specific volume and chemical composition of the mixed crystals are isomorphous. A similar continuous curve is obtained with mixtures of magnesium and manganese pyrophosphates. The curves sometimes show a break, as is the case with the dihydrogen phosphates of potassium and ammonium. Isomorphous mixtures are formed only when not more than 20 per cent. of the second constituent is present. Intermediate mixtures do not form homogeneous crystals. This is illustrated in J. W. Retgers' curve, Fig. 91, showing that the two substances are not miscible in all proportions, but the two portions of the curve are parts of one straight line corresponding with the isomorphous character of the two salts. Otherwise expressed, the solubility of each substance in the other may be limited like the solubility of many salts in water, or if the one in the other may dissolve the other in all possible proportions.

There has been some differences of opinion as to whether the formation of mixed crystals with isomorphous substances must take place in all proportions, or if gaps may occur; in other words, if the term isomorphous be applied only to those substances which form a continuous series of mixed crystals, and excluded from those which form only partial series of mixed crystals. In opposition to J. W. Retgers, W. Stortenbecker (1903) considers that if the substances are truly isomorphous, no gaps will occur, while B. Gossner (1906) also considers that isomorphous salts may exhibit gaps, and this the more, the greater the difference in the molecular volume (molecular weight divided by the specific gravity) of the respective compounds. This, in turn, is possibly conditioned by the relative sizes of the structural units of the two salts. According to B. Gossner (1907), also, if the molecular volume of the isomorphous substances be nearly the same—*e.g.* nickel or zinc fluosilicates and double alkali sulphates—the salts will form a continuous series of mixed crystals; while if the molecular volumes are very different—*e.g.* copper or cobalt fluosilicates and double alkali sulphates—there will be a break in the series of mixed crystals. If the continuous curve (Fig. 91) or broken curve (Fig. 92) are not in the same straight line, the two salts, even if perfectly miscible in all proportions, would not, according to J. W. Retgers' definition, be called isomorphous. For instance, ammonium and ferric chloride are not isomorphous, although octahedral ammonium chloride forms coloured mixed crystals by taking up a small amount of ferric chloride.

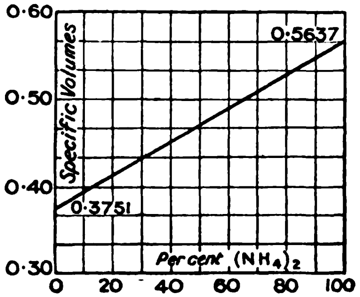

FIG. 91.—Specific Volumes of Mixed Crystals of Ammonium and Potassium Aluminium Sulphates.

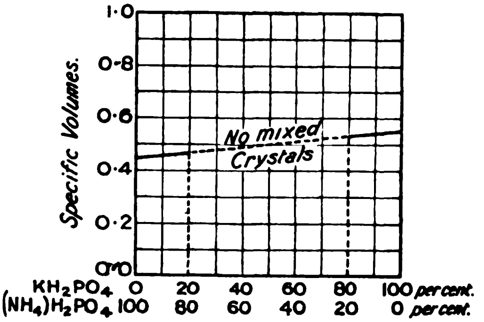

FIG. 92.—Specific Volumes of Mixed Crystals of Ammonium and Potassium Dihydrogen Phosphates.

The formation of mixed crystals is conditioned or favoured by substances of analogous structure, and this phenomenon is therefore regarded as strong evidence of isomorphism, but the formation of mixed crystals is not a *sufficient* criterion of isomorphism, since there is quite a large number of cases of their formation by substances of different form; nor is the formation of mixed crystals a *necessary* criterion of isomorphism, since the isomorphous salts may interact forming another chemical individual instead of producing mixed crystals. In other words, double compounds may be formed which interfere with the application of J. W. Retgers' rule—*e.g.* J. W. Retgers found with a mixture of rhombic silver nitrate and potassium nitrate, each can dissolve a little of the other still forming rhombic crystals, but the two salts crystallize together forming a double salt, $KAg(NO_3)_2$, which is monoclinic and has a specific volume 0·31. If the double salt were an isomorphous mixture, it would have a specific volume 0·38. The point corresponding with this mixture thus lies off the straight dotted line, as shown in Fig. 93. Similar results are obtained with mixtures of potassium and sodium sulphates, the point corresponding with $3K_2SO_4.Na_2SO_4$ is a long distance from the line connecting the two components; similarly, mixtures of magnesium and calcium carbonates show a deviation for *dolomite*, $MgCO_3.CaCO_3$; and potassium chloride and cupric chloride—$CuCl_2.2H_2O$—form $2KCl.CuCl_2.2H_2O$.

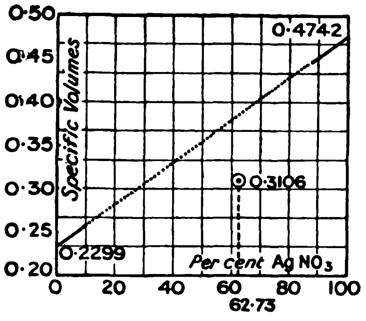

FIG. 93.—Specific Volumes of Mixtures of Silver and Potassium Nitrates.

Overgrowths.—In 1816 J. L. Gay Lussac[24] found that a crystal of alum continues to grow when placed in a solution of another alum. If a crystal of dark violet chromium alum be placed in a saturated solution of ordinary potassium alum, a transparent colourless overgrowth—*lame de superposition*—of potassium alum is deposited as a crust over the dark-coloured chromium alum as a nucleus. Similarly, a crystal of colourless zinc sulphate—$ZnSO_4.7H_2O$—can be coated with an overgrowth of green nickel sulphate—$NiSO_4.7H_2O$—and *vice versa*; crystals of sodium nitrate grow on Iceland spar; and a pale amethyst triclinic crystal of manganese sulphate—$MnSO_4.5H_2O$—can be coated with blue copper sulphate—$CuSO_4.5H_2O$—and *vice versa*. The parallel overgrowths formed in this way have been called **episomorphs.** C. von Hauer grew episomorphs of magnesium sulphate on magnesium chromate or nickel sulphate; of potassium magnesium sulphate on the corresponding cobalt and nickel salts. In nature also episomorphs of potash and soda felspars are common. H. Kopp (1873) stated that this power of forming overgrowths, as well as the power of forming mixed crystals, enables isomorphism to be detected even when no particulars about the crystalline form or about the chemical composition are available. There are some exceptions to the test for isomorphism—trigonal potassium sulphate can be coated with a layer of hexagonal potassium sodium sulphate—$KNaSO_4$; etc.

Isomorphous substances were found by F. M. Jäger and H. Haga [25] to yield similar radiograms although the relative intensities of the spots were often different. C. Viola concluded that mixed crystals of magnesium and zinc sulphate are formed in layers composed alternately of each salt, and therefore differ radically from solid solutions. L. Vegard and H. Schjelderup have also examined the X-ray spectra of mixed crystals of potassium chloride and bromide, and of potassium and ammonium bromide. They found that the crystals behaved as single entities and there was no indication that the crystals were composed of thin homogeneous laminæ. G. Tammann examined the effect of reagents which attack one of the components of binary mixed crystals of gold and copper, and gold and silver. The action is not proportional to the amount of the soluble constituent; indeed, there are limits of composition between which the resistance to attack is very great.

Strictly speaking, all substances with a similar crystalline form are isomorphous. The similarity of external geometrical form is *primâ facie* evidence of the similarity of internal structure, so that those crystalline substances are isomorphous whose structure is analogous (E. Mitscherlich). If the molecular volumes are sufficiently close, isomorphous substances usually form (i) homogeneous mixed crystals (J. W. Retgers); (ii) they form parallel overgrowths on each other (H. Kopp); (iii) they are mutually active in inducing crystallization when a supersaturated solution of the one is inoculated with a small fragment of the other; and (iv) are generally of analogous chemical constitution. None of these tests is an infallible criterion, and here, as is so often the case, a conclusion can be drawn only after carefully balancing the available circumstantial evidence. C. Hlawatsch recognizes degrees of isomorphism, and he has discussed the nature of isomorphism, and classified substances according to their degree of isomorphism on the lines of the following scheme:

(1) The substances exhibit no chemical analogy, but show similarities in certain zones which frequently grow parallel. (2) The substances show analogies in their angles, but do not exhibit the same cleavages or habit. This may be termed isogonism. (3) The substances form mixed crystals, but have not analogous structure. (4) The last case is not to be confused with that presented by isopolymorphous substances when the two modifications possess very different stability. (5) The substances show like structure expressed, not merely by similarity of form, but by like cleavage, twinning, and habit. (6) The substances have similar crystal structure, and may form mixed crystals, but do not belong to the same crystal sub-class. (7) The substances possess similar structure with identical symmetry, and form mixed crystals, but are not chemically analogous. (8) The substances show chemical analogy in addition to the other characters. (9) Lastly, they possess chemical analogy, form mixed crystals, have similar structure, and angular relations which are functions of the atomic weights of the interchangeable elements.

According to G. Tammann (1907), chemically analogous elements are usually isomorphous. Elements in the same groups in periodic system usually form mixed crystals and not compounds, while many elements not in the same group but chemically similar also form mixed crystals. In binary alloys, elements of high melting point usually form mixed crystals with those of low melting point. A. Arzruni, in his *Die Beziehungen zwischen Krystallform und chemischer Zusammensetzung* (Braunschweig, 1898), arranges sixty-eight of the elements in ten isomorphous series (*isomorphe Reihen*):

Series I.—H, K, Rb, Cs, NH_4, Tl, Na, Li, Ag. *Series II.*—Be, Zn, Cd, Mg, Mn, Fe, Os, Ru, Ni, Pd, Co, Pt, Cu, Ca, Sr, Ba, Pb. *Series III.*—La, Ce, Di, Y, Er. *Series IV.*—Al, Fe, Cr, Co, Mn, Ir, Rh, Ga, In (Ti). *Series V.*—Cu, Hg, Pb, Ag, Au. *Series VI.*—Si, Ti, Ge, Zr, Sn, Pb, Th, Mo, Mn, U, Ru, Rh, Ir, Os, Pd, Pt, Te (?). *Series VII.*—N, P, V, As, Sb, Bi. *Series VIII.*—Nb, Ta. *Series IX.*—S, Se, Cr, Mn, Mo, N, Te (?), As, Sb. *Series X.*—Fl, Cl, Br, I, Mn, Cy.

A given element may appear in different isomorphous series. In illustration, manganese, in its different states of oxidation, belongs to different classes. There are also certain regularities exhibited by the members of a sub-group in Mendeléeff's periodic arrangement.

There is undoubtedly a profound connection between the similarity of crystalline form and the similarity of chemical structure. The thousand and one known cases typified by the isomorphism of potassium sulphate and selenate were supposed to be a result of the chemical similarity of the replaceable elements, and isomorphous replaceability was found to be a periodic function of the elements since the elements belonging to the same sub-group in the periodic system usually gave isomorphous compounds. T. V. Barker[26] has compiled a number of examples of what he calls "unusual types of isomorphism," in which there is no similarity of valency structure. The following are taken from T. V. Barker's list, where the number of known analogues of any particular compound is indicated in brackets:

Monoclinic system.	$a:b:c$	β
$CuTiF_6.4H_2O$ (2)	0·7471 : 1 : 0·5564 ;	104° 9′
$CuCbOF_5.4H_2O$ (1)	0·7627 : 1 : 0·5629 ;	103° 20′
$CuWO_3F_4.4H_2O$ (1)	0·7648 : 1 : 0·5629 ;	103° 14′
K_3HSnF_8 (1)	0·6277 : 1 : 0·4928 ;	93° 0′
K_3HCbOF_7 (0)	0·6279 : 1 : 0·4900 ;	93° 14′
$MnCl_2.4H_2O$ (1)	1·1525 : 1 : 0·6445 ;	99° 25′
$BeNa_2F_4$ (0)	1·9913 : 1 : 0·6929 ;	99° 20′
$(NH_4)_2SeO_4$ (2)	1·8900 : 1 : 1·1987 ;	115° 29′
Cs_2HgI_4 (0)	1·3155 : 1 : 0·9260 ;	110° 4′

Rhombic system.	$a:b:c$
$K_2SnCl_4.2H_2O$ (3)	0·6852 : 1 : 0·7586
$K_2FeCl_5.H_2O$ (4)	0·6911 : 1 : 0·7178

Rhombic system.	$a:b:c$
$KClO_4$ (8)	0·7817 : 1 : 1·2792
$BaSO_4$ (5)	0·8152 : 1 : 1·3136
KBF_4 (1)	0·7898 : 1 : 1·2830
K_2SO_4 (15)	0·5727 : 1 : 0·7418
K_2BeF_4 (4)	0·5708 : 1 : 0·7395
$[N(CH_3)_4]_2HgCl_4$ (1)	0·5766 : 1 : 0·7893

Tetragonal system.	$a:c$
Xenotime, YPO_4 (0)	1 : 0·6177
Zircon, $ZrSiO_4$ (1)	1 : 0·6400
Cassiterite, SnO_2 or $SnSnO_2$ (4)	1 : 0·6726
KIO_4 (3)	1 : 1·5534
$CaWO_4$ (7)	1 : 1·5268
$KOsO_3N$ (1)	1 : 1·6319
$KRuO_4$ (0)	1 : 1·6340

Rhombic crystals of aragonite, $CaCO_3$, and nitre, KNO_3, have axial ratios respectively $a : b : c = 0·622 : 1 : 0·721$ and $0·591 : 1 : 0·701$; both salts have a similar crystalline form but a very different chemical constitution. Similarly with rhombohedral calcite, $CaCO_3$, and sodium nitrate, $NaNO_3$, with the respective rhombohedral angles of 74° 55′ and 73° 27′, and axial ratios $a : c = 1 : 0·854$ and $1 : 0·8297$. The constitutional formulæ of calcium carbonate (calcite) and sodium nitrate are represented respectively by

$$O{=}C{<}^{O}_{O}{>}Ca$$

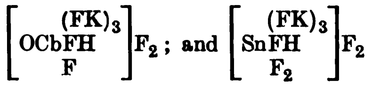
$$^{O}_{O}{\geqslant}N{-}ONa$$

so that if these formulæ really indicate internal structures the observed isomorphism must be due to some obscure accidental cause. The facts indicated a similarity in crystal structure; the valency theory indicated complete dissimilarity. As a result, some denied the apparent isomorphism of these compounds, and narrowed the definition of isomorphism so that a special name **homomorphism** or **isogonism** was devised for the phenomena presented by substances which differ in chemical constitution, but have a similar crystalline form. Attempts to evade the difficulty presented by calcite and sodium nitrate where the total sum of the valencies is in case twelve, by assuming that the sexavalent groups CaC and NaN replace each other isomorphously. The explanation is futile, because it fails to account for the replaceability of the alkali metals by the ammonium radicle, where the valency summations are respectively one and nine. Hence, adds T. V. Barker, "the equality of valency summation has nothing to do with isomorphism."

The X-ray spectrum has enabled W. L. Bragg (1914) to show a close *structural* relationship between the crystals of calcium carbonate and potassium nitrate, which are not considered to be isomorphous. Tetragonal zircon, $ZrSiO_4$, and thorite, $ThSiO_4$, are isomorphous with rutile, TiO_2, and cassiterite, SnO_2. The difference in structure is not so apparent if the constitutions be represented: ZrO_2SiO_2, ThO_2SiO_2, $(TiO)_2$. In virtue of isogonism, the supposed relations which have been traced between chemical composition and crystalline form are often quite accidental. In the triclinic system, isogonism is usually an indication of isomorphism, but its significance becomes less and less as the crystals increase in symmetry. T. V. Barker claims that it is no longer advisable to limit the term isomorphism to cases of chemical and crystal symmetry by interpreting the chemical similarity in terms of the older valency hypothesis. It is true that the dissimilarity in the constitution of these substances with similar crystals is so great that it might be hazarded that "isomorphism may be totally independent of chemical structure;" but this view is untenable, for it is the valency structure which is at fault. If the constitution of these compounds be interpreted on A. Werner's co-ordination structures, there are indications that the compounds with apparently dissimilar structure will prove to have analogous structures. For example, the molecular formulæ of the first three compounds in T. V. Barker's list are not very similar, but when expressed according to A. Werner's system, the case is somewhat different:

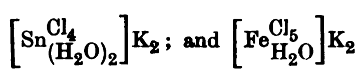
$$\left[TiF_6\right]Cu+4H_2O;\ \left[Cb\overset{O}{\underset{F_5}{}}\right]Cu+4H_2O;\ \text{and}\ \left[W\overset{O_2}{\underset{F_4}{}}\right]Cu+4H_2O$$

Again, J. C. G. de Marignac's compounds K_3HSnF_8 and K_3HCbOF_7 appear closely related when represented by A. Werner's formulæ:



$$\left[\begin{matrix}(FK)_3\\ OCbFH\\ F\end{matrix}\right]F_2;\ \text{and}\ \left[\begin{matrix}(FK)_3\\ SnFH\\ F_2\end{matrix}\right]F_2$$

There is no analogy in the chemical formulæ of the compounds $2KCl.SnCl_2.2H_2O$ and $2KCl.FeCl_3.H_2O$, either in this molecular form or when expressed by the complex salt formulæ $K_2SnCl_4.2H_2O$ and $K_2FeCl_5.H_2O$. The co-ordination formulæ, however, show a close analogy:



$$\left[Sn\overset{Cl_4}{\underset{(H_2O)_2}{}}\right]K_2;\ \text{and}\ \left[Fe\overset{Cl_5}{\underset{H_2O}{}}\right]K_2$$

Again, $[Mn(H_2O)_4]K_2$ and $[BeF_4]Na_2$ are similar if it be assumed that the molecules of water which are co-ordinated can be replaced isomorphously by halogen atoms. The isomorphism of $ZnI_2.4NH_3$ with potassium beryllium fluoride leads to the assumption that the internal structures are similar in this sense: $[Zn(NH_3)_4]I_2$ and $[BeF_4]K_2$, where the positive ion of one compound is analogous with the negative ion of the other. A. Werner also represented $KOsO_3N$ and KBF_4 respectively by the co-ordination formulæ $[OsO_3N]K$ and $[BF_4]K$. Hence, adds T. V. Barker, co-ordination evidently supplies a medium in which analogy of chemical composition in isomorphous compounds formerly classed as homomorphic or isogonic, comes strongly into the foreground.

Isodimorphism—In 1829, J. F. W. Johnston[27] drew attention to the fact that a plumbiferous calcite, which he named *plumbocalcite*, and which not only contained calcium carbonate but also the lead carbonate. Hence, the latter must crystallize in two forms, so that in addition to rhombic cerussite, there must also be a rhombohedral form of lead carbonate which can crystallize with the corresponding form of calcium carbonate. Hence, both lead and calcium carbonate were called *isobimorphs*. Such a form of lead carbonate has not yet been discovered, but J. F. W. Johnston's reasoning was sound. Some years later M. L. Frankenheim made a similar discovery with respect to calcium carbonate and potassium nitrate. Many examples are now known in which there are two independent series of isomorphous salts, and the phenomenon is called **isodimorphism.** The pyrite and marcasite families of minerals form two independent series of isomorphous crystals. The following were compiled by J. P. Iddings (1906):

	Cubic.	Rhombic.
FeS_2	pyrite	marcasite
$CoAs_2$	smaltite	saffrolite
$NiAs_2$	chloanthite	rammelsbergite
$(Co, Fe)(S, As)_2$	cobaltite	glaucodote
$NiS_2.Ni(Sb, As)_2$	corynite	wolfachite

Each of the sulphates $RSO_4.7H_2O$ (where R may be Mg, Zn, Ni, Co, Fe, Mn) is dimorphous, forming rhombic and also monoclinic crystals. The rhombic crystals of all the salts form one isomorphous series, and the monoclinic crystals of all the salts form another isomorphous series. The isodimorphism is here limited to certain proportions of the constituents. For example, mixtures of iron and magnesium sulphates give homogeneous *monoclinic* mixed crystals if less than 54 per cent. of magnesium sulphate, $MgSO_4.7H_2O$, be present, and *rhombic* mixed crystals if more than 81 per cent. be present. The specific volume curve of the mixed crystals does not therefore lie in one straight line. This is illustrated by J. W. Retgers' diagram, Fig. 94.

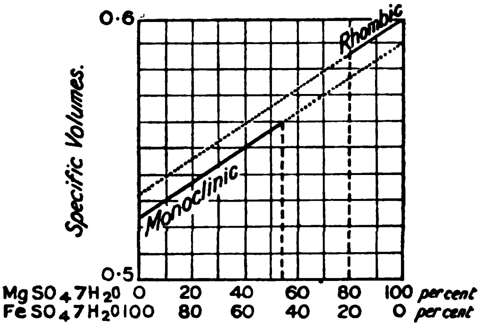


FIG. 94.—Specific Volumes of Mixed Crystals of Magnesium and Ferrous Sulphates—Limited Isomorphism.

Similarly, a mixed solution of silver and sodium chlorates gives mixed cubic crystals if the sodium chlorate be in excess, and mixed tetragonal crystals if the silver chlorate be in excess. J. W. Retgers found that copper sulphate solutions crystallizing in the presence of a small proportion of zinc sulphate (0 to 7·98 per cent.) furnishes *triclinic* mixed crystals of $CuSO_4.5H_2O$ and $ZnSO_4.5H_2O$; and if a larger proportion of zinc sulphate be present, 65·59 to 83·35 per cent., *monoclinic* crystals of a mixture of $CuSO_4.7H_2O$ and $ZnSO_4.7H_2O$; while if a relatively large proportion of zinc sulphate, 97·68 to 100 per cent., be present, *rhombic* crystals of a mixture of $CuSO_4.7H_2O$ and $ZnSO_4.7H_2O$ are formed. Similar results are obtained with mixtures of copper and magnesium sulphates. H. W. Foote (1902) has shown that *tetragonal* beryllium sulphate, $BeSO_4.4H_2O$. forms mixed tetragonal crystals with beryllium selenate, $BeSeO_4.4H_2O$, provided the molecular proportions of the respective salts in solution does not exceed 7·33 : 1; while if the solution contains a less proportion of the sulphate, a series of *rhombic* crystals can be prepared when the molecular proportions of the beryllium sulphate to selenate lie between 4 : 1 and pure beryllium selenate.

The composition of mixed crystals of one salt with a maximum proportion of the other is called the *mixing limit*. Thus, tetragonal mixed crystals of beryllium sulphate and selenate have reached the mixing limit when their composition has $BeSO_4.4H_2O : BeSeO_4.4H_2O = 7{\cdot}33 : 1$. J. H. van't Hoff (1898) suggested an interesting analogy between mixed crystals and ordinary solutions. Pairs of salts which crystallize together are likened to perfectly miscible liquids like alcohol and water, while salts of the second class, whose isomorphism is limited, are likened to partially miscible liquids like aniline and water. The analogy has been pushed still further. At temperatures exceeding 165°, aniline and water mix in all proportions, while below that temperature the two liquids are but partially miscible; hence, it is inferred that unless other changes intervene, salts which are but partially miscible as ordinary temperatures may be perfectly miscible at more elevated temperatures.

According to the phase rule, tetragonal $BeSO_4.4H_2O$ will contain a maximum proportion of $BeSeO_4.4H_2O$ when the solution from which it is deposited is saturated with regard to the mixed crystals of $BeSeO_4.4H_2O$ and $BeSO_4.4H_2O$. In such systems there are four phases—vapour, solution, and two solids—and three components—the two salts and water; the system is accordingly univariant. Accordingly, if one of the possible variables—temperature, pressure, or concentration of phase—be changed, the others must be fixed and unalterable. For instance, if the temperature be fixed, the concentration of each phase and the vapour pressure must be fixed; and if the temperature be changed, another variable must be changed. Hence, the composition of mixed crystals at the mixing limit will change with change of temperature, and this is in agreement with observations.

Two or more compounds which, judged by all analogies, might be expected to be isomorphous may exhibit pronounced differences in crystalline form; but, by suitably altering the conditions, they may furnish a second form, so that the isomorphism of the series is established. Monoclinic felspar—orthoclase—usually contains some sodium; while triclinic soda felspar—albite—contains some potassium. Hence P. Groth (1874) [28] inferred that this is a case of isodimorphism, and that two pure varieties—monoclinic and triclinic soda and potash felspars—should exist. The prediction was verified two years later by A. des Cloizeaux's discovery of microcline, the triclinic form of potash felspar; and later, by P. Barbier discovery of barbierite, the monoclinic form of albite. Sodium phosphate forms two distinct crystals—rhombic and monoclinic. The arsenate appears in only one of these forms. Hence it is inferred that a monoclinic sodium arsenate isomorphous with rhombic sodium phosphate remains to be discovered.

§ 11. The Rectification of Atomic Weights by Isomorphism

When one body is isomorphous with another whose molecule contains a known number of atoms, then the number of atoms per molecule of the other body is also known because isomorphism is a mechanical consequence of the identity of atomic structure.—J. J. BERZELIUS (1833).

While perhaps not accepting J. J. Berzelius' dictum without modifying the meaning of "number of atoms" to allow for cases of isomorphism where a radicle like NH_4 containing five atoms can take the place of one atom of the alkali metals in some isomorphous salts, yet J. J. Berzelius' statement of the law of isomorphism can be used as a control in deducing the chemical composition of a salt; and also in atomic weight determinations for deciding between two numbers which are multiples of a common factor. The method is restricted to crystalline compounds; and it is only applicable in conjunction with other methods of atomic weight determinations, since at least one member of the isomorphous series must be known.

E. Mitscherlich deduced the number 79 for the atomic weight of selenium by this method, and he also gave selenious and selenic acids formulæ corresponding with sulphurous and sulphuric acids respectively, on account of the isomorphism of the sulphates and the selenates. The analyses of potassium sulphate and of potassium selenate gave:

	Potassium.	Oxygen.	Sulphur.	Selenium.	Total.
Potassium sulphate . .	44·83	36·78	18·39	—	—100·00
Potassium selenate . .	44·83	36·78	—	45·40	—127·01

Assuming that the molecule of potassium sulphate contains one atom of sulphur; that the molecule of potassium selenate contains the same number of atoms; and that the atomic weight of sulphur is 32, we have:

$$\text{Atomic weight S} : \text{Atomic weight Se} = 18·39 : 45·40,$$

Hence, 32 : atomic weight Se=18·39 : 35·34; consequently, the atomic weight of selenium is 79·00. About 1836 the atomic weight of copper was supposed to be 63·4, and of silver, 216·6. The analysis of the native sulphides of these elements were accordingly represented by the formulæ Cu_2S and AgS. But J. B. A. Dumas (1837) pointed out that the two minerals are isomorphous, and various mixed sulphides of the two elements are known by the general term, Fahlerz. Hence the constitution of the two sulphides is probably the same; assuming the formula of the one to be Cu_2S, that of the other will probably be Ag_2S, and the atomic weight of silver 108·3, not 216·6. This result agrees with evidence deduced from other independent sources. More exact determinations of the atomic weight of silver make this element 107·9; but this does not affect the principle of the argument.

EXAMPLE.—Analyses of alumina show that Al : O=18·1 : 16; the equivalent of aluminium in 9·03; hence the formula of alumina might be:

	AlO	Al_2O_3	AlO_2	AlO_3 . . .
Ratio . . . O : Al . . .	16 : 18·1	48 : 27·1	32 : 36·2	48 : 54·2, . . .

that is, the atomic weight of aluminium might be 18·1, 27·1, 36·2, 54·2 . . . There is nothing in the composition of the oxide to show which of these numbers should be selected. It is known, however, that ferric oxide—Fe_2O_3—forms a series of iron alums isomorphous with the aluminium alums; hence, it is inferred that the constitution of aluminium oxide is Al_2O_3—like that of ferric oxide—and that the atomic weight of aluminium is 27·1.

§ 12. The Formulæ of Minerals, and of Isomorphous Mixed Salts

Whether and when formulæ can be employed for minerals must be learned from faithful analyses.—T. BERGMANN (1779).

We can scarcely doubt that there is a fixed proportion of elements in each mineral substance, which constitutes its true nature, so that what exceeds a given limit should be to that degree regarded as accidental and foreign.—R. J. HAÜY (1801).

A great many minerals can be synthesized in the laboratory. The chemist can then use fairly pure materials and obtain fairly pure products. On the contrary, nature, in her great laboratory, has rarely dealt with pure materials, and accordingly, her products—the minerals—are usually contaminated with much impurity. The determination of the formulæ of minerals is exceptionally difficult mainly because (1) the molecular weights can seldom be determined, and the formulæ are therefore nearly always empirical; (2) the material available for analysis is more or less impure; (3) members of certain isomorphous groups of elements—iron, aluminium, chromium, etc.; calcium, magnesium, iron, manganese, etc.; sodium, potassium, lithium, etc.—can replace one another in every conceivable proportion. Usually the crystalline form as well as the analysis, is necessary for establishing the individuality of any mineral. Thus, H. A. Miers (1902) has said: It is necessary to employ at least two properties, namely, the chemical composition and the crystalline form; these two when completely known are necessary and sufficient for the definition and determination of any mineral. Colour, structure, state of aggregation, and minor details of chemical composition are used to distinguish subordinate varieties of the main types.

The ultimate composition of any native calcium carbonates is exceedingly complex. The same remark is more or less true for most native minerals; at least chemical formulæ which rigorously followed the analyses would be very complex. **The formulæ for minerals are commonly represented as if pure minerals occurred in nature.** Ideally pure minerals are seldom found native, and accordingly the standard formulæ represent idealized or imaginary minerals to which real minerals approximate more or less closely. The secondary constituents present in but small quantities are usually ignored and the main constituents are alone included in the formulæ. For example, the analyses of a sample of *limestone* from Buxton furnished:

CaO	MgO	K_2O	Na_2O	CO_2	Fe_2O_3 and Al_2O_3	SiO_2
54·75	0·31	0·25	0·24	43·78	0·26	0·88

Neglecting constituents less than one per cent., the remaining CaO and CO_2 are in the proportions needed for $CaO.CO_2$, or $CaCO_3$. The sample here selected was fairly pure and clean; it contained 98·5 per cent. of calcium carbonate. In the case of less pure minerals there is sometimes a doubt as to what is the best representative formula, and the identification of the mineral is then based on its external or physical properties rather than on its ultimate composition, for it has to be assumed that the deviations are due to admixed impurities in order to avoid conflict with the constant composition law. The difficulty is so real that many mineralogists define a mineral species as a natural inorganic substance whose chemical and physical properties are constant only within certain limits.

EXAMPLES.—(1) Clean crystals of *cerussite* from Tsumeb (S.W. Africa) furnished H. Dubigk (1913) on analysis: PbO, 83·27; CO_2, 16·64; insoluble matter, 0·24 per cent. Show that the best representative formula is $PbCO_3$.

(2) J. T. Bell (1892) analysed a sample of *cuproplumbite*, and found: copper, 61·32 per cent.; lead, 18·97; sulphur, 17·77; and silica (SiO_2), 1·58 per cent. Show that this analysis agrees with the formula $5Cu_2S.PbS$, assuming that the copper occurs in the mineral in the cuprous condition.

(3) A sample of *hodgkinsonite* from New Jersey (U.S.A.) furnished C. Palache and W. T. Schaller (1913) with: SiO_2, 19·86; MnO, 20·68; ZnO, 52·93; CaO, 0·93; MgO, 0·04; H_2O, 5·77 per cent. Show that $MnO.2ZnO.SiO_2.H_2O$ best represents the analytical data.

(4) A *marl* from South Lincolnshire furnished on analysis: CaO, 42·6; MgO, 7·9; CO_2, 41·6; K_2O, 0·3; Al_2O_3, 0·8; Fe_2O_3, 0·5; SiO_2, 5·1; H_2O, 0·8 per cent. Here the water, potash, alumina, ferric oxide appear to be of secondary importance. Divide the weights of each of the remaining constituents by the respective molecular weights, and reduce to the nearest whole number. There remains: $9CaO.2MgO.11CO_2,SiO$, or $9CaCO_3.2MgCO_3.SiO_2$. The substance is thus considered to be a mixture of calcium and magnesium carbonates with silica, and other impurities.

Minerals with isomorphous groups of elements.—In minerals, the members of an isomorphous series of bases appear to be replaceable one with another to an undetermined extent, while the type of mineral or the crystalline form remains the same. For example, in lime garnet, $3CaO.Al_2O_3.3SiO_2$, a certain proportion of the lime, CaO, may be replaced by ferrous oxide, FeO, and by magnesia, MgO, while a certain proportion of the alumina, Al_2O_3, by ferric oxide, Fe_2O_3. If the composition of the mineral is to be represented by a simple formula of the garnet type, the sum of the lime, magnesia, and ferrous oxide and not their individual proportions must be taken to represent the bases, and the sum of the alumina and ferric oxide must be taken as one sesquioxide. An analyses will then be represented by the formula, $(Ca, Mg, Fe)O.(Al, Fe)_2O_3.3SiO_2$; or more generally $R''O.R_2'''O_3.3SiO_2$.

EXAMPLE.—The analysis of a sample of *siderite* furnished :

CO_2	FeO	MnO	MgO	CaO	
38·5	55·6	2·8	1·8	1·0	Total, 99·7.

The basic elements belong to the same isomorphous group. To find if the mineral is of the type $RO.CO_2$, where R may represent Fe, Mn, Mg, or Ca, it is usual to first calculate the percentage amount of oxygen in the acids and bases. This gives

Acidic oxygen in	Basic oxygen in				
CO_2	FeO	MnO	MgO	CaO	
28·0	12·3	0·6	0·7	0·3	Total, 13·9.

There is thus 13·9 per cent. of oxygen in the basic radicles and 28·0 in the acidic radicles. This is very nearly in the ratio 1·2 required by the general formula $RO.CO_2$. The formula for this type of mineral may therefore be written, $(Fe, Mn, Mg, Ca)CO_3$; or $(Fe, Mn, Mg, Ca)O.CO_2$; or $RO.CO_2$; or RCO_3.

Instead of proceeding in this way, the amounts of the isomorphous bases CaO, MgO, MnO, which can be replaced by the equivalent amounts of the isomorphous FeO, can be calculated. Thus, what amount x of FeO is equivalent to 2·8 of MnO? The molecular weight of FeO is 72, and of MnO 71, consequently the proportion $71 : 72 = 2·8 : x$ gives nearly $x = 2·8$. By treating the MgO and CaO in a similar way, 3·2 and 1·3 are obtained respectively. The basic radicles are thus equivalent to $55·6 + 2·8 + 3·2 + 1·3 = 62$ of FeO. The composition of the idealized siderite is thus FeO, 63 per cent., CO_2, 38·5 per cent. Converting these numbers into molecular ratios in the usual manner, the formula of the idealized siderite becomes $FeCO_3$.

Consequently, while mixed crystals or solid solutions are not accepted as chemical units, individuals, or compounds, in mineralogy, those mixed crystals which give rise to *known minerals* are regarded as mineralogical individuals ; and mineralogy merges into chemistry when all the possible products of isomorphous crystallization are taken into account whether they occur in nature or are known solely as laboratory products. The so-called earthy and non-crystalline minerals are regarded as bearing the same relation to possible crystalline minerals as an amorphous precipitate of, say, barium sulphate bears to the mineral barytes.

§ 13. Index of Refraction and Dispersion

The physical character of any chemical compound, and its composition are dependent each on the other, and present two aspects of the same problem, which can never be solved but by a consideration of both.—T. S. HUNT (1891).

When a ray of light travels from one medium to another of different density, it is refracted, bent, or deflected towards or away from the vertical according as the density of the second medium is greater or less than the first. Between 1620 and 1625, W. Snell discovered the law—*the law of sines*—which determines the angle of deflection. If a ray of light, IO, Fig. 95, enters the denser medium at O, not normal to the surface, it travels through the new medium along the path OR, such that if NON' is perpendicular or normal to the surface, and i the angle which the incident ray makes with the normal, and r the angle which the deflected or refracted ray also makes with the normal, the ratio of the velocities of the light in the two media is proportional to the ratio of the sines of the angles of incidence i and refraction r, and *the ratio of the sine of the angle of incidence to the sine of the angle of reflection has always the same numerical value* ; that is,

$$\frac{\text{Velocity in rarer medium, } V_1}{\text{Velocity in denser medium, } V_2} = \frac{\sin i}{\sin r} = \text{Constant} \quad . \quad . \quad (1)$$

The constant is usually symbolized by μ or n. This ratio, sin i/sin r, is called the **index of refraction.** The index of refraction can also be regarded as a number which expresses the ratio of the velocity of light in vacuo to its velocity in the medium, and the index of refraction less unity, $\mu-1$, expresses the fractional shortening of the velocity which occurs when light passes through a transparent substance. For instance, the refractive index of air is 1·000292 at 0° and 760 mm. This means that while passing through air of standard temperature and pressure, light is retarded nearly three-ten-thousandths of its velocity in vacuo. The magnitude $(\mu-1)\times10^6$ is sometimes called the *refractivity* of the substance.

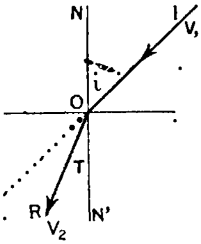

Fig. 95.

The determination of the index of refraction involves fundamentally the measurement of these two angles, and the intruments used for this purpose are called refractometers, etc. A ray of white light is *spread out* or *dispersed* into a number of coloured rays when it passes from one medium to another ; and, in consequence, a definite ray of light, corresponding with a definite part of the spectrum, is used for the measurement of indices of refraction, and two such points are used for the measurement of the dispersion. The index of refraction varies with the wave-length of the particular ray so that the index of refraction with rays from different parts of the spectrum is different. This is illustrated diagrammatically in Fig. 96, which shows how the rays at the violet V-end of the spectrum are refracted more than those at the red R-end. The earlier observations of the indices of refraction were not very precise, for they were referred to a part of the spectrum having a particular colour. Each colour occupies a certain range in the spectrum whose boundaries are not well defined, since two independent observations with the same coloured ray may really refer to different parts of the spectrum. The more conspicuous lines A, D, F, and H of the solar spectrum, or the α-, β-, and γ-lines of the hydrogen spectrum are in use, and they are recorded respectively as μ_A, μ_D, μ_F, μ_H, μ_α, μ_β, and μ_γ. The wave-lengths of the chief Fraunhofer lines in Angström units, are

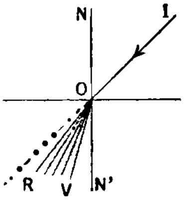

Fig. 96.

A	B	C	D	E	F	G	h	H
7677	6867	6563	5893	5270	4861	4841	4103	3969
K	—	H_α	Na	—	H_β	$H\gamma$	H_δ	—
Red			Yellow	Green	Blue			

The index of refraction for sodium light is a characteristic constant, *e.g.*

Cryolite.	Potash alum.	Halite.	Barytes.	Xenotime.	Strengite.	Diamond.
1·34	1·46	1·54	1·64	1·72	1·81	2·42

The index of refraction of crystalline substances may vary with the direction in which the ray of light is propagated ; it may also vary with temperature. J. L. C. Schroeder van der Kolk, in his *Tabellen zur mikroskopischen Bestimmung der Mineralien nach ihrem Brechungsindex* (Wiesbaden, 1906), has arranged a long list of minerals in the order of the refractive indices of their crystals with the idea of facilitating the rapid identification of small fragments of the mineral from measurements of their refractive index. In some cases, the method needs supplementing by other tests because a very limited number of minerals have indices of refraction so nearly alike, and within the limits of experimental error, that they cannot be distinguished with certainty.

The relation between the index of refraction and density.—As a rule, substances with the greatest density have the greatest index of refraction, but there are a few exceptions—*e.g.* methyl iodide has a density 2·258 and an index of refraction 1·524; while quinoline has a density 1·095, and an index of refraction 1·609. Isaac Newton[1] argued from the corpuscular theory of light:

> If light be swifter in bodies than in vacuo in the proportion of the sines which measure the refraction of the bodies, the forces of the bodies to refract light are very nearly proportional to the densities of the same bodies excepting that unctuous and sulphurous bodies refract more than others of the same density.

Newton then demonstrated that in spite of differences in density, D, the ratio $(\mu^2-1)/D$ is approximately constant; P. S. de Laplace (1805) put Newton's proof on a sounder theoretical basis.

> If the molecular force, like gravitation, is proportional to the mass, the force exerted by a body on a corpuscle of light near its surface will be proportional to the density of the substance when, unlike gravitation, the molecular force is sensible at insensible distances, and insensible at sensible distances. P. S. de Laplace then showed how the change in the velocity of the light corpuscles occurs only at the superficial transitional layer between the æther and the particles of matter; and he also showed how this change can be expressed as a definite integral which reduces to μ^2-1, and which is proportional to the density D, such that $(\mu^2-1)/D$ is a constant.

Serious experimental work on the relation between the index of refraction and the density of a substance was undertaken by J. P. Biot and F. J. D. Arago in 1806 and by P. L. Dulong in 1826, in order to test Newton's formula $(\mu^2-1)/D=$constant. As a result the formula was found to be an accurate description of the relation between the index of refraction and density of gases. The agreement between theory and experiment did not prove the truth of the corpuscular theory of light, for that hypothesis was soon afterwards abandoned in favour of the undulatory theory; but of course the coincidence still remained as an empirical fact.

In 1858, J. H. Gladstone and T. P. Dale[2] tried how Newton's formula held for substances other than gases, and found the empirical rule

$$\frac{\mu-1}{D}=\text{Constant}$$

to be much more nearly in accord with their observations than the older formula. This expression had been found by D. Beer, in 1853, to hold good for gases. Meanwhile, in 1880, L. Lorenz of Copenhagen and H. A. Lorentz of Leyden independently deduced the relation:

$$\frac{\mu^2-1}{\mu^2+2}\cdot\frac{1}{D}=\text{Constant; or }\frac{\mu+1}{\mu^2+2}\cdot\frac{\mu-1}{D}=\text{Constant}$$

H. A. Lorentz developed the expression from the electromagnetic theory of light, and also from the electron theory. L. Lorenz worked from the undulatory theory of light.

> L. Lorenz assumed that the body is isotropic and consists of spherical molecules between which light is propagated with the same velocity as in free space. He further assumed that in the mixed discontinuous medium—æther and molecules—the light may be regarded as if it were propagated with a definite mean wave-length and mean velocity, and with a periodically varying amplitude of vibration. As a matter of fact the wave-length of the light in a molecule may be much smaller than it is in the æther. Hence L. Lorenz really replaced the actual discontinuous medium by a hypothetical mean medium, a method which is not justifiable *a priori*.

All three expressions hold fairly well for gases at ordinary pressures because when μ is nearly unity, as is the case with gases, $(\mu+1)/(\mu^2+2)$ is nearly $\frac{2}{3}$; and for gases,

---

therefore, H. A. Lorentz and L. Lorenz's expression is nearly equivalent to J. H. Gladstone and T. P. Dale's formula multiplied by $\frac{2}{3}$; and to twice I. Newton's formula. As a result of numerous comparative experiments on liquids and solids, it has been found that neither J. H. Gladstone and T. P. Dale's nor H. A. Lorentz and L. Lorenz's formula is entirely in accord with all the facts. Each formula has its own special advantages, and each breaks down under quite different experimental conditions. Many other formulæ have been proposed—*e.g.* by E. Ketteler (1888) [3] and W. F. Edwards (1894)—but after much theoretical and mathematical work, no formula yet proposed has been proved entirely in accord with observations. This probably means that the simplifying assumptions, used in deducing the formulæ, want revising.

Nomenclature.—The ratio $(\mu-1)/D$ or $(\mu^2-1)/(\mu^2+2)D$ for an element or compound is called the specific refractory power or the **specific refraction** of the substance. If the index of a substance is 1·501, and the specific gravity 0·880, the specific refraction by H. A. Lorentz and L. Lorenz's formula is $(1{\cdot}501^2-1)/(1{\cdot}501^2+2)0{\cdot}880=0{\cdot}337$; and by Gladstone and Dale's formula $(1{\cdot}501-1)\div0{\cdot}880=0{\cdot}57$. The product of the specific refraction and the molecular weight of a compound is called the **molecular refraction**, and the product of the atomic weight and the specific refraction of an element is called the **atomic refraction** of the element. In measuring the index of refraction, light of a definite wave-length is employed, and the difference between the indices of refraction of a substance for light of two definite wave-lengths—say the red (?) ray and the blue (?) ray of the hydrogen flame; or the *C* and *D* lines of the solar spectrum—is called the **specific dispersion** of the substance, and the difference between the molecular refractions of a substance for light of two definite wave-lengths is called the **molecular dispersion**; and similarly, for the **atomic dispersion**, and for the specific dispersion. The dispersive power was represented by J. H. Gladstone as the ratio of the dispersion and the density—thus, the **specific dispersive power** when multiplied by the molecular weight, furnished the **molecular dispersive power**. Thus, the specific dispersion for the *H* and *A*-rays of the spectrum is $\mu_H-\mu_A$, and the specific dispersive power is $(\mu_H-\mu_A)/D$. The **dispersive power** of a substance has also been defined as the ratio of the specific dispersion of the index of refraction of the mean ray less unity. Thus, this dispersive power is $(\mu_H-\mu_A)/(\mu_F-1)$. The term $\mu-1$ in J. H. Gladstone and T. P. Dale's formula is sometimes called the **refractive energy** of the substance, and $(\mu-1)/D$, the **specific refractive energy.** The term $\mu-1$ is now usually called the **refractivity** of the substance.

The refractivities or refractive indices of gases can be corrected for temperature and pressure either by reference to the equation $pv=RT$, or to one of the many corrected forms [4]—J. D. van der Waals', D. Berthelot's, etc. H. A. Lorentz and L. Lorenz's formula is generally preferred because it has a sounder theoretical foundation; and it is more generally adaptable to the experimental material than J. H. Gladstone and T. P. Dale's—*e.g.* it is valid for a wider interval of temperature, and it is less influenced by the state of aggregation of the substance under examination.

G. Quincke (1883) tested the two rival formulæ by varying the density by hydrostatic pressure, and calculated the values for the density and accordingly also the compressibility, from the observed pressure and the index of refraction. He found H. A. Lorentz and L. Lorenz's formula gave values too small; I. Newton's too large; and with J. H. Gladstone and T. P. Dale's formula the values were sometimes too large and sometimes too small. The mean percentage errors were respectively −14, +17, and ±16. H. Landolt and R. Weegmann [5] found the results indicated in Table IV showing that J. H. Gladstone and T. P. Dale's formula fails signally in bridging the gap in density between liquid and vapour. The general conclusions of G. Quincke's and H. Landolt's comparison of the two rival formulæ are:

(1) When the same specimen of a substance has been examined in the liquid and gaseous state, H. A. Lorentz and L. Lorenz's formula has proved superior in the marked degree.

(2) The effect of increasing the density by hydrostatic pressure fits better with J. H. Gladstone and T. P. Dale's formula than with H. A. Lorentz and L. Lorenz's.

(3) Both formula usually apply well to the change from the liquid to the solid state, but the results are more in favour of J. H. Gladstone and T. P. Dale's formula.

(4) J. H. Gladstone and T. P. Dale's formula gives more accurate results when applied to calculate the index of refraction of a mixture from those of its constituents, for it varied on the average 0·05 per cent.—the deviation in the worst case was 0·16 per cent.; with H. A. Lorentz and L. Lorenz's formula the average deviation was 0·16 per cent., in the worst case 0·6 per cent. Hence, J. H. Gladstone and T. P. Dale's formula gives the better results with chemical optical analysis when it is used, say, to determine the amount of a particular substance dissolved in a solvent from the observed index of refraction and density.

TABLE IV.—COMPARISON OF LORENTZ AND LORENZ'S AND GLADSTONE AND DALE'S FORMULÆ FOR SPECIFIC REFRACTION.

(5) The refraction equivalents—*vide infra*—obtained by J. H. Gladstone and T. P. Dale's formula for carbon dioxide, oxygen, hydrogen, nitrogen, and the halogens, hold good for H. A. Lorentz and L. Lorenz's formula; but according to J. W. Brühl, the latter formula is preferable since it gives a smaller percentage error in the calculation of the refraction equivalent of a molecule from those of its atoms.

These facts, said W. Sutherland (1889), ought to furnish logicians with instructive examples in the theory of evidence. H. Dufet (1883)[6] and W. Sutherland (1889) have further shown that a theoretical foundation can be given to the empirical rule of J. H. Gladstone and T. P. Dale.

If V_0 be the velocity of light in vacuo, *i.e.* in free æther; V_1, the velocity in passing through the atoms themselves; and V, the velocity in an atom-strewn medium, then in a unit length of path—since velocity × time = distance traversed—the time occupied in passing through a given medium will be the reciprocal of the respective velocities; and the *loss of time* in the passage of light through the atom-strewn medium, owing to the retardation produced by the atoms, will be proportional to the retardation in passing through an atom, and

$$\frac{1}{V_0}-\frac{1}{V}=kls\left(\frac{1}{V_0}-\frac{1}{V_1}\right)\frac{D}{M}$$

where D/M represents the number of atoms in unit volume; l the mean length of the path through an atom; s the mean sectional area of an atom; and k is the constant of proportion. When multiplied through by V_0, and substituting μ for V_0/V from (1), this relation reduces to $(\mu-1)M/D=kls(N-1)$, where μ denotes the refractive index of the medium, and N that of the substance of the atom itself; M/D, the atomic domain; and the product ls, the average volume of the atom itself. W. Sutherland assumed that the bracketed term on the right is constant, so that the expression reduced to J. H. Gladstone and T. P. Dale's rule, $(\mu-1)/D$=constant. The delay produced by matter is due to the breaking up of the front of the light-wave by the interspersed atoms, and the subsequent loss of time in travelling from atom to atom before the front of the wave recovers its plane form. Assuming that this retardation is proportional to the length of the path, and to a function of the density, say, $a'D+bD^2+\ldots$, then for unit path, $(\mu-1)M/D=kls(N-1)+m(a+bD+\ldots)$; and the specific refraction is $(\mu-1)/D=[kls(N-1)/M+a']+bD$, where the bracketed term is constant, say a.

W. Sutherland's formula for specific refraction resembles J. H. Gladstone and T. P. Dale's specific refraction, but a term bD, proportional to the density, is added to the constant. This furnishes,

$$\frac{\mu-1}{D}=a+bD$$

where a and b are constants to be evaluated from observations of μ and D at two different temperatures. For gases and vapours, the term bD may be neglected on account of the smallness of the term D. W. Sutherland also claims that the revised formula is the best yet advanced, and that it is capable of representing the relation between the index of refraction under all circumstances within the limits of experimental error, where the uncorrected formula of J. H. Gladstone and T. P. Dale fails. Some examples are indicated in Table V.

TABLE V.—W. SUTHERLAND'S FORMULA FOR SPECIFIC REFRACTION.

Compound.	Constant b	Liquid.		Vapour (100°).	
		10° Obs.	20° Obs.	Observed.	Calculated.
Ether . . .	0·044	0·4935	0·4930	0·4599	0·461
Ethyl acetate .	0·017	0·4174	0·4172	0·4024	0·407
Ethyl iodide . .	0·022	0·2663	0·2658	0·2356	0·223
Chloroform . .	0·023	0·3000	0·2996	0·2694	0·265
Carbon disulphide .	0·050	0·4977	0·4970	0·4348	0·435

The agreement between the observed and calculated results in all cases excepting ethyl iodide is good.

E. T. Wherry [7] found that with the refractive indices for the ordinary ω-ray and the extraordinary ϵ-ray of tetragonal crystals are related with the axial ratio so that

$$\frac{\omega^2-1}{\omega^2+2}:\frac{\epsilon^2-1}{\epsilon^2-2}=\frac{c}{a}$$

where the axial ratios are based on the atoms present, and not on the standard axial ratio obtained by taking the most prominent pyramidal form to be (111). There are some disturbing factors with complex compounds, but with the simpler compounds the rule gave good results with a few organic compounds, and minerals of the zircon group. With cassiterite, the two ratios are 0·945 and 0·951; with rutile, 0·926 and 0·911; this is taken to mean that in these minerals the space lattice must have the same number of layers of atoms in the horizontal as in the vertical direction. In zircon and xenotime, the refraction ratios are equal to 3 : 2 times the standard ratio $c:a$, meaning that in the unit cell of these minerals there are three horizontal layers of atoms for every two vertical layers.

The effect of pressure on the refractive index.—The effect of variations of pressure on the index of refraction of gases has been investigated between 0·05 and 200 atm. W. Kaiser [8] found that for pressures between 20 and 760 mm., with sulphur and carbon dioxides, the variation of the index of refraction with pressure, $d\mu/dp$, increases faster than the variation of the density of the gas with changes of pressure; with pressures higher than atmospheric, E. Mascart [9] found the relation $\mu=1+ap+bp^2$ described his results for air, nitrogen, oxygen, carbon monoxide, carbon dioxide, nitric oxide, nitrous oxide, and cyanogen very well.

The effect of pressure on the refractive index of a few liquids (Na light) is as follows:

	Water (20°)	Alcohol (17·5°)	Benzene (20°)	Ether (8°)	Carbon disulphide (20°)
$d\mu/dp$.	0·00001514	0·00004174	0·00005060	0·00006161	0·00006583

The effect of temperature on the refractive index.—The exact relation between the temperature and the refractive index has not been established. J. P. Biot[10] represented his measurements of the refractive index of gases between 0° and 25°, by $\mu=\mu_0-a\theta$, where μ_0 represents the refractive index at 0°, and a is a constant independent of temperature. V. von Lang added another term to Biot's formula for his results between 0° and 100°; thus, for air, he used $\mu=\mu_0-0{\cdot}0_6905\theta+0{\cdot}0_72\theta^2$. E. Mascart used the more complicated expression: $(\mu-1)(1+a\theta)=$constant. If the relation $(\mu-1)D=$constant be valid, then, for ideal gases, at pressure p and p_0 with the corresponding temperatures $\theta°$ and $\theta_0°$,

$$\frac{\mu-1}{p}(1+a\theta)=\frac{\mu_0-1}{p_0}(1+a\theta_0)$$

and hence $\mu-1$ varies inversely as $(1+a\theta)$. He assumed that the temperature coefficient of refraction a, and the ordinary coefficient of thermal expansion a' to be the same. The observed differences showed that a was about 12 or 15 per cent. greater than a'; V. von Lang found the opposite, for a' was greater than a; and J. R. Benoit obtained $a=a'$. Hence G. W. Walker made some careful measurements of the two constants, and found a to be less than a' for air and hydrogen by respectively $0{\cdot}0_47$ and $0{\cdot}0_316$; and a greater than a' for carbon and sulphur dioxides by respectively $0{\cdot}0_49$ and $0{\cdot}0_326$. The influence of temperature on the refractive index of a number of minerals and liquids has been represented by formula of the type $\mu=a+b\theta+c\theta^2+\ldots$ Since changes of temperature are always accompanied by changes of density, it is generally assumed that the velocity of the propagation of light in a body is not affected by variations of temperature except in so far as the density of the substance is simultaneously altered; and the influence of density, D, is given by J. H. Gladstone and T. P. Dale's or L. Lorenz and H. A. Lorentz's formula. H. D. Ayres[11] found both Lorentz and Lorenz's and Gladstone and Dale's formulæ to apply equally well at −189·2° between 10·1 and 149·5 cm. pressure of mercury. He found that the refractivity $\mu-1$ of hydrogen, oxygen, nitrogen, and carbon dioxide varied lineally with the density at temperatures from 0° to −189·0°. K. Scheel compared the calculated values of the density D at −190° with the values D' observed by M. W. Travers and G. Senter, and by A. Bestelmayer and S. Valentiner. Assuming that the density of the gas is unity at 0° and 760 mm., the density D at $\theta°$ were calculated, by K. Scheel, from $(\mu-1)/D=$constant, and the observed densities of hydrogen and nitrogen between 0° and −190° were found to be about 0·4 per cent. greater than the calculated values.

The refractive index at the critical temperature.—P. A. Guye[12] has shown that J. D. van der Waals' constant b is related with the molecular refraction μ, by the expression:

$$b=k\frac{\mu^2-1}{\mu^2+2}\cdot\frac{M}{D}$$

where M denotes the molecular weight, D the density, and k is a constant which, according to I. Traube, is equal to 4·03. With the 35 inorganic compounds examined by P. A. Guye,

$$1{\cdot}8\frac{T_c}{p_c}=\frac{\mu^2-1}{\mu^2+2}\cdot\frac{M}{D}$$

where T_c denotes the absolute critical temperature and p_c the critical pressure, if v_c denotes the critical volume. J. D. van der Waals showed that $\mu_c=3b$, and that $p_cv_c=21{\cdot}76T_c$. This means that **the refraction constants of a substance are**

independent of the pressure, temperature, and state of aggregation, and for all substances at the critical temperature $v_c=1\cdot126$. V. Smith has compared this deduction for the gases and liquids indicated in Table VI.

TABLE VI.—THE CRITICAL VALUES OF μ FOR SOME GASES AND LIQUIDS.

	θ	$\mu_{D}\theta^{\circ}$	T	Critical value of μ	Deviation, per cent.
Gases :					
Oxygen . .	0°	1·000271	−118·8	1·126	0

Chlorine . .	14·0°	1·367	148·0	1·131	0
Carbon dioxide .	15·5°	1·192	31·35	1·101	−2·2

The effect of dispersion on the refractive index.—The effect of dispersion on the index of refraction μ for rays of wave-length λ can be calculated from A. L. Cauchy's formula,[13] $\mu=a+b\,\lambda^{-2}+c\,\lambda^{-4}+\ldots$, where a, b, c, . . . are constants to be computed from measurements of μ and λ. The constant a is sometimes called A. L. Cauchy's coefficient of refraction ; b, c, . . . are coefficients of dispersion. Several other formula have been proposed—*e.g.* by F. Redtenbacher, and by C. Briot—and they all give quite good results for the visible part of the spectrum, but fail as the invisible red is approached. S. P. Langley found C. Briot's formula gave the best results with the invisible red rays, but even these were not satisfactory. A. L. Cauchy's formula is usually preferred because of its simplicity. It agrees very well with observations for substances of low dispersive power, but not so well with substances of high dispersive power. The relation between the refractivity and the wave-length is then represented by an expression of Cauchy's type :

$$\mu-1=a\left(1+\frac{b}{\lambda^2}\right)$$

where a and b are constants. For mercury, $a=0\cdot001755$, and $b=22\cdot65\times10^{-11}$. It is found that in four cases—helium, argon, krypton, and xenon—where the measurements are available, if the refractivity $\mu-1$ for infinite wave-length λ be plotted against the value of b in this formula, the result is a straight line.[14]

It has been shown, by F. L. Perrot, A. E. H. Tutton, etc.,[15] that the index of refraction and the dispersion of a series of isomorphous crystals usually increase when one element is replaced by another with a greater atomic weight. For example, potassium, rubidium, and cæsium sulphates have respectively the values $D=1\cdot4947$, 1·5113, and 1·5644 ; and for anhydrite, $CaSO_4$, $D=1\cdot57518$; celestine, $SrSO_4$, 1·62367 ; barytes, $BaSO_4$, 1·63717 ; and anglesite, $PbSO_4$, 1·88226.

The relation between the refractive index and chemical composition.—In 1826, P. L. Dulong[16] concluded from his experiments that the specific refraction of a *mixture* of gases is the mean of the specific refractions of the constituents calculated for the partial pressures of the gases in the mixture ; while the specific refraction of a compound is not a mean of those of the component gases, for it is sometimes greater and sometimes less. J. H. Gladstone and T. P. Dale (1863) investigated the effect of chemical constitution on the refractive energies. One of the most important facts developed by this study from a chemical point of view is that the refractive equivalent of an atom is not a constant, but depends upon the way the atom is linked with other atoms. J. H. Gladstone and T. P. Dale said:

> We sought to determine the amount of change in the optical properties which results from a replacement of one element by another, the type remaining the same, . . . in order to attain a knowledge of the action of the individual elements on the rays of light transmitted by them. . . . The general conclusion is that *every liquid has its own specific refractive energy composed of the specific refractive energies of its component elements*, modified by the manner of combination, and which is unaffected by change of temperature, and accompanies it when mixed with other liquids.

The subject was followed up by H. Landolt (1864), J. W. Brühl (1886), etc., and as a result, it was found that the molecular refraction or dispersion of compounds is:

(1) An additive property in that it depends on the number and kind of atoms in the molecule—*e.g.* the atomic refractions and dispersions of hydrogen and chlorine are virtually the same whether they are free, or combined.

(2) It is also a constitutive property in that it depends on the mode of combination of the different elements—*e.g.* the atomic refraction and dispersion of carbon is very different according to the way it is combined—single, double, or triple-bonded carbon atoms have different values. While the atomic refraction of single-bonded carbon and carbonyl, CO, carbons are nearly the same, the atomic dispersion of the one is nearly double that of the other. Similar remarks apply to oxygen, and more particularly to nitrogen.

The refractive indices of the elements gaseous at ordinary temperatures have been measured directly; the opaque metals do not lend themselves to this treatment although the method has been used in case of a few metals which can be beaten into thin enough sheets to permit the passage of light. A. Kundt[17] determined values for half-a-dozen metals in this way; the values for gold, silver, and platinum so determined are respectively 0·58, 0·27, and 1·64. P. Drude also developed a method for measuring the refractive indices of the metals which are based on the angle of reflexion, and accordingly obtained values for the refractive indices of over a dozen metals. The results of A. Kundt and of P. Drude did not agree very well. The molecular refractions of a number of compounds has been measured directly, and values for the constituent elements have been computed on the assumption that the atomic refraction is an additive quality. The indices for a number of inorganic salts have also been estimated from the indices of refraction obtained for their aqueous solutions on the assumption that J. H. Gladstone's additive formula

$$\text{Molecular refraction} = (18n+M)R_1-18nR_2$$

holds good. Here M denotes the molecular weight of the compound; R_1 and R_2 the refraction constants of water and of the solution respectively; and n denotes the number of gram-molecules of water per gram-molecule of salt. After comparing the observational data of a large number of compounds, J. W. Brühl drew up tables of the atomic refractions and dispersions of a number of elements based on constants calculated from observations on the refractive index reduced by Lorentz and Lorenz's formula. Different constants are obtained when J. H. Gladstone and T. P. Dale's formula[18] is used. Table VII contains values of the atomic refraction, $w(\mu^2-1)/(\mu^2+2)D$, compiled by W. A. Roth and F. Eisenhohr in their *Refractometrisches Hilfsbuch* (Leipzig, 1911).

The additive or mixture law.—The molecular refractions of a number of organic compounds were found by H. Landolt to be the sum of the atomic refractions of their constituent atoms when due allowance is made for the modifications in the atomic refractions of elements united in special ways. If a substance of molecular weight M contains n_1 atoms each of atomic refraction R_1; n_2 atoms of atomic refraction R_2; . . . then the molecular refraction is

$$\text{Molecular refraction}=n_1R_1+n_2R_2+ \ . \ . \ . =\Sigma nR$$

The results of this method of investigation have established the proposition that the atoms of the elements have the power of retarding light; and that in some cases this power is not materially changed when the atoms pass from one compound to another; but closer investigation shows that the specific refractive energies of the atoms are greatly modified by the nature of the combination. The relation between the different atoms is an important factor. Thus, J. W. Brühl showed that the refractive effect of oxygen is greater when the oxygen is united to carbon than when it is united to two other elements; and E. Conrady [19] further showed that still a different value for oxygen is obtained with oxygen in the ethers. J. H. Gladstone showed that hydrogen in the weak acids has but 40 per cent. of its value in the strongly ionized acids; M. le Blanc found two distinct values for chlorine; E. Wiedemann found two for sulphur; and seventeen values have been obtained for nitrogen. In some cases, the additive rule is applicable more particularly when the compound contains but a few elements combined in the same way; but in general, the additive mixture law breaks down completely for chemical compounds. It is, however, valid for mere mixtures which exert no chemical action on one another. The observed and calculated values for air, for example, coincide—within the limits of experimental error. The principle has been applied to the technical analysis of gases, and of many solutions. The molecular refraction (and likewise also the molecular dispersion) of compounds calculated in this way may then furnish concordant results; and the results have been used as circumstantial evidence in favour of particular hypotheses about the constitution [20] of the compound under investigation.

TABLE VII.—ATOMIC REFRACTIONS AND DISPERSIONS—$w(\mu^2-1)/(\mu^2+2)$.

	Atomic refraction.				Atomic dispersions.	
	H_α	D	B_β	H_γ	$H_\beta - H_\alpha$	$H_\gamma - H_\alpha$
Carbon	2·413	2·418	2·438	2·466	0·025	0·056
Hydrogen	1·092	1·100	1·115	1·122	0·023	0·029

Ether oxygen	1·639	1·643	1·649	1·662	0·012	0·019
Hydroxyl oxygen	1·522	1·525	1·531	1·541	0·006	0·015
Chlorine	5·933	5·967	6·043	6·101	0·107	0·168
Bromine	8·803	8·865	8·999	9·152	0·211	0·340
Iodine	13·757	13·900	14·224	14·521	0·482	0·775
Ethylene bond	1·686	1·733	1·824	1·893	0·138	0·200
Acetylene bond	2·328	2·398	2·506	2·538	0·139	0·171
Nitrogen in primary aliphatic amines	2·309	2·322	2·368	2·397	0·059	0·086
Nitrogen in secondary aliphatic amines	2·475	2·499	2·561	2·603	0·086	0·119
Nitrogen in tertiary aliphatic amines	2·807	2·840	2·940	3·000	0·133	0·186
Nitrite nitrogen	3·054	3·070	3·108	3·129	0·055	0·065
Nitrogen in amides (C−N=C)	3·740	3·776	3·847	3·962	0·139	0·220

EXAMPLES.—(1) Assuming that in benzene, C_6H_6, there are two ethylene linkages, compare the calculated and observed molecular refractions, given the index of refraction is 1·50144 and the density 0·880, and the molecular weight 78. From Table VII $(6\times2{\cdot}365)+(6\times1{\cdot}103)+(3\times1{\cdot}836)=26{\cdot}3$; etc.

(2) Compare the atomic refraction and dispersion of hydroxylamine on the assumption that the formula is H_2N-OH with the observed values 7·23 and 0·19 respectively.

	Atom refraction.	Dispersion.
N in ammonia	2·497	0·072
O in OH group	1·610	0·019
3 H atoms	3·150	0·120
H_2N-OH	7·257	0·211
Found	7·23	0·19

The approximate agreement of the observed and calculated values of the atomic refraction and dispersion is taken to favour the hypothesis that the constitution of hydroxylamine is $H_2=N-OH$. Hydrogen peroxide furnishes another example.

The errors involved in the computation of the refractive equivalents of some of the elements are sometimes as great as 12 per cent.; and when it is remembered that in comparing the observed and calculated refractivities of a compound, the differences seldom exceed 10 per cent., it will be obvious that the errors in the data are as large as the magnitude under observations. In such cases, the process of investigation is of comparatively little value. Many attempts have also been made to establish a relation between the dispersive power of a substance and chemical composition,[21] but the results are not so good as with refractivities, probably because dispersion is more readily influenced by composition than refractivity.

The refractivity of compounds is an additive property for liquids and solids when the refractive constants are determined from the compounds themselves. In gases, this is not true. Out of sixteen gaseous compounds of which the refractivities of the components have been measured in a free state, C. Cuthbertson [22] did not find one to agree with the additive rule—with the nitrogen compounds the deviations varied between 5 and 14 per cent.; with sulphur dioxide the deviation is 18 per cent.; with selenium hexafluoride, 30 per cent.; and with tellurium hexafluoride, 45 per cent. C. Cuthbertson says the failure of the additive rule is not far to seek:

> The true refractive constant of an element is, evidently, the retardation caused by the free gaseous atom. The forces which compel atoms of different elements to combine, and to assume the liquid or solid states, whatever they may be, are evidently very powerful, and it is unreasonable to expect that causes which can modify other attributes of matter in ways and to an extent which we are unable to predict should have no effect, or always the same effect, on its power to retard light. It is therefore to the study of the gaseous refractive indices that it is necessary to turn in the hope of obtaining really accurate information with regard to the optical properties of matter.

TABLE VIII.—REFRACTIVE INDICES OF SOME GASEOUS ELEMENTS (C. CUTHBERTSON).

Element.	$\mu-1=a\left(1+\frac{b}{\lambda^2}\right)$		Refractivity, $(\mu-1)\times10^6$		Empirical ratio.
	a	b	$\lambda=\infty$	$\lambda=5893$	
Hydrogen	$0{\cdot}0_31358$	$6{\cdot}67\times10^{-11}$	135·8	138·4	
Helium	$0{\cdot}0_46956$	$2{\cdot}2\times10^{-11}$	69·56	70·0	1
Neon	0·0001374		—	137·4	2
Argon	$0{\cdot}0_35584$	$5{\cdot}6\times10^{-11}$	558·4	567·4	8
Krypton	$0{\cdot}0_38378$	$6{\cdot}97\times10^{-11}$	837·8	854·6	12
Xenon	$0{\cdot}0_31364$	$610{\cdot}14\times10^{-11}$	1364·6	1404	20
Fluorine	0·000195		—	195	2
Chlorine	0·000768		—	768	8
Bromine	0·001125		—	1125	12
Iodine	0·00192 (violet) 0·00205 (red)		—	—	20
Oxygen	$0{\cdot}0_32663$	$5{\cdot}07\times10^{-11}$	266·3	270·2	2
Sulphur	0·001045	$721{\cdot}2\times10^{-11}$	1046	1111	8
Selenium	0·001565		—	1565	12
Tellurium	0·002495		—	2495	20
Nitrogen	$0{\cdot}0_329061$	$7{\cdot}7\times10^{-11}$	290·6	297·1	2
Phosphorus	0·001162	$15{\cdot}3\times10^{-11}$	1162	1212	8
Arsenic	0·001552		—	1552	12
Zinc	0·002050		—	2050	
Cadmium	0·002675		—	2675	
Mercury	0·001755	$22{\cdot}65\times10^{-11}$	1755	1866	

The refractive indices of gases.—J. P. Biot and F. J. D. Arago[23] measured the refractivities of hydrogen, oxygen, and nitrogen; to these P. L. Dulong added chlorine; F. P. le Roux, iodine, sulphur, phosphorus, arsenic, and mercury; E. Mascart, bromine; W. Ramsay and co-workers, the five inert gases—helium, neon, argon, krypton, and xenon; and C. Cuthbertson and co-workers added selenium, tellurium, zinc, cadmium, and fluorine. The earlier less accurate determinations have also been revised by a number of different workers. The results are indicated in Table VIII. The refractivities of the five mono-atomic gases are almost exactly in the ratios 1 : 2 : 8 : 12 : 20—the last three being as 2 : 3 : 5. A similar ratio obtains with the halogens; and with the other families indicated in the table. There is a 4·7 per cent. error with selenium; a 8·7 per cent. error with tellurium; arsenic has a deviation of about 17 per cent. No simple ratio was observed with the zinc family, for mercury with the highest atomic weight has the lowest refractivity. However, it must be added that some chemists doubt if mercury is rightly placed with the zinc family. The anomalous dispersion of iodine in the red will be noticed. The estimated refraction equivalents of the alkali metals by J. H. Gladstone also fall in line—the values for potassium rubidium and cæsium being respectively 7·85, 12·1, and 19·2. Rearranging the data,

—	—	125 × 20	96 × 20	70 × 20	—	—

An examination of the horizontal rows in Table IX shows that refractivity must be closely connected with valency; the elements with the higher atomic weights have the lowest refractivities although the relation between the two is not known. J. H. Gladstone thought that the product of the specific refractivity and the square root of the chemical equivalent is approximately constant—1·3 for the univalent elements, and 1·01 for the bi-, ter-, quadri-, and quinquevalent elements. Improved observational data do not support Gladstone's rule. An increase of valency is accompanied by an increase of refractivity. Only part of the refractivity is concerned with valency, or the non-valent elements would not retard light at all.

According to the electronic hypothesis of matter, the electrons bound within the atoms by quasi-elastic forces, are supposed to be stimulated into oscillatory motions by incident waves of light; the mode of motion is influenced by the orientation of the atoms in the molecules. The same electrons probably also play an important rôle in the union of the atoms to form the molecules. It is now assumed that the retardation of light in passing through a material medium is caused by the expenditure of energy in starting and maintaining the motion of the electrons which form part of the atom. These electrons are supposed to have a natural period of vibration of their own, and the loss of energy and velocity is greatest with rays whose wave-length approaches most nearly to the natural period of vibrations of the constituent electrons—the long red waves, for example, are retarded 1 to 2 per cent. less than the shorter violet waves.

Valency and the refractive index.—According to H. A. Lorentz's theory, the refractivity is directly proportional to the number N of electrons in unit volume of the medium, and inversely as the difference in the frequency of the free vibrations

n_0 of the atoms which are instrumental in effecting refraction, and n that of the incident light; $n\lambda = V$, so that

$$\mu - 1 = \frac{C}{{n_0}^2 - n^2}$$

Calculations show that the numerator of this expression is proportional to N, the number of electrons in unit volume such that $C = \frac{1}{8}\pi^{-2}e^2N/m$, where π denotes the well-known constant, m is the mass, and e the electric charge. Then if v denotes the number of valency bonds associated with an element, P. Drude's theory of dispersion[24] leads to the conclusion that the sum of the valencies contained in the molecules of a compound is proportional to the accepted chemical valencies; or that C is proportional to the positive valency v of the atom, or that C/v is a constant which has the same value for all gases. Thus,

TABLE X.—THE RELATION BETWEEN VALENCY AND THE REFRACTIVE INDEX.

	$C \times 10^{-27}$	v	$\frac{C}{v}$
Hydrogen	1·692	1	1·692
Oxygen	3·397	2	1·699
Phosphorus	7·610	4½	1·691
Nitrogen	5·034	3	1·678
Sulphur	4·808	3	1·603

The results are not so good with the last two elements; but the agreement in all cases is fairly close, giving grounds for the assumption that the number of electrons concerned in dispersion is proportional to the received valency of the element. According to this theory, L. Natanson inferred that the product of v with the term Δ should be independent of the nature of the gas, and be the same for all gases referred to the normal state. Here:

$$\Delta = \frac{3(\mu_1 - \mu_2)\lambda_1^2\lambda_2^2}{2(\mu_1 - 1)(\mu_2 - 1)(\lambda_1^2 - \lambda_2^2)}$$

where μ_1 and μ_2 are the refractive indices corresponding with two different rays of wave-length λ_1 and λ_2 respectively. The mean values of the product $v\Delta$ for hydrogen, oxygen, nitrogen, carbon monoxide, sulphur dioxide, hydrogen disulphide, and carbon monoxide are approximately constant, but deviations occur with some of the hydrocarbons. For example:

	H_2	O_2	N_2	CO_2	SO_2	H_2S	CO
v . . .	2	4	6	8	8	6	4
Δ . . .	7·99	3·87	2·73	2·16	2·23	2·80	3·68
$v\Delta$ . . .	15·98	15·48	16·38	17·28	17·84	16·80	14·72

whereas the values of $v\Delta$ for methane ($v=8$), ethane ($v=14$), ethylene ($v=12$), and acetylene ($v=10$) are respectively 27·95, 25·50, 32·72, and 34·45.

The study of the refractive indices of gases is therefore promising to throw light on the intimate structure of atoms and molecules. The sterility of the enormous amount of work which has been done on the refractivities of liquids and solids, says C. Cuthbertson, proves that in these states of aggregation the causes which obscure the simplicity of the results are too powerful, and that it is vain to hope for much addition to our knowledge in this direction. The little work which has been done on the refractivities of gases has furnished a few simple relations, which by their very simplicity seem to be the outward and visible truth which ought to be pursued by the accumulation of more data.

The relation between the index of refraction and the magnetic rotatory power.—J. H. Gladstone and W. H. Perkin[25] have shown that there is some connection between the rotation of a polarized ray under the influence of magnetization, and the retardation of the rays in passing through a material substance as represented by the index of refraction and dispersion. The three properties are additive in an analogous manner, and a change in the active valency of an element is attended by a parallel change in all three properties. With the halogen acids all three properties exhibit parallel deviations from the normal when measured in solutions of iso-amyl ether, and in water :

TABLE XI.—MAGNETIC ROTATORY POWER OF HYDROCHLORIC ACID.

Hydrochloric acid.	Molecular magnetic rotation.	$M\frac{\mu-1}{D}$	Molecular dispersion.
Free	2·187	11·20	0·54
Aqueous solution . . .	4·412	14·45	1·12
Solution in isoamyl ether . .	2·238	71·36	0·51

The relation between the index of refraction and the dielectric constant.—The numbers in Table XI point to a relationship between electromagnetism and the velocity of light. According to J. C. Maxwell's electromagnetic theory of light,[26] if K and K_1 respectively denote the dielectric constants of two transparent media, and μ the limiting value towards which the index of refraction approaches when the wave-length of the rays become indefinitely large, then $\mu^2=K/K_1$. If one of the two media be air, for which K_1=unity, then $\mu^2=K$, meaning that the specific inductive capacity, or the dielectric constant of any medium relative to air unity, is equal to the square of the index of refraction of that medium when μ^2 is measured for the slowest vibrations of light, and K for the most rapid electrical oscillations ; the agreement between the observed values of K and μ^2 becomes very close, as is illustrated in Table XII.

TABLE XII.—OBSERVED VALUES OF $K=\mu^2$.

Substance.	K	μ^2
Air	1·000590	1·000588
Hydrogen	1·00264	1·000276
Phosphorus	4·20	3·60
Selenium	5·96	6·60
Liquid chlorine	1·87	1·88
Bromine	2·57	3·10
Iodine	4·00	4·00
Carbon disulphide	2·67	2·67

The value of K for water is 80 and μ varies between 1·33 and 1·34; and for alcohol, K=26, and μ varies between 1·36 and 1·37. Hence, as F. Heerwagen showed, there appears no kind of relation between μ and K for water. H. A. Lorentz and L. Lorenz's relation $(\mu^2-1)/(\mu^2+2)D$=constant becomes $(K-1)/(K+2)D$ =constant, when $K=\mu^2$, and L. Boltzmann found the results to be satisfactory. For gases, $(K-1)/D$=constant, and at a constant temperature, therefore, $K-1$ is proportional to the pressure. The results were confirmed by A. Palaz, P. Fuchs, A. Rosa, P. Lededew, and K. Bädeker. F. Linde found that the formula is not applicable to liquid and gaseous carbon dioxide, sulphur dioxide, nitrous oxide, and chlorine. F. Ratz could not use the formula satisfactorily for his experiments on the influence of temperature and pressure on the dielectric constant, while O. Hasenhörl obtained satisfactory results. A. Batschinsky found the formula fails when K is greater than μ^2. R. Millikan, F. Beaulard, and V. Boccara and M. Pandolfi obtained good results with many mixtures. S. Pagliani found that better results are obtained with the formulæ $(K-1)N/KV$=constant; and $(K-1)/K\sqrt{N/M}$=constant, where N denotes the number of atoms in a molecule; M, the molecular weight; and V, the molecular volume.

The experiments of A. P. Cole, L. Arons and H. Rubens, and of A. Ellinger[27] show that for rays of very great wave-length—say 60 to 600 cm. in air—the index of refraction of water is nearly $\mu=9$. Similarly, for alcohol, the index of refraction for waves 209 cm. long in air was 5·24, and the square of this number agrees well with the dielectric constant of alcohol for low-frequency oscillations. This shows that J. C. Maxwell's formula, $\mu^2=K$, is valid for these substances with radiations of great wave-length.

According to J. A. Fleming,[2] substances of simple symmetrical constitution—*e.g.* liquid elemental gases, saturated hydrocarbons, paraffins—follow Maxwell's rule $\mu^2=K$ for light waves; and they have dielectric constants between 2 and 3, and values of μ lying between 1·4 and 1·7, and these values are not much affected by changing the frequency of the incident waves from zero to billions per second. The molecules of which bodies are composed can double the dielectric constant of the intermolecular spaces without changing the qualitative characteristics of the æther—according to Thwing's rule: the dielectric constant of these bodies is nearly 2·6 times their density. Substances made up of molecules with groups of radicles—hydroxyl, nitryl, etc.—do not generally follow Maxwell's rule, and they have dielectric constants which are much more sensitive to changes in frequency—as a rule, increasing the frequency decreases the dielectric constant.

Again, electromagnetic waves travel much more slowly through dielectrics than through empty space; with water, the velocities in space and in the liquid are as 9 : 1 for all electric waves yet produced, while for visible light waves the ratio is nearly 1·3 : 1; for alcohol, the ratio varies from 5 : 1 to 2·5 : 1 in passing from the longest to the shortest waves yet produced electrically, while for visible light rays the ratio is 1·3 : 1. Low temperatures annul the difference in the velocity ratios for long and short waves. For substances like paraffin, hydrocarbons, liquid oxygen, and bodies of simple chemical constitutions there is no marked difference between the velocities of the waves of different wave-length.

J. A. Fleming assumes that there is a slight displacement of the electric charges (electrons) on the atoms in opposite directions when the molecules of inert substances—like the paraffins and saturated hydrocarbons with symmetrical atoms—are subjected to an electric force. This displacement is the same whether the stress has a frequency of some billions per second, as in the case of a ray of light, or 100 per second, as in the case of electrical oscillations; and Maxwell's rule is fulfilled. On the other hand, with unsymmetrical molecules—like water $H^{\bullet}-OH'$—the electric charges are so displaced that the molecules have an electrical moment, and under the influence of an electric force, they are oriented in space like small magnets in a magnetic field. This displacement is over and above the strain due to the charges of the molecule in that it bestows an abnormal value on the dielectric constant. These abnormal values become normal on lowering the temperature because the molecules aggregate into more complex groups which no longer possess an electric moment, and are no longer liable to orientation in the electromagnetic field. Waves of high frequency produce the same result as very low temperatures, because the inertia of the molecules under rapid alternations of electric force (billions per second) prevents the orientation of the molecules.

J. Stefan (1872)[28] drew attention to a simple relation between the index of refraction, μ, of a gas and the mean free path, l, of the molecules such that $(\mu-1)l$=a constant. R. Clausius (1879) developed the idea, on the lines of J. C. Maxwell's theory, and showed that the expression $(K-1)/(K+2)$ represents the ratio of the real volume of the molecules of a substance to the volume they actually occupy *en masse*. The idea was extended by O. F. Mosotti and F. Exner (1885), who developed the idea with respect to the equivalent expression $(\mu^2-1)/(\mu^2+2)$ such that if the molecules have a spherical form, and do not touch, the relation between the specific inductive capacity or the dielectric constant, K, and the space v actually occupied by the molecules $v=(K-1)/(K+2)$, and since, for vibrations of great wave-length, $\mu^2=K$, the spaces occupied by the molecules will be $v=(\mu^2-1)/(\mu^2+2)$. If the true molecular volume be represented by v, and if ΣM represents the sum of the atomic volumes, when A_1, A_2, . . . represent the atomic volumes and n_1, n_2, . . . the number of atoms of each kind respectively present in the molecule, the fraction of unit space actually occupied by the molecule will be $\Sigma nA/V$, and I. Traube assumed this to be proportional to V, that is, to $(\mu^2-1)/(\mu^2+2)$, so that:

$$\Sigma nA=k\frac{\mu^2-1}{\mu^2+2}V\ ;\ \Sigma nA=k\frac{\mu^2-1}{\mu^2+2}\cdot\frac{M}{D}$$

where k is a constant, and $V=M/D$, where M denotes the molecular weight, and D the density. I. Traube obtained a value 3·46 for the constant k for a long series of saturated organic compounds. The constant k decreases with an increase in the number of double linkages in saturated organic compounds.

H. Davies showed that if the absolute volume of unit mass of liquid be v, the volume at absolute zero be v_0—the b of J. D. van der Waals' equation—and if the volume of the liquid at the temperature T° K. be V; then, if $v_0=kV$:

$$\frac{v}{V}=\frac{1}{2akT_c};\ \frac{K-1}{K+2}=\frac{1}{2akT_c}$$

where a denotes the coefficient of cubical expansion. The values of the constant k calculated from this expression for the liquids tried deviate very little from 2·5. Hence, the ratio of the volume at the absolute zero to the real volume occupied by a number of molecules is 2·5. H. Davies also showed that:

$$\frac{K-1}{K+2}\cdot\frac{M}{D}=\frac{Mv_c}{10};\ \text{and}\ \frac{K-1}{K+2}\cdot\frac{M}{D}=2{\cdot}3\frac{T_c}{p_c}$$

observation gave $2{\cdot}43T_c/p_c$, when p_c is measured in atmospheres. P. A. Guye found empirically that the molecular refractive power is $1{\cdot}8T_c/P_c$.

The refractive index of crystals of isomeric compounds.—The specific refraction of isomeric substances has been suggested as a possible method of distinguishing between metamerism and polymerism. With metamers the difference in the specific refraction is small, and said to be less than about 0·5 per cent. The following examples have been cited in illustration:

TABLE XIII.—METAMERS.

TiO_2	Specific gravity D	μ	$\frac{\mu-1}{D}$	Difference.	Percentage deviation.
Anatase . .	3·840	2·5011	0·3909	0·0004	0·1
Brookite . .	4·065	2·5872	0·3905	0·0017	0·4
Rutile . .	4·239	2·6642	0·3926		

With polymers, the difference in the specific refraction is large, say, over one per cent. For example:

TABLE XIV.—POLYMERS.

$CaCO_3$	Specific gravity, D	μ	$\frac{\mu-1}{D}$	Difference.	Percentage deviation.
Calcspar . .	2·713	1·5958	0·2196	0·0068	3·1
Aragonite . .	2·950	1·6277	0·2128		

With the three aluminium silicates there appears both metamerism and polymerism.

TABLE XV.—METAMERS AND POLYMERS.

$AlSiO_5$	Specific gravity, D	μ	$\frac{\mu-1}{D}$	Difference.	Percentage deviation.
Andalusite . .	3·180	1·6357	0·1999	0·0003	0·3
Cyanite . .	3·603	1·7182	0·1883	0·0045	2·3
Sillimanite . .	3·235	1·6613	0·2044		

It will be observed, however, that the molecular structure of none of these examples has been established, and the argument therefore proceeds in a vicious circle.

CHAPTER XII

THERMODYNAMICS AND THERMOCHEMISTRY

§ 1. Matter and Energy

> All physical science starts from certain postulates. One of them is the objective existence of a real world.—T. H. HUXLEY (1887).
>
> Substance is like a river in continual flow; the energies undergo constant changes and do work in infinite variety. There is hardly anything that stands still or remains still.—MARCUS AURELIUS.

SIDE by side with ponderable matter, capable of being weighed, early science accepted imponderable matter such as electricity, fire, heat, etc.; and, up to the beginning of the nineteenth century, it was generally assumed that heat is a substance which was variously styled caloric, igneous fluid, phlogiston, etc. Indeed, A. L. Lavoisier was influenced by the time-honoured tradition, and in his *Traité élémentaire de chimie* (Paris, 1793), included *lumière* and *calorique* in his *Tableau des substances simples* to be regarded as elements, although he knew quite well that they had no perceptible weight. Even J. Fourier, in his classical *Théorie de la chaleur* (Paris, 1816), regarded heat as a material substance; and J. J. Berzelius, in his *Lehrbuch der Chemie* (Dresden, 1825), classed *Licht- und Wärmestoff* among the *einfache unwägbare Stoffe*.

As a result of Newton's theory of gravitation, it was soon recognized that matter seems to have a property, called *mass*, which shows itself as *weight* under the influence of gravity. Matter also occupies space so that it is always extended in some shape or form; and further, matter is invariably associated with energy. Consequently, matter, as perceived by the senses, possesses certain attributes—weight and form—which appear to be permanent and essential qualities abiding in all known kinds of matter; whereas other properties—*e.g.* colour, odour, etc.—appear to be secondary and accidental attributes which are peculiar to specific forms of matter. This distinction between the primary and secondary qualities of matter was recognized by Democritus, *c.* 350 B.C.; it appeared among the tenets of Albertus Magnus, who in his *De generatione elementorum* said:

> That matter and power are the principles of each body is clear, for having taken away all the accidental forms, we arrive at length at a substantial form which, being abstracted *per intellectum*, there remains a something very occult which is *prima materia*.

The idea was further emphasized by J. Locke in 1689. Matter may also be found under different conditions of temperature, electrification, motion, etc.; and daily experience teaches us that changes are continually taking place in the conditions of bodies around us. Change of position, change of motion, of temperature, volume, and chemical combination are but few of the myriad changes associated with bodies in general.

The forms of energy.—There are many different forms of energy—electrical, chemical, mechanical, thermal, and actinic—and by suitable means these can be mutually converted one into the other; *e.g.* the galvanic battery converts chemical into electrical energy, and the dynamo converts mechanical into electrical energy. Much of the motive power used in the industrial arts is derived from the chemical action between coal and oxygen in the furnace of a steam engine. Heat and light are also well-known concomitants of chemical action. Hence, it is inferred that heat, electricity, mechanical motion, light, and chemical action are all different forms of one distinct entity—energy. The different forms of energy are supposed to be the external aspects of one single basic form of energy, which, in the words of S. A. Reeve (1909), we may never hope to comprehend. Examples of the mutual identity of the different forms of energy multiply daily in familiar experience. The idea was dimly foreshadowed in the seventeenth century by F. Bacon in his essay *De forma calidi* (1627), which was offered as a model of method for investigating nature. Here Bacon argued that the facts could be satisfactorily explained only by assuming that heat is a kind of motion among the particles of a body; heat and mechanical motion are mutually convertible. The same idea was accepted by R. Hooke (1667), Isaac Newton (1675), R. Descartes (1677), R. Boyle (1680), J. Locke (1689), and others.[1] The same idea was emphasized by Count Rumford[2] who, in *An inquiry concerning the weight of heat* (1798), proved that heat could not be a material substance because unlimited quantities can be developed by friction, and concluded that heat must be motion. H. Davy, likewise, in 1812 showed that ice can be liquefied by friction, and the resulting liquid contains a far greater amount of heat than the ice, and he concluded:

> The immediate cause of the phenomena of heat is motion, and the laws of its communication are precisely the same as the laws of the communication of motion.

The later work of J. P. Joule (1846–9) and others has fixed the generalization that **any one form of energy can be transformed, wholly or partially, directly or by intermediate steps, into any other form.** This is the so-called **law of transformation of energy.** All types of machinery are devices for transforming energy from one form into another; and all phenomena in the material world can be represented as transformation of energy. Industrial operations usually involve the expenditure of considerable amounts of energy. For instance, *mechanical energy* is expended in crushing and grinding rocks, rolling metals, transporting materials, etc.; *thermal energy* is expended in the steam engine, and used for melting metals, burning lime and cement, bricks and pottery, etc.; *electrical energy* for illumination, electroplating, refining metals, production of aluminium, etc.; *light energy* for illumination and photography; *chemical energy* in the manufacture of chemical compounds, explosives for blasting and warfare, driving gas engines, etc.

Energy and work.—As a first approximation, every change in the condition of the various bodies around us is supposed to be due to the action of what T. Young (1807)[3] called *energy*. In other words, energy is regarded as an operative physical agent which has the power of changing the condition of bodies. Whenever a body is changing its condition, there energy is in action. Energy is the cause, change of condition the effect. The action of energy may be resisted. Change can take place only when the restraint is withdrawn or overcome. The action by which energy produces a tendency to change is called a **force.** The word *tendency* here means that the change will take place the moment the restraining influence is withdrawn. Force is thus supposed to be an imaginary intermediate link between the physical cause of a phenomenon and the resulting effect. Force is thus a manifestation of energy. Whenever resistance is overcome, energy must be expended. Hence, energy is sometimes defined as "the power to overcome resistance." Work is said to be performed whenever change takes place in opposition to a force opposing that change. Work is a manifestation of the transfer or transformation of energy. The work is done at the expense of the energy, and the amount of work is equivalent to the quantity of energy transferred. The work performed is equal to the energy expended, and just as quantity of matter is measured by weight so quantity of energy is measured by work. Consequently, energy is sometimes defined as the capacity for doing work; or, as W. Ostwald (1892)[4] puts it: *Wir werden allgemein Energie als Arbeit, oder alles, was aus Arbeit entsteht und sich in Arbeit umwandeln lässt, definiren*—energy is work and all else that can be produced from or converted into work. Not all energy is capable of doing work. There are two kinds of availability of energy for work; energy appears as if it were on two planes, a higher and a lower. The work value is a measure of the availability of energy on the higher plane; the work value of energy on the lower plane is nil. Consequently, the definition of energy as capacity for work, is valid only when it refers to a particular form of energy which is in a condition to do work; it is not a definition of energy.

Two factors are involved during the expenditure of energy in doing work: (1) The *magnitude* of the resistance; and (2) the *extent* to which the resistance is overcome. Thus, when a particle moves a certain distance s by the application of a force F the amount of energy expended is measured by the work done, and is equal to the product Fs; if a gas suffers a change in volume dv, when subjected to a steady pressure p, the work dW done during the change in volume, or the energy expended during the operation, is equivalent to the product $p.dv$. This latter problem is so important to the chemist in studying the energy changes which occur during chemical reactions in which the volume of the end-products is different from that of the initial-products, that it must be considered in more detail.

The work done by a gas when it changes its volume without changing its temperature.—Imagine a gas occupying a volume v_1, confined in a cylinder, Fig. 1, fitted with a piston to move up and down without friction; and let the constant pressure p press the piston downwards. Let the gas expand from a volume v_1 to a volume v_2 when the work performed will be equivalent to $p(v_1-v_2)$. This expression is a convenient approximation, for it can be rigorously true only when the change in volume is very small because the pressure of the atmosphere on the expanding gas does not remain quite constant, but changes slightly as the volume increases. Hence, the very small amount of work dW done when the gas suffers an indefinitely small change of volume dv, is $dW=p.dv$. With an ideal gas, $p=RT/v$; and when the expression $dW=RT(dv/v)$, obtained by substituting this value of p in pdv, is integrated for a change in volume from v_1 to v_2, the work of expansion W (temperature constant) is $W=RT \log (v_2/v_1)$, or $W=RT \log (p_1/p_2)$. The second expression represents the work done during the expansion of a gas from a pressure p_1 to a pressure p_2; and it is obviously derived by substituting for v_1 and v_2 from the relation $p_1v_1=p_2v_2$; or $v_2/v_1=p_1/p_2$. Remember also that natural logarithms are supposed to be used; if ordinary logarithms are employed, the terms on the right must be multiplied by 2·3026. The same expression also represents the work required to concentrate a solution with a vapour pressure p_1 to one with a vapour pressure p_2.

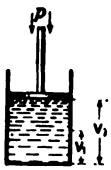

FIG. 1.

This shows that the maximum work performed by an ideal gas in increasing its volume from v_1 to v_2 is either

$$W=RT \log \frac{v_2}{v_1}; \quad \text{or,} \quad W=RT \log \frac{p_1}{p_2}$$

Otherwise expressed, the maximum work performed by an ideal gas under the given conditions is (i) dependent only on the initial and final volumes or pressures, but is independent of their absolute magnitudes; (ii) proportional to the absolute temperature; and (iii) the same magnitude for all gases which obey the ideal gas laws. The values for the constant R are indicated in Table I.—*e.g.* if the pressures are expressed in atmospheres, and volumes in litres, R is 0·0827, and the results are in litre-atmospheres.

EXAMPLES.—(1) A unit mass of gas, at 20°, is allowed to expand at a constant temperature from a pressure of 10 atm. until its pressure is one atm. The work of expansion is $2{\cdot}3026 \times 2 \times (273+20) \times \log_{10}10$ gram-cals., when $R=2$.

(2) One gram of liquid water (volume 1·043 c.c.) at 100° changes to vapour (volume 1660 c.c.) at 100° against atmospheric pressure, show that the work of expansion is equivalent to 168 joules, nearly, given $R=8{\cdot}31$.

Energy and matter are inseparable.—Our knowledge of the material world can be conveniently described in terms of two entities or abstractions: 1. Energy; 2. Matter. It is sometimes advantageous to keep these two concepts distinct; although energy and matter are separable only in thought, in reality they are indissolubly joined together. Energy is not matter, nor matter energy.[5] There can be no matter without energy, nor energy without matter. To summarize, matter is a term grouping together entities which possess certain properties in common; energy likewise is a term grouping together certain phenomena which, like matter, have many forms; and sometimes a third term, æther, is used for grouping together certain relations between matter and energy.

At first sight, common sense and science seem to support the supposition that there is a real universe existing in all its completeness quite independent of all relation to the intelligence; and that observations are made on real things which are apprehended or perceived as existing fully formed and complete in themselves. According to **the energetic hypothesis of matter,** the *objective* reality of matter is a derived idea, for the existence of matter as something external to ourselves is assumed in order to explain certain *subjective* sensations; consequently, our knowledge of the material world is founded upon our perceptions, which are in turn based upon the evidence of our senses. We do not see material objects directly, but rather experience a sensation presumably due to the formation of a picture of the object upon the retina, and which is possibly a chemical effect induced by energy radiated from the object on to the retina. Again, the mechanical energy of vibrating air may produce sensations in the auditory organs; and the mechanical energy of pressure or tension may produce sensations in the organs of touch. In this way, it can be shown that all our perceptions of the material world are derived from sensations produced by manifestations of various forms of energy. Take away the manifestations of energy, and nothing remains, since a body without a quality is indistinguishable from nothing. In this sense, the objective reality of matter can be regarded as an hypothesis, postulated to explain our subjective sensations. W. Ostwald accordingly emphasized the old idea that matter is a redundant hypothesis, a creature of the imagination designed as a carrier or vehicle of energy; and that the only things we really know are manifestations of energy. Energy and only energy is the thing in itself; energy is the real substratum of the physical and chemical world. In his *Studien zur Energetik*, W. Ostwald (1892)[6] thus describes his conversion to the energy hypothesis:

> The more intimately acquainted I became with the properties of energy, the clearer became the proof that matter is nothing but a complex of different factors of energy which possess the property of being reciprocally proportioned. The traditional fundamental properties of matter show themselves as modes of expression or factors of energy.

G. F. Fitzgerald (1896), M. Planck (1896), and L. Boltzmann (1896)[7] and others have challenged the validity of the energetic view as an elemental hypothesis which cannot be reduced to simpler terms, for kinetic energy is defined as the product of half the mass m of a moving body into the square of its velocity V, or $\frac{1}{2}mV^2$, but mass is defined in terms of kinetic energy, and the definitions thus proceed in a circle.

It is best, however, to leave the metaphysical chemist to deal with matter defined as the unknown cause of known sensations, and answer for himself such questions as: What is matter in and by itself? What is the thing matter *per se?* Whether it is better to regard matter as a passive vehicle for energy, or a particular form of energy having no existence apart from energy? The working chemist finds it convenient to assume that all sensible objects occupying space have a material substratum which accompanies these objects in their motions from place to place; and he defines: **Matter is that which possesses weight and occupies space.** Matter is thus a convenient word for grouping together those things which have the common property of weight and form. Air, water, glass, copper, etc., are forms of matter; heat, light, electricity, and magnetism are forms of non-matter—energy; colour, odour, etc., are specific properties of particular forms of matter.

Energy, like matter, is indestructible.—Whenever it has been possible to make accurate measurements, it has been found that any quantity of one form of energy is made to disappear, an equivalent quantity of another form, or forms of energy, appears. L. A. Colding, in his *Thesis on Energy* (Copenhagen, 1843),[8] said:

> Energy is imperishable and immortal, and therefore wherever and whenever energy seems to vanish in performing certain mechanical, or other work, it merely undergoes a transformation, and re-appears in a new form, but the total quantity of energy still abides.

This is the quantitative aspect of the mutual transformability of the different forms of energy. No gain or loss of energy has ever been observed in an isolated system. This is the famous **law of conservation or persistence of energy,** which appears to have been foreshadowed by R. Descartes and the Cartesian school as the law of the indestructibility of momentum or motion; and by G. W. von Leibniz as the law of conservation of *vis viva*, or force as it was then called. The perdurability of energy was also foreshadowed by Isaac Newton in 1687,[9] and by F. Mohr in 1837, although, as E. Mach[10] has shown, almost all eminent investigators had a more or less confused idea of it; and, since the time of S. Stevinus (1605), and G. Galilei in the seventeenth century, it has served as the foundation of the most important extensions of the physical sciences; and adds:

> This theorem is usually considered to be the flower of the mechanical world,—the highest and most general theorem of natural science, to which the thought of many centuries has led.

Action and reaction, said Isaac Newton, are equal and opposite; and further,

> If the activity of an agent be measured by the product of the force into its velocity, and if similarly the counter-activity of the resistance be measured by the velocities of its several parts, whether these arise from friction, adhesion, weight, or acceleration, etc., then activity and counter-activity in all combinations of machines will be equal and opposite.

The same principle was recognized to be of universal application by J. R. Mayer, in a memoir: *Bemerkungen über Kräfte der unbelebten Natur* (1842),[11] which was rejected as eminently heretical by some of the supremely orthodox journals at that time. This work was followed by that of W. R. Grove, *On the correlation of the physical forces* (London, 1843), and almost simultaneously by that of J. P. Joule,[12] in a paper, *On the calorific effects of magneto-electricity, and on the mechanical equivalent of heat*, and by that of H. von Helmholtz, *Ueber die Erhaltung der Kraft* (1847). In the writings of the brilliant N. L. S. Carnot, published after his death in 1832, there occur these remarkable words:

> Heat is simply motive power or motion which has changed its form, for it is but a movement amongst the particles of a body. Whenever motive power is destroyed, an equivalent quantity of heat is produced; and reciprocally whenever heat is destroyed, motive power is developed. It is therefore possible to establish the *thèse générale* that motive power is a quantity which is invariable in nature; that is, to speak correctly, motive power is a quantity which can neither be produced nor destroyed. True enough, it may change its form, or produce sometimes one kind of motion, and sometimes another, but it is never annihilated.

Hence, in all chemical changes, two entities—matter and energy—remain quantitatively the same, but qualitatively different. "The transactions of the material universe," said J. C. Maxwell, in that inimitable work *Matter and Motion* (London, 1894), "appear to be conducted, as it were, on a system of credit. Each transaction consists of a transfer of so much credit or energy from one body to another. The act of transfer or payment we call work." H. St C. Deville, in his *Leçons sur la dissociation* (Paris, 1864), emphasized the same idea a little differently. He said:

> All the labours and all the tendencies of modern science lead to the identification of all the forces which come into play in physical and chemical phenomena; all the numerical relations which have been obtained, establish their equivalence in the most rigorous manner.

Quantitative relation between the different forms of energy.—Energy in all its forms can be expressed in terms of one basal unit the **erg**; an erg is equivalent to a force of one **dyne** acting through one centimetre; that is, a dyne acting through one cm. generates one erg of energy. A dyne is that force which acting for one second on one gram produces a velocity of one cm. per second. The dyne is also equivalent to a weight of one gram divided by g, the **acceleration of gravity** in cm. per sec. per sec.—where $g=980{\cdot}665$ cm. per sec. per sec. at latitude 45° and sea-level. A pressure of one atmosphere equals 1,013,000 dynes per sq. cm. Weights considered as forces can be expressed and measured in terms of the dyne. The gravitational unit of energy or work is the weight of 1 gram through 1 cm., and this is equal to g dynes per cm.—that is, to g ergs. For a latitude 45° at sea-level, g is 980·617 dynes per cm. For a latitude λ, and height h metres above sea-level, Helmert's formula is $g=980{\cdot}617-2{\cdot}593\cos 2\lambda-0{\cdot}0003086h$.

The principle of the mutual convertibility of the different forms of energy assumes that there are measurable relations between the different forms, and that the modes of measurement are homologous. The possibility of measuring energy when converted from one form into another is dependent on an equation showing in what ratio the transformation has been accomplished. The ratio between heat and mechanical energy was worked out in a fairly satisfactory way by J. P. Joule in 1846–9, when he found that " 772 lbs. falling one foot would heat a pound of water 1° ; " and he called this ratio **the mechanical equivalent of heat.** Later, more exact determinations of this constant give a rather higher number than that found by J. P. Joule ;[13] the best available data range from $4{\cdot}181$ to $4{\cdot}192\times10^7$ ergs per gram-calorie at 15° ; and the best representative value is taken to be **$4{\cdot}182\times10^7$ ergs per gram-calorie at 15°.** If a **calorie** be defined as the amount of heat required to raise the temperature of one gram of water at 15° one degree, then 42·670 grams falling one centimetre will generate one calorie. Hence a calorie is equivalent to 42,670 gram-centimetres of energy. Another ratio commonly employed is the so-called **joule,** such that one joule is equivalent to 10,198 gram-centimetres of mechanical energy. Hence,

1 calorie=4·182 joules ; 1 joule=0·2423 calorie

Table I summarizes the quantitative relationship between the different forms of energy, and is convenient for reference.

TABLE I.—NUMERICAL EQUIVALENTS OF SOME FORMS OF ENERGY.

One	Gram-calorie.	Gram-centimetre.	Watt-hour.	Erg.	Litre-atmosphere.	Joule.
Gram-calorie .	1	42670	$11{\cdot}62\times10^{4}$	$41{\cdot}86\times10^{6}$	$41{\cdot}33\times10^{-3}$	4·186
Gram-cm. .	$23{\cdot}41\times10^{-6}$	1	$27{\cdot}24\times10^{9}$	80·6	$96{\cdot}77\times10^{-8}$	$98{\cdot}06\times10^{-6}$
Watt-hour .	860·3	$3{\cdot}670\times10^{7}$	1	36×10^{9}	35·53	3600
Erg . .	$24{\cdot}23\times10^{-9}$	0·00101980	$27{\cdot}78\times10^{-12}$	1	$98{\cdot}70^{-11}$	10^{-7}
Litre-atm. .	24·54	$10{\cdot}332\times10^{4}$	$28{\cdot}15\times10^{-3}$	$10{\cdot}13\times10^{8}$	1	101·3
Joule . .	0·2423	10198	$27{\cdot}78\times10^{-5}$	10^{7}	0·00987	1
Gas constant, R	1·9885	847	—	$8{\cdot}31\times10^{7}$	0·08207	8·316

The index notation is used for representing small or large magnitudes as powers of 10. Thus $10^1=10$, and $10^{-1}=\frac{1}{10}$th, or 0·1 ; $10^2=100$, and $10^{-2}=\frac{1}{100}$th, or 0·01 ; $10^3=1000$, and $10^{-3}=\frac{1}{1000}$th, or 0·001. The positive index, therefore, represents the same number of cyphers as the index number, and the negative index one cypher less after the decimal point than the index number.

Perpetual motion.—The law of persistence of energy is sometimes called **the first law of thermodynamics,** or **the first law of energetics,** and it can be expressed another way. No machine can generate energy or do work of itself without consuming at least an equal quantity of pre-existing energy. Energy cannot be produced from nothing, something must be consumed. A machine can do no work without the aid of an external driving force—energy. It is impossible to construct a machine which will do work without parting with energy ; when all the energy is consumed, the machine can do no more work until more energy is supplied from without. This revised statement of the law of persistence of energy is called **the law of excluded perpetual motion.** This law does not mean that perpetual motion is theoretically impossible, but it does mean that work cannot be done without a supply of compensating energy, for no work can be performed without a loss of motion or the expenditure of energy. Isaac Newton's first law really postulates perpetual motion as the normal state of a body moving without constraint in a frictionless medium. Perpetual motion implies a sustaining and propelling source of energy in order to compensate the losses necessarily entailed in overcoming friction, etc. No system can furnish an inexhaustible supply of energy. Neither gravitation nor magnetism can supply energy which will make good its own loss.

Even as early as 1269, P. Peregrinus alluded to the quest for the *perpetuum mobile* as a pursuit where many had " wandered about wearied with manifold toil." In all times, recent and modern, sanguine seekers after perpetual motion have attempted to circumvent the law of the conservation of energy. C. E. Benham has said that " the playful way in which nature presents us with phenomena sometimes seems as if they has been cunningly devised to lure and entrap the human mind into a belief in the possibility of achieving this unattainable result." The impossibility of perpetual motion seems to contradict the one phenomenon which is universal and constant and which is more striking than any other. From the incessant movements of celestial spheres down to the congeries of rapidly vibrating atoms and electrons in every created thing, everything appears to be in perpetual motion. It is therefore inferred that the apparent perpetuity of the movement is illusory ; that these movements represent but an intermediate stage in a vast universe which is slowly sinking into a state of final quiescence, when all motion will cease to be. It must be candidly confessed that we can offer no real proof of the truth of this law, other than the uncontradicted experience of mankind with finite systems which admit of observation.[14] It is obviously not sound reasoning to infer that because a phenomenon always has been, it will therefore always be. Knowledge which has appeared to be certain for hundreds of years may suddenly prove to be gross ignorance. We assume that if perpetual motion has been possible it would have been discovered long ago. Of course a similar argument might have been used in 1890 against the existence of a gas like argon in the atmosphere, and the " uncontradicted experience " would have been contradicted four years later. Consequently, evidence of this kind can never attain certainty, and we can only say that the wider the uncontradicted experience, the stronger is its testimony that the empirical law is valid, and the less likely is the necessity to arise for a thorough revision of the fundamental statement. The search for a perpetual motion through centuries of laborious work has been fruitless. It has brought nothing but failure. So great is our faith in the truth of this unproved law that a demonstration showing that any supposed process would involve a perpetual motion or the creation or destruction of energy, is considered sufficient proof that the supposed process is impossible. We assume with M. Faraday (1857) : " No hypothesis should be admitted nor any assertion of fact credited that denies this principle. No view should be incompatible or inconsistent with it." Most scientific societies would refuse to consider seriously papers which violated the assumed law of excluded perpetual motion.

Algebraic statement of the law of conservation of energy or the first law of energetics.—According to the principle of the conservation of energy, if an amount of work W be performed by a body against external forces (say, atmospheric pressure), when q units of heat are absorbed by the system, the change in the internal energy dU which the system suffers in consequence of the isothermal change will be :

$$\underset{\text{internal energy.}}{\overset{\text{Decrease of}}{dU}} = \underset{\text{absorbed.}}{\overset{\text{Heat}}{(+q)}} \quad \underset{\text{performed.}}{\overset{\text{Work}}{-W}}$$

in words, the changes in the internal energy U, which a system suffers in consequence of an isothermal change, is equivalent to the amount of heat absorbed less the external work W done by the system.

In 1862, R. Clausius[15] drew a clear distinction between the external and internal work which a body can do when it changes its state. The term **external work,** W, refers to work due to the action of external forces on the system, *e.g.* (i) Expansion against an external pressure (usually atmospheric); (ii) Resistance to changing its form (*i.e.* distortion); (iii) Changes in surface area against capillary forces; and (iv) Electric or magnetic forces when a body is moved from a high to a lower potential. The term **internal energy or work,** U, includes: (i) The increased kinetic energy of the molecules which causes a rise of temperature; (ii) Intermolecular work done by or against molecular forces when the volume, cohesion, or elasticity is changed; (iii) Intramolecular vibrations, *i.e.* atomic vibrations within the molecule; and (iv) Chemical work as when a body changes its state, etc.

From the energetic point of view, the heat q is conventionally *positive* if the system *absorbs* heat; and *negative* if the system evolves heat; if the external work W be done *by* the system, W will be *negative*, and *positive* if done *on* the system; the internal energy, U, is *negative* when *U diminishes*, and *positive* when U increases. If the system does no external work, as occurs when a chemical reaction takes place in a calorimetric bomb, $W=0$, and $U=q$, meaning that in an isothermal change the system will gain an amount of internal energy equivalent to the amount of heat absorbed. In most calorimetric work, the pressure, not the volume, is constant, and if v_1 and v_2 respectively denote the initial and final volumes under a constant pressure p, and U_1 and U_2 the initial and final energies of the system, the preceding equation can be written:

$$U_2-U_1=q-p(v_2-v_1)\text{ ; or, }q=(U_2+pv_2)-(U_1+pv_1)$$

Hence, the heat absorbed in the reaction depends on the initial and final states of the system. In the more general case, if $v_1, v_1' \ldots$ represent the volumes of the substances consumed in a reaction under the respective pressures $p_1, p_1' \ldots$, $v_2, v_2' \ldots$, and $p_2, p_2' \ldots$, the corresponding values for the substances produced on the reaction, then, if U_1 represents the internal energy of the substances destroyed in the reaction, and U_2 that of the substances produced,

$$U_2-U_1=q-\{(p_2v_2+p_2'v_2'+\ldots)-(p_1v_1+p_1'v_1'+)\}$$

which may be more conveniently symbolized, $U_2-U_1=q-(\Sigma p_2v_2-\Sigma p_1v_1)$. Where q denotes the thermal value of a reaction at ordinary atmospheric pressures, the symbol Q may be used in place of q, and

$$Q=(U_2+\Sigma p_2v_2)-(U_1+\Sigma p_1v_1)\text{ ; or }Q=U+\Sigma pv$$

The magnitude $U+\Sigma pv$ is called the heat content of a given system.

EXAMPLES.—(1) If one gram of liquid water, whose volume is 1·043 c.c. at 100°, be converted into vapour occupying 1661 c.c. at 100°, against atmospheric pressure in consequence of the absorption of 537 cals. (heat of vaporization), show that the increased internal energy in consequence of the vaporization will be 2087 joules. The external work of expansion is 168 joules; and $537\times4{\cdot}2=2255$ joules is equivalent to 537 cals. Hence, $U=168$ less $2255=-2087$ joules. If the vaporization could be made to take place without an increase in volume, no external work would be done, and the increase in internal energy would be equivalent to 2255 joules.

(2) If a zinc rod be immersed in a solution of copper sulphate a reaction symbolized $Zn+CuSO_4=ZnSO_4+Cu$ occurs, and the transformation of chemical energy generates a calories of thermal energy; no external work is done, so that $W=U$. If the system be so arranged that the chemical energy is transformed into electrical energy—say, by placing a zinc rod in a solution of zinc sulphate contained in a porous pot immersed in a solution in which a copper rod is partly immersed, and connecting the exposed parts of the two rods by wire—b calories of thermal energy are at the same time evolved. Then U, the electrical energy produced, will be equivalent to $b-a$ cals.

Relation between the laws of conservation of energy and of matter.—In 1902, Lord Rayleigh[16] showed that if a real change in weight could be demonstrated during a chemical reaction, perpetual motion would be possible. In the reversible chemical action $A \rightleftharpoons B$, let the system in the state A be initially at a low level, and then raised (in vacuo) to a higher level when the system is transformed into the state B. Then let the system be returned to the lower level and transformed into the state A. The temperature is maintained constant during the whole of the operations. The reversed chemical reactions compensate one another and there is no gain or loss of energy; the operations of raising and lowering the two systems do not compensate one another unless the weights of the system in the two states A and B are the same. If the weights be different, the cycle of operations can be so executed that work is gained, and perpetual motion becomes possible. Hence, unless something has been overlooked, there cannot be a difference in the weights of a system in the two states A and B. In spite of this demonstration, attempts are not infrequently made to show that chemical changes involve a real loss of weight too small to be detected by the balance.

Kinetic and potential energy.—There is an important difference between a stone lying on the ground and a similar stone lying on the table. Both appear alike to be motionless, yet the latter possesses more available energy than the former. For example, the stone on the table, in descending to the ground, could be made to transfer its energy to the mechanism of a clock, and do work. The available energy would thus be transformed into mechanical motion. For the same reason, a wound watch spring possesses more available energy than a similar spring not wound up. Thus available energy may be conventionally regarded as active (*i.e.* kinetic) or passive (*i.e.* latent or potential). When a marble is rolling along the ground, it has the power, in virtue of that motion, to change the state of another marble with which it might collide. A body, therefore, might possess energy in virtue of its motion. This energy is said to be in a *kinetic* or active condition. In 1686, G. W. von Leibniz, in a memorable controversy with R. Descartes, established the proposition that the *vis viva*—the living energy—or, as it is now called, the available **kinetic energy** K, of a body of mass m moving with a velocity V, is $K=\frac{1}{2}mV^2$. This energy may be transformed into heat when the motion of the body is arrested. In contrast with this, it is sometimes convenient to use the term **potential energy,** suggested by W. J. M. Rankine in 1853, for the available energy which is potential to, possible to, or latent in a body in virtue of its condition with respect to surrounding objects; in G. W. von Leibniz's terminology this would be the *vis mortua* of the system. The distinction between potential and kinetic energy was recognized by Aristotle (*c.* 320 B.C.), and he called the former ἐν δύναμει (dynamic) and the latter ἐν ἐνεργεία (energetic); and in 1803, N. L. S. Carnot called potential energy the *force vive latente.*

When a stone is lifted above the ground, the energy expended and the work done depend upon the weight w of the stone, and the height h to which the stone has been lifted. Consequently, the available potential energy E of the stone will be $E=wh$. The meaning is that a measurable quantity of energy is stored up or rendered passive in some way, and that this same amount of energy can be recovered. For instance, when the stone returns to the ground, it will in falling acquire an equivalent amount of kinetic energy. Kinetic and potential energy are here referred to the earth as constant, for obviously the suspended stone would have no available potential energy if it could never fall. Again, water in an elevated position can do work, in virtue of the law that all liquids will flow to the lowest level that circumstances will permit. Consequently, water at the top of a hill possesses potential energy. A bent spring, a raised hammer, compressed air, and a piece of iron in the vicinity of a magnet, all possess potential energy. Substances which in virtue of their relative condition, or the motions of their constituent molecules, are capable of entering into chemical actions, are also said to possess potential energy. Such are gunpowder, a mixture of metallic zinc and sulphuric acid, etc. The light, heat, sound, and mechanical motion which attend the explosion of gun-cotton are equivalent to the chemical energy stored in the explosive.

For convenience, the different forms of energy are usually classified as mechanical and kinetic energy; potential energy involving stress or strain; thermal energy; actinic and radiant energy; electric energy; magnetic energy; and chemical energy. Each of these, in turn, can be regarded either as energy of tension, or energy of motion.

§ 2. Thermochemistry

Heat and cold are nature's two hands by which she chiefly worketh.—FRANCIS BACON (1627).

Sine igni nihil operamur.—C. GLASER (1663).

It has been shown that matter, as we know it, can be resolved into two abstractions—matter and energy. Neither exists alone. We have no acquaintance with the one apart from the other. Isolated, matter and energy are pure abstractions. Each one completes and presupposes the other. The element phosphorus, for instance, can be regarded as a form of matter which is always associated with a certain amount of free or available energy, because it is able to do chemical work, and we cannot conceive of energy coming from nothing. We cannot answer: How much energy is associated with the phosphorus? The actual amount available possibly depends upon the nature of the substance with which it is brought in contact. Similarly with oxygen. When these two elements—oxygen and phosphorus—are brought in contact, under the right conditions for the degradation of energy, chemical action sets in, and the chemical energy is degraded or transformed into heat or light. The resulting compound—phosphorus pentoxide—still contains some chemical energy, for if it be mixed with water, a great amount of heat is developed, chemical energy is degraded, and phosphoric acid results. The phosphoric acid still contains chemical energy because more energy is degraded in the form of heat when the phosphoric acid is brought into contact with sodium hydroxide. **Every chemical reaction involves a change both in the form of the matter and in the form of the energy of the system.**

Modern chemistry would make C. Glaser's old motto read: Without available energy nothing can change. What is generally understood by descriptive material or chemistry deals with matter, not with energy. Chemistry proper is essentially concerned with both energy and matter; and hence, it can no longer leave the development of the energy concept, as was formerly done, exclusively to physics and mechanics. The fundamental part played by energy in determining the nature and character of chemical processes was for a long time obscured by the erroneous notion that all forms of energy are but forms of mechanical energy. This idea was perhaps the illicit consequence of man's early familiarity with mechanical energy. First impressions are obstinately persistent. It was not easy for man to realize that mechanical energy is but one phase of a much wider and more comprehensive concept which includes all the other different forms of energy. It has been as difficult for the chemists to recognize that energy is an entity with which he has to deal, as it was for the alchemists to realize that gases and vapours are of material importance in the study of chemical changes.

The law of Lavoisier and Laplace.—The free or available chemical energy of different substances is usually degraded in the form of heat during chemical action. The system gets hotter because heat is evolved by the reacting substances —such reactions are said to be *exothermic or thermopositive reactions* in contrast with *endothermic or thermonegative reactions* which consume heat and thus cause the system to become cooler. That branch of chemistry which deals with the relation between thermal and chemical energy is called **thermochemistry.** The heat evolved during a chemical reaction is proportional to the quantity of the reacting substance, and as a convenient standard, the amount of heat given out at constant volume and temperature per gram-molecule of the reacting substance is called **the heat of the reaction**; this heat Q is wrongly supposed to be a measure of the decrease in the internal energy of the substance. Experiment shows that a definite chemical process generates a definite amount of heat. Every compound has a definite heat of formation, which is numerically equal to the heat required for the decomposition of the compound back into its elements, but of opposite sign. Action and reaction, says Newton's third law, are equal and opposite. This is obviously a corollary of the law of the conservation of energy. If it were not so, heat would be gained or lost when a compound is formed and then decomposed back into its original constituents. Such a result is at variance with the principle of the persistence or conservation of energy. The fact that **every compound has a definite heat of formation which is numerically equivalent to its heat of decomposition but of opposite sign,** is sometimes called the **law of Lavoisier and Laplace,** because A. L. Lavoisier and P. S. de Laplace[1] first pointed out this generalization, in their *Mémoires sur la chaleur*, published between 1780–4. Consequently, under a given set of conditions, it seems as if each atom and each molecule is charged with an amount of energy which is as definite as the quantity of matter itself. The important conclusion of A. L. Lavoisier and P. S. de Laplace was later verified by the work of H. Hess (1836–40), T. Andrews (1844), P. A. Favre and J. T. Silbermann (1844–6), T. Woods (1851), and others,[2] and data were accumulated showing the thermal values of various chemical reactions. A large mass of thermochemical data for various chemical or physicochemical processes has been accumulated by J. Thomsen, M. Berthelot, and others, and most has been compiled in H. Landolt and R. Börnstein's *Physikalisch-chemische Tabellen* (Berlin, 1912).[3]

The symbols used in thermochemistry.—It will be remembered that in physics, the unit of heat is the **calorie,** and a calorie represents the amount of heat required to raise the temperature of one gram of water, at some convenient standard temperature, through 1° C. Consequently, 100 cals. will raise the temperature of 100 grams of water 1°, or of 1 gram of water 100°. Sometimes it is convenient to take a pound of water as the unit, and a **pound-calorie** is then the amount of heat required to raise the temperature of a pound of water 1° C.; if the degree Fahrenheit be the unit of temperature, the amount of heat required to raise the temperature of one pound of water 1° F.—say from 60° F. to 61° F.—is called a **British thermal unit**, B.T.U.; the latter unit is used by many engineers. To convert a big calorie into a B.T.U. multiply by 3·9681 and for the converse operation multiply by 0·2522; to convert a pound-calorie into a B.T.U. multiply by 1·8; and for the converse operation, multiply by 0·555.

In chemistry it is convenient to represent the thermal value or heat of a reaction by reference to the formula weight or the gram-molecule of the substance concerned in the reaction. Thus, the heat of formation of phosphorus pentoxide, taken at P_2O_5, is 370,000 cals. This means that 370,000 cals. are generated when 142 grams of phosphorus pentoxide are formed by burning 62 grams of phosphorus in oxygen; or 62 grams of phosphorus burning in oxygen will give sufficient heat to raise the temperature of 370,000 grams, or 370 kilograms of water, 1°. To avoid dealing with large numbers it will be more convenient to consider a **Calorie** as the amount of heat required to raise the temperature of 1000 grams of water 1° C. This is the so-called **kilogram-calorie,** or the **big calorie,** and calorie is then written with a capital C. Thus *cal.* refers to the gram-calorie, *Cal.* refers to the kilogram-calorie. Hence the energy degraded in the form of heat when phosphorus burns in oxygen is equivalent to 370 Cals. This is represented in symbols, $2P+5O=P_2O_5+370$ Cals. Some represent gases by means of italics, solid by clarendon type, and liquids by ordinary type; and some put a bar over the symbol for gases, and under the symbol for solids; some also abbreviate the first equation $(2P, 5O)=370$ Cals.

Within certain limitations to be discussed later, the heat produced in a chemical reaction has been attributed solely to the degradation of chemical energy, but in many cases there are disturbing factors from differences in the physical properties of the initial and end products of the reaction, etc. For example—

(1) *Differences in the states of aggregation or volume of the initial and final products of the reaction.* Thus, a compound formed in a gaseous reaction may become liquid or solid. If the states of aggregation of the reacting constituents are not self-evident, they must be represented in the equation, otherwise, latent heats of fusion or vaporization may lead to ambiguity. Thus, with vapour at 0°, $2H+O=H_2O_{gas}+57·82$ Cals. means that the union of 2 grms. of hydrogen with 16 grms. of oxygen is attended by the evolution of 57·82 big calories when the water produced is in the form of steam; if the steam be condensed to a liquid at 0°, $2H+O=H_2O_{liq}+68·63$ Cals. The extra 10·81 Cals. represent the heat given out when 18 grms. of steam are condensed to a liquid; for solid ice, another 1·4 Cals. would have to be added to allow for the heat of solidification of 18 grms. of liquid water into ice.

It is necessary to distinguish clearly between the observed heat changes and the real heat changes due to the degradation of chemical energy as heat. The observed thermal value of a chemical reaction may be greater or less than that which corresponds with the chemical energy actually degraded during a given chemical reaction. For example, in the reaction between metallic sodium and chlorine gas, $2Na_{solid}+Cl_{2gas}=2NaCl_{solid}+194·6$ Cals., there is a large *contraction,* and work is done *on* the system by the pressure of the atmosphere; on the other hand, when hydrochloric acid acts on zinc, there is a comparatively large *expansion,* and work is done *by* the system against atmospheric pressure. With hydrogen and chlorine, when one volume of each elementary gas produces two volumes of hydrogen chloride, $H_2+Cl_2=2HCl+22·0$ Cals., there is no disturbing factor of this kind. Suppose that we start with a mixture of two volumes of hydrogen and one volume of oxygen, and finish with liquid water, there is a tremendous contraction in volume. This contraction occurs under atmospheric pressure (76 cm.). Hence, the atmosphere does work *on* the system, and that work appears as heat which raises the temperature of the system, and makes the observed heat of combination appear greater than it really is. The work can easily be calculated, and it is equivalent to 0·9 Cal.

One gram-molecule of steam occupies 22·3 litres. The gases from which the steam was formed occupied 1½ times this volume, *i.e.* 33·45 litres. A column of mercury 1 sq. cm. sectional area and 76 cm. long weighs $76\times13·59=1033$ grms.—since the specific gravity of mercury is 13·59. This pressure exerted along a path of 33·45 cm. will be $33·45\times1033$

gram-centimetres, or 33·45 × 1·033 kilogram-centimetres. Since 42·65 kilogram-centimetres are equivalent to one calorie, 33·45 × 1033 ÷ 42·65 = 80 cals., or 0·8 Cal. This discussion can be generalized. Every kilogram-molecule of any gas at 0°, occupying 22·4 cubic metres, when evolved during a chemical reaction, will absorb 0·542 Cal., and $0{\cdot}542(1+0{\cdot}00366\theta)$ cal. when the gas is evolved at the temperature θ. The heat absorbed in this way is evolved again when the gas is absorbed by a liquid or solid.

Correcting the observed heat of combination of hydrogen and oxygen 69·3 Cals. for the contraction due to the condensation of steam to liquid water, we get, per kilogram-molecule (18 kilograms) of water:

Apparent energy degraded in the reaction	69·53 Cals.
Energy due to the contraction	0·81 Cal.
Energy actually due to the reaction	68·72 Cals.

Consequently, when the gases are measured at constant pressure, not quite one per cent. of the heat of the reaction is due to work done on the gas by atmospheric pressure. Otherwise expressed, the thermal value of the reaction at constant volume will be 68·72, and at constant pressure 69·53. The difference is not great, and it is within the limits of experimental error when the results of different observers are compared.

Gas engineers [4] express the calorific power of a gas in terms of the number of pounds of water which can be raised 1° F. by the complete combustion of one cubic foot of the gas, at n.t.p., on the assumption that the water formed during the combustion is condensed to the liquid state at 212° F. This is the *gross calorific value.* If the steam formed by the burning gas remains as a gas, the latent heat of steam must be deducted from the gross calorific value, the result is termed the *net calorific value* of the gas.

The apparent failure of chemists to handle the great mass of thermochemical data satisfactorily is in part due to the fact that the real heats of chemical reactions are obscured by unknown latent heats, and heat spent in doing work of different kinds. W. Sutherland (1895) [5] claims that "the ideal condition in which thermochemical data should be presented, is that in which they relate to the heats of formation at constant volume of the gaseous products from gaseous elements." By direct calculation he makes an estimate of the heats required to vaporize a number of metals and non-metals, and also of their binary compounds. He corrects the heats of formation of a number of binary compounds so as to make them represent the heats of formation of gaseous compounds as the result of the combination of gaseous metals and non-metals. It is then found that the atoms in combining chemically evolve integral multiples of a quantity of heat 3·8; and that each atom in passing from the elementary to the combined state evolves a definite amount of heat irrespective of the other atoms with which it combines. This generalization has not yet been established directly from observed data; if it be true, allowance would have to be made for a third factor since the available evidence rather shows that the amount of heat evolved during a chemical combination also depends upon the mutual relations of the atoms in the molecules.

(2) *Reactions in solution.*—Again, if the reacting substances are in solution, a certain amount of heat may, or may not, be dissipated in the act of solution. For example, 13·7 Cals. are evolved when a dilute solution of sodium hydroxide is mixed with a dilute solution of hydrochloric acid. The dilute solution is represented by the suffix *aq*. Thus, $\mathrm{NaOH_{aq.}+HCl_{aq.}=NaCl_{aq.}+H_2O+13{\cdot}7}$ Cals. If the sodium chloride were prepared by passing hydrogen chloride gas into a dilute solution of sodium hydroxide, more heat is evolved, because 17·4 Cals. are evolved when 36·4 grms. of hydrogen chloride are dissolved in water: $\mathrm{NaOH_{aq.}+HCl_{gas}=NaCl_{aq.}+H_2O+31{\cdot}1}$ Cals.

(3) *Effects of allotropism and isomerism.*—Again, the physical and chemical condition of the reacting substances must be taken into consideration. At the beginning of his thermochemical studies, M. Berthelot [6] was careful to emphazise

the fact that *la quantité de chaleur dégagée dans une réaction quelconque mesure la somme des travaux chimiques et physiques accomplis dans cette réaction.* The heats of combination of hydrogen in oxygen and in ozone would not be the same because of the reaction $2O_3=3O_2+68{\cdot}2$ Cals. Allowance would have to be made for the extra energy associated with the ozone. The molecules of ozone are charged with energy at a higher potential than the molecules of oxygen, and when the ozone passes into ordinary oxygen, this energy is degraded in the form of heat. The fact that the molecules of ozone are charged with a large amount of energy is supposed to explain why ozone decomposes so readily into oxygen—sometimes with explosive violence. Precipitated silver (108 grms.), dried at 120°, liberates 0·76 Cal. when dissolved in mercury, while the same amount of silver beaten into a thin plate, and treated similarly, evolves 2·03 Cals. The extra energy stored in the hammered metal is liberated as heat during the dissolution in the mercury. If two similar springs, one wound, and the other unwound, be dissolved separately in acid, it is said that a greater amount of heat is developed during the dissolution of the wound spring, because the energy stored in the wound spring is degraded as heat during the dissolution in acid.

(4) *Preliminary dissociation of the reacting molecules.*—It will be observed that in the reaction between two gaseous elements A and B, with molecules respectively A_2 and B_2, the heat evolved or absorbed in breaking the molecules down into atoms is ignored. The assumption is virtually made that the heats of formation of the molecules of the elements from their atoms is zero. This cannot be justified even if we are ignorant of these constants. The observed heat Q of the formation of the compound AB from the molecules of its component elements is a resultant effect. Let q_a denote the heat of formation of the molecules A_2, and q_b the corresponding value for the molecules B_2. It then follows (from Hess' law, *vide infra*) that the heat of formation, q, of the compound AB from its elements is really $Q+\frac{1}{2}(q_a+q_b)=q$. An estimate of the thermal values of chemical reactions can be made when the equilibrium constant K is known. In this way, E. Briner (1914)[7] computed the heats of formation of a gram-molecule of the following elements :

	I_2	Br_2	Cl_2	S_2	H_2	N_2
Temperature . .	1390°	1050°	1670°	2177°	2427°	3500°
Equilibrium constant	0·66	0·06	0·01	0·50	0·10	—
Heat of formation .	32·4	57·0	113·0	120·0	130·0	150·0 Cals.

Hence, in the reaction $H_2+Cl_2=2HCl+44{\cdot}0$ Cals., the dissociation of the hydrogen molecules absorbs 130·0 Cals. and the chlorine molecules 113·0 Cals., or jointly, 243·0 Cals., so that the observed thermal value of the reaction 44·0 Cals. must be increased to 287·0 Cals., if the hydrogen chloride molecules are formed from atoms. Hence, the real thermal value of the reaction $H+Cl=HCl$ is not 22·0 but 143·5 Cals. Similarly,

	HCl	HBr	HI
Heats of formation from molecules, Q .	22·0	12·4	1·45 Cals.
Heats of formation from atoms, q . .	143·5	105·9	84·8 ,,

So far as the evidence goes, E. Briner (1914) concludes : **The heats of formation of all the compounds from the atoms of their elements are exothermal.** The observed heat of formation, Q, of a compound from its elements is therefore the difference between two magnitudes such that $Q=q-\frac{1}{2}(q_a+q_b)$, and a compound will appear to be exo- or endo-thermal according as the heat of its formation from atoms is greater or less than the mean of the heats of formation of the molecules of its component elements from their atoms. The heat of formation of the nitrogen molecule from its atoms is comparatively large, and accordingly, this element forms many endothermal (NO, N_2O, NCl_3, etc.) or feebly exothermal (NH_3, etc.) compounds. K. Fehrle (1918) has attempted to calculate the heat of a reaction on the assumption that the atoms of spherical molecules rotate about a common centre.[8]

(5) *Differences in the specific heats of the initial and final products of the reaction.*—Heat may also appear to be generated during a chemical reaction which is partly due to differences in the specific heats of the initial and final products of the reaction. If the latter be less than the former, some of the heat generated will be due to the fact that latent heat originally present can no longer be accommodated, so to speak, owing to the diminished capacity of the system for heat, and there is an output of heat during the reaction in excess of that corresponding with the degradation of energy. In illustration, J. Thomsen (1882) has shown that when ½N-sodium hydroxide is neutralized by an equivalent amount of hydrochloric acid, the thermal capacity of the system increases about 1·37 per cent. Hence, measurements of the thermal changes which occur during a chemical reaction should be supplemented by measurements of the heat capacities of the substances concerned in the reaction.

The temperature coefficient of a reaction.—Consider a reaction in which a substance A changes into B such that A→B. Let the reaction proceed at the temperature T_1 when Q_1 units of heat are absorbed; then heat the product B to the temperature T_2. If C_p and C_p' respectively denote the thermal capacities or molecular heats of the initial and final products of the reaction, the total energy absorbed in changing A at T_1 to B at T_2 is equal to $Q_1+C_p'(T_2-T_1)$. Again, the same final state can be obtained by heating A to T_2, and allowing the reaction to occur at that temperature. Let Q_2 denote the heat of the reaction at T_2, then it follows from the law of conservation of energy: $Q_2+C_p(T_2-T_1)=Q_1+C_p'(T_2-T_1)$; or $(Q_2-Q_1)/(T_2-T_1)=C_p'-C_p$. If the difference T_2-T_1 be taken indefinitely small, say dT, the difference Q_2-Q_1 will also be indefinitely small, say dQ, and at the limit, we thus obtain

$$\frac{dQ_p}{dT}=C_p'-C_p$$

where dQ/dT is the so-called *temperature coefficient of the reaction*. This equation is sometimes called—after G. Kirchhoff (1858)[9]—**Kirchhoff's equation.** The equation can be taken to mean that *at any assigned temperature, the change in the quantity of heat concerned in a reacting system, kept at constant volume, per degree rise of temperature is equal to the difference in the thermal capacities of the initial and final states of the system*, which for convenience can be written $-\Sigma C_p$. From Mayer's formula, $C_p-C_v=R-p$, it follows that $-\Sigma C_p=-\Sigma(C_v+R)$, and hence

$$\frac{dQ_p}{dT}=-\Sigma C_p;\text{ or, }\frac{dQ_p}{dT}=-\Sigma(C_v+R)$$

The influence of temperature on the heat of a reaction is *directly* determined by measuring the heat of the reaction at two different temperatures; the equation enables this magnitude to be calculated when the specific heats of the initial and final products of the reaction are known. If the molecular heats of the initial and final products of a reaction are the same, $C_v=C_v'$, and the temperature coefficient will be zero, otherwise expressed, the amount of heat evolved during the reaction will be the same at all temperatures. If C_p' be greater than C_p, the molecular heat of the product of the reaction will be greater than the original initial substance, the heat of the reaction will decrease with the rise of temperature; and if C_p be greater than C_p', the molecular heat of the product of the reaction will be less than that of the initial substance, the heat of the reaction will increase with rise of temperature.

EXAMPLES.—(1) According to L. Holborn and F. Henning (1907), the molecular heat of hydrogen, H_2, and of oxygen, O_2, is $4·68+0·00026T$, and of water, H_2O, $5·61+0·000717T$. Hence, the difference between C_v' and C_v for the reaction $2H_2+O_2=2H_2O$ at constant volume is $3(4·68+0·00026T)-2(5·61+0·000717T)=2·82-0·000654T$, and this is the temperature coefficient of the reaction.

(2) According to H. V. Regnault (1862), the molecular heat of hydrogen at constant

volume is $4{\cdot}82(\theta-18)$, of oxygen $4{\cdot}96(\theta-18)$, and of steam, H_2O, $18(\theta-18)$; and J. Thomsen observed that at 18°, the thermal value of the reaction $H_2+O=H_2O+67{,}484$ cals. What is the thermal value of the reaction $H_2+O=H_2O$ at 50° at constant volume? Here $H_2+O=H_2O$ is represented by $(4{\cdot}82+2{\cdot}48-18)\ (50-18)$ or $-10{\cdot}7\times32=342{\cdot}4$. Hence, the thermal value of the given reaction at 50° is 67,484 less $342{\cdot}4=67{,}142$ cals., nearly, when the volume of the system is the same at 50° as it was at 18°.

(3) According to L. Holborn and F. Henning (1907), the molecular heats of oxygen or carbon monoxide is $4{\cdot}68+0{\cdot}00026T$, and of carbon dioxide $5{\cdot}106+0{\cdot}00334T-7{\cdot}35\times10^{-7}T^2$. Hence show that dQ/dT for the reaction $2CO+O_2=2CO_2$ is $3{\cdot}828-0{\cdot}0059T+0{\cdot}000000735T^2$.

According to I. W. Cederberg,[10] the molecular heat of a vapour C_p and of solid or liquid C_p', at $T°$ is $C_p=2{\cdot}5R+1{\cdot}3125aT^{\frac{3}{4}}$; $C_p'=1{\cdot}3125a'T^{\frac{3}{4}}$, where a and a' are constants characteristic of particular substances. Consequently, from G. Kirchhoff's equation, for the heat of vaporization λ,

$$\frac{d\lambda}{dT}=2{\cdot}5R-1{\cdot}3125(a-a')T^{\frac{3}{4}}\text{; or, }\lambda=\lambda_0+2{\cdot}4RT-0{\cdot}75(a-a')T^{\frac{7}{4}}$$

where λ_0 denotes the latent heat of vaporization at absolute zero. Similarly, for the thermal value of a reaction Q_v,

$$\frac{dQ_p}{dT}=\Sigma2{\cdot}5R-\Sigma1{\cdot}3125(a-a')T^{\frac{3}{4}}\text{; }Q_p=Q_0+2{\cdot}5\Sigma RT+0{\cdot}75\Sigma(a-a')T^{\frac{7}{4}}$$

where Q_0 represents the heat of the reaction at 0°.

§ 3. The Principle of Maximum Work

> In exothermic combination the sum of the specific energies of the component elements exceeds the specific energies of the compounds formed, while in endothermic combination, the specific energies of the compounds formed is greater than the aggregated specific energies of the components.—J. B. Stallo.

The heat developed during a reaction represents a certain amount of potential energy which was associated with the atoms in some way; and there is a temptation to generalize, as J. Thomsen [1] did in his paper *Die Grundzüge eines thermochemischen Systems*, in 1853, and assume that the total quantity of heat developed during a chemical reaction is a measure of the chemical affinity of the reacting substances—*die ganze durch eine chemische Wirkung erzeugte Wärmemenge ist also ein Masse für die durch dem Process entbundene chemische Kräfte*—and that every chemical change which can take place without the aid of external energy will be accompanied by an evolution of heat. *L'affinité était la cause*, said H. St. C. Deville (1860), *la chaleur dégagée est l'effet produit par cette force et lui est proportionelle.* The same idea was emphasized by M. Berthelot in his *Recherches de thermochimie* in 1869, when he boldly formulated his celebrated **principle of maximum work : Every chemical change which takes place without the aid of external energy, tends to the production of that system which is accompanied by the development of the maximum amount of heat**—*le principe du travail maximum : tout changement chimique, accompli sans l'intervention d'une énergie chimique étrangère, tend vers le production du corps ou du système de corps qui dégage le plus de chaleur.* To take an oft-cited mechanical analogy, the heat evolved by the impact of a falling body on the ground bears a definite relation to the height from which it fell, and heights might be measured by the heat developed by falling bodies if it were not that more convenient methods are available. With chemical reactions, the heat evolved is assumed by M. Berthelot to measure the mechanical work done, *i.e.* the loss of chemical energy; otherwise expressed, **elements with the stronger affinity for one another disengage most heat during chemical action.** The production of heat does not of course explain why the reaction takes place any more than the heat developed when a falling body strikes the earth explains gravitation.

It follows from Berthelot's principle that reactions which proceed spontaneously, when once they have started, liberate some form of energy, generally heat, during the progress of the reaction. In illustration, the heat of formation of calcium oxide is 131 Cals.; of lead oxide, 50 Cals.; and of mercuric oxide, 31 Cals. Calcium oxide is not decomposed by heating it to redness in a tube, either alone or in a current of hydrogen; lead oxide is not decomposed by heating it alone, but it is decomposed by heating it in a current of hydrogen; and mercuric oxide is reduced by either treatment. Again, the heats of solution of the following metals in dilute hydrochloric acid, per equivalent of metal, expressed in grams, are:

K	Na	Ca	Mg	Zn	Fe	Cu
61·8	57·2	54·3	54·1	17·4	10·7	−10 cals.

This agrees with the order of affinity for these metals deduced from other considerations. The negative heat of the reaction between copper and dilute hydrochloric acid corresponds with the fact that the action does not occur under ordinary circumstances, and the heat of the reaction has to be determined indirectly from the action of the acid on the oxide of the element in question.

There are some objections to the principle of maximum work as formulated by M. Berthelot. Lord Rayleigh, in a paper *On the dissipation of energy* (1875), showed that it is not the evolution of heat but the dissipation of energy which determines whether a chemical transformation is possible or not; no dissipation of energy, no transformation. Six years earlier, A. Horstmann[2] had also shown that the evolution of heat is not the real criterion for the possibility of chemical change. The main facts which indicate that something is wrong with Thomsen's and Berthelot's criteria, are as follows:

(1) The principle assumes that reactions proceed completely to an end, whereas in a balanced reaction, the reaction may be exothermal in one direction, and endothermal in the other. According to the principle of maximum work, the exothermal change ought to go completely to an end. Hence, the principle is not in agreement with facts.

(2) A reaction may not always proceed to the stage directly which develops the maximum amount of heat, as illustrated by successive reactions—*e.g.* the action of chlorine on sodium hydroxide gives a mixture of sodium hypochlorite and chloride which involves a smaller heat of reaction than if all the sodium was converted into

chloride. This objection might be met by insisting on the importance of the word *tends* in the enunciation of the principle, were it not for some evidence that the products are sometimes comparatively stable.

(3) In a series of compounds of the same type, those with the greatest heat of formation are not always the most stable. Thus, the heats of formation of the carbonates of silver and lead are respectively 25·96 Cals. and 72·88 Cals.; and of the nitrates of silver and lead, respectively 30·06 Cals. and 54·05 Cals. Hence, it might be concluded that the lead salts are the more stable when heated. This is not the case. Lead nitrate begins to decompose at 203° (20 mm. pressure), while the silver salt does not decompose at 350° (in vacuo) to any appreciable extent. It is probable that lead nitrate is the more stable salt when in solution.

(4) Several spontaneous chemical reactions are known to be accompanied by an absorption of heat. The heat of the endothermal reaction between iodine and hydrogen is nearly −6 Cals. The solution of many salts in water, the action of lead iodide on potassium sulphate, etc., are further illustrations of endothermal reactions which proceed contrary to the principle of Berthelot. When a solution of ammonium nitrate is mixed with a solution of potassium carbonate, −3·1 Cals. are absorbed in the formation of potassium nitrate and ammonium carbonate. No measurable amount of heat is absorbed or evolved when the two latter compounds are mixed, and hence, $K_2CO_3+2NH_4NO_3=(NH_4)_2CO_3+2KNO_3-3{\cdot}1$ Cals. This endothermal reaction has been explained by assuming that heat is evolved by the reaction between the potassium carbonate and ammonium nitrate, and that the dissolution of the products in water accounts for the absorption of heat. It may be true that the solution of salts in water involves (i) a physical process—the liquefaction of the salt attended by an absorption of heat; and (ii) a chemical process—the union of the salt with water. The cooling effect which attends the solution of many salts was once thought to be explained by saying that the heat absorbed in the first-named process exceeded that in the second.

(5) Many systems require a preliminary impulse to start the reaction, and hence, it would be necessary to introduce a clause to provide for this phenomenon.

The principle of maximum work must therefore be either amended or abandoned. For example, it has been amended to read: **Every change which takes place without the aid of external energy must do work, and a system which cannot do work is incapable of spontaneous change and is in stable equilibrium.** Hence, the criterion for spontaneous reactions is not the production of heat, for many spontaneous reactions absorb heat. The reaction between hydrogen and iodine can do positive work equivalent to +5·0 Cals. per gram-molecule of iodine, but the heat of the reaction is negative, −6·0 Cals. Further investigations have shown that it is not at all improbable that all chemical and physical reactions will be exothermal and complete at absolute zero, −273°; and consequently, the principle of maximum work will probably apply at that temperature. At ordinary temperatures, the principle is only approximately exact.

Explosive compounds.[3]—Chemical *union* is usually (not always) accompanied by the evolution of heat, and chemical separation by an absorption of heat. There are some exceptions—endothermal compounds—which are formed with an absorption of heat, and hence decompose exothermally. If the thermal value of a reaction is a measure of the available energy which is degraded as heat during the reaction, it follows that energy must somehow be stored up in endothermal compounds, and that such compounds are ready to give up energy to form another state of things with less potential energy. Just as a bent strip of flexible steel will fly back to its original position on being released, so does the potential energy of endothermal compounds tend to "fly back" so to speak, other compounds with less potential energy being formed. If a reaction takes place in a very short time it is frequently explosive. The non-explosibility of endothermal reactions corresponds with the fact that these reactions are self-cooled and brought to a standstill by the absorption of heat, whereas in exothermal processes, the reaction once begun, is rapidly accelerated by the self-heating which results from the evolution of heat. Other things being equal, the greater the evolution of heat, the greater the probability of an explosive reaction. Thus, with the oxalates of the metals—RC_2O_4—which decompose: $RC_2O_4=R+2CO_2$, where R is the symbol for one of the metals, Zn, Pb, Cu, Hg, Ag_2,

$$\text{Heat of decomposition}\ .\quad \underbrace{\overset{ZnC_2O_4}{-49}\quad \overset{PbC_2O_4}{-17}}_{\text{Non-explosive.}}\qquad \underset{\text{Doubtful.}}{\overset{CuC_2O_4}{+6}}\qquad \underbrace{\overset{HgC_2O_4}{+17}\qquad \overset{Ag_2C_2O_4}{+30\ \text{Cals.}}}_{\text{Explosive.}}$$

The heat of decomposition of a given compound will vary if the course of the reaction varies. Hence, a compound might decompose with explosive violence one way and non-explosively another—*e.g.* potassium chlorate. Nitroglycerol, too, when ignited by a flame burns quietly enough, but if it be subjected to a mechanical shock, or heated to a high enough temperature, it decomposes with spectacular violence.

It does not follow that because the heat of formation of a compound from its elements is positive, therefore the compound cannot decompose exothermally, since other products of decomposition may be formed, *e.g.* the heat of formation of liquid nitroglycerol—$C_3H_5N_3O_9$—from its elements is +415 Cals., and if it be decomposed back into its elements, the heat of decomposition must be −415 Cals. As a matter of fact, when the compound decomposes into carbon dioxide, water vapour, free nitrogen, and free oxygen, +1580 Cals. are evolved, not absorbed. The absorption of heat during the formation of an endothermal compound, from its elements, in general, shows that more energy is needed to tear asunder the atoms of the reacting molecules, say $A_2=A+A$, and $B_2=B+B$, than is given out by the union $2A+2B=2AB$. Take acetylene or cyanogen in illustration. Endothermal compounds are not therefore to be regarded as compounds which have been formed in opposition to the affinities of their constituent elements, because that would imply the existence of a *negative affinity* or a negative form of energy which is an idea quite outside the range of experience. If the atoms in the molecule of an endothermal compound repelled one another, it seems highly probable that the molecule would break up unless it were continually subjected to an external stress.

§ 4. The Principle of Reversibility

While a transformation of energy is initiated only when equilibrium is unstable, yet it occurs always in the direction of a recovery of stability.—S. A. REEVE.

We do not know what is the exact relation between the thermal value Q of a reaction and temperature although we do know that the heat of a reaction alters with variations of temperature. It is assumed *pro tempore* that the relation between Q and the absolute temperature T can be represented by an expression of the form $Q=Q_0+\alpha T+\beta T^2$, when the numerical values of the constants α and β can be determined from measurements of Q at three or more different temperatures; Q_0 should represent the value of Q at absolute zero. For the reaction $CO_2+H_2=CO+H_2O$, it has been found that the constants assume these values: $Q=-10232$

$0{\cdot}1685T+0{\cdot}00101T^2$. When the heat of the reaction is zero, $Q=0$, and T ust be either 3100° or 2830°. Experiment shows that the second value is nearer e truth. Hence, the reaction must be exothermal below 2830°, endothermal ove, and thermally neutral near this temperature. The reaction $H_2+I_2=2HI$ endothermal below 320°, exothermal above, and thermally neutral near this mperature. This shows that **some endothermal compounds become exothermal** ; **higher temperatures**—*e.g.* the formation of hydrogen sulphide, and probably one, hydrogen peroxide, silver oxide, etc.; and conversely, **some exothermal ompounds become endothermal at higher temperatures**—*e.g.* the formation of licon hexachloride, the reaction between carbon dioxide and hydrogen, etc. hese changes correspond with a reversal of the thermal value of the reaction at he elevated temperature. The consequence is that a compound may be unstable t low temperatures, and stable at higher temperatures, and conversely, stable t low temperatures, and unstable at higher temperatures. Hydrogen peroxide nd ozone are examples of the former, water an example of the latter.

This reversal of the direction of a reaction with a change of temperature shows ow necessary it is to indicate the conditions of a reaction when stating the character f the change. Thus, carbon dioxide is usually a neutral gas, but it oxidizes zinc vapour at elevated temperature, and steam likewise is an oxidizing agent for iron and carbon at high temperatures.

The most stable compounds are usually but not always those with the greatest heats of formation. In a general way, the higher the temperature, the less the stability of exothermal compounds; and conversely, endothermal compounds generally become more stable as the temperature is raised, because an absorption of heat is necessary for their formation. Here is another illustration of the principle of reversibility previously discussed. **A compound formed with the evolution of heat is decomposed by the addition of heat**; water, for example, is an exothermal compound, and steam is decomposed when heated to a high temperature; the higher the temperature the greater the amount decomposed, or dissociated into its elements: $2H_2O \rightleftharpoons 2H_2+O_2$. For instance, W. Nernst and H. von Wartenberg (1906) found:

Temperature	1000°	1500°	2000°	2500°
Amount dissociated	0·00003	0·0221	0·5880	3·98 per cent.

This means that if 100 grms. of steam be heated to 2500°, at atmospheric pressure, the mixture will be in equilibrium when it contains approximately 96 grms. of steam, 3·55 grms. of free oxygen, and 0·45 grm. of free hydrogen. If the temperature be lowered some of the hydrogen and oxygen will recombine; if the temperature be raised more steam will be decomposed. When a substance decomposes with a change in the physical conditions—temperature, pressure, etc.—and the products of decomposition recombine when the original conditions are restored, the process of decomposition is said to be **dissociation.** Conversely, **a compound formed by the absorption of heat is decomposed by the withdrawal of heat**; for instance, ozone is an endothermal compound. The equilibrium conditions at different temperatures in the presence of oxygen are:

Temperature	0°	100°	500°	1000°	2000°	3000°
Per cent. of ozone	$9{\cdot}5\times10^{-16}$	$3{\cdot}5\times10^{-11}$	$9{\cdot}6\times10^{-5}$	$2{\cdot}2\times10^{-2}$	0·9	3·6

Quite an appreciable amount of ozone will be in equilibrium with oxygen at the higher temperatures, but at ordinary temperatures the amount is inappreciable. W. Ostwald (1891)[1] has said:

> It is generally believed that at a high temperature, such as that which exists in the electric arc, and in the sun's atmosphere, all compounds must be dissociated into their elements. This view is certainly not justified. On the contrary, what we actually know about the stability of compounds is that all compounds which are formed with an absorption of heat become more stable with rising temperatures, and *vice versâ*. Owing to the fact that the majority of compounds known to us are formed from their elements with the evolution of heat, and in consequence, become more unstable as the temperature rises,

it has been concluded that this is generally the case; but if we remember that acetylene and cyanogen—two compounds formed with the absorption of heat—are readily formed in quantity at the high temperature of the blast furnace, and in the arc light, we see the possibility that spectra occurring at high temperatures may belong to compounds which exist only at elevated temperatures.

§ 5. Hess' Law

> Each element as well as each compound embodies a distinct and invariable amount of energy as well as a distinct and invariable amount of matter, and the energy is as constitutive and essential a part of the existence of such element or compound as its weight.—J. B. STALLO.
>
> The calorimeter is perhaps as necessary for determining the energy communicated to or from a system undergoing chemical change as the balance is for determining the masses affected.—C. J. REED (1901).

G. H. Hess (1840)[1] measured the heat developed during the formation of a compound made in several different ways and came to the conclusion that **the amount of heat evolved during the formation of a given compound is the same whether the compound is formed directly or in a series of intermediate stages**—*wenn eine Verbindung stattfindet, so Warmemenge constant, es mag die Verbindung direct oder indirect und zu widerholten Malen geschehen*—this is called **Hess' law.** This law tacitly assumes the law of conservation of energy; G. H. Hess seems to have regarded the law as axiomatic or self-evident without proof. It is a direct corollary from the law of conservation of energy, and is interesting since it came before J. R. Mayer or J. P. Joule. The principle may be illustrated by making calcium chloride by the action of quicklime on dilute hydrochloric acid. It is found that:

$$CaO+2HCl_{aq}=CaCl_{2aq}+H_2O+46 \text{ Cals.}$$

Instead of this, (i) first slake the quicklime, and $CaO+H_2O=Ca(OH)_2+15$ Cals.; then (ii) dissolve the calcium hydroxide in water, and $Ca(OH)_2+Aq=Ca(OH)_{2aq}+3$ Cals.; finally (iii) mix the lime with dilute hydrochloric acid, and $Ca(OH)_{2aq}+2HCl_{aq}=CaCl_{2aq}+H_2O+28$ Cals. These three steps in the formation of the solution of calcium chloride give a total $28+3+15=46$ Cals. as the heat of formation. The same result was obtained by the direct action of the dilute acid on quicklime.

Just as in mechanics the work done by a falling body is always the same whatever be the path described, and whatever be the time occupied in the descent, for the body may fall perpendicularly, down an inclined plane, down a parabolic or other path, yet the work in every case is measured by the perpendicular height it actually falls, so experiments have led to the inference that

(i) **The heat of formation of a compound is independent of its mode of formation.**—This result is but a particular application of the law of persistence of energy, and it may be expressed by saying that the change of energy of a system in passing from one state to another depends upon the initial and final states of the system, and not on the intermediate states. Starting with given raw materials, suppose that it were possible to make a compound by two different processes so that the total heat of formation of the compound formed by one of the processes were greater than that by the other process, then it would be possible to devise a process involving the creation or destruction of energy.

(ii) **The thermal value of a reaction is independent of the time occupied by the process.**—The thermal value of a reaction is the same whether it takes place slowly or quickly. In the former case, the heat may have time to be dissipated by conduction or radiation, and, in consequence, appear to be less than when the tion takes place quickly—it is here assumed, of course, that the system is not cted by external forms of energy. In practice, the risk of error, and consequently the experimental errors, are great with very slow reactions.

It also follows as a corollary to Hess' law that **the thermal value of a reaction e sum of the heats of formation of the final products of the reaction less the ts of formation of the initial products of the reaction.** Let Q denote the thermal e of a reaction, Q_1 the heat of formation of the initial products, and Q_2 of the l products of the reaction, then $Q=Q_2-Q_1$. This corollary to Hess' law is able because it enables the heat of formation of a compound from its elements be computed when a direct determination is either impracticable or very cult. This may occur when the heat evolved during the mutual action of two ls is difficult to measure accurately. For instance, if the heat of formation of on dioxide from carbon is $C+O_2=CO_2+96{\cdot}96$ Cals., and from carbon monoxide $+O=CO_2+68{\cdot}20$ Cals., we have $(C+O_2)-(CO+O)=96{\cdot}96-68{\cdot}20$, or 28·76 ., and consequently the heat of formation of carbon monoxide $C+O=CO$ 28·76 Cals. Again, it is required to compute the thermal value of reaction $SO_3+BaO=BaSO_4$, when measurements show that SO_3+H_2O $_2SO_4+18{\cdot}7$ Cals.; $BaO+H_2O=Ba(OH)_{2sol}+13{\cdot}9$ Cals.; and that $Ba(OH)_2$ $_2SO_4=BaSO_4+2H_2O+18{\cdot}4$ Cals. Hence, $BaO+SO_3=BaSO_4+51{\cdot}0$ Cals. in, to determine the heats of formation of hydrogen iodide and hydrogen bromide n it is known that $Cl+HBr=HCl+Br_{liq}+12{\cdot}5$ Cals., and that $Cl+HI=HCl$ $_{olid}+28{\cdot}2$ Cals.; and that the heat of formation of hydrogen chloride is 22·0 . In the first case, $22{\cdot}0-12{\cdot}5=9{\cdot}5$; and in the second, $22{\cdot}0-28{\cdot}2=-6{\cdot}2$. ce, $H+Br=HBr+9{\cdot}5$ Cals. and $H+I=HI-6{\cdot}2$ Cals.

imilarly, the thermal value of a reaction can be calculated when the heats of ation of the different substances which take part in the reaction are known. s, by consulting some book of Laboratory Tables we can write the heats of ation of the substances concerned in the reduction of lead oxide by carbon oxide:

$$\begin{array}{l} CO+PbO=CO_2+Pb \\ 29{\cdot}2 \quad 50{\cdot}3 \quad 97{\cdot}3 \text{ Cals.} \end{array}$$

$29{\cdot}2+50{\cdot}3=97{\cdot}3+x$, where x denotes the thermal value of the reaction; equently, $x=97{\cdot}3-(29{\cdot}2+50{\cdot}3)$, or 17·8 Cals., and the reaction is accordingly bolized: $CO+PbO=CO_2+Pb+17{\cdot}8$ Cals. The heat of formation of silver ride, AgCl, is 29 Cals. and of silver bromide, AgBr, 27·1 Cals. Is the reaction $r+Cl=AgCl+Br$ likely to occur? The heat of the last reaction is 29—27·1 9 Cals., and hence the reaction is likely to take place. Further, if copper preates silver from a dilute solution of silver nitrate, $2AgNO_{3aq}+Cu=Cu(NO_3)_{2aq}$ $g+25{\cdot}3$ Cals., will zinc precipitate silver from dilute silver nitrate when it is wn that $Cu(NO_3)_{2aq}+Zn=Zn(NO_3)_{2aq}+Cu+61{\cdot}7$ Cals.? Probably yes, because heat of the reaction $61{\cdot}7-25{\cdot}3=36{\cdot}4$ Cals. Both conclusions are in agreement observations. *The energy of a chemical reaction is not primarily inherent in any f the reacting components, but belongs to the system as a whole*; this energy may epresented as the sum of two or more constants which are peculiar to the ective elements involved in the reaction.

XAMPLES.—(1) It is required to compute the heat of formation of $K+Cl=KCl$, when known that the heat of formation of $K+O+H+Aq=KOH_{aq}+117$ Cals.; $2H+O$ $O_{liq}+68{\cdot}4$ Cals.; $H+Cl_{aq}=HCl_{aq}+39{\cdot}3$ Cals.; heat of solution of KCl in r, $-4{\cdot}4$ Cals.; and that $KOH_{aq}+HCl_{aq}=KCl_{aq}+H_2O+13{\cdot}7$ Cals. This last ion can be written: $(H+Cl+Aq)+(K+O+H+Aq)-(K+Cl+Aq)-(2H+O)$ 13·7 Cals. Consequently, after substituting the given data, and transforming algeally, we get $K+Cl+Aq+101{\cdot}6$ Cals.; and hence, $K+Cl+Aq=KCl_{aq}+101{\cdot}6$

Subtract the heat of solution $-4{\cdot}4$ Cals., and we get $101{\cdot}6-(-4{\cdot}4)=106$ Cals. for thermal value of the reaction $K+Cl=KCl$. It will be noticed that the solution of ssium chloride in water is an endothermal process, and hence, the heat of formation of $_{aq}$ is less than that heat of formation of KCl.

2) Show that when silver chloride, AgCl, is mixed with hydriodic acid, HI, silver

iodide, AgI, and hydrochloric acid, HCl, will probably be formed when it is known that the heat evolved during the formation of silver iodide is $Ag+I=AgI+18{\cdot}6$ Cals. of silver chloride, $Ag+Cl=AgCl+34{\cdot}8$ Cals.; hydrochloric acid (aqueous solution), $H+Cl_{aq}=HCl_{aq}+39{\cdot}3$ Cals.; and hydriodic acid in aqueous solution, $H+I=HI_{aq}+13{\cdot}2$ Cals. Ansr. 10·0 Cals. will be evolved during the reaction $AgCl+HI=AgI+HCl$, and reactions generally occur which are attended by the evolution of an appreciable quantity of heat.

The heat of formation of many substances has been determined from the **heat of combustion,** *i.e.* the heat which is developed when the substance is completely oxidized. The method is particularly applicable for compounds whose heats of formation cannot be directly determined, either because the reaction is too slow or because the compound cannot be formed directly from its elements. It is, however, necessary to know the heats of formation of the products of combustion as well as the heat of combustion.

EXAMPLE.—The heat of combustion of methane, CH_4, is 213·5 Cals., and the heats of formation of the carbon dioxide 96·96 Cals.; and of water, 68·6 Cals. Hence, since $CH_4+4O=CO_2+2H_2O+213{\cdot}5$, $Q_2-Q_1=$ the required heat of formation of methane is $(96{\cdot}96+2\times68{\cdot}6)-213{\cdot}5=20{\cdot}26$ Cals.

The heats of combustion of a few compounds are indicated in Table II. Heats of combustion are dependent on constitution, so that isomeric compounds may have different values; similar remarks apply to the heats of combustion of polymeric substances. Each radicle in a compound has a definite heat of combustion, called its **thermochemical constant**—given the thermochemical constants of the constituents of a molecule, the heats of combustion follow additively. Conversely, given the heats of combustion of a compound, the presence of particular radicles can be inferred.[2] The principles just outlined can thus be applied: (1) To the determination of the thermal values of reactions which cannot be conveniently determined by calorimetric measurements; and (2) To the prediction of various chemical transformations.

TABLE II.—HEATS OF COMBUSTION.

	Heat of combustion.	Heat of formation.		Heat of combustion.	Heat of formation.
Methane, CH_4	213·5	18·5	*o*-Xylene, C_8H_{10}	1084·0	20·3
Ethane, C_2H_6	372·3	23·3	Naphthalene, $C_{10}H_8$	1241·8	−27·4
Propane, C_3H_8	528·4	30·5	Anthracene, $C_{14}H_{10}$	1694·3	−33·3
Butane, C_4H_{10}	687·2	35·0	Methyl alcohol, CH_3OH	170·6	61·4
Ethylene, C_2H_4	341·1	−14·6	Ethyl alcohol, C_2H_5OH	325·7	69·9
Acetylene, C_2H_2	313·8	−51·4	Methyl ether, $(CH_3)_2O$	344·2	51·5
Benzene, C_6H_6	784·1	−4·0	Ethyl ether, $(C_2H_5)_2O$	651·7	70·5
Toluene, C_7H_8	933·1	2·3			

It must be borne in mind that all deductions from these principles are "subject to revision" owing to our ignorance of all the factors concerned in the reactions. It might also be well to emphasize the fact that there is a relatively large error of experiment in the determination of the heats of chemical reactions. The numbers obtained by different experimenters vary, sometimes considerably. For instance, the heats of combustion of acetylene and ethylene are variously given:

	W. G. Mixter (1901).	M. Berthelot (1893).	J. Thomsen (1884).
Acetylene	313·8	315·7	310·0 Cals.
Ethylene	345·8	341·1	333·4 Cals.

These discrepancies are sometimes of considerable magnitude. For example,[3]

J. Thomsen found the heat of the reaction between lead acetate and zinc to be 34·95 Cals., P. Favre gave 31·2 Cals., and T. Andrews, 37·71 Cals.—a total variation between the extremes of 6·51 Cals. The heat of formation of cupric oxide, CuO, and therefore of all salts derived from it, is 37·16 Cals. according to J. Thomsen; 43·77 Cals. according to P. A. Favre and J. T. Silbermann; and 38·30 Cals. according to T. Andrews. The heat of formation of ferric chloride, $FeCl_{3}aq$, is variously given by J. Thomsen at 99·95 Cals., by P. A. Favre and J. T. Silbermann at 106·76 Cals., and by T. Andrews at 102·06 Cals.

These errors are magnified very much when the thermal value of a reaction is estimated indirectly by the application of Hess' rule.

§ 6. The Degradation or Dissipation of Energy

There can be little question that the principle of the dissipation of energy implicitly contains the whole theory of chemical combination.—P. G. TAIT.

Water may be transported from the top of a mountain to the valley below in a variety of ways; it may come down in underground channels, rivers, or rain; or in the form of snow, glaciers, or an avalanche. So may energy pass from a state of high to a state of low potential in many and various ways, giving rise to mechanical, thermal, actinic, chemical, electrical, or magnetic phenomena. In reality, the so-called different forms of energy correspond with the tendencies which any given system may have to change in particular directions. If there is a tendency for the different parts of a system to come into closer contact, we have gravitation and cohesion; if there is a tendency to an equalization of temperature, thermal energy; and when there is a tendency to undergo transformation into another substance, chemical energy. Hence, the definition: **a chemical reaction is one mode by which energy can be transferred from one state to another.** Energy cannot be developed from nothing, but it is derived from certain natural reservoirs—living beings, falling water, moving air, fuels, etc.—in which energy is accumulated; and certain machines—the steam engine, galvanic battery, turbine, etc., draw from the reservoir and transform one form of energy into another form without changing the total amount of energy. Thus, heat, light, and electricity may be liberated during chemical changes. To avoid the assumption that this energy comes from nothing, it is postulated that the original system contained a definite amount of free or available energy—chemical energy. As H. Hertz (1894) expressed it: In order to explain what is palpably before our eyes we are compelled to imagine behind the things we see, other invisible things, and to search behind the barriers of sense for a secret hidden accomplice. The hidden factor is here conveniently assumed to be potential or chemical energy.

Not dead is matter though inert it seems,
A hidden life ensouls the eternal mass.—C. A. LANE.

If a substance can unite with another, it is said to possess chemical energy, because it can do chemical work; and conversely, substances which cannot combine chemically with other substances have no available chemical energy, for they can do no chemical work. During a chemical reaction, the chemical energy is transformed into an equivalent amount of some other form of energy which is usually, though not always, heat. Hence, the relation between chemical energy and heat (thermal energy) is an important subject, which, for convenience, is called **thermochemistry**; and the general study of heat as a form of energy is called **thermodynamics.** Chemical energy may also be transformed into electrical energy during a chemical reaction, and that branch of chemistry which deals with the relation between chemical energy and electricity (electrical energy) is called **electrochemistry.** Just as chemical changes which are always accompanied by an evolution of heat are called *exothermal reactions*, so reactions which are accompanied by an evolution of electrical energy have been called *exo-electrical reactions;* and conversely, for *endothermal reactions* and *endo-electrical reactions*. So far as we can tell, in all phenomena, the same energy is at work, and the same fundamental principles apply to all the specialized forms of energy. There is not a set of mutually exclusive laws for chemistry, another set for electricity, another for heat or for mechanics. Convenience alone dictates specialized versions of the same fundamental laws for electricity, chemistry, etc. Strictly speaking, no form of energy can be singled out and called potential energy, since each form of energy is potential with respect to the other forms into which it can be converted.

The factors of energy.—Water will flow from one vessel to another only when there is a *difference in the level* of the liquid in the two vessels. The actual volume of the water in either vessel does not matter. Again, heat will pass from one body to another only when the temperature of the one is higher than the temperature of the other. The flow of heat is not determined by the quantity of heat in either the hot or the cold body, but rather by the *difference in the temperature* of the two bodies. The heat in the fire-box of a locomotive can do work, not because it is hot, but because it is hotter than its surroundings. In his well-known *Réflexions*, N. L. S. Carnot (1824)[1] compared the production of work by *une chute d'eau* with the fall of heat from a higher to a lower temperature, and referred to the latter as *une chute du calorique*. Again, if two reservoirs of gas be connected by a cylinder fitted with a sliding piston, the motion of the piston will not be determined by the volume of the reservoir, nor by the quantity of energy contained in the gas, but it will be determined by the *difference in the pressure* of the gas in the two cylinders. Air confined in a closed vessel at atmospheric pressure might appear to possess no energy because it can do no work; but reduce the pressure of the surrounding air, and the air confined in the vessel is then capable of performing work.

It is therefore possible to show that each form of energy has a dual nature, and that every form of energy appears as if it were of two dimensions, for it can be compounded of two factors [2]—mass and difference of level; thermal capacity (or maybe entropy) and temperature; volume and pressure of gas. The one factor is called the **quantity, mass, or capacity factor,** and the other, the **strength, or intensity factor.** The two factors are combined not as a sum but as a product, for if one factor diminishes towards zero, the other increases towards infinity:

$$\text{Available energy} = \text{Capacity (quantity) factor} \times \text{Intensity (strength) factor}$$

To pass from generals to particulars, it is convenient to say that with **volume energy,** the factors are pressure and volume; with **surface energy,** the factors are surface area and surface tension; with **distance energy,** distance and force; with **kinetic energy,** mass ($\frac{1}{2}m$) and velocity (V^2); with **electrical energy,** quantity and difference of potential; etc. When the capacity factor is high and the intensity factor low, more or less work may be got from that form of energy than if the capacity factor is low and the intensity factor is high—all depends on the relative magnitudes of the two different factors; and two different sources of energy with very different intensity and capacity factors may be able to perform the same amount of work. If $C_1, C_2, \ldots$ denote the capacity factors, and $I_1, I_2, \ldots$ the corresponding intensity factors of the different forms of energy associated with a system, then, when the respective intensity factors change by small amounts $dI_1, dI_2, \ldots$, the work dW done by the system will be equivalent to

$$dW = C_1dI_1 + C_2dI_2 + \ldots; \text{ or } dW = \Sigma C.dI$$

The degradation of energy.—The law of conservation of energy does not describe the direction in which a change will occur. It simply states that the amount of energy lost by one body must be precisely equal to that gained by another; it does not say whether heat will flow from a hotter to a colder body or conversely. Experience answers the question. Heat will be conducted from a hot to a colder dy ; salt will diffuse from a solution of high to one of lower concentration ; and nerally, the trend of natural processes is all in one direction. This general tendency n be formulated mathematically in terms of the transformations of energy which me into play, and the relations which determine the final state of equilibrium. is enables a prediction to be made as to the direction in which any given chemical physical process will progress.

In 1856, R. Clausius[3] laid down the hypothesis: *Die Wärme kam nicht von lbst aus einem kälteren in einen wärmeren Körper übergehen*—**heat cannot sponta-eously pass from a body at a low to a body at a higher temperature,** but it can e forced to do so either (i) by the application of energy from an external supply, *g.* freezing machines and refrigerators raise heat from a cold to a hotter body by erforming work on the system ; or (ii) by a double transformation first into another orm of energy, say mechanical motion, and back again into heat. The pre-eding is one of the protean forms under which the **second law of thermodynamics** r **the second law of energetics** can be stated ; it is also known as **Carnot's principle,** ecause N. L. S. Carnot first developed the idea in his celebrated memoir entitled, *Réflexions sur la puissance motrice du feu,* published in Paris in 1824. W. Ostwald (1892) expressed the same idea in his *Studien zur Energetik* previously cited : **The unlimited conversion of energy without intensity differences is impossible.** Several attempts have been made to deduce the second law from the first by W. J. M. Rankine, S. H. Burbury, C. Szily, R. C. Nichols, L. Boltzmann,[4] etc. R. Clausius says that the second law is not contained in the first.

Just as water will always run down from a high to the lowest level that circumstances will permit, so generally, **in all processes with which we are acquainted, every known form of energy at a high potential always tends to run down to energy at the lowest potential circumstances will permit—the law of minimum free energy**—and one of the most interesting facts in connection with all natural changes is this constant running down or degradation of energy. The law of minimum free energy is analogous with the counter-statement in mechanics that a body will always fall as far as it can, and that if it be free to fall, it will fall. The energy so degraded has no longer a capacity for doing work, and the definition of energy as a capacity for work is therefore faulty, for the principle of the conservation of energy cannot be taken to mean that as the result of a given transformation the capacity of the system to do work has remained constant.

Energy may be degraded slowly in a long series of transformations, or suddenly in one bound ; in either case, the free energy under the new conditions becomes less available for doing work. **Every change which takes place in nature does so at the cost of a certain amount of available energy.** When we inquire whether or not a certain transformation can take place, the question to be answered is : Will the occurrence involve the degradation of energy ? If not, the transformation will not take place under the given conditions. A moment's reflection will show that in every transformation, the intensity factor will be diminished, and energy then becomes less available for doing work. **The intensity factor of energy controls the direction of a given transformation,** while the capacity factor largely controls the quantity of change, that is, the amount of work performed during the change. Water placed in a series of vessels in communication with one another will come to rest when the surface of the water is at the same level in both vessels. Difference of level here means that the gravitational energy has a different intensity in each vessel. An electrical current will flow whenever there is an inequality of the intensity factor—*i.e.* a difference of potential—at different parts of the circuit. **If the intensity factors of any particular form of energy in a system are not equal, the system will be in a state of unstable equilibrium ; such a condition will not be permanent, and energy will flow, so to speak, from one part to another until the different intensity factors become equal.**

This principle is true for any closed system, and if the universe is a closed system, it must also dominate the universe. It has been pointed out that the earth is only part of the universe, and it is continually gaining energy from the sun by radiation, and losing energy, also by radiation from itself. Accordingly, owing to the universal and unceasing tendency towards a degradation of energy, the universe is steadily passing from a state in which energy at a high potential will be uniformly distributed at one uniform low potential. The universe will then have a dead inert motionless existence at a uniform temperature. Then follows the so-called *thermodynamic paradox*—energy is continuously being degraded ; the past duration of the universe extends through infinite time, therefore, unless energy at a low potential is being restored to a higher potential, the degradation of energy should have been completed long ago. Hence, it has been postulated that by some hitherto unrecognized phenomenon, unavailable energy at a low potential is being raised to available energy at a high potential, and that the second law of thermodynamics is being somewhere and somehow reversed. It is, however, mere speculation to assume that because the second law of thermodynamics is based on experience, and that there *may be* localities in the universe where it does not apply, or that it *may not* have held good in past times, therefore there *must be* a source for the restoration of degraded energy. H. Elliot (1895) argued that it is just as likely that the universe is infinite as that past time is infinite, and that even the lapse of infinite time would not involve the extinction of all differences of potential.

An ancient philosopher—Heracleitus of Ephesus—has said that πavτà ῥεῖ—all things are in motion, and it might be added that that motion always involves the degradation of energy. The transformation of energy in a given system only ceases when the available energy has run down to the level of its surroundings. The system is then said to be in a **state of stable equilibrium.** The stability of a system thus indicates how the system is related to its surroundings. For stability, a system must be in equilibrium with its environment. A physical or chemical change will progress until the different forms of energy which come into play are exactly balanced, and this determines the final state of equilibrium of the system.

The condition of equilibrium.—In an isolated system, the condition necessary for the equilibrium of any form of energy is that its intensity shall have the same uniform value throughout. For instance, if the opposite sides of a bar of metal have a different temperature, heat will be conducted from the hot to the cold end until the temperature is everywhere the same ; a mass of gas will be in equilibrium when it has one uniform pressure (of course neglecting the effect of gravitation, which may be regarded as extraneous energy) ; etc. **When one form of energy is exactly balanced by another form, the system is in equilibrium, and a virtual change of one form of energy will be balanced by a corresponding change in the other form or forms of energy.** *Virtual change* is a convenient term often used to represent an infinitesimally small change " existing in effect, but not in actuality." It is not clear at first sight what this phrase means. A virtual change is not a real change, but rather an abstraction, and in place of " virtual," possible or potential might be substituted.[6] For instance, if a ball be suspended by an elastic string, gravitation pulls the ball downwards, and elastic energy pulls it upwards ; a virtual displacement of energy will occur if the ball were pulled an infinitesimally small distance downwards, and the gravitational energy so expended were exactly counterbalanced by the gain in the opposing elastic energy. The algebraic sum of the energies involved in a virtual displacement of equilibrium must be zero when the system is in equilibrium. This is the so-called **principle of virtual work,** which is symbolized :

$$\Sigma dE=0\ ;\ \text{or,}\ \Sigma dW=0$$

where E and W respectively denote the energy and work performed ; and the summation symbol Σ is intended to show that the algebraic sum of all the correlated forms of energy is to be taken. For example, in a reversible chemical reaction in equilibrium, the reacting substances and the products of the reaction are to be taken ; the energy of the one increases and of the other decreases by a virtual displacement of equilibrium. In a system where the mechanical forms of energy capable of doing work are balanced, the principle of virtual work states that the sum of the virtual work performed by the forces will be zero, that is, $\Sigma dW=0$. The principle of virtual work was described by J. Bernoulli in 1717, and developed by J. L. C. Lagrange in 1788. Its application to chemistry was emphasized by W. Ostwald in 1892.

The law of mass action has been deduced from this principle. When a system of reacting substances is in equilibrium, the volume energy of the component substances is $\Sigma vdp = 0$. Let p and v respectively denote the partial pressures and volumes of the initial substances, and P and V corresponding values for the products of the reaction. From Boyle's law, $pv = nRT$, and $p = nRT/v$; by differentiation, $dp = -nRTdv/v^2$; by substitution of dp in the condition of equilibrium, $-RT(n\Sigma d\log v - N\Sigma d\log V) = 0$. Consequently, at a constant temperature, replacing the molecular volumes v by their reciprocals, the molecular concentrations c and C, we obtain $n\Sigma d \log c - N\Sigma d \log C = 0$; and on integration, $\Sigma \log c^n + \log k = \Sigma \log C^N + \log k'$, where k and k' are integration constants; and n and N respectively denote the relative number of gram-molecules of the initial and final products of the reaction. The last expression can be represented $k\Sigma c^n = k'\Sigma C^N$, or

$$\frac{c_1^{n_1}c_2^{n_2}\ldots}{C_1^{N_1}C_2^{N_2}\ldots,} = \frac{k'}{k} = K$$

Expressed in words, in an opposing reaction, at equilibrium, the product of the concentrations of the original substances is equal to the product of the concentrations of the end-products of the reaction and the equilibrium constant, or, the effect of each reacting substance is proportional to its concentration. This is the famous law of mass action of Guldberg and Waage. J. Larmor and T. B. Robertson[7] have shown that the mass law of Guldberg and Waage can be derived from the gas law $pv = RT$, or $p(v-b) = RT$, where b is constant.

Metastable equilibrium.—We are very familiar with systems in which the energy has not run down to the level of its surroundings and yet everything appears to be in a state of stable equilibrium. The stability is only apparent. As a matter of fact, available energy does not always *of itself* run down to the level of its surroundings. For some unknown reason, an influence—conventionally called *chemical inertia, hysteresis, or passive resistance*—prevents the initiation of the process of degradation of energy, a preliminary impulse is needed to start the process of degradation in motion. Passive resistance is here used as a grouping or classification term. It explains nothing. Just as the throttle-valve of a steam-engine must be moved before the engine can start on its journey, or some watches, after winding, require a slight shake before they start, so may a preliminary impulse be required to set the process of the degradation of energy in motion. The flapping of an eagle's wing may suffice to start an avalanche rolling down the mountain side; with gunpowder, the preliminary impulse may take the form of heat; with a mixture of hydrogen and oxygen, an electric spark, or the mere presence of spongy platinum; with a mixture of hydrogen and chlorine, a flash of light, or the addition of a piece of charcoal; with fulminate of mercury, a sudden shock; while the addition of a minute crystal will start the process of crystallization in a supercooled solution of sodium thiosulphate. We may thus have **a state of metastable, apparent or false equilibrium,** as well as a state of true or stable equilibrium. We naturally inquire: Is there any test to distinguish between states of real and states of apparent equilibrium? We know that if a gas is in equilibrium with regard to volume and pressure, it will satisfy the conditions of Boyle's law; volume and temperature, Charles' law; etc., but we have not always such useful tests at our disposal.

§ 7. Bound and Free Available Energy

> Matter, whatever it is, must be held to be so adorned, furnished, and formed that all virtue, essence, action, and motion may be the natural consequence and emanation thereof.—FRANCIS BACON.
>
> Energy is the result of a particular state or condition of matter in virtue of which any definite portion may effect changes in any other portion.—C. F. BARKER (1892).

Mechanical and other forms of energy can often be transformed completely into heat, but the reverse operation is subject to certain limitations since a certain proportion always escapes conversion and is lost. Similarly, when a system undergoes a chemical or physical change, a certain portion of the energy is simultaneously transformed into heat. The loss or leakage of energy does not mean that energy is annihilated; there is nothing to suppose that the law of the perdurability or conservation of energy is invalid. The so-called loss of energy means that part of the energy is degraded—by friction, viscosity, etc.—from a high to a low potential, and the capacity of the transformed energy for work is diminished. It is impossible to transform a quantity of heat into work without an accompanying change in the condition of a portion of the energy of such a nature that its capacity for work is correspondingly diminished. It therefore follows that the principle of conservation of energy is incapable of experimental demonstration, for it is only possible to measure the ratio in which the transformation of energy from one form to another is accomplished. Again, the definition of energy as capacity for work is not altogether satisfactory because a fractional part of the heat does not conserve its capacity to perform work when a transformation of heat into work is attempted.

H. von Helmholtz, in his *Ueber die Thermodynamik der chemischen Prozessen* (1882),[1] pointed out a useful concept by showing that the total available energy of a system appears as if it were on two different planes—one portion, called the **free energy** of the system, is capable of doing chemical, electrical, or mechanical work; and a second portion, called the **bound energy,** is rendered unproductive during the change, for it is frittered away as heat. The latter can be regarded as energy which must of necessity be wasted during the operation, or as the **energy-cost of the reaction.** The free energy of a system is a measure of the work which can be performed by the chemical process; the bound energy represents the energy lost by leakage during the reaction, because nature has determined that the rate of exchange, so to speak, is against the conversion. This must not be taken to mean that the energy of a body or system of bodies is not homogeneous, and can be separated into two parts with different properties; for the proportion of free to bound energy in any given process changes with the temperature. The actual proportion appears to be determined by the changes in the kinetic energy of the molecular or atomic motions; by the separation of the molecules against intermolecular attractions; by changes in the rotational or vibratory energy of the atoms; by alterations in the electrical state or thermal capacity of the molecular systems concerned in the reaction; etc. Again, the free energy, or the energy which can perform work during an isothermal change, is not always derived from the internal energy, thus, the internal energy of an approximately ideal gas does not change during an isothermal expansion when the gas performs no external work.

Free energy.—The maximum amount of work a reaction can do when it is carried out reversibly at a constant temperature, is called the free energy of the reacting system. If the free energy of a spontaneously occurring natural process were negative, it would progress without absorbing energy from its surroundings, and on being reversed (by the addition of heat), it would transform this heat into work, and a perpetual fount of energy would be available. This is in conflict with the law of excluded perpetual motion; and it is accordingly inferred that every spontaneous process must do work, and that a system incapable of doing work is incapable of spontaneous change; such a system must also be in a state of stable equilibrium, and accordingly, **for stable equilibrium, the free energy of a system must have a minimum value.** If a system can do no work, it cannot change except by the application of external energy. **The decrease in the free energy of a reacting system is a measure of the work which can be performed by the chemical process.** Free energy is thus synonymous with the ability to perform work. That system which can perform the greatest amount of work, when it is carried out isothermally and reversibly, will be most likely to occur; *i.e.* **of all possible chemical changes, that which involves the greatest decrease in the free energy will be most likely to occur.** Given a table of the free energy changes which occur during the formation of various compounds from their elements, by different processes, it would be possible to calculate the change in the free energy attending other reactions, just as in ordinary thermochemical calculations, the thermal value of a given reaction can be calculated from the heat of formation of the various reacting components. Tables of the free energy may thus take the place of tables of the heats of formation of different compounds, and be employed to predict (i) The maximum work which may be expected from a given reaction; (ii) The minimum amount of work which would be necessary to produce a certain reaction; (iii) The circumstances under which a given reaction will progress; and (iv) How nearly a given reaction will run to an end.

The available, total, or internal energy.—The absolute amount of energy of a substance cannot be measured because all measurements are concerned with differences of energy existing between different bodies or systems of bodies, or between a substance in two different states. This is not particularly a disadvantage, since it is all that is required in the present state of science. For convenience, the total available energy involved in any reaction is considered to be the algebraic sum of the free and bound energy. The total intrinsic or internal energy U—sometimes called the potential energy—transformed in a reaction is measured in a calorimeter as the heat of the reaction Q when due allowance is made for external work done on or by the reacting system against atmospheric pressure. In the latter case, the *potential energy* of the system is the difference between the heat energy Q and the external work. The total energy must not be confused with the free energy. The whole of the free energy in any given system may disappear without diminishing the total energy of the system. If U represents the total energy of an isolated system, W the free, and q the bound energy, then, by the law of the conservation of energy, U is constant; and if W becomes zero, $q=U$. In that case, the Q units of energy of the system can do no work. On the other hand, if $q=0$, then $U=W$, and all the energy of the system is free and capable of doing work. If $q=\frac{1}{2}U$, half the total energy can do work, and half will not be utilizable for doing work. M. Berthelot's principle of maximum work assumes that the total energy of a chemical reaction is equal to the free energy, that is, to the energy available as work, when the work is carried out reversibly. There is nothing to show that $U-W=0$, and accordingly, heat may be absorbed or evolved when a reaction is carried out under these conditions. It is not the maximum production of heat energy which determines if a reaction will necessarily occur, since some spontaneous reactions absorb heat.

Reversible and irreversible processes.—When a body has fallen a certain distance in vacuo, it would rise again the same distance as it fell if its velocity could be reversed; and by relieving the pressure on liquid water confined in an air-tight cylinder, fitted with a frictionless piston, and maintained at a constant temperature, the water could all be vaporized, and by reversing the pressure, the vapour could be condensed back to its original liquid state. In reality, a frictionless piston is impossible, and only when the pressure required to compress the vapour is exactly equivalent to that required for the expansion is the process considered to be strictly reversible. Again, by raising the temperature of a closed vessel containing calcium carbonate, the compound will dissociate, and by lowering the temperature, the products will recombine to form the original compound; similarly, if a cylinder contains a saturated solution of, say, potassium nitrate in the presence of some of the undissolved salt, the solution will alter its strength by diffusion, if the temperature be slowly raised; and if slowly cooled to its former temperature, the original condition will be restored. If there were any leakage of energy due to the viscosity of the solution, so that more heat energy were required for the heating than for the cooling, the process would not be considered strictly reversible. A process is considered to be strictly reversible only when it can be made to pass back from its final to its initial stage successively, and in the reverse order through all the stages traversed in the direct process by the application of external agents which are equal in magnitude but in opposite directions. In illustration of an irreversible process, if a cylinder containing a saturated solution of magnesium sulphate, $MgSO_4$, in presence of an excess of the same salt, be treated as in the case of the cylinder of potassium nitrate, the heptahydrate, $MgSO_4.7H_2O$, separates during the cooling. Again, if potassium chlorate be heated in a closed vessel, the oxygen and potassium chloride which are formed will not recombine to reform potassium chlorate when the system cools, and hence the process is irreversible. G. H. Bryan[2] has stated:

> While students of reversible phenomena have had fairly straightforward problems to solve, the problem of irreversibility still remains to a great extent a mystery and nobody seems to have got to the bottom of it. The irreversible phenomena of the universe all have a certain definite trend, and lead to the transformation of energy into certain definite forms. We say that certain forms of energy are less available than others, but why the less available forms are those associated with what are commonly called heat phenomena is a riddle . . . still unsolved.

No known natural process is strictly reversible, because, if a process goes in one direction, experience shows that it cannot be made to go in exactly the opposite direction by reversing the same outside agency. Among the various causes which make real processes more or less irreversible are viscosity in liquids, imperfect elasticity in solids, friction, diffusion, radiation, radioactivity, conduction, and types of electrical, magnetic, and chemical action. It is, however, possible to imagine two transformations—direct and inverse—to be conducted by a continuous series of infinitesimally small changes so that the system is all the time infinitely near being in a state of equilibrium; and it has been agreed to call such a process reversible. Hence, **in a reversible transformation or process, two imaginary operations are performed on a system whereby the system traverses the same intermediate states in a continuous series of indefinitely small stages, but in the reverse order,** so that the transformation is attended by the production of as much external work W as would have been expended in restoring the system to its original condition W', and the total work performed in a reversible cycle is zero, for $W=W'$. *More* work cannot be produced by a direct transformation than is required for its reverse, or perpetual motion would be possible; and if *less* work is required, the system is irreversible. Hence, **if a change is reversible, it works under the most favourable conditions, for it furnishes the maximum amount of work which it is capable of producing,** or else the minimum amount of work is expended in bringing about the change—otherwise expressed, in a reversible transformation, the free energy is a maximum, the bound energy a minimum.

§ 8. The Amount of Heat which can be Utilized for doing Work

Every change in the distribution of matter in a given system, under given conditions is accompanied by a definite energy change. Therefore the laws which govern changes of energy, are the laws which govern transformations of matter.—A. J. Lotka (1913).

To what extent can heat be converted into work ? The maximum quantity of heat q which can be reversibly converted into work W under ideally perfect conditions, working between the temperatures T and $T+dT$, at constant volume without doing external work, was shown by N. L. S. Carnot (1824) [1] to be equal to the product of the change of temperature into the quantity of heat q absorbed, divided by the absolute temperature. In symbols,

$$dq=dW=q\frac{dT}{T}; \quad \text{or,} \quad dW=\frac{q}{T}dT \quad . \quad . \quad . \quad (1)$$

Hence, said R. Clausius (1850),[2] when the temperature of a quantity of heat q is changed by a small amount dT, the fraction dT/T of q is transformed into work provided no heat is lost. N. L. S. Carnot illustrated the principle by referring to an arrangement for utilizing a fall of water. Suppose water to be in a reservoir T_1 feet above sea-level feeding a mill T_2 feet below ; let w denote the amount of water which falls in unit time. If the disposition of the system be ideally perfect, the energy of the falling water available per minute at the mill will be the weight of water multiplied by the fall, or wT_2, or, referred to sea-level, the free energy of the water at the reservoir, per minute, is wT_1. The free energy of the water starting on its downward journey from the mill is wT_1-wT_2, or $w(T_1-T_2)$, so that the amount of free energy utilized at the mill is $w(T_1-T_2)/wT_1$ or $(T_1-T_2)/T_1$ per minute. If q represents the total quantity of free energy of the water in the reservoir, the amount actually utilized will be $q(T_1-T_2)/T_1$. Making the necessary changes in the meaning of the terms, this same result is obtained by integrating equation (1), if W is put equal to W_1-W_2 or to q_1-q_2,

$$W=q\frac{T_1-T_2}{T_1}$$

meaning that the theoretical maximum quantity of work W which can be obtained from a quantity of heat q working between the absolute temperatures T_1 and T_2, is equal to the product of the quantity of heat into the change of temperature divided by the higher temperature, and is independent of the nature of the working substance. If the combustion of carbon under a steam boiler furnishes a quantity of heat q, then, under the very best (ideal) conditions, the amount of work W which can be derived from the steam engine will be $q(T_1-T_2)/T_1$, where T_1 denotes the temperature of the boiler, and T_2 that of the condenser. This shows that the ideal limit to the efficiency of a thermal process, or the fraction of the total energy q capable of doing work W/q, is equal to the ratio of the difference of the absolute temperatures between which the operation is performed and the maximum absolute temperature.

In processes available industrially, the lower temperature limit is fixed by the temperature of the cooled water, and the upper temperature limit is fixed by the temperature generated by the combustion of the fuel in air—about 1500°. The efficiency of a process dependent on steam and cold water is increased by using higher pressures in the boiler, but the pressure of steam in a boiler rises very rapidly with rise of temperature, and this limits the efficient use of high pressure steam boilers.

Carnot's theory has been reasoned out another way : The amount of energy given out by a cooling gas is proportional to the change of temperature, so that the maximum amount of energy can be obtained only by cooling the gas to absolute zero, and consequently, if the gas be cooled one-tenth of its way to zero, it will yield but one-tenth of the available energy.

Examples.—(1) The explosions in the cylinder of a gas engine raise the temperature to 927°, and the temperature of the exhaust is 127°, what is the theoretical efficiency of the process? Since the efficiency of a process indicates the fractional part of the total energy utilized in doing work, the required efficiency will be $dq/q=dT/T$, or $(1200-400)/1200$, or two-thirds of the heat would be converted into useful work under ideal conditions, and the remaining third would be wasted.

(2) The temperature of the boiler of a steam engine is 127°, and the condenser 17°, what percentage of the heat is theoretically wasted? Here the theoretical efficiency is $(400-290)/400=0{\cdot}275$, or 27·5 per cent. Hence, 72·5 per cent. of the heat energy is wasted.

Equation (1) may be called **Carnot's equation.** It can be extended to chemical reactions by assuming that the reaction takes place in one direction at the temperature T, and in another direction at a temperature $T+dT$; and if W and Q respectively denote the free and total energy at the temperature T, q in the expression dq/q, or $dW/q=dT/T$, can be replaced by $W-Q$, where W represents the free energy or maximum work, and Q the thermal value of the reaction, *i.e.* the heat absorbed (+) or evolved (−) in the reaction as measured in the calorimeter. Hence, $W-Q=q$, and $W-Q$ represents the bound energy absorbed or evolved during the reaction. Consequently,

$$W-Q=T\frac{dW}{dT} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

This form of the expression is called **Helmholtz's equation,** after H. von Helmholtz (1882), although A. Horstmann[3] had previously deduced a similar equation in 1870. Equation (2) means that the difference between the free and total energy in a chemical reaction under the given conditions is equal to the product of the absolute temperature T and the temperature coefficient of the free energy, dW/dT, which represents the change in the amount of work performed per unit change of temperature.

It will be evident that Berthelot's rule—that the total energy of the thermal value of a reaction is numerically equal to the free energy or maximum work which the reaction can perform—will be strictly valid only at absolute zero, when $T=0$, for dW/dT always has a finite value, and the term $T.dW/dT$ can be suppressed. At absolute zero, therefore, $W-Q=0$, or $W=Q$, and the thermal value of the process measures the driving force of the reaction. At ordinary temperatures, which, after all, are not very far removed from absolute zero, the difference between $W-Q$ and $T.dW/dT$ is not usually great, and Berthelot's rule becomes a useful approximation, particularly in chemical technology, where a measure of chemical energy in terms of the thermal energy of a process is desired. There are so many cases where the rule is approximately correct, that one is apt to forget that it is after all but a "half truth" and not the "whole truth."

H. von Helmholtz's equation is used in the interpretation of a great many phenomena. W. Nernst (1907)[4] was so impressed with its importance that he said: "It contains in a general manner all that the laws of thermodynamics can teach concerning chemical processes." In illustration, it can be applied (1) to show the influence of temperature on the thermal value of a reaction—J. H. van't Hoff's equation; (2) to show the relation between pressure and processes of volatilization, melting, and allotropic transformations—Clapeyron's and Clausius' equations; (3) to show the effect of temperature on the electromotive force of a cell—H. von Helmholtz's equation; (4) to show the influence of temperature on the surface energy of a liquid—Lord Kelvin's equation; etc.

EXAMPLE.—How does the pressure of an ideal gas kept at a constant volume change with temperature? For an ideal gas, $Q=0$. Let the gas at a temperature T change to a temperature $T+dT$, when the pressure changes from p to $p+dp$. Then, $W=pdv$, and $dW=dp.dv$. Substituting these results in Helmholtz's equation, $pdv=T(dp.dv/dT)$, or $p/T=dp/dT$, which is virtually Charles' law.

§ 9. Non-productive Energy. Entropy

Nature never undertakes any change unless her interests are served by an increase of entropy, while man endeavours so to make use of those changes allowed by nature that his own interests—namely the acquisition of available energy—are served as completely as possible.—M. Planck (1903).

No change occurs in nature without incurring waste.—J. Swinburne (1904).

The driving force of all natural events is the difference between the existing entropy and its maximum value.—L. Boltzmann.

While work may be wholly converted into heat, only a definite fraction of heat can be converted into work; otherwise expressed, if a quantity of heat Q_1 is received by a system at a temperature T_1, only the portion $Q_1-Q_2=Q_1(T_1-T_2)/T_1$ can be converted into work by a reversible process; the remaining quantity of heat Q_2 is simply transferred to the lower temperature T_2. The reversibility of the process implies that the portion of heat which was not transformed into work can be restored to its former temperature level T_1, with the same expenditure of work $Q_1-Q_2=Q_1(T_1-T_2)/T_1$. If the process is not reversible, and no known natural process is reversible in this sense, more heat flows to the lower level T_2 than in the reversible process, and accordingly less heat is transformed into work; the surplus cannot be brought up to its former level T_1 except by the expenditure of more work than is represented by $Q_1(T_1-T_2)/T_1$. Hence, in all real thermal processes, a fraction of the heat is lost for mechanical work; and there is a constant wastage of mechanical energy. The expression $Q_1-Q_2=Q_1(T_1-T_2)/T_1$, indicated above, reduces to

$$\frac{Q_1}{T_1}=\frac{Q_2}{T_2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

meaning that when a body changes from one state to another by the addition of a quantity of heat Q_1 at T_1, the change can be reversed by taking away a quantity of heat Q_2 at T_2, provided these four quantities are related so that $Q_1/T_1=Q_2/T_2$. A gas, therefore, which receives Q_1 units of heat at T_1 will retain its energy until it has given up the equivalent of Q_2 units of heat at T_2. If the process is not reversible, $Q_1/T_1-Q_2/T_2$ is not zero, but some greater magnitude.

In 1854, W. J. M. Rankine [1] called the magnitude Q/T the *thermodynamic function*, but R. Clausius' term **entropy**—from ἐντροπή, a change—has alone been adopted. R. Clausius said:

> I hold it better to borrow terms for important magnitudes from the ancient languages so that they may be adopted unchanged in all modern languages . . . I have intentionally formed the word *entropy* so as to be as similar as possible to the word *energy*; for the two magnitudes, to be denoted by these words, are so nearly allied in their physical meanings, that a certain similarity in designation appears to be desirable.

Entropy is here symbolized by ϕ. When a body at the absolute temperature T receives a small amount of heat dQ, the entropy is said to have increased by an amount $d\phi=dQ/T$. If a gas of entropy ϕ, pressure p, temperature T, and volume v receives heat and performs work so that it undergoes various changes and returns to its former values of T, p, and v, its entropy will be the same as it originally possessed—*viz.* ϕ. Neither the heat added to and taken from the gas nor the work done by and upon the gas are necessarily the same; but the entropy given to and taken from the gas is exactly the same.

It can be shown (i) that what is true of a gas is also true of a liquid and of a solid—homogeneous or heterogeneous; (ii) that the entropy ϕ of a complex system is the sum of the entropies of its component parts $\phi_1+\phi_2+\phi_3+\ldots=\phi$; and (iii) that if the entropy of unit mass of a material in a given state be ϕ, the entropy of a mass m of the same material in the same state is $m\phi$; accordingly also (iv) that $m_1\phi_1+m_2\phi+\ldots=m\phi$, where m_1, m_2 . . . denote the masses of the component parts of the system of mass m; ϕ_1, ϕ_2 . . . their entropies.

The measurement of entropy.—When a body receives 100 units of heat at a temperature 50° K., its entropy will be increased 100/50 or 2 entropy units. This unit was called a *claus* by J. Parker (1891), and a *rank* by J. Perry [2]—respectively after R. Clausius and W. J. M. Rankine. Hence entropy can be measured as

$$\text{Entropy}=\frac{\text{Units of heat}}{\text{Absolute temperature}}\text{ units}$$

The measurement of the entropy of a system is made under such conditions that, excluding changes of volume, the system gives up no energy other than heat. The external pressure of a changing body may not be equal to the internal pressure; for instance, in most chemical reactions, the volume of the system alters quite independently of the heat changes. The total change of energy is then equivalent to the heat energy Q evolved or absorbed from outside minus the amount of energy W consumed in the work of expansion against an atmospheric pressure p, plus the change $p.dv$ in the volume energy. The total change of energy divided by the absolute temperature T represents the change expressed in entropy units, or

$$\text{Entropy}=\frac{Q-W+pdv}{T}\text{ units}$$

Here, $Q-W$ represents the change in the internal energy. If the conditions are such that the external pressure is equal to the internal pressure required to produce the change in volume, W will be equal to pdv, and the entropy will then be $\phi=Q/T$. This condition is not usual; in general, the entropy depends on the total change of internal energy, plus the change in volume energy. For example, when a gas expands into a vacuum, its temperature does not change, and its internal energy is not changed, for Q and W are both virtually zero, but the volume energy is increased by pdv. The entropy of the change is therefore pdv/T. To bring the gas back to its former condition requires an expenditure of energy equivalent to pdv. The entropy of the two operations can change only by the gas receiving or giving up heat to its surroundings. Hence, the entropy of the gas at the end of the operation is the same in magnitude as it possessed just after expanding into the vacuum, and this value is greater than it possessed at the beginning by the magnitude of the volume change pdv. The change of ice into water at 0° in vacuo is measured by the heat rendered latent, λ/T, since both W and pdv are zero.

EXAMPLE.—If a gram of water at the absolute temperature T receives dQ units of heat as its temperature is raised to $T+dT$, then, since dQ for water is very nearly equal to dT, the gain of entropy $d\phi$ will be $d\phi=dQ/T$, or $d\phi=dT/T$; and if the entropy of liquid water at 0° or 273° K. be conventionally regarded as zero, the entropy ϕ, at T° K., will be, in natural logarithms,

$$\int_0^T d\phi=\int_{273}^T\frac{dT}{T};\ \text{or}\ \phi=\log\frac{T}{273}$$

If the water at T° be also converted into steam at T°, it will be necessary to add on the term λ/T, where λ denotes the latent heat of vaporization, at T°.

If a body absorbs an amount of heat dQ so that its energy increases by an amount

$C_v dT$, where C_v denotes the thermal capacity at a constant volume, and the work pdv is done against atmospheric pressure, $dQ=C_\iota dT+pdv$, and the entropy of the body will be

$$d\phi=\frac{dQ}{T}\text{ ; or }d\phi=\frac{C_\iota dT+pdv}{T}\quad . \quad . \quad . \quad . \quad (2)$$

From the gas equation $pv=RT$, it follows that $p/T=R/v$, and supposing that C_v is independent of the change of temperature, the entropy ϕ of a perfect gas, per gram-molecule, is

$$=C_v\int\frac{dT}{T}+R\int\frac{dv}{v}+I\text{ ; or }\phi=C_v\log T+R\log v+I\quad . \quad . \quad (3)$$

Several different but equivalent forms of this relation for ideal gases can be obtained by means of the relation $pv=RT$; and $C_p-C_v=R$. The integration constant, I, can be evaluated only by the introduction of another assumption. To overcome this difficulty, W. Nernst[3] postulates what he calls the *third law of thermodynamics : In an isothermal process involving liquid or solids, the change of entropy approaches zero as the temperature approaches absolute zero; and at the limit, the absolute zero of temperature, the entropy of every substance is zero* Consequently, if the entropy at absolute zero be taken as zero, the entropy at any assigned temperature will have a definite positive value determined solely by the thermodynamic state of the system. This means that when a body is heated from the absolute temperature T, the entropy will be given by

$$\phi=\int_0^T\frac{dQ}{T}\text{; or, }\phi=\int_0^T C_v\frac{dT}{T}\quad . \quad . \quad . \quad . \quad (4)$$

when the changes of volume are negligibly small, provided also that the body suffers no change of state—*e.g.* from solid to liquid ; or from one crystalline form to another. It will be observed that the integration constant has been eliminated in virtue of Nernst's assumption. It cannot be assumed that the specific heat at constant volume is independent of temperature ; and before the integration is performed, the relation between the specific heat at constant volume, C_r, and temperature must be known.

For very low temperatures P. Debye's limiting equation[4] $C_v=a(T/\theta)^3$ can be used for evaluating ϕ ; here a is a universal constant, and θ is a characteristic constant for each substance. For ordinary temperatures, P. Debye's formula is too complicated for practical use. S. Pagliani (1915), and G. N. Lewis and G. E. Gibson (1917) have evaluated the integral for a number of elements ; the latter, using a method of approximation, obtained the values for the atomic entropies of the 48 elements indicated in Table III.

In order to determine the free energy of formation of any compound from its elements, it will be sufficient to know the entropy of the compound and of its elements at the same temperature, as well as the heat of formation of the compound from the equation $dE-dQ=-Td\phi$, where dE denotes the increase of free energy ; dQ the thermal value of the reaction ; and $d\phi$ the increase in entropy at the constant temperature T. G. N. Lewis and G. E. Gibson add : The atomic entropies of the elements appear to show the same sort of periodicity with respect to atomic weights that occurs with other important atomic properties ; and according to S. Pagliani the entropies at the melting point calculated from (4), for C_p in place of C_v, diminish as the atomic weights increase—particularly for the groups in Mendeléeff's system when the metals are separated from the non-metals. As a result of his examination of G. Tammann's statement[5] that the entropy per gram atom of the metals before fusion is the same for all the metals, S. Pagliani found that the products of the entropies and the atomic weights of the elements are not constant.

Physical analogies of the mathematical concept of entropy.—It is extremely difficult to get a physical apart from a mathematical conception of entropy. The work W performed by an ideal gas expanding a volume v against a constant pressure p, is $W=pv$; so is the entropy related to the quantity of heat and temperature by the formally analogous expression $Q=T\phi$. We are here in the same position with regard to the entropy ϕ as if in the former case we had no conception of volume v. We might then speculate as to the physical significance of volume just as to-day we wonder what is the physical significance of entropy. Volume would then be defined as something whose change is measured by the ratio W/p, just as entropy is a magnitude whose change is measured by the ratio Q/T. Again, just as volume is regarded as the capacity factor and pressure the intensity factor of the volume energy of a gas, so it has been suggested that entropy is the *capacity factor* and temperature the intensity factor of heat energy. G. Zeuner[6] called entropy, *heat weight—Wärmegewicht*—probably as a result of an analogy between the part entropy plays in the energy developed by the fall of heat from a state $T_1\phi_1$ to the state $T_2\phi_2$, and the part played by weight in the energy developed by the fall of a mass from a state h_1w_1 to a state h_2w_2—when h represents the height, and w the weight of the bodies indicated by the subscripts.

TABLE III.—THE ATOMIC ENTROPIES OF THE ELEMENTS AT 25°.

Element.	Entropy.	Element.	Entropy.	Element.	Entropy.
Aluminium	6·9±⅓	Iodine	15·7±1	Potassium	19·7±⅓
Argon (gas)	36·4±2	Iridium	8·7	Rhodium	7·6
Beryllium	7·3	Iron	6·6	Ruthenium	6·9
Bromine (liquid)	18·5±2	Lanthanum	13·7	Silicon (metal)	4·7±⅓
Cadmium	11·6	Lead	15·4±⅓	Silver	10·2±⅓
Calcium	11·0±⅓	Lithium	7·6	Sodium	12·2±⅓
Carbon-diamond	0·6±⅓	Magnesium	8·3±⅓	Sulphur (rhom.)	7·6±1
Carbon-graphite	1·3±⅓	Manganese	7·3	Sulphur (monoc.)	7·8±1
Cerium	13·8	Mercury (liquid)	17·8±1	Thallium	14·6±⅓
Chlorine (gas)	25·7±2	Molybdenum	7·5	Thorium	13·6
Chromium	5·8	Nickel	7·2	Tin	11·5
Cobalt	7·2	Nitrogen (gas)	22·8±1	Titanium	6·6
Copper	8·0±⅓	Oxygen (gas)	24·1±1	Tungsten	8·4
Gold	11·0	Osmium	7·8	Uranium	11·1
Helium (gas)	29·2±1	Palladium	8·9	Zinc	9·8±⅓
Hydrogen (gas)	15·9±1	Platinum	10·0	Zirconium	9·5

Following a suggestion by O. E. Meyer, in 1872, L. Boltzmann[7] showed an intimate relation between the entropy of a system and *the probability of a particular state* in which the system can exist. It is assumed that the state of the system can be defined by the volume, temperature, etc. When an isolated system can pass from one state A to another state B, the probability of, say, the state A represents the relative chance that the system will exist in that state and not in the other. If the probability of the state A were ½, there is an even chance that the system will exist in either state just as there is an even chance of heads or tails appearing after the toss of a penny. In all spontaneous natural processes, the probability of the state of the system increases and tends towards a maximum probability (unit probability is certainty). The entropy of a system, said L. Boltzmann, is determined by the probability of the state of its molecular motion; and M. Planck has shown that if P denotes the probability of the state of a system, and ϕ its entropy, $\phi=k\log P$, where k is a universal constant which is independent of the chemical nature, and other variations in the condition of the system. In illustration, it is just as probable that heat will pass from a cold to a hotter body—say that a kettle of water over a fire will become colder—as that the entropy of a system will decrease by a spontaneous natural change. With R. Clausius, the transformation value of a particular state is equal to the difference between the entropies of the initial and final states ; with L. Boltzmann, the entropy of a physical system is a definite condition which depends solely on the probability of that state.

The law of maximum entropy.—If a system of two bodies A and B, respectively at the absolute temperatures T_1 and T_2, be in thermal communication, and so isolated that no heat is lost or gained from external sources, the total energy remains unaltered although heat passes from the hotter body A, at the temperature T_1, to the colder body B, at the temperature T_2. When the infinitesimally small quantity of heat dQ has passed from A to B, the entropy of A is diminished by dQ/T_1, and the entropy of B is increased by dQ/T_2. Consequently, the entropy of the whole system will be increased so that

$$\text{Gain of entropy}=\left(\frac{1}{T_2}-\frac{1}{T_1}\right)dQ$$

This expression must be positive, since T_1 is greater than T_2. The effect of the transfer of an infinitesimally small quantity of heat dQ from a hot to a colder body is to increase the entropy of the system. The transfer of heat, and consequently also the gain of entropy, will continue by a series of infinitesimally small stages until the bodies A and B have one common temperature, when the entropy of the system will have attained its maximum value. While the first law of thermodynamics says that in an isolated system, all possible changes of state leave its energy unaltered, the second law may be understood to mean that in an isolated system all possible spontaneous changes of state produce an increase in its entropy. The law of maximum entropy holds good however many bodies be included in the system, and unless something has been overlooked, it will apply to the whole universe considered as one system. In all changes, nature seeks to realize the condition of maximum entropy ; every spontaneous change is accompanied by an increase of entropy, and the tendency to change ceases only when the increase of entropy is the greatest possible. If the entropy of a system were to decrease, heat would pass from a cold to a hotter body ; the equalization of temperature which attends the passage of heat from a hot to a colder body increases the entropy of a system.[8] The very process which increases the entropy of the system is attended by a loss of available energy, so that, in this sense, an increase of entropy and a decrease of available or free energy are correlated phenomena. The degradation of energy will be complete when the entropy acquires a maximum value, and the free energy is zero.

Entropy and work of diffusion.—From equation (3), if a series of gases of molecular weight M_1, M_2 . . . which have no chemical action on one another, be contained in separate compartments, respectively of volume v_1, v_2 . . ., the entropy of the gas of molecular weight M_1 contained in the first compartment will be $\phi_1=M_1(C_{v_1}\log T+R\log v_1)$, and the total entropy of the gases in all the compartments will be

$$\phi=\Sigma MC_v\log T+\Sigma MR\log v \quad . \quad . \quad . \quad . \quad (5)$$

Similarly, the entropy of an intimate mixture of a volume V, of the same gases when $V=v_1+v_2+$ . . ., is

$$\phi_m=\Sigma MC_v\log T+\Sigma MR\log V \quad . \quad . \quad . \quad (6)$$

The difference between these two magnitudes represents the change of entropy which occurs on diffusion. The difference $\phi_m-\phi$ with a mixture of two gases, where $V=v_1+v_2$, reduces to

$$\text{Increase of entropy, } \phi_m-\phi=\mathrm{R}\log\frac{\mathrm{V}^M}{v_1^{m_1}v_2^{m_2}} \quad . \quad . \quad (7)$$

where $M=m_1+m_2$ and $V=v_1+v_2$. The numerator of this expression is always greater than the denominator, and therefore the entropy of a uniform mixture of gases is greater than the entropy of the same gases before they were mixed by diffusion. Hence, the diffusion of gases is an irreversible process, for work will have to be expended in separating the mixture into its constituents ; and work should be obtained if the gases are allowed to mix in suitable vessels.[9] In 1875, Lord Rayleigh showed that the work performed during the physical mixing of volumes v_1 and v_2 of two different gases at the same temperature and pressure is the same as that which would be gained during the expansion of the first gas from the volume v_1 to the volume $V=v_1+v_2$—namely, $pv_1 \log V/v_1$, where p denotes the partial pressures of the two gases of volumes v_1 and v_2 when $V=v_1+v_2$, *vide supra*, together with the work gained during the expansion of the second gas from a volume v_2 to a volume $V=v_1+v_2$—namely, $pv_2 \log V/v_2$—when the expansions are made in a vacuum. Consequently, the work gained by mixing two gases of volume v_1 and v_2 respectively at the constant pressures p, when $v_1+v_2=V$, is

$$\text{Work of diffusion} = p \log \frac{V}{v_1^{v_1}+v_2^{v_2}} \quad . \quad . \quad . \quad (8)$$

Thus the rule is brought under Dalton's principle that each gas behaves towards the other as a vacuum. In all cases the gases are supposed to follow Dalton's partial pressure law, where the total pressure is the sum of those pressures which would be exerted by each gas in the absence of the other. The result does not depend upon the physical nature of the gases, and there appears no reason why the argument should not be valid for two portions of the same gas. Hence arises the so-called *Gibbs' paradox*, because it follows that if the gases are chemically identical, there will be no change of state, and no change of entropy, accordingly $\phi_m-\phi$ will be zero and $\phi_m=\phi$. Consequently, M. Planck regarded the increase of entropy on diffusion as a sign that the gases are chemically different, and he suggested that the *chemical difference* between two substances cannot be represented by a magnitude which varies in a continuous manner, because the magnitude varies discontinuously; on the other hand, the *physical differences* between two bodies can be represented by a continuous function. This is taken to establish a fundamental difference between the chemical and physical properties of a substance.[10]

The relation between the laws of maximum entropy and the degradation of energy.—Imagine a system of three bodies, A at a temperature T_1 which is higher than T_2, the temperature of the second body B; and let C be the third body at a temperature T, the lowest temperature of all. If a small quantity of heat dQ performs work in passing A to C by a Carnot's cycle, the maximum available work is $(T_1-T)dQ/T_1$. Similarly, when a portion of heat dQ is transferred from B to C, the maximum available work is $(T_2-T)dQ/T_2$. By subtraction, it will be seen that there is a decrease dE in the availability of the energy of the system which is equivalent to

$$dE=T\left(\frac{1}{T_2}-\frac{1}{T_1}\right)dQ$$

but the increase in the entropy of the system is represented by the product of the bracketed and succeeding term. Consequently,

$$dE=Td\phi$$

A finite quantity of heat can be so transferred by the summation of a succession of infinitesimal instalments. This means that when heat passes from one part of an isolated system to another part, in consequence of a difference of temperature, there is a degradation of energy which is equal in amount to the product of the increase of the entropy of the system, and the absolute temperature of the coldest part. An increase of entropy thus corresponds with a decrease of the available and an increase of the unavailable energy. For stable equilibrium, the entropy of a system must have a maximum value.

The relation between entropy and free energy.—Under what conditions is it possible to predict the direction in which a particular process or reaction will proceed? In answer, the change will take place in that direction which involves a decrease in the free energy or an increase in the entropy of the system. The so-called intrinsic or internal energy U represents the work the system can do in virtue of its actual condition without any supply of energy from without. For example, when heat energy is communicated to a gas, it may separate the molecules or the atoms further apart against molecular or atomic attractions; it may change the kinetic energy of molecular or atomic motion; it may change the rotational or vibratory energy of the atoms; and it may change the electrical state of the molecules. If a system with the total intrinsic energy U_1 and entropy ϕ_1 changes or reacts so as to produce another system with the total intrinsic energy U_2 and entropy ϕ_2, at any given temperature, T, a reaction can take place only with the expenditure of free energy, and U_1-U_2 must be greater than $T(\phi_1-\phi_2)$. In reversible isothermal changes, a system with a positive value of $(U_1-U_2)-T(\phi_1-\phi_2)$ will tend to react; and whether or not a reaction will take place in a particular mixture depends on whether what H. von Helmoltz [11] called the

$$\text{Free energy of a system}=(U_1-U_2)-T(\phi_1-\phi_2) \quad . \quad . \quad (9)$$

$$\text{Free energy of a system}=(U_1-T\phi_1)-(U_2-T\phi_2) \quad . \quad . \quad (10)$$

has a positive, negative, or zero value. This function $U-T\phi$, is sometimes symbolized ψ; so that $\psi=\psi_1-\psi_2$; if ψ be negative, the system will be stable; if ψ has a positive value, the system will be unstable; and if ψ be zero, the system will undergo no change. Hence, this expression may be regarded as a **stability function**—it is usually called a *potential*, or *thermodynamic potential*, and ψ may be taken to represent the driving force of a reaction. The entropy itself is a test of the stability of a system, for equilibrium is stable when the entropy has a maximum value. As a rule, the application of the entropy test to a system is more difficult than the free energy or the thermodynamic potential test. It was not possible to give an exact definition of chemical affinity until thermodynamics had been developed. The thermodynamic potential or free energy can be employed as a measure of chemical affinity.

In ordinary thermochemical calculations, the quantities of energy absorbed and evolved during the reaction are made to balance. The balancing is quite illusory. The fallacy underlying the assumption that the driving force of a reaction $\psi_1-\psi_2$ represents the thermal value or heat of a reaction as measured in a calorimeter, rests on the fact that the energy $T(\phi_1-\phi_2)$ which is not available for doing work is ignored. In formulating the principle of maximum work it was tacitly assumed that the driving force of a reaction which occurs without change of state is equivalent to U_1-U_2 units of heat, and that if U_1-U_2 be a positive quantity, the reaction is necessarily exothermal. It will be obvious that the term $T(\phi_1-\phi_2)$ can be suppressed only at absolute zero, for only when $T=0$ will $T(\phi_1-\phi_2)$ be also zero. Consequently, the thermal value of a reaction can be a measure of the driving energy of a reaction, only at absolute zero. At ordinary temperatures, which are, after all, not far removed from absolute zero, the difference between (U_1-U_2) and $(U_1-U_2)-T(\phi_1-\phi_2)$ is not very great, and M. Berthelot's rule is a useful approximation—particularly in chemical technology—where a measure of chemical energy in terms of heat energy is required.

If a reaction can take place, with the absorption of heat, the internal energy of the system U_2, after the change, will be greater than the original internal energy U_1; and U_1-U_2 will have a negative value; but in order that free energy may be available for doing work during the change, ϕ_2 must be so much greater than ϕ_1 that when $T(\phi_1-\phi_2)$ is subtracted from U_1-U_2 the driving force of the reaction will still have a positive value. If the external work be involved in the change, as will be the case when work pv is performed on or by a uniform and constant pressure p, the term $p(v_2-v_1)$ must be included in the expression for the free energy of the system, and consequently,

$$\text{Free energy of a system}=(U_1-T\phi_1+pv_1)-(U_2-T\phi_2+pv_2) \quad . \quad . \quad (11)$$

The fundamental equation for the free energy of a system thus assumes the form

$$dE=dU-Td\phi \quad . \quad . \quad . \quad . \quad . \quad (12)$$

meaning that in any isothermal process, or chemical reaction, the increase dE in the free energy of the system is equal to the difference between the increase dU in the internal energy of the system and the product of the absolute temperature, T, and the increase, $d\phi$, of the entropy.

J. W. Gibbs (1878)[12] in his important paper, *On the equilibrium of heterogeneous substances* (1875), used these functions with the object of facilitating mathematical operations. He called $\psi=U-T\phi$, the *force function* for constant temperature; $\zeta=U-T\phi+pv$, the force function for constant temperature; and $\chi=U+pv$, the heat function for constant pressure. They are often styled the *psi, zeta,* and *chi functions of Gibbs*. P. Duhem (1895) called Gibbs' ψ-function the internal thermodynamic potential; and the ζ-function, the thermodynamic potential for constant pressure, or the thermodynamic potential or the potential of the system.

It will be observed that while the difference $(U_1-U_2)-T(\phi_1-\phi_2)$ represents the change in the free energy of the system during the isothermal change, (U_1-U_2) represents the change in the total intrinsic energy of the system; the remainder, $T(\phi_1-\phi_2)$ represents the unavailable energy which H. von Helmholtz called the *bound energy* of the system. J. Swinburne[13] has further emphasized H. von Helmholtz's conception by showing that the degradation of energy is a liability which is incurred when any form of energy is converted into heat, for only part may be available for work, the remaining part which is eventually and unavoidably produced or left as heat at the lowest possible temperature is of no use; it is waste. Entropy furnishes a measure of this waste, for

> An increase of entropy is a quantity which, when multiplied by the lowest available temperature gives the increased waste. In other words, the increase of entropy multiplied by the lowest available temperature gives the energy that either has been already irrevocably degraded into heat during the change in question, or must, at least, be degraded into heat in bringing the working back to the standard state.

The product of the absolute temperature of a process conducted at a constant uniform temperature T, into the difference between the entropy at the beginning and end of the operation, *viz.* $T(\phi_1-\phi_2)$, represents the energy cost of the reaction, or the amount of energy rendered unproductive during the change; it is in some respects analogous with the so-called latent heat of a change of state, and hence has also been called the *latent energy* of a reaction. The term *latent* suggested for say the heat of liquefaction by J. Black implied that the heat was still present, but latent, dormant, or held in abeyance. The term latent energy for that portion of energy which is degraded into a lower plane of availability during a process or reaction is quite inappropriate and should be avoided. The loss of work-value suffered by energy during a physical or chemical process may be due to a change in the constitution or the state of aggregation of the body, or to a change in the thermal capacity of the initial and final substances concerned in the reaction.

A reversible change is an idealized phenomenon which is supposed to take place in every respect, in an opposite direction, so that when completed, the system is in the same condition as it was at the beginning. *Actually*, no change takes place in nature without incurring some waste. Consequently, a reversible change is an imaginary cyclic phenomenon in which there is no waste of energy. If energy were wasted during a reversible change, there would be, on reversal, a decrease of the incurred waste, and a perpetual motion would be possible, for, in spite of friction, etc., the available energy would not diminish. The entropy of a reversible system remains constant, so that if there is an increase of entropy in one part, this must be compensated by an equal decrease in another part.

Consider an indefinitely large quantity of each of two reacting gases A and B in a state of equilibrium, to be confined in a suitable compartment, and further, suppose a compartment containing an indefinitely large quantity of pure A, and another compartment with pure B, each at the same concentration as it has in the equilibrium compartment. Let the component B be transferred by a semi-permeable membrane or other reversible method from the equilibrium compartment to its own special B-compartment, and replenish the equilibrium compartment with one equivalent of A taken from the A-compartment. Let the two operations be carried on simultaneously, so that the concentrations remain unchanged throughout the process. The temperature remains uniformly constant at T. If ϕ_1 denotes the entropy of an equivalent mass of A and ϕ_2 that of B,

$$\phi_1-\phi_2=-\frac{Q}{T} \quad . \quad . \quad . \quad . \quad . \quad (13)$$

where Q denotes the heat absorbed per equivalent at constant pressure, and the negative sign shows that the change of entropy is equal to the heat absorbed divided by the temperature. This is regarded as the symbolic expression of the second law of thermodynamics applied to chemical reactions. From equation (3), $\phi_1=C_{v1}\log T+R\log C_1+I_1$; $\phi_2=C_{v2}\log T+R\log C_2+I_2$. Accordingly, by substitution in (9), and rearranging terms,

$$\log\frac{C_1}{C_2}=-\frac{Q_p}{RT}-\frac{\Sigma C_v}{R}\log T-\frac{\Sigma I}{R} \quad . \quad . \quad . \quad (14)$$

The equilibrium constant K can be used in place of the ratio of the concentrations C_1/C_2. The sign Σ is used for the summation sign for the specific heats and the integration constants. The argument can be extended to include any number of reacting components on the assumption that the specific heats of all the gases taking part in the reaction are independent of temperature, and that the gases follow the ideal law $pv = RT$, so that their total energies are independent of the pressure. Equation (14) is the general form of the law of mass action.

Again, if equation (14) be differentiated, and G. Kirchhoff's equation $dQ_p/dT=-\Sigma(C_p+RT)$ be substituted, and remembering that $Q_p+\Sigma RT=Q_v$, J. H. van't Hoff's important equation

$$\frac{d\log K}{dT}=-\frac{Q_v}{RT^2}$$

showing the relation between the equilibrium constant and the thermal value of the reaction at constant volume, is obtained—*vide infra.*

§ 10. The Work done by Affinity during a Chemical Reaction

The doctrine of chemical affinity is unquestionably the great and distinguishing principle of the science of chemistry as the laws of motion are of mechanical philosophy.—J. BLACK (1803).

Every chemical change performs work which is equivalent to a certain amount of mechanical energy.—W. STILLIE (1865).

Chemical action usually produces changes in the state of aggregation or density of the reacting substances, and so performs work as well as produces heat. As indicated above, H. von Helmholtz (1882) emphasized the necessity for distinguishing between that part, dE, of chemical energy, which can do work (free energy) from that part, $Td\phi$, which is degraded solely as heat (bound or latent energy), since, as previously indicated, the total chemical energy $dU=dE+Td\phi$. Every spontaneous reaction involves a decrease in its free energy, and an increase in the bound energy. It is the decrease in the free energy, and not the development of heat, which determines the direction of a chemical reaction. Hence, **the decrease in the free energy of a system is a measure of the work which can be done by chemical affinity during a chemical reaction; and is equivalent to the maximum work gained when the process is conducted reversibly at a constant temperature.**

J. H. van't Hoff, in his *Études de dynamique chimique* (Amsterdam, 1884), considers that the magnitude of chemical affinity is equivalent to that of the work the reaction can do when it is carried out in such a manner that the driving forces are always balanced by equal and opposite external forces; otherwise expressed, **the affinity of a chemical reaction can be measured in terms of the amount of work the reaction can do when it is carried out at a constant temperature in a reversible manner.** The work *in maximo* which can be obtained in a chemical change is closely related to the free energy of the reaction; this work cannot always be determined by direct measurement, although in the case of gases, and also in the case of dilute solutions when the gas laws are applicable, it can often be calculated from (i) The change in the vapour pressure, or, in the case of dilute solutions, the osmotic pressure; (ii) The chemical equilibrium constants; or (iii) The electromotive force of the reaction; for example, the chemical affinity of the reaction $H_2+Cl_2=2HCl$ can be determined by measuring the electromotive force of a cell whose electrodes are chlorine and hydrogen gases, with hydrochloric acid as electrolyte.

When a gas at a pressure p_1 changes its volume isothermally at $T°$, so as to correspond with a pressure p_2, the work, W_v, done by the gas is $W_v=RT\log(p_1/p_2)$, as previously indicated, provided that Boyle's and Charles' laws are applicable. Since the volume of a gas varies inversely as its concentration C, usually expressed in gram-molecules per litre, it follows that $p=CRT$, and hence, the free energy W_v involved in changing a gas from a pressure p_1 to a pressure p_2, at constant volume, is

$$W_v=RT\log\frac{p_1}{p_2};\ \text{or,}\ W_v=RT\log\frac{C_1}{C_2};\ \text{or,}\ W_v=RT\log K \quad . \quad (1)$$

for gaseous reactions of the type $A\rightleftharpoons B$, when $k_1C_1=k_2C_2$, where k_1 and k_2 are constants such that $C_1/C_2=K=k_1/k_2$. The equations, therefore, can be used to calculate the maximum work or the free energy of physical or chemical processes which pass isothermally from A with an initial concentration C_1 or vapour pressure p_1 to a state of equilibrium with B which has a concentration C_2 or vapour pressure p_2, without doing any external work, that is, the volume is supposed to be constant. These relations are generally applicable to reactions in gaseous systems or in dilute solutions at constant volume and temperature. One of the simplest illustrations occurs during the transformation of rhombic sulphur—vapour pressure p_1—to monoclinic sulphur—vapour pressure p_2.

EXAMPLE.—The affinity of a gram-molecule of water for a gram-molecule of an aqueous solution of sulphuric acid, $H_2SO_4.H_2O$, which has a vapour pressure 0·0184 cm. of mercury, at 25°, is given by the first of equations (1), when the vapour pressure of the acid with the addition of another gram-molecule of water, $H_2SO_4.2H_2O$, is 0·1125 cm. at the same temperature. Hence, $W_v=RT \log (p_2/p_1)$, or $W_v=2\times 298\times 2{\cdot}3\times \log$ (0·1125/0·0184), or $1371\times \log 6{\cdot}135$, or 1080·cals. The factor 2·3 transforms natural into common logarithms. The observed heat of the reaction, according to J. Thomsen (1870), is 1874 cals.

It was shown by J. H. van't Hoff, in his *Études de dynamique chimique* (Amsterdam, 1884), that if hydrogen and oxygen, of the concentrations C_{H_2} and C_{O_2}, pass isothermally and reversibly into water vapour when the initial concentration of the water vapour is c_{H_2O}, and the equilibrium concentrations of these three gases are respectively c_{H_2}, c_{O_2}, and c_{H_2O} at the absolute temperature T, the maximum work W is a measure of the affinity of the reaction $2H_2+O_2\rightarrow 2H_2O$ per gram-molecule of oxygen or per two gram-molecules of hydrogen, where

$$W=RT\left(\log \frac{C^2_{H_2}C_{O_2}}{C^2_{H_2O}}+\log \frac{c^2_{H_2O}}{c^2_{H_2}c_{O_2}}\right) \quad . \quad . \quad . \quad (2)$$

By Guldberg and Waage's law, for equilibrium, $c^2_{H_2O}=Kc_{H_2}c_{O_2}$, and the last equation can be reduced to

$$W=RT\left(\log K-\log \frac{C^2_{H_2O}}{C_{H_2}C_{O_2}}\right) \quad . \quad . \quad . \quad . \quad (3)$$

or generally

$$W=RT \log K-RT\Sigma n \log C \quad . \quad . \quad . \quad . \quad (4)$$

where C refers to the concentration of the saturated vapour of each constituent; and the term $\Sigma n \log C$ refers to $N_1 \log C_{B_1}+N_2 \log C_{B_2}+\ldots-n_1 \log C_{A_1}-n_2 \log C_{A_2}$—in the chemical equation $n_1A_1-n_2A_2+\ldots=N_1B_1+N_2B_2+\ldots$ If the concentrations of the initial and the final products of the reaction are arbitrarily made unity, the affinity of the reaction is simply expressed by the relation

$$W=RT \log K \quad . \quad . \quad . \quad . \quad . \quad (5)$$

The affinity of the process $2H_2+O_2\rightarrow 2H_2O$ per gram-molecule of hydrogen is therefore $\frac{1}{2}W$.

EXAMPLES.—(1) The equilibrium constant in the reaction $H_2+I_2=2HI$ at 300° is nearly 80. What is the affinity of the reaction $H_2+I_2\rightarrow 2HI$ at this temperature when the initial concentration of the three components of the reaction is in each case unity ? From (4), $2\times 573\times 2{\cdot}3 \log_{10} 80=4631$ cals. nearly. The thermal value of the reaction is negative—6000 cals.—so that there is a marked difference between the free energy and the thermal value of the process.

(2) In the reaction $2H_2+O_2=2H_2O$ at 727°, the equilibrium constant is $1{\cdot}25\times 10^{-20}$. Hence, the free energy of the reaction $2H_2+O_2\rightarrow 2H_2O$ at this temperature, when the initial concentration of the hydrogen, oxygen, and water vapour are unity, is $-2\times 1000\times 2{\cdot}3 \log 1{\cdot}25\times 10^{-20}$, or 90,600 cals. nearly.

(3) In the reaction $CaO+H_2O\rightarrow Ca(OH)_2$, if p_0 be the initial and p the equilibrium pressure of the steam at a temperature T, the affinity of the reaction is $W=RT \log (p_0/p)$; and if the initial pressure of the steam be one atmosphere, $W=-RT \log p$. Except at a very high temperature, p is less than unity, so that W will be positive, meaning that steam

will unite with the lime, and if W be negative, the hydroxide will dissociate. At 25°, the dissociation pressure of calcium hydroxide is 9×10^{-13} atm., and therefore, the affinity of the water vapour for lime is $W = 2 \times 2{\cdot}3 \times 298 \times \log (9 \times 10^{-13})$, or $-2 \times 2{\cdot}3 \times 298 \times -13{\cdot}95 = 19{,}120$ cals. Similar remarks apply to the reaction $CaO + CO_2 \rightarrow CaCO_3$.

(4) What is the affinity of iron for oxygen under the partial pressure of oxygen in the atmosphere when the dissociation pressure of ferrous oxide at 1000° abs. is $3{\cdot}1 \times 10^{-18}$ mm. ? The equilibrium constant K for the reaction $2Fe + O_2 = 2FeO$ is $K = 1/p$, where p is the dissociation pressure of the gas from the ferrous oxide. The oxygen of the atmosphere is under the partial pressure of one-fifth of an atmosphere, and a pressure of $3{\cdot}1 \times 10^{-18}$ mm. is $3{\cdot}1 \times 10^{-18}/760 = 4{\cdot}1 \times 10^{-21}$ atm. Hence, $W = RT(\log\frac{1}{5} - \log p)$, or $2{\cdot}3 \times 2 \times 1000$ $(\log_{10} 0{\cdot}2 - \log 4{\cdot}1 \times 10^{-21})$, or 4600 (1·3010–21·6128), or $4600 \times 19{\cdot}6882$, or 90,000 cals. nearly. H. le Chatelier's number for the heat of the reaction of two gram-molecules of iron with a gram-molecule of oxygen is 129,900 cals.

It is sometimes possible to calculate the free energy of a reaction indirectly as in the case of heats of reactions. Thus, the equilibrium constant in the reaction $2CO = 2C + O_2$ is very small even at high temperatures; the free energy of the reaction at 1000° abs. can be computed from the free energy of the reaction $CO + \frac{1}{2}O_2 \rightarrow CO_2$, which is 47,200 cals.—and the free energy of the reaction $2CO \rightarrow C + CO_2$, which is -610 cals. Subtracting the latter algebraically from the former, and $CO + \frac{1}{2}O_2 - 2CO \rightarrow CO_2 - C - CO_2 + (47{,}200 + 610)$ cals., or $C + \frac{1}{2}O_2 \rightarrow CO - 47{,}810$ cals.; or the free energy of the reaction $2CO \rightarrow 2C + O_2$ is -95620 cals.

Examples.—(1) If the free energy of the reaction $2CO = 2C + O_2$ at 1000° is $-95{,}620$ cals., and of the reaction $2FeO = 2Fe + O_2$, $-95{,}400$ cals., show that the free energy of the reaction $FeO + C \rightarrow Fe + CO$ is 110 cals.

(2) According to G. Bodländer,[1] assuming that the thermal values of the reactions are independent of the temperature, the free energy of formation of zinc oxide is $Zn + \frac{1}{2}O_2 = ZnO + (85{,}800 - 30{\cdot}8T + 2{\cdot}29T \log p_0)$ cals., where p_0 denotes the partial pressure of the oxygen expressed in atmospheres. Similarly, the free energy of formation of water is $H_2 + \frac{1}{2}O_2 = H_2O + \{57600 - 22{\cdot}4T + 2{\cdot}29T \log (p_1{}^2 p_0/p_2{}^2)\}$ cals., where p_0 denotes the partial pressure of the oxygen, p_1 that of the hydrogen, and p_2 that of the water expressed in atmospheres. By subtraction of the first from the second equation, the free energy of the reaction, $ZnO + H_2 = Zn + H_2O$, at 1000° C., or 1273° K., will be $57{,}500 - 85{,}800 - (30{\cdot}8 - 22{\cdot}4)1273 + 2{\cdot}29 \times 1273 \times \log p_1^2 p_2^{-2}$ cals. This shows that zinc oxide is reduced at 1000° by hydrogen at atmospheric pressures only when the partial pressure of the water vapour does not exceed $p_2 = 0{\cdot}001$ atm. or 0·76 mm., because only under these conditions is free energy available for the reaction. Analogous results are obtained with the reduction of ferrous oxide by hydrogen, for the free energy of the formation of ferrous oxide is $Fe + \frac{1}{2}O_2 = FeO + (64600 - 25{\cdot}9T + 2{\cdot}29T \log p_0)$ cals.

§ 11. The Effect of Temperature on Chemical Equilibria

Le problème de l'affinité est le problème central de la chimie.—S. Arrhenius.

There are four important stages in the evolution of the modern idea of chemical affinity: (i) The growth of the concept connotated by the term *affinity*; (ii) The discovery of the *law of mass action* as a result of the work of C. F. Wenzel (1777), C. L. Berthollet (1803), L. Wilhelmy (1850), A. V. Harcourt and W. Esson (1866), C. M. Guldberg and P. Waage (1867), etc.; (iii) The recognition of the significant part played by *free energy* in determining the character and state of chemical phenomena as a result of the work of J. W. Gibbs (1876), H. von Helmholtz (1882), J. H. van't Hoff (1884–7), W. Ostwald (1892), etc.; and (iv) The effect of *temperature* on chemical equilibria as a result of the work of J. H. van't Hoff (1884–7), H. le Chatelier (1884), F. Haber (1905), W. Nernst (1906), etc.

The two great principles of thermodynamics—embodied in the statements that all the changes which take place in an isolated system produce a decrease in the free energy (second law), and leave the amount of energy unchanged (first law)—have furnished Helmholtz's equation, $W-Q_p=T.dW/dT$, which shows a relation between the affinity, W, the thermal value, Q_p, and the absolute temperature, T, of a chemical process. With the aid of the calculus, this equation can be written:

$$\frac{d}{dT}\left(\frac{W}{T}\right)=-\frac{Q_p}{T^2};\ \text{or,}\ \frac{W}{T}=-\int_0^{\mathrm{T}}\frac{Q_p}{T^2}dT+I\quad . \quad . \quad . \quad (1)$$

where I is the so-called integration constant. The last equation embodies one solution of the main problem of chemical affinity, namely, to predict what will occur if a number of substances are mixed together under given conditions of temperature, pressure, electromotive force, etc. The affinity of a chemical reaction can be calculated for any temperature T when (i) the relation between the thermal value of the reaction and the temperature is known, and when (ii) the integration constant I has been evaluated. Since $W=RT\log K$, it follows, substituting for W,

$$\frac{d}{dT}(\log K)=-\frac{Q_p}{RT^2};\ \text{or,}\ \log K=-\int_0^{\mathrm{T}}\frac{Q_p}{RT^2}dT+I\quad . \quad . \quad (2)$$

The first of equations (2) can be written in the alternative form

$$\frac{1}{dT}\left(\frac{dK}{K}\right)=-\frac{Q_p}{RT^2}$$

which shows that the fractional change, dK/K, in the value of the equilibrium constant, per degree, dT, (i) is proportional to the heat Q_p of the reaction; and (ii) inversely proportional to the square of the absolute temperature. The equation also shows that a rise of temperature, dT, will displace the equilibrium conditions in the same direction as the reaction which absorbs heat. For endothermal reactions where Q_p is negative, the equilibrium constant increases with rise of temperature; and conversely, for exothermal reactions, where Q_p is positive, the equilibrium constant decreases with rise of temperature. This is *the principle of reversibility* previously discussed. The above result was obtained by J. H. van't Hoff in 1887, and has been called the equation of the *reaction isochore* (ἴσος, equal, χῶρος, place) by W. Nernst (1889), because the volume is kept constant during the change. J. H. van't Hoff's equation, (2), also represents the influence of temperature on the system kept at a constant volume; Q_p represents the heat emitted during the formation of a substance whose concentration appears in the numerator of $K=C_1/C_2$. There is a formal relation between Clapeyron-Clausius' and van't Hoff's equations:

$$\frac{d}{dT}(\log p)=\frac{\lambda_p}{RT^2};\ \frac{d}{dT}(\log K)=-\frac{Q_p}{RT^2}\quad . \quad . \quad . \quad (3)$$

The difference lies in the interpretation of the symbols; in the one case, p represents a pressure, while the corresponding K in the other case is a product of concentrations, but in dilute solutions and gases, concentration can be expressed in terms of osmotic or gaseous pressure. The term $\lambda=-Q_p$ refers to the diminution in the internal energy, or the heat evolved by the reaction under a constant pressure p.

If the numerical value of the integration constant I could be deduced from the known laws of heat, the problem concerning the effect of temperature could be solved, but the two laws of thermodynamics *per se* leave the problem undetermined. Although the two laws of thermodynamics can be applied generally to a great variety of phenomena, they fail to yield precise conclusions, applicable to particular cases, without the use of certain experimental data to evaluate the integration constants[1] which arise because of our ignorance of the absolute values of the energy of the system at any temperature. Nernst's theorem is an attempt to solve this problem by assuming that at absolute zero, the entropy is zero, and this is taken as a standard of reference. There are two cases to consider before the integration of equations (2) can be performed:

I. The thermal value Q_p of the reaction does not alter appreciably with changes of temperature.[2] If the equation be integrated on the assumption that Q_p is constant over a small range of temperature, and that K_1 and K_2 respectively denote the equilibrium constants at the two temperatures T_1 and T_2, then, since R is approximately 2,

$$\log_{10}\frac{K_2}{K_1}=1{\cdot}15Q_p\left(\frac{1}{T_1}-\frac{1}{T_2}\right) \quad . \quad . \quad . \quad . \quad (4)$$

By means of this equation it is possible to compute the thermal value of a reaction which changes but little between the temperatures T_1 and T_2 when the equilibrium constants for these temperatures are known, Q_p may represent the heat of sublimation, the heat of vaporization, the heat of solution, the heat of dissociation, as well as the thermal value of strictly chemical reactions. The thermal values calculated by means of this equation are in close agreement with the observed values when the necessary conditions obtain ; this is illustrated by Table IV.

TABLE IV.—THE THERMAL VALUES OF PHYSICAL AND CHEMICAL CHANGES.

Heat of	Q in Cals.	
	Calculated.	Observed.
Vaporization of water	10·10	10·30
Solution of boric acid in water	5·2	5·6
Sublimation of ammonium sulphide	21·55	21·64
Combination of $BaCl_2+2H_2O$	3·82	3·83
Dissociation of nitrogen peroxide	12·90	12·50
Precipitation of silver chloride	15·99	15·85

When the heats of formation of a substance at any temperature are known, the percentage dissociation at any assigned temperature can be calculated on the assumption that this equation is valid, since if any four of these five magnitudes are known, the fifth can be computed.

EXAMPLES.—(1) Calculate the heat of solution of mercuric chloride from the change of solubility with temperature when the solubility at the absolute temperature 283° is 6·57, and 11·84 when the temperature is 323°. Substituting these numbers in the above equation, Q is 2700 (nearly) cals. The observed value is nearly 3000.

(2) At 670°, the dissociation pressure of barium dioxide is 80 mm., and at 720°, 210 mm. Show that the heat of the reaction, $2BaO_2=2BaO+O_2$, approximates $-36{\cdot}1$ Cals., and that the maximum work furnished by the formation of two gram-molecules of barium dioxide from the monoxide and oxygen at 670°, and at the same partial pressure as it occurs in the atmosphere, is equivalent to 1203 cals.

When but one value of K at the temperature T is available, the integration of (2) furnishes the expression :

$$\log_{10}K=-0{\cdot}22\frac{Q_p}{T}+I \quad . \quad . \quad . \quad . \quad (5)$$

where I is the integration constant, and Q_p the thermal value of the reaction at constant pressure, and does not vary with changes of temperature. F. E. C. Scheffer considers that the expression $\log K=aT^{-1}+b$ is sufficiently in agreement with measurements of the equilibrium for all reactions which have been studied. If the reaction takes place at a constant pressure, an allowance can be made for the work done, and the thermal value of the reaction at constant volume, Q_v, is related to that at constant pressure, Q_p, by the expression $Q_p=Q_v-\Sigma nRT$, where ΣnRT represents the work done by the system against this pressure, and Σn denotes the difference between the sum of the molecular coefficients of the products of the reaction taken negative, and of the initial products taken positive—for instance, in the reaction $2H_2+O_2=2H_2O$, $\Sigma n=2+1-2=1$.

II. The thermal value Q of the reaction changes with variations of temperature.—It has been assumed that Q is constant, but if Q varies with temperature, the relation between Q and T must be known before the integration of (2) can be performed. It is usual to represent the relation between Q and T by the empirical formula of the type $Q=Q_0+\alpha T+\beta T^2$ . . ., where Q_0, α, β . . . are constants whose numerical values are calculated from the observed values of Q and T, and Q_0 is the value of Q when the temperature is at the absolute zero. If this expression for Q be substituted in the second of equations (1), and the integration be performed,

$$W=Q_0+IT-\alpha T\log T-\beta T^2-\tfrac{1}{2}\gamma T^3-\ldots \qquad (6)$$

which represents the affinity W in terms of the heat of the reaction at the temperature T.

Liquid and solid systems.—In his memoir *Ueber die Berechnung chemischer Gleichgewichte aus thermischen Messungen* (1906), W. Nernst[3] introduced the hypothesis that in the case of *condensed systems*—that is, systems involving only liquid or solid substances—the temperature coefficients of the free and total energy—*viz.* dW/dT and dQ/dT—decrease to indefinitely small values as absolute zero is approached ; and, the limiting value of

$$\frac{dW}{dT}=\frac{dQ}{dT}=0, \text{ at absolute zero, when } T=0$$

Consequently, the curves showing the relation between the affinity W, or the total energy Q, and temperature T, will coincide at absolute zero, and the equality will be usually maintained only for a short region of temperature in the neighbourhood of absolute zero. The measurement of Q and of W cannot be performed in the vicinity of absolute zero, and consequently, Nernst's hypothesis—called **Nernst's heat theorem**—cannot be directly verified. The hypothesis, however, has been verified indirectly, and the results are in satisfactory accord with experiment. It will be observed that if dQ/dT be zero when $T=0$, the term involving α must vanish from the expression $Q=Q_0+\alpha T+\beta T^2+$ . . ., because otherwise, at absolute zero, when $T=0$, $dQ/dT=\alpha$. The differential coefficient, dQ/dT, represents the specific heat of a gas, and consequently W. Nernst's assumption also includes the assumption that the specific heat of a gas is zero at absolute zero.[4] If very high temperatures be not under consideration, the higher powers of T can be neglected because their numerical coefficients are very small, and

$$Q=Q_0+\beta T^2 \qquad (7)$$

For similar reasons, if dW/dT be zero, I and α in the expansion (6) must vanish, and

$$W=Q_0-\beta T^2 \qquad (8)$$

Consequently, *for systems involving only liquids and solids the integration constant is zero*, in agreement with results previously obtained by G. N. Lewis (1899),[5] and others. Again, *for condensed systems, the numerical value of the affinity of a reaction can be computed from heat measurements alone.* Experiments show that for many reactions, where the evolution of heat is great, the coefficients β, γ . . . are very small, and W and Q have nearly the same value Q_0 ; and in these cases, M. Berthelot's rule—the principle of maximum work—will apply.

According to G. Kirchhoff's equation, the variation of Q with temperature, *viz.* dQ/dT, is equal to the difference in the specific heats, or rather the thermal capacities at constant volume of the initial (C_1) and final (C_2) products of the reaction ; in symbols, $dQ/dT=C_2-C_1$; and if γ, δ . . . are negligibly small, $dQ/dT=2\beta T^2$ $=C_2-C_1$, which gives the value of β ; hence, if Q be determined for any temperature T, Q_0 can be calculated from (7), and hence the free energy or affinity W, or log K can be calculated when Q_0, β, and T are known.

EXAMPLE.—From H. V. Regnault's measurements (1844) of the specific heats of rhombic and monoclinic sulphur, the numerical value of C_2-C_1 is nearly $0{\cdot}1840-0{\cdot}1764=0{\cdot}0076$. Consequently, $329\beta=0{\cdot}0038$, or $\beta=1{\cdot}15\times10^{-5}$. The heat of transformation at 368° absolute, according to G. Tammann (1903), is nearly 3·13 cals. Hence, $3{\cdot}13=Q_0+1{\cdot}09\times10^{-5}\times368^2$; or $Q=1{\cdot}57+0{\cdot}0000115T^2$. According to J. N. Brönsted,[6] the results obtained by comparing the observed and calculated values of Q at different temperatures are satisfactory. Similarly, $W=RT\log K=1{\cdot}57-0{\cdot}0000115T^2$. The curves obtained by plotting corresponding values of Q and T and W and T are indicated in type II, Fig. 2. Here, W decreases, and Q increases with increasing values of T, and at absolute zero the two curves coincide.

Equations (7) and (8) show that the two curves change symmetrieally for solid and liquid systems as indicated in Fig. 2, for the coefficients β, γ . . . may be positive or negative, and there are two possibilities for the slopes of the curves representing the changes of W and Q with temperature T. Deviations from symmetry occur when the change in the specific heat of the reacting substance is not a linear function of temperature.[7] For the reaction $CuSO_4+H_2O_{ice}\rightarrow CuSO_4.H_2O$, H. Schottky [8] found $Q=4520+0{\cdot}00408T^2$, and $W=4520-0{\cdot}00408T^2$, and this reaction is therefore representative of type II, Fig. 2, where the free energy W decreases, while the thermal value Q of the reaction increases with rise of temperature, and at 291° K. the free energy is less than the thermal value of the reaction. Again, for Clark's cell, $Zn+Hg_2SO_4+7H_2O_{ice}\rightarrow ZnSO_4.7H_2O+2Hg$, W. Nernst [9] finds that $Q=38505-0{\cdot}0017T^2$, and $W=38505+0{\cdot}0017T^2$. Here, the free energy W increases with temperature, while the thermal value Q of the reaction decreases as illustrated by the curve type I, Fig. 2.

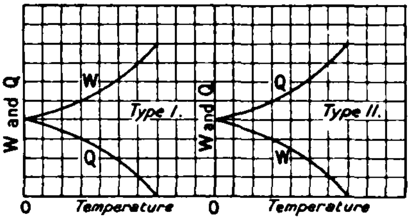

FIG. 2.—Variations of Q and W with Temperature.

At the transition point, say, in the passage of rhombic to monoclinic sulphur, the free energy must be zero, and $W=0$. Consequently, the transition temperature $T=(Q_0/B)^{\frac{1}{2}}$ from (7) and (8). The free energy of the change of rhombic to monoclinic sulphur is represented by the relation $W=1{\cdot}57-0{\cdot}0000115T^2$, consequently, the transition temperature is approximately 368° K., or (368°−273°)=95°. The observed value is 94·4°.

Gaseous systems.—The preceding discussion refers to solid or liquid systems, and it has been extended to gaseous systems when the molecular heat of the reaction at one temperature and the molecular heats of the gaseous substances at a few other temperatures are known. If Q denotes the heat of the reaction, it has been shown that $Q=Q_0+\alpha T+\beta T^2+\gamma T^3+\ .\ .\ .$, and this value of Q may be substituted in van't Hoff's equation (2). On integration,

$$RT\log K_v=Q_0+\alpha\log T+\beta T+\tfrac{1}{2}\gamma T^2+\ .\ .\ .\ +I \quad . \quad . \quad (9)$$

To evaluate the integration constant I, turn to Clapeyron-Clausius' equation, $\lambda=RT^2(d\log p)/dT$, a solution of which is possible when λ can be represented as a function of the temperature. If $\lambda=-\lambda_0+\alpha'T+\beta'T^2+\ .\ .\ .$, where λ_0 represents the internal molecular heat near absolute zero, and α', β' . . . are numerical constants. It follows, after the substitution and integration, that

$$\Sigma n\log C=-\frac{\Sigma n}{R}\left(\frac{\lambda_0}{T}-\alpha'\log T-\beta'T-\frac{\lambda'}{2}T^2-\ .\ .\ .\right)\Sigma nI' \quad . \quad (10)$$

Substituting $W=Q_0-\beta''T^2-\tfrac{1}{2}\gamma''T^3-\ .\ .\ .$, and the above value for $\Sigma n\log C$, in van't Hoff's equation $W=RT\log K-RTn\log C$, the result can be reduced to the form

$$RT\log K=(Q_0'-\Sigma n\lambda_0)+\Sigma n\alpha'T\log T-(\beta''-\Sigma n\beta')T^2-\ .\ .\ .\ +RT\Sigma nI'$$

This deduction from Clapeyron-Clausius' equation has a formal analogy with the deduction (9) from van't Hoff's equation, and both refer to the same quantity RT log K. Assuming that the equations are identities, the coefficients of like powers of T in both equations can be equated each to each: $Q_0=Q_0'-\Sigma n\lambda_0$; $-a=\Sigma na'$; $-\beta=-\beta''+\Sigma n\beta'$; and $I=\Sigma nI'$. Hence, the integration constant of the equations for the vapour pressures of the reacting components can be used to evaluate the constant I of a given reaction, for the revised equation (9) may be written

$$\log K_v=\frac{Q_0}{RT}-\frac{a}{R}\log T-\frac{\beta}{R}T-\frac{\gamma}{2R}T^2+\ .\ .\ .\ +\Sigma nI' \quad . \quad (11)$$

It will be remembered that K_r, the equilibrium constant of the chemical equation $n_1A_1+n_2A_2+\ .\ .\ .\ =N_1B_1+N_2B_2+\ .\ .\ .$, is equivalent to

$$K_v=\frac{c_1^{n}c_2^{n}\ .\ .\ .}{C_1^{N_1}C_2^{N_2}\ .\ .\ .}\text{; and } K_p=\frac{p_1^{n}p_1^{n_2}\ .\ .\ .}{P_1^{N_1}P_2^{N_2}\ .\ .\ .}$$

when the partial pressures are used. From Boyle's law $p=CRT$ it follows that $P_{B_1}^{N_1}=C_{B_1}^{N_1}(RT)^{N_1}$, etc., and consequently, $K_p=K_v(RT)\Sigma n$, or log $K_p=$log K_v $+\Sigma n$ log $R+\Sigma n$ log T. Substituting for log K_v in equation (10); using common instead of natural logarithms; and

$$\log_{10} K_p=\frac{Q_0}{4{\cdot}57T}-\frac{a-\Sigma nR}{R}\log T-\frac{\beta}{4{\cdot}57}T-\ .\ .\ .\ \frac{\Sigma n(I+\log R)}{2{\cdot}3} \quad (12)$$

The constant $\Sigma n(I+\log R)/2{\cdot}3$ is represented by $\Sigma n\mathbf{C}$, where **C** is called by W. Nernst the **chemical constant** of the substance. When the different terms of the vapour pressure equation (10) have been introduced, the constant I' for any given substance can be calculated, and thus **C** can be determined. To evaluate the chemical constants, it is therefore necessary to have a great number of accurate measurements extending over a wide range of temperature: (1) The thermal value of the reaction at a given temperature; (2) the equilibrium constant of the same reaction at the given temperature; and (3) the specific heats of all the substances which take part in the reaction, from the given temperature T down to absolute zero. The observation data available are not very accurate, and a number of empirical formulæ have been recommended. For example, W. Nernst recommended $\mathbf{C}=1{\cdot}33\log T_b-0{\cdot}00098T_b$, where T_b denotes the absolute boiling point of the substance. This equation is obtained from the empirical observation, that the chemical constant is nearly 0·14 times Trouton's constant λ/T, and W. Nernst's observation that $\lambda/T=9{\cdot}5\log T_b-0{\cdot}007T_b$.

It follows from what precedes, that the chemical constant

$$\mathbf{C}=\frac{I+\log R}{2{\cdot}3}=\frac{\lambda_0}{4{\cdot}57T}-1{\cdot}75\log_{10}T+\frac{\beta}{4{\cdot}57}T+\log_{10}p \quad . \quad (13)$$

where λ_0 is the molecular latent heat at absolute zero; and β is a constant depending on the change of specific heat with temperature, The number 1·75 was obtained on the assumption that at the lowest temperatures, the molecular heats of all gases are 1·5 greater at constant volume, and 3·5 greater at constant pressure than the molecular heats of the corresponding condensation products. W. Nernst's later work showed that these assumptions cannot be justified, and the formula there becomes an empiricism.[10] A. C. Egerton deduced an expression from $\lambda=RT^2(d\log p)/dT$; $\lambda=\lambda_0+S_0C_pdT-S_0c_pdT$; $c_p=c_v+aT^{\frac{1}{2}}$, or $c_p=c_v+9a^2vT/\beta$, whence $9a^2vT/\beta=aT^{\frac{1}{2}}$; and W. Nernst and F. A. Lindemann's molecular heat formula. His expression enables the chemical constant to be evaluated from β_v, a.

and two values of p, or one value of p and the value of λ_0. A. C. Egerton thus obtains for the chemical constant of

Hg	Cd	Zn	W	Mo	Pt	A	H
1·633	1·42	1·49	3·5	4·4	1·5	1·65	1·68

The chemical constants for a few substances (pressure in atmospheres) indicated in Table V have been calculated mainly by W. Nernst.

TABLE V.—NUMERICAL VALUES OF CHEMICAL CONSTANTS **C**.

	C		**C**		**C**
He . . .	−1·15	I_2 . . .	3·9	H_2O . .	3·6
Ne . . .	−0·10	HCl . .	3·0	CCl_4 . .	3·1
A . . .	−0·35	HBr . .	3·2	$CHCl_3$ . .	3·2
Kr . . .	0·82	HI . .	3·4	CH_4 . .	2·8
X . . .	1·10	NO . .	3·5	C_2H_6 . .	2·6
H_2 . . .	1·6	N_2O . .	3·3	C_2H_4 . .	2·8
N_2 . . .	2·6	H_2S . .	3·0	C_2H_2 . .	3·2
O_2 . . .	2·8	SO_2 . .	3·3	C_6H_6 . .	3·0
CO . . .	3·5	CO_2 . .	3·2	C_2N_2 . .	3·4
Cl_2 . . .	3·1	CS_2 . .	3·1	C_2H_5OH .	4·1
Br_2 . . .	3·2	NH_3 . .	3·3	Hg . .	1·4

The quotient obtained by dividing W. Nernst's chemical constant by the logarithm of the critical pressure in atm. varies from 1·5 to 1·8. Thus, the critical pressure of chlorine is 92·5 atm. and log 92·5=1·971 ; hence 3·1÷1·97=1·6. This means that the chemical constant **C** of a liquid is proportional to the logarithm of the pressure p, so that $\mathbf{C}=1\cdot65 \log_{10} p$. For monatomic gases, $\mathbf{C}=-1\cdot62+1\cdot5 \log M$, where M represents the molecular weight of the gas.

The methods of evaluating the chemical constants are: (1) Direct comparison with the vapour pressure curve; (2) The method of chemical equilibrium ; (3) Some empirical formulæ—*e.g.* S. Young's modification of Clapeyron-Clausius' equation, above. It must be added that the evaluation of the chemical constant is the weakest part of the discussion, and the results obtained by the different methods are not always concordant, probably owing to the inaccuracy of the available data. For example, two equally satisfactory empirical formulæ for the specific heat of a gas may lead to widely different values for the chemical constant. Thus A. Langen gives the chemical constants of nitric oxide, +0·92 ; oxygen. 1·021—0·539 ; carbon monoxide, —0·04 ; nitrogen, 0·05 ; carbon dioxide, —0·406 ; water, —1·930 ; and ammonia, —2·454. However, as B. Weinstein has emphasized, although the results which have been obtained *die Zulässigkeit des Gleichungssystems zweifellos feststellen*, yet the uncertainty in the numerical values of the constants can be removed only by observations extending over wide ranges of temperature.

Remembering that $a=-\Sigma na'$, where a' is a constant in the vapour pressure curve, and therefore $a-\Sigma nR=-\Sigma n(a'+R)$, W. Nernst puts $a'+R=3\cdot5$ cals. as a first approximation, so that $a-\Sigma nR=-\Sigma n3\cdot5$; or $(a-\Sigma nR)/R=\Sigma n1\cdot75$. Substituting these results in equation (12), and

$$\log_{10} K_p=\frac{Q_0}{4\cdot57}+\Sigma n1\cdot75 \log T-\frac{\beta}{4\cdot57}T- \dots +\Sigma n\mathbf{C} \quad . \quad (14)$$

the values of $a, \beta, \gamma, \dots$ can be determined from the relation $dQ/dT=a+2\beta T+3\gamma T^2+\dots$ from G. Kirchhoff's equation, where dQ/dT is equal to the difference between the molecular thermal capacity of the initial and end products of the reaction ; Q_0 is evaluated from the relation $Q=Q_0+aT+\beta T^2+\dots$ For gaseous reactions in which the initial and final products occupy the same volume, Σn is zero, and $\Sigma n1\cdot75 \log T$ is then a zero term, but neither $\Sigma n\mathbf{C}$ nor βT is necessarily zero.

These relations, obtained by the application of W. Nernst's theorem to J. H. van't Hoff's equation, enable the equilibrium constant of a gaseous reaction, and consequently also the free energy or affinity of a reaction, to be calculated from three sets of data : (i) The thermal value of the reaction at the temperature T ; (ii) The molecular heats of the reacting substance over the range of temperature in question ; and (iii) The chemical constants of the reacting substances. As H. le Chatelier[11] stated in 1888, the chemical constants are definite functions of certain physical properties of the reacting substances. Consequently, *the indeterminate integration constant in J. H. van't Hoff's equation can also be expressed as a sum of constants which are characteristic of each reacting substance.* This can also be done quite independently of W. Nernst's heat theorem (1906), as was demonstrated by M. Planck (1897) and by F. Haber (1905).[12] Another important feature of this investigation is that it enables the integration constant I to be calculated from the characteristic function $\Sigma nI'$, that is, the chemical constants of the substances concerned in the gaseous reactions can be computed without making any observations on the reaction itself. As H. le Chatelier predicted in 1888, the evaluation of the nature of this function will lead to a complete knowledge of the laws of chemical equilibrium, and it will enable chemists to determine the conditions of equilibrium of a given chemical reaction, *à priori*, and independently of new experimental data.

CHAPTER XIII

THE KINETIC THEORY OF ATOMS AND MOLECULES

§ 1. The Molecular Theory of Matter

If we would become imbued with the spirit of the new philosophy of chemistry, we must begin by believing in molecules.—J. P. COOKE.

FOR purely chemical reasons, which culminated in Avogadro's hypothesis, chemists have invested matter with an imaginary structure which explains, very well, the various transformations which matter undergoes. Matter—which in bulk appears to the eye continuous and perfectly uniform in all its properties and parts—is supposed to be made up of extremely small discrete particles called molecules. **Molecules are the imaginary units which make up matter en masse.** Molecules are made up of one or more atoms. **Atoms are the imaginary units which make up individual molecules.**

Molecular structure of matter.—Matter must be either a discrete or a continuous medium. The phenomena which attend diffusion in solids, liquids, and gases lead us to reject the hypothesis that matter is continuous, for how can two continuous media occupy the same period of time ? A study of the compressibility of gases—Boyle's law—leads to the same view. There appears to be no limit to the expansion or dilatability of a gas ; and therefore, says A. W. Rücker (1901), it is inconceivable that any real substance or thing which can at the same time be present in every part of a given space would also be present in every part of a space a million times as great. How can a continuous medium on rarefaction (that is, diminution of pressure) expand indefinitely ? How can compression diminish the volume of matter itself ? If matter be discrete, we can readily answer these queries. Compression involves a closer packing or a crowding together of the molecules by diminishing the space between them. This very explanation was given by Hero of Alexandria[1] *circa* 177 B.C.

> The particles of air do not fit closely in every part, but void spaces are left between them as in the sand on the seashore ; the grains of sand must be imagined to correspond to the particles of air, and the air between the grains of sand to the void spaces between the particles of air. Hence, when any force is applied to air, the air is compressed, and, contrary to its nature, falls into the vacant spaces from the pressure exerted on its particles ; but when the force is withdrawn, the air returns again to its former position from the elasticity of its particles, as is the case with horn shavings and sponge, which, when compressed and set free again, return to the same position, and exhibit the same bulk.

Conversely, rarefaction involves an increase of the space between the molecules, so that the molecules become less closely packed and less crowded together. If matter be discrete we can also understand how one substance can diffuse into another—hydrogen into air ; and aniline dye into water. There are also numerous examples of the diffusion of one solid metal into another, the penetration of solid metals by gases, etc., which show that solid metals are porous to certain elements. Mercury will pass through a piece of tin, a centimetre thick, in half a minute. The porosity of metals was recognized by G. Homberg[2] in 1713, and, in his *Observations sur des matières qui pénètrent et qui traversent les métaux sans les fondre*, he gave examples of substances which will pass through the pores of the metals. Again, the volume of a mixture of two liquids is not necessarily the same as the joint volume of the separate components, even though no chemical reaction, recognized as such, occurs.

A mixture of 500 c.c. of alcohol and 500 c.c. of water occupies 940 c.c., which is much less than 1000 c.c., and the difference is still greater in the case of sulphuric acid and water provided the temperature at which the volume of the solutions is measured is the same. Conversely, a solution may occupy a greater volume than the joint volume of its separate constituents. Thus 111·1 c.c. of *p*-nitrotoluene and 100 c.c. of carbon disulphide give not 211·1 c.c. but 224·7 c.c. of the mixture—an expansion of 13·6 c.c. Similarly, the volumes of solutions of the ammonium halides in water are greater than the joint volumes of salt and water.

Many other examples might be quoted which indicate that (1) one substance may be actually penetrated by another; or that (2) the molecules of one substance may be so disposed that the molecules of another substance can be accommodated between them much as a scuttle of coal might at the same time accommodate a bucket of sand; (3) matter is compressible or expansible so that it occupies a different volume in contact with another substance than it does alone. The molecules seem to lead a more or less independent existence, and the space between the molecules furnishes accommodation for the introduction of other particles.

There are many other lines of argument pointing in the same direction: If transparent substances like glass or water were infinitely homogeneous, the velocity of propagation of light through them would be independent of the period of vibration or the wave-length of the ray of light. A. L. Cauchy (1836),[3] therefore, inferred that transparent substances are not infinitely homogeneous because the velocity of propagation of light does depend on the period of vibration; and the coarse-grainedness of liquids and transparent solids is comparable with the wave-length of light.

W. Ostwald in his *Grundriss der allgemeinen Chemie* (Leipzig, 1904) did not accept the interpretation of the evidence for the granular structure of matter, for he confessed that he did not then know any facts which could not be described without this assumption; but in a later edition (London, 1912), he said that after a fruitless search extending over a century, a final proof of the grained, atomistic, or molecular nature of matter has been obtained by studying the properties of colloidal systems, and the effects of electrical discharges in gases. A study of the physical and the chemical properties of matter has thus led to the conclusion: **Matter is discrete not continuous; and it is made up of minute particles called molecules.** This hypothesis is called the molecular theory of matter.

Are the molecules stationary or in motion? Here again the phenomenon of diffusion has led to the further assumption that the molecules of matter are in rapid motion. How could gases diffuse one into the other in such a remarkable way if the molecules were at rest? Again, in Rumford's celebrated experiment (1798) it was proved that mere friction produces heat in *unlimited* quantities, and hence it was argued that it is "extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated in the manner *heat* is excited and communicated in this experiment, except it be motion." Heat must be a mode of motion. Again, if heat be a mode of motion the motion is not apparent; it is not a motion of the body as a whole, but rather a motion of the fundamental particles of matter. This internal motion, too, must be more rapid the higher the temperature, a conclusion which is in harmony with the phenomenon of diffusion. Diffusion is produced by the internal movement of the particles of matter, and this is the more rapid, the higher the temperature. The fact that gases rapidly fill a confined space, however large, has been explained by assuming that the molecules repel one another, but, as H. Davy emphasized in his *Essay on heat, light, and the combinations of light*,[4] in 1799, the so-called repulsive force can be identified with the thermal oscillations of a body:

Heat may be defined as a peculiar motion, probably a vibration of the corpuscles of bodies, tending to separate them. . . . To distinguish this motion from others . . . the name *repulsive motion* has been adopted.

The phenomena which attend the expansion and diffusion of matter lead to the assumptions: (i) that matter has a granular structure, for it consists of discrete parts of molecules; and (ii) that the molecules are in a state of incessant independent motion, and that they are travelling to and fro in all directions. The physical evidence here outlined is altogether independent of assumptions as to the nature and properties of the molecules; it can be supplemented by an enormous mass of other facts from diverse sources; and it is strongly supported by chemical phenomena as interpreted by Dalton's and Avogadro's hypotheses.

According to the kinetic theory as expounded by P. Gassend in 1658, and others, the difference between solids, liquids, and gases is due to a difference in the average distances between the molecules, and in the mobilities of the molecules. The physicists' definition of a molecule is: a minute portion of a substance which moves about as a whole, so that its parts, if it has any, do not part company during the motions.

§ 2. The Kinetic Theory of Gases—Boyle's Law

What *is* must be studied before what *was* can be inferred. Precedent states remain visionary unless they can be linked to actual and observable conditions.—A. M. CLERKE.

The molecules of a gas seem to lead to a more or less independent existence; and their average distance apart is much greater than with liquids or solids. The molecules of a gas appear to be continually moving with a great velocity in approximately straight lines in all directions. The molecules spend most of their time travelling about like missiles, without the kinetic energy of the motions predominating in any one direction. There is an interchange of energy during the collisions of the molecules, and the immense number of collisions leads to a rapid distribution of any excess of energy which the motions of any one molecule might possess, and thus the pressure, etc., is rapidly equalized. The molecules in their travels are not only colliding with one another but they are also bombarding the walls of the containing vessel; in consequence, the molecules are continually changing their speeds and directions. It is clear that an outside pressure must be exerted on the walls of the vessel every time a molecule strikes the boundary walls, but every bombardment known to human experience involves several losses—*e.g.* energy, velocity, and momentum are lost. **The molecules are supposed to be perfectly elastic** so that after each collision they rebound with the same velocities as before, otherwise, it is said, their momentum would decrease with each collision and the pressure of the gas would decrease with time, which it does not. Gases have been confined many months under pressure without sign of loss; but attempts to so detect a diminution of pressure are foredoomed to failure since any slackening the average speed of the molecules would probably be immediately restored by collision with the boundary walls, if the prevailing temperature determined the average speed of the molecules.

Hence, the kinetic theory of molecules postulates: (i) The molecules are perfectly elastic; and (2) in spite of the law of excluded perpetual motion, we have what H. Poincaré called *un éternal paradox*, for it is inferred that **the molecules of a gas**

are in a state of perpetual motion. A hypothesis is weak when it is based upon more or less arbitrary fictions, and not on something about which we have experience. Still there are hypotheses which are strong and vigorous in spite of their explaining the known in terms of the obscure—*ad obscurum per obscurum*. For instance, we have no experience of an interstellar æther, and yet the undulatory theory of light has thriven on such a medium ; nor yet have we any experience of perfectly elastic solids, and yet the kinetic theory of molecules has grown about this fiction. The preceding assumptions suffice for some important deductions which enable the condition of the molecules of a gas to be inferred with some degree of probability.

Boyle's law.—Assume that a closed vessel contains an indefinitely large number, n molecules, and that the ceaseless cannonade of these molecules on the walls of the vessel produces an average pressure p. Imagine n similar molecules to be squeezed into the same vessel. This will double the number of impacts on the sides of the containing vessel so that the pressure will rise from p to $2p$. The concentration of the gas will also be doubled. This is nothing but another way of stating Boyle's law. The argument is due to Robert Hooke[1] in 1678. R. Hooke's own words are :

> If therefore a quantity of this body be enclosed by a solid body, and that be so contrived as to compress it into less room, the motion thereof (supposing the heat the same) will continue the same, and consequently the Vibrations and Occursions will be increased in reciprocal proportion, that is if it be condensed into half the space the Vibrations and Occursions will be double in number. If into a quarter the Vibrations and Occursions will be quadruple. . . . Again, if the containing vesesl be so contrived as to leave it more space, the length of the Vibrations will be proportionally enlarged and the number of Vibrations and Occursions will be reciprocally diminished, that is, if it be suffered to extend to twice its former dimensions, its Variation will be twice as long, and the number of its Vibrations and Occursions will be fewer by one half, and consequently its endeavours outward will be also weaker by half.

The further mathematical study of a system of elastic spheres, ceaselessly moving at different speeds in all directions is based upon the principle of averages. It does not consider the motion of an individual molecule, but rather the average motions of the entire system of spherical particles.

Boyle's law can then be obtained in another manner : Suppose a gas containing n molecules, each of mass m, be confined in a cube with edges each l cm. long, and that the molecules are moving with a mean velocity V. Although the molecules travel about in every conceivable direction, it is fair, for purposes of calculation, to consider the molecules are divided into three equal sets with velocities parallel to three adjacent sides of the cube. At any instant, therefore, we assume that $\frac{1}{3}n$ molecules are travelling with a mean velocity V parallel to any particular edge, and therefore perpendicular to the two corresponding faces of the cube. One molecule moving with a velocity V will take l/V seconds to pass from side to side, and it will therefore strike a side $\frac{1}{2}V/l$ times per second. At each collision with the face of the cube, the velocity of the molecule is reversed in direction that its momentum changes from mV to $-mV$; that is, its momentum changes $2mV$. The total change of momentum by $\frac{1}{3}n$ molecules striking a side $\frac{1}{2}V/l$ times per second will therefore be the product $\frac{1}{2}V/l \times 2mV \times \frac{1}{3}n$, or $\frac{1}{3}nmV^2/l$. This measures the total force or pressure exerted on one face of the cube. But the total surface of one face of the cube is l^2. Hence, the total pressure per unit area is $p=\frac{1}{3}nmV^2/l \div l^2=\frac{1}{3}nmV^2/l^3$. But l^3 represents the volume v of the cube. Hence

$$pv=\frac{1}{3}nmV^2 \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The product of the pressure and volume of a gas is equal to one-third the sum of the masses of all the molecules into the square of the mean velocity of the translatory motions of all the molecules. For unit volume also, the average kinetic energy of the molecules of the gas is equal to the pressure p. If the number n, the mass m, and the mean velocity V of the molecules does not change, the expression $\frac{1}{3}nmV^2$

will be a constant; and hence also the product pv will be constant. This is in accord with Boyle's law. Since $pv=RT$ it follows that

$$RT=\tfrac{1}{3}nmV^2\text{; or } RT=\tfrac{1}{3}NV^2 \quad . \quad . \quad . \quad . \quad (2)$$

where N denotes the number of gram-molecules per c.c. **Dalton's law of partial pressures** follows as a corollary, because the total pressure exerted by a mixture of gases must be the sum of the partial pressures exerted by the individual molecules provided they exert no physical or chemical action upon one another. By definition, the mass M of any substance is equal to the product of the density D into the volume v, and accordingly, the density of a mass of n molecules each of mass m occupying a volume v will be $D=nm/v$. Substituting this relation in the preceding equation, and

$$p=\tfrac{1}{3}DV^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

which is sometimes called **Bernoulli's equation,** and which shows that the pressure of a gas is equal to one-third the product of its density into the square of the mean velocity of the translatory motions of the molecules.

The **mean kinetic energy** of the molecules is $K=\tfrac{1}{2}nmV^2$, and accordingly, equation (1) can be written $\tfrac{3}{2}pv=\tfrac{1}{2}nmV^2$, showing that the product $\tfrac{3}{2}pv$ is equal to the mean kinetic energy of the molecules, or

$$\text{Kinetic energy}=\tfrac{3}{2}RT \quad . \quad . \quad . \quad . \quad . \quad (4)$$

since $pv=RT$. Hence, the pressure of unit volume of a gas is two-thirds the kinetic energy—expressed in proper units—whatever be the temperature. This enables the molecular energy of a gas to be expressed in terms of a magnitude which can be measured directly. Both magnitudes have their origin in molecular motion; and both change proportionally with the absolute temperature, so that

$$\frac{p}{T}=\frac{p_0}{T_0}, \text{ or } p=p_0(1+\alpha\theta)\text{; and } \frac{K}{T}=\frac{K_0}{T_0}, \text{ or } K=K_0(1+\alpha\theta) \quad . \quad (5)$$

where p_0 and K_0 represent the values of the pressure and kinetic energy per unit volume at 0°, or at $T_0=273$; and p and K the corresponding values at the absolute temperature T. It follows therefore that the kinetic energy of molecular motion is the mechanical measure of the temperature.

The mean kinetic energy is also equal to $\tfrac{1}{2}MV^2$, when $M=nm$. Consequently, $3RT/M=V^2$, and since the numerical value of R is $83{\cdot}15\times10^6$ ergs, the so-called mean velocity V of the molecules is

$$V=15800\sqrt{\frac{T}{M}} \text{ cm. per second} \quad . \quad . \quad . \quad (6)$$

From (3), when the pressure is constant, the velocity V will be inversely proportional to the square root of the density D, for $V^2=k/D$, where k represents a constant; or $V_1\sqrt{D_1}=V_2\sqrt{D_2}$. This is **Graham's diffusion law.** If V denotes the mean velocity of the molecules of a gas, the average kinetic energy is $\tfrac{1}{2}MV^2$, and by Graham's law, the velocity is equal to a constant, say $\sqrt{2k}$, divided by $\sqrt{D}$, or the mean kinetic energy is kM/D; but by Avogadro's rule, $M=k'D$, and hence the mean kinetic energy is equal to a constant k. The temperature and pressure are supposed to be invariable. Hence, **the mean kinetic energy of the molecules of all gases at the same temperature and pressure is the same.** Since the mean kinetic energy a gram-molecule of a gas, $\tfrac{1}{2}MV^2$, is equal to $\tfrac{3}{2}RT$, it follows that if there are $6{\cdot}062\times10^{23}$ molecules per gram-molecule of the gas, the kinetic energy per molecule at 0° and 760 mm. is $5{\cdot}62\times10^{14}$ erg.

How fast do the molecules move?—Bernoulli's equation makes possible an extraordinary calculation—no less than the mean velocity of the translatory motions of the molecules. The other two magnitudes which occur in the equation can be directly measured. J. P. Joule made this calculation in 1848; although J. J. Waterston presented an analogous calculation to the Royal Society nearly three years earlier.[2]

A gram-molecule of hydrogen—that is, 2·016 grms.—at 0°, and under a pressure of 760 mm., occupies very nearly 22400 c.c. The density of hydrogen is therefore very nearly 2·016/22400=0·0000896. Again, a pressure of 760 mm. of mercury is equivalent to a weight of 1033·3 grms. per sq. cm., and since a weight of one gram falling freely acquires an acceleration of 981 cm. per second, owing to gravitational attraction, it follows that 1033·3 grms. will acquire an acceleration of 981 × 1033·3 cm. per second. By substituting these results in Bernoulli's equation: $1033{\cdot}3 \times 981 = \frac{1}{2} \times 0{\cdot}0000896 \times V^2$, or $V = 184100$ cm. per second.

It is not to be assumed that all the molecules of hydrogen have this particular speed, nor that any single molecule retains this speed over any lengthened period. Some of the molecules no doubt have a greater velocity, others a smaller velocity. A molecule of hydrogen starting off with a velocity above the average will soon have both its speed and direction changed by encounters with other molecules. The velocity V under consideration represents the mean velocity, or the velocity of mean square of the whole of the molecules of the given gas at the temperature of melting ice. If the gas contains n molecules, and the velocities of the different molecules are $v_1, v_2, \ldots$ there must be a quantity V^2 such that $nV^2 = v_1^2 + v_2^2 + v_3^2 + \ldots + v_n^2$; this quantity V is called *the velocity of mean square* of the moving particles, and V is called here the *mean velocity*. At 0°, therefore, the mean velocity of the molecules of hydrogen is nearly 1·84 kilometres per second, that is, about 6100 ft., or just over a mile per second. The arithmetical mean U of the velocities of all the molecules is rather less than the mean velocity V, such that $U = 0{\cdot}921V$, or $V = 1{\cdot}08U$ or,

$$U = 14550\sqrt{\frac{T}{M}} \text{ cm. per second} \quad . \quad . \quad . \quad (7)$$

The speeds of the molecular motions of other gases can be calculated in a similar manner, or Graham's law can be used. The results for seven typical gases at 0° and 20° are indicated in Table I.

TABLE I.—THE MEAN VELOCITIES OF DIFFERENT GASES.

	Molecular weight, M.	Mean velocity V cm. per second.	
		At 0°.	At 20°.
Hydrogen, H_2	2·016	$1{\cdot}84 \times 10^5$	$1{\cdot}90 \times 10^5$
Oxygen, O_2	32·00	0·46	0·48
Nitrogen, N_2	28·02	0·49	0·51
Argon, A	39·88	0·41	0·43
Water, H_2O	18·016	0·61	0·64
Carbon dioxide, CO_2	44·00	0·39	0·41
Mercury, Hg	200·6	0·18	0·19

M. Cantor[3] has made an experimental demonstration of the speeds of molecular motion. When a copper plate is inserted in a vessel of chlorine, part of the molecules of the gas which bombard the plate rebound, and part unite with the metal to form the chloride. If p denotes the pressure of the gas on the surface of an inert substance, and p' the pressure on the surface of the copper, $p - p' = \frac{2}{3}wV$, where w denotes the mass of chlorine absorbed per sq. cm. per second. and V the velocity of the molecules which react with the copper, by suitably suspending plates of glass with the right half of one face and the left half of the opposite face coated with copper. M. Cantor was able to measure the difference of pressure $p - p'$ from the forward movement of the coppered faces; w could be determined by direct weighing. When $w=\frac{1}{3}\times10^{-6}$ grm., and $p-p'=10{\cdot}7\times10^{-4}$ dynes per sq. cm., the mean velocity of the molecules of chlorine absorbed by the copper is 48 metres per second. The mean velocity of *all* the molecules at 0° is 310 metres per second.

O. E. Meyer, in his *Die kinetische Theorie der Gase* (Breslau, 1877), has shown that in a gas at rest as a whole, the number of molecules which strike unit area of the containing vessel in unit time is $\frac{1}{4}nmU$, or since $nm=D$, the density of the gas, the number of grams of gas molecules which strike unit area in unit time is $\mu=\frac{1}{4}DU$, and since $D=M/v=Mp/RT$ from the gas equation, it follows that $\mu=MpU/4RT$, where p is expressed in bars. Substituting the value of U from (7), when $R=83{\cdot}15\times10^6$ ergs per degree.

$$\mu=43{\cdot}7\times10^{-6}p\sqrt{\frac{M}{T}} \text{ grms. per sq. cm. per sec.} \qquad (8)$$

A gram-molecule of gas contains $6{\cdot}062\times10^{23}$ molecules, and therefore, the number of molecules of gas which strikes a sq. cm. of surface per second is

$$N=2{\cdot}652\times10^{19}p\sqrt{\frac{M}{T}} \qquad (9)$$

For hydrogen, at a pressure $p=10^6$ bars, and 20°, $\mu=13{\cdot}8$ grms. per sq. cm. per second. That is, the total number of molecules striking a sq. cm. of surface is equivalent to the number of molecules contained in 154 litres of hydrogen gas—although, of course, the same molecules may strike the surface many times.

I. Langmuir[4] has applied this equation to compute the vapour pressure of tungsten, molybdenum, and platinum.

Consider a surface of metal in equilibrium with its saturated vapour. According to the kinetic theory, equilibrium is looked upon as a balance between the rates of vaporization and condensation. These two processes are conceived to be going on simultaneously at equal rates. At temperatures so low that the vapour pressure of a substance does not exceed a millimetre, the actual rate of evaporation of a substance may be considered to be independent of the presence of the vapour around it. That is, the rate of evaporation in a high vacuum is the same as the rate of condensation in presence of a saturated vapour. Similarly, the rate of condensation may be considered to be determined only by the pressure of the vapour.

I. Langmuir therefore argues that the vapour pressure of a metal like tungsten can be calculated, by means of equation (8), from the observed rate of evaporation or loss of weight at constant temperature when heated in vacuum tubes. At 2800° K., for example, the loss of weight of a tungsten filament was observed to be $0{\cdot}43\times10^{-4}$ grms. per sq. cm. per second. Consequently, from (8), the vapour pressure is $38{\cdot}1\times10^{-3}$ bar, or $28{\cdot}6\times10^{-6}$ mm. of mercury.

I. Langmuir has further compared the energy lost by convection from tungsten wire heated in hydrogen gas with the loss calculated from the kinetic theory, and found that the two results are in agreement at temperatures below 2100° K.; at higher temperatures, the observed losses are greatly in excess of the theoretical results. The increased loss of heat is supposed to be expended in the dissociation of the hydrogen molecules as they strike the tungsten wire. The augmented loss does not occur below 3500° K. in nitrogen or mercury vapour. The calculated dissociation of hydrogen $H_2\rightleftharpoons2H$ at 2500° K. is 3·7 per cent.; at 3330° K. 5·3 per cent.; and at 4500° K, the dissociation is almost complete. The number of hydrogen molecules which strike the hot wire at very low pressures can be calculated from (7), and the heat losses from the surface of the wire can be measured; consequently, the heat carried away by each molecule of the gas can be computed.[5] At high temperatures, the heat losses become approximately constant; and, assuming that every hydrogen molecule which strikes the filament is then dissociated, it is possible to calculate a lower limit for the heat of the reaction. In this way, it was found $2H\rightarrow H_2+130$ Cals. at constant volume and 3000° K.; and similarly, $2H\rightarrow H_2+136$ Cals. at constant pressure.

Again, I. Langmuir found that tungsten wires heated in oxygen gas are chemically attacked, and the tungstic oxide so formed volatilizes and condenses on the walls of the bulb, and leaves the surface of the filament clean. Equation (6) again enables the rate at which the oxygen molecules strike the wire to be calculated, and on comparing the result with the rate at which the filament is actually attacked, I. Langmuir found that only a fraction of the total number of molecules of oxygen which strike the filament are chemically fruitful. About 0·033 per cent. of the oxygen molecules which strike the filament react chemically with the tungsten at 800°, and 15 per cent. at 2500°. At this latter temperature, therefore, only one molecule in every seven of those which strike the tungsten actually form tungstic oxide, WO_3.

§ 3. The Kinetic Theory of Gases—Charles' Law and Avogadro's Hypothesis

Nihil enim viveret sine calore.—L. A. SENECA (c. 50).

Heat is motion which in its strife acts upon the smallest particles of bodies.—FRANCIS BACON (1620).

That all kinds of fiery burning bodies have their parts in motion; that heat argues a motion of the internal parts, and that in all extremely hot shining bodies, there is a very quick motion that causes light, will be generally granted.—ROBERT HOOKE (1665).

Heat consists in a minute vibratory motion of the particles of bodies.—ISAAC NEWTON (1675).

Heat is considered by men of science to be a mode of motion of the molecules of matter; and the texts at the head of this section show that the idea is very old. The dynamical theory of heat was advanced as an hypothesis by F. Bacon, I. Newton, and R. Boyle, and established by the experimental work of Count Rumford, H. Davy, J. P. Joule, etc.

The kinetic theory and Charles' law.—The average speed of molecular motion is assumed to determine the temperature. Each change of temperature, however slight, is supposed to be attended by a corresponding change in the average speed of the moving molecules. From Boyle's and Charles' laws, $pv=RT$; when V is the mean velocity of the molecules of a gas, $pv=\frac{1}{3}nmV^2$, or $RT=\frac{1}{3}nmV^2$; and since R, n, and m are constant, it follows that $V^2=kT$, where k is a constant; otherwise expressed, for a given gas at a given pressure, the mean molecular velocity V^2 depends only upon the one variable—temperature. J. J. Waterston [1] first developed this hypothesis in 1845—**the mean kinetic energy of the molecules of a gas is proportional to the temperature—Waterston's hypothesis.** The same postulate was made independently by R. Clausius, and shown to be a necessary consequence of J. C. Maxwell's law of the equipartition of energy. It is sometimes called *Clausius' postulate.* The hypothesis that temperature is a quantity of the same kind as molecular kinetic energy is one of the most important fundamental postulates of the kinetic theory. From this it follows that at the same temperature, the mean kinetic energy of the molecules of all gases (which obey the ordinary gas laws) is the same. The total kinetic energy of a gas is proportional to the product pv. Hence, if the temperature be altered, pressure remaining constant, the kinetic energy (*i.e.* temperature) must alter to the same extent, and hence also the volume. Otherwise expressed, if the pressure remains constant, the same alteration of temperature will alter the volume to the same extent. This is Charles' law. Since the mean kinetic energy of the translatory motions of the molecules of any gas is constant, and when two or more substances at different temperatures are in intimate contact, their temperature will assume one constant value, it is accordingly assumed that equality of temperature means equality of the kinetic energies of the molecules, and Waterston's hypothesis takes the form: **Two gases are in thermal equilibrium when the mean kinetic energies of their molecules are the same.** Since real gases—which exert no chemical or physical action on one another and which are under the same conditions of temperature and pressure—can be mixed without change of pressure or temperature, it is assumed that the molecules of equal volumes of two gases at the same temperature and pressure possess the same total kinetic energies. The sense impression we call temperature is our mode of perceiving the kinetic energy of the translatory motions of the molecules.

The kinetic theory and Avogadro's hypothesis—From what has just been stated, it follows that equal volumes of two gases at the same temperature and pressure have the same value for the product pv. Hence, also, the total kinetic energy of the one gas will be equal to the total kinetic energy of the other; or the product $n_1m_1V_1^2$ for one gas will be equal to the product $n_2m_2V_2^2$ for the other. Again, the average kinetic energy, $\frac{1}{2}MV^2$, per molecule in the two systems will be equal if the temperature is the same; and hence, $\frac{1}{2}m_1V_1^2=\frac{1}{2}m_2V_2^2$; or, by substitution in the preceding relation, $n_1=n_2$. This is the symbolic way of saying that equal volumes of two gases under the same physical conditions contain the same number of molecules, or that the pressure of a gas at any temperature depends on the number of molecules and not on their kind; that is, Avogadro's hypothesis.[2] It is possible to argue backwards from Avogadro's hypothesis, and deduce the assumption indicated above. The one is dependent upon the other. Remember, therefore, that, contrary to what some enthusiastic writers have asserted, Avogadro's hypothesis has rendered it necessary to introduce *an unknown and unverifiable assumption* into the reasoning. According to J. C. Maxwell (1879):

> If the system is a gas, or a mixture of gases not acted on by external forces, the theorem that the average kinetic energy for a single molecule is the same for molecules of different gases is not sufficient to establish the condition of equilibrium of temperature between gases of different kinds, such as oxygen or nitrogen, because when the gases are mixed we have no means of ascertaining the temperature of the oxygen and nitrogen separately. We can ascertain the temperature of the mixture only by putting a thermometer in it.

The kinetic theory should not be quoted as a *proof* that Avogadro's hypothesis is true. Avogadro's rule is a corollary of J. J. Waterston's hypothesis.

The average distance traversed by a molecule between two collisions—the average free path.—The term average free path, L, of a molecule denotes the average distance traversed by a molecule between two successive collisions; that is, the sum of the free paths of all the molecules divided by the total number of molecular paths. The average free path is a pure length, and is determined by the concentration or number of molecules per unit volume, and it does not depend upon the average speed of the molecular movements. The magnitude in question for liquids at ordinary temperatures and pressures is of the same order as the millionth of a millimetre, for Lord Kelvin[3] has shown by several independent lines of argument—electrification of metals by contact, the tension of soap films, and the viscosity of air—that in ordinary solids and liquids the average distance between contiguous molecules is less than the hundred-millionth, and greater than the two-thousand-millionth of a centimetre. The length of the path L which a molecule, moving amid a swarm of molecules at rest, can traverse without collision is nearly

$$\text{Average free path, } L=\frac{\lambda^3}{\pi r^2}$$

where λ denotes the mean distance between any two neighbouring molecules, and r is the radius of the sphere of action of each molecule, so that πr^2 is the sectional area of one of these spheres. It is assumed that the sphere of action of a molecule cannot contain the centre of that of another molecule.

Let unit volume of a gas contain N molecules; let this volume be divided into N small cubes each of which on the average contains only one molecule; let λ denote the length of the edge of one of these imaginary cubes, and accordingly, only one molecule is contained in a cube of capacity λ^3. When a molecule A moves forward a distance x, it traces out a cylindrical space of volume $\pi r^2 x$, and if perchance [4] the centre of a molecule happens to be inside this cylinder, a collision will take place. Assume that the probability of a collision is in the ratio of these two volumes when x is small. Hence, the probability P of a collision when a molecule moves a distance x is $P=\pi r^2 x\lambda^3$. If there are n molecules moving like A, when n is very large, Pn molecules will collide in the distance x, and $Pn(1-P)$ molecules will pass on. Of the latter, $Pn(1-P)$ will collide in travelling another distance x, and $Pn(1-P)^2$ will pass on. Hence, Pn travel a distance between 0 and x; $Pn_2(1-P)$ travel a distance between x and $2x$; $Pn(1-P)^2$, a distance between $2x$ and $3x$; etc. The total paths traversed by all the n molecules before collision will therefore be $Pnx+Pn(1-P)2x+Pn\ (1-P)^2 3x+\ .\ .\ .$ When this series is summed by the rules of algebra, it becomes nearly equal to nx/P, meaning that a distance nx/P is traversed by n molecules before collision; or a distance x/P is traversed by one molecule before collision; but $P=\pi r^2 x/\lambda^3$, so that the average free path $L=\lambda^3/\pi r^2$ as indicated above.

It has been assumed that all but one of the molecules in the enclosure are at rest. It will be obvious that if all the particles are in motion, the probability that the particle A will collide with others will be increased, for the particles can also be struck by others from the sides and which would not be encountered as a result of its own motion. The increase in the probability of a collision shortens the free path to say l in accord with R. Clausius' demonstration [5] that the number of collisions will be increased in the proportion 4 : 3, and therefore the average free path of a particle in a swarm of molecules in uniform motion is

$$\text{Average free path, } L=\frac{3}{4}\cdot\frac{\lambda^3}{\pi r^2}$$

J. C. Maxwell, R. Clausius, and others have deduced relations between the viscosity η of a gas and the average free path of the constituent molecules. If a fluid—liquid or gas—streams through a tube of narrow bore, it experiences a resistance to flow so that the velocity of flow decreases uniformly from the centre outwards until it reaches the walls of the tube where the velocity is zero. Each layer of the fluid, parallel to the direction of flow, exerts a tangential force on the adjacent layer tending to decrease the velocity of the faster-moving layers, and to increase that of the slower-moving layers. The property in virtue of which a fluid exhibits this phenomenon is called the **viscosity of the fluid.** From the analogy between viscosity and friction some—particularly the Germans—employ the term *internal friction—innere Reibung*—of the fluid. Isaac Newton assumed that the viscosity is directly proportional to the rate of decrease of velocity V in the different layers of the fluid. If the tangential force be F, and the area of the plane be s, then $F=\eta sV$, where η is the constant of proportion, the so-called *coefficient of viscosity*, which can thus be defined as the tangential force per unit area required to maintain unity velocity gradient between two parallel plates in the fluid, at unit distance apart.

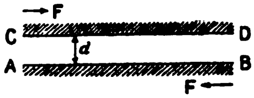

FIG. 1.

If a plane layer of fluid, CD, Fig. 1, moves with a velocity V_1 parallel to another plane layer of the same fluid, AB, at a distance d from it, and moving in the opposite direction with a smaller velocity V_2, the change of velocity per unit distance—the so-called *velocity gradient*—is $V=(V_1-V_2)/d$. Let the force acting on an area F required to produce this velocity gradient be F; this force must act in the direction CD on the upper plane and in the opposite direction on the lower plane. The simplest assumption regarding the force F was made by Isaac Newton, who assumed that the force F is proportional to the velocity gradient V, in the immediate neighbourhood of the plane; this force is also proportional to the area s of the plane. Hence, $F=\eta sV$.

The viscosity of gases is assumed to be an effect of the interchange of molecules between different layers of gas, and the tangential force per unit area is measured by the rate at which momentum is transferred per unit area between adjacent layers. The molecules which travel from a faster into a slower moving layer possess more momentum in the direction of flow than those moving in the opposite direction. The net rate of transfer of momentum across unit area of a plane is, according to Isaac Newton's second law, a measure of the force F,

$$F=\tfrac{1}{3}kL\eta MV$$

where k is a constant.

Let the velocity V of the layer CD, Fig. 1, be taken as $V_1=kd$, where k is a constant; and $F=\eta v/d$ per unit area. Assume that the motion of the molecules produces the same effect as would be obtained by resolving the particles into three groups—one-third move perpendicular to the plane CD, and the other two perpendicular to one another and parallel with the plane CD; and further on the average half the molecules moving vertical to the plane CD pass upward, and the other half downwards. Hence, one-sixth of the molecules moving with an average velocity V, that is $\tfrac{1}{6}nV$, traverse L, the mean free path, and their average velocity is the same as that of a layer at a distance L below CD, namely $k(d-L)$. These molecules carry a momentum $\tfrac{1}{6}k(d-L)nMV$, where M denotes the mass of each of the n molecules. A stream of the same number of molecules comes from AB, with the velocity of a layer $d+L$, and their momentum is $\tfrac{1}{6}k(d+L)nMV$. The difference, $\tfrac{1}{3}kLnMV$, represents the total momentum lost by the layers above the plane CD to those below.

The loss of momentum causes a drag on the adjacent layer such that $F=\eta v/d$ per unit area. Equate these two values of F together, and reduce the result to its simplest terms, remembering that $k=v/d$,

$$\eta=\tfrac{1}{3}LnMV\,;\ \text{or,}\ \eta=\tfrac{1}{3}LDV$$

where the density D of the gas is equal to nM. For instance, taking the density of air, $D=0{\cdot}001293$, and the experimentally determined viscosity $\eta=0{\cdot}00018$, and $V=48{,}000$ cm. per second; the mean free path is nearly $L=8\times10^{-6}$ cm. at 0°. In deducing this equation, it has been assumed that the molecules all possess the same velocity V, introducing the correction for Maxwell's distribution of velocities. L. Boltzmann represented the viscosity of a gas at 0° by the expression:

$$\eta=0{\cdot}3502DUL \quad . \quad . \quad . \quad . \quad . \quad (10)$$

where U denotes the average velocity of the molecules. Consequently, the average length L of the free path—that is, the average distance traversed by a molecule of the gas between two collisions—can be calculated, from the relation between viscosity and the free path. Some results at 0° and 760 mm., with L. Boltzmann's equation, are indicated in Table II. A molecule of nitrogen, for instance, travels about 450 metres per second, it collides with other molecules about five thousand million times per second, and the average distance between two consecutive collisions is about eight ten-thousandths mm. The density of the gases is known, and their

viscosities have been experimentally determined from observations on the damping effects of the various gases on vibrating pendulums (O. E. Meyer), or oscillating discs (J. C. Maxwell),[6] and by other methods.

R. Clausius' theoretical value for the effect of temperature on the viscosity of a gas, is

$$\eta=20{\cdot}43L\sqrt{\frac{DT}{273}};\ \text{or},\ \eta=20{\cdot}43L\left(\frac{DT}{273}\right)^{0\cdot5}$$

where T denotes the absolute temperature of the gas; and D, the density at 0° C., and atmospheric pressure—air unity. Observations show that this expression gives better results if the exponent be empirically taken nearer 0·77 than 0·5. W. Sutherland's formula has an empirical constant dependent upon the nature of the gas.

From L. Boltzmann's equation, it follows that the average free path is inversely proportional to the pressure of the gas, so that while the average free path of the gas at 760 mm. is about 16×10^{-6} cm., the value increases to about 0·025 cm. when the pressure falls to 0·5 mm. Consequently, the average free path of a molecule of a gas is about 700 times its diameter, and over a million times the diameter when the pressure is reduced to about half a millimetre of mercury. The size of a molecule is therefore small in comparison with its average free path. With increasing pressures, the increase of density is proportional to the diminution of the average free path, so that the product Dl is constant. Consequently, the velocity depends only on the temperature of the gas. For any gas, therefore, the viscosity is independent of the pressure if the temperature is constant, and the viscosity increases with the temperature. The converse obtains with liquids, for here the viscosity usually increases with rise of temperature. These results were deduced from the kinetic theory for gases, and the prediction was subsequently confirmed experimentally. The relation did not obtain with very high and very low pressures—in the former case, attractive forces come into play, and in the latter case, the molecules might travel the whole distance between the walls of the confining vessel without encountering another molecule. In deducing the formula, the assumption is made that the free path is so small that terms involving higher powers of L can be neglected. When the gas is rarefied, the molecules have more free space for their movements, and they do not collide so frequently. When the gas is sufficiently rarefied to make the higher powers significant, the formula is no longer applicable.

Direct determinations [7] of the average free path have been made by J. Franck and G. Hertz, who measured the maximum distance at which two plates must be placed apart in a gas in order that the ions passing from one plate to another may produce fresh ions by collision one with another. The results with hydrogen agree but approximately with the computed values:

Pressure	45	81	152	1670 bars
Average free path (Obs.)	0·436	0·256	0·149	0·014 cm.
Average free path (Calc.)	0·388	0·215	0·115	0·011 cm.

The number of collisions between the molecules per second—the collision frequency.—If the average free path of the hydrogen molecule is 16×10^{-6} cm., and the average velocity of translatory motion is $16{\cdot}96\times10^{4}$ cm. per second, it follows that the number of collisions per second must be the quotient of the distance U traversed per second, into the length of the free path L, provided the paired time of the colliding molecules be negligibly small. Hence, a molecule undergoes nearly 10,000,000,000 collisions per second. The last column in Table II shows estimates made with a number of gases. Why does a gas not diffuse through another gas with a speed comparable with the velocity of translatory motion of its molecules? The hydrogen molecule, for instance, has a velocity of $1{\cdot}696\times10^{5}$ cm. per second, but the average free path is only $16\times10{-}^{6}$ cm., so that the molecule collides with other molecules nearly ten thousand million times per second. A molecule is therefore continually abutting against other molecules, and being deflected from a straight path, so that its rate of progress in any particular direction is comparatively slow.

The average diameter of the molecules.—It is difficult to define precisely what is meant by the size of molecules primarily because their shape is unknown. Whatever be the structure of the molecule, the diameter of the molecule is understood to be a number which represents the smallest distance apart to which the centres of two molecules can approach one another. It is highly improbable that the molecules are elastic spheres, and the assumption that the molecules are spherical will therefore introduce an error which affects the different magnitudes concerned in free path and collision formulæ approximately the same, and accordingly J. H. Jeans [8] defines the molecular diameter as the diameter of a sphere such that spheres of this diameter undergo the same number of collisions as occur in actual gases. With solids, however, where free paths and collisions do not come into consideration, he regards the molecular diameter as the diameter of a sphere which occupies the same space as the molecule, and the more the molecules differ from the spherical shape, the more will the value so obtained differ from the former value. Calculations of the molecular diameter based on the volume occupied by matter in the solid or liquid states of aggregation, with the additional assumption that the molecules are packed as close as is physically possible, must give results too large—they are, however, regarded as useful in fixing an upper limit to the size of the molecules.

Solid hydrogen at 13·2° K. has a density of 0·0763, or one c.c. weighs 0·0763 grm. Since the mass of a molecule of hydrogen is $3·27 \times 10^{-24}$ grms. the number of molecules per c.c. of the solid will be $2·33 \times 10^{22}$. If this number of spheres be packed as closely as possible, they will occupy a volume $2·33 \times 10^{22} \times d^3 \div N$ c.c., where d represents the diameter of each molecule. This volume must be less than 1 c.c. If it be 1 c.c., $d = 3·93 \times 10^{-8}$ c.c. This is therefore the upper limit to the molecular diameter. For some unknown reason, in some cases the upper limit so obtained is less than the values obtained by other methods of calculation presumably more exact—*e.g.* xenon, benzene, chlorine, carbon dioxide, ethylene, etc.

O. Loschmidt, in his memoir *Zur Grösse der Luftmolecule*, made the first estimate of the actual size of the molecules of a gas in 1865. R. Clausius, J. C. Maxwell, J. H. Jeans, S. Chapman, and W. Sutherland have deduced expressions for this constant. R. Clausius obtained $\pi n d^2 L = 0·75$; J. C. Maxwell made the constant 0·707; and J. H. Jeans made it 0·933, to allow for the persistence of the original velocity for a small period of time after a collision. J. H. Jeans, after making an allowance for the persistence of the velocity after a collision, found

$$\text{Mean free path, } L = \frac{1·2547}{\sqrt{2}\pi n d^2} \quad . \quad . \quad . \quad . \quad (11)$$

where d denotes the diameter of the molecule; n, the number of molecules per c.c.; and L, the average free path. From (10), $\eta = 0·350DUL$, when $D = 0·001293$; $U = 45100$ cm. per sec.; and on substituting the value of L from (11), it follows that $nd^2 = 3306$ sq. cm. The result now depends upon what value is assigned to the constant n, values for this constant are estimated in the next section. Estimates of the maximum and minimum diameter of a molecule have been made by several different methods—the viscosity of gases, the thermal conductivity of gases, the rate of diffusion, the deviations from Boyle's law, liquid films, contact electricity, refractive dispersion, and the dielectric constant or refractive index of a gas.[9] The results agree fairly well with those deduced from the kinetic theory. In illustration, J. H. Jeans, *The Dynamical Theory of Gases* (Cambridge, 1916), obtained the values indicated in Table III for the molecular diameters estimated by four different methods, and expressed in centimetres. M. Knudsen computes the molecular weight of a gas from the viscosity data.

TABLE III.—J. H. JEANS' ESTIMATES OF MOLECULAR DIAMETERS.

Gas.	Coefficient of viscosity I.	Conduction of heat II.	Coefficient of diffusion III.	Deviations from Boyle's law.	Average of I to III.
Hydrogen	$2{\cdot}68\times10^{-8}$	$2{\cdot}68\times10^{-8}$	$2{\cdot}68\times10^{-8}$	$2{\cdot}52\times10^{-8}$	$2{\cdot}68\times10^{-8}$
Helium	2·86	2·28	—	1·96	2·22
Steam	4·54	—	—	—	4·54
Carbon monoxide	3·78	3·80	3·72	—	3·76
Ethylene	5·52	5·52	5·48	—	5·50
Nitrogen	3·76	3·82	3·82	3·54	3·80
Air	3·82	3·82	3·82	3·30	3·72
Nitric oxide	3·82	2·84	—	—	3·72
Oxygen	3·62	3·60	3·62	—	2·62
Argon	3·64	3·60	—	—	3·62
Carbon dioxide	4·54	4·84	4·30	3·40	4·56
Nitrous oxide	4·6	4·62	4·54	—	4·58
Ethyl chloride	4·12	—	—	—	5·12
Chlorine	5·36	—	—	—	5·36
Benzene	7·44	—	—	—	7·44

The number of molecules in unit volume of a gas.—If all gases obeyed the laws of Boyle and Charles, and Avogadro's hypothesis were valid, all gases would have the same number of molecules per unit volume under the same conditions of temperature and pressure. Assuming that the molecules of a gas are spherical, then, the volume of each sphere will be $\frac{1}{6}\pi d^3$, where d denotes the diameter of the molecule. If the gas contains N molecules per gram-molecular weight of gas at 0° and 760 mm., their aggregate volume will be $\frac{1}{6}\pi Nd^3$. Again, let v denote the apparent or total volume of a gas, and let b denote the space occupied by the molecules; the volume not occupied by molecules will be $v-b$; and if $v=b$, the molecules will be in contact provided b does not vary with pressure. J. D. van der Waals' estimate[10] of the value of b from H. V. Regnault's observation is, for air, $b=0{\cdot}00198$; and J. Rose-Innes' estimate from H. Callendar's observations, $b=0{\cdot}00209$. The mean is 0·002035. The values of b expressed in c.c. per gram-molecule of the gas, and calculated from the deviations of the gases from Boyle's and Charles' laws, are

	H_2	O_2	N_2	A	H_2O	CO_2	Hg
b	16·28	31·56	39·50	32·22	30·52	42·83	35·67

According to J. D. van der Waals, the actual volume of the molecules is one-fourth the value of b; consequently, $\frac{1}{4}b=\frac{1}{6}\pi nVd^3$,

$$b=\frac{2}{3}\pi Nd^3$$

Consequently, $Nd^3=0{\cdot}00097$ c.c. Since $Nd^2=3306$ sq. cm., by eliminating d, it follows that $(Nd^2)^3/(Nd^3)^2=N=4{\cdot}92\times10^{19}$. This result, for air, is rather lower than the value obtained for other gases. The errors of observation are considerably magnified in the calculation—those of b are doubled, and those of η are trebled. Again, when evaluated by electrical methods N is approximately 4×10^{19} per c.c. The numerical value of the constant N has been determined by nearly a dozen independent methods, and the most reliable determinations approximate $N=6{\cdot}062\times10^{23}$ molecules per gram-molecule of the gas, and this number is called **Avogadro's constant.** The number n per c.c. of the gas is $N/22412$, or $2{\cdot}7048\times10^{19}$ molecules per c.c. of the gas at 0° and 760 mm. The approximate agreement of the numbers is so close that R. A. Millikan[11] could say:

> To-day we are counting the number of atoms in a given mass of matter with as much certainty and precision as we can attain in counting the inhabitants of a city. No census

is correct to more than one or two parts in a thousand. . . . There is little probability that the number of molecules in a cubic centimetre of gas under standard conditions (0° and 760 mm.) differs by more than this amount from $2·70 \times 10^{19}$.

The letter R used for the gas constant appears to have been taken by Isaac Newton in his *Philosophiæ naturalis principia mathematica* (London, 302, 1713) from the term resistance. In his study of the inner resistance of a gas, he showed that if two parallel plates, at a distance r apart, move with a difference of velocity v, the inner resistance for unit surface is proportional to the increase of velocity v/r so that $R=-\eta(v/r)$, where η is the coefficient of friction. E. Clapeyron (1834) employed R to represent the constant in the gas equation $pv=R(a+\theta)$, where a is constant, now represented by 273. E. Clapeyron used 267. According to the kinetic theory of gases, Newton's η is equal to $\frac{1}{3}nmvl$, so that $R=\frac{1}{3}nmv^2l/r$.[12]

§ 4. Attempts to Obtain a More Exact Gas Equation

All nature widens upwards. Evermore
The simpler essence lower lies.
More complex is more perfect, owning more
Discourse, more widely wise.—TENNYSON.

The general equation of state $pv=RT$ does not exactly describe the behaviour of real gases with respect to changes in volume with variations of temperature and pressure. The same gas does not behave in the same way at high and at low pressures. The laws of Boyle and Charles are fairly exact for some gases—*e.g.* hydrogen, oxygen, etc.—at temperatures and pressures not far removed from normal atmospheric conditions; and it is often convenient to neglect small deviations with other gases—*e.g.* carbon dioxide, ethylene, etc. This means that gas calculations with $pv=RT$ are made upon imaginary gases sometimes styled *ideal or perfect gases.* When the pressure upon the gas is very great, the error becomes quite appreciable, and it is necessary to revise the simple gas law: $pv=RT$. This was emphasized by H. V. Regnault in his *Relation des expériences entreprises pour detérminer les principales lois physiques et les données numériques qui entrent dans le calcul des machines à vapeur* (Paris, 1847). He said:

> The law does not express the actual relations between the same quantities of gas and the pressure which they support, and it is desirable to find if it is possible to represent these relations by a new law. . . . Unfortunately this relation is evidently too complex to hope to find it by purely experimental methods. It is to be hoped that mathematicians will try to find the form of this function by developing certain hypotheses on the nature of molecular forces ; the necessary data for calculating the constants can be readily obtained from observed measurements, and the formulæ themselves subjected to *un criterium rigoureux*.

The effect of the size of molecules.—The reduction in the volume which occurs when a gas is highly concentrated is smaller than corresponds with Boyle's relation, and this is now explained in the following way : Under great pressures the volume of the molecule becomes comparable in magnitude with the space through which the molecule can move. The volume of the space in which the molecules move is alone reduced by pressure, and therefore only part of the total volume occupied by the gas can be reduced by pressure. Hence, at high pressures the apparent volume and the product pv appear to be greater than is described by Boyle's law. With hydrogen, for instance, when the pressure is doubled, the volume is not quite halved. The same remark applies to other gases, *e.g.* carbon dioxide, at great pressures. This is illustrated by the upward course of the curves, Fig. 3, Cap. IV.

Let b denote the space occupied by the molecule as it moves to and fro between the boundary walls AB, Fig. 2. If this distance be halved, AC, while the volume of the molecule remains constant, the molecule will have less than half its former distance to pass from one side to the other. For instance, suppose that AC represents one unit, and AB two units, and the diameter of the molecule is $\frac{1}{10}$th unit ; the molecule oscillating between AB then moves through 1·9 units of space in one journey ; and between AC through 0·90 unit, not 0·95 unit. Hence, the molecule will strike the walls more frequently than before per unit time, and the outward pressure due to molecular bombardment will increase more rapidly with decreasing volume, than is described by Boyle's law. Boyle's law refers to the whole volume of the gas, but rather should it refer to the space in which the molecules move. Consequently, $v-b$ should be substituted in place of the v of Boyle's law, and the result is: $p(v-b)=RT$, where b is called the **molecular co-volume.** An application of the theory of probability to the kinetic theory has led to the view that b is very nearly four times the volume actually occupied by the whole of the molecules contained in unit volume of the gas, so that a molecule is represented to be a complex vibratory system with a material nucleus $\frac{1}{4}b/n$ in size, which requires b/n volumes of space in which to perform its oscillatory movements—n represents the number of molecules in unit volume of the gas—hence b is also called the **vibratory volume** of the molecule. The fundamental assumptions have not been so firmly established that there is no room for doubt, and some consider that b represents the real volume of the molecules ; others believe that b is much greater than four times the size of the material nucleus of the molecules. In any case, virtually all are agreed that b is not quite constant, but varies with the temperature, and possibly also with pressure changes. J. D. van der Waals, in his celebrated *Over de Continuiteit van den Gasen Vloeistoftoestand*,[1] published at Leiden in 1873, worked on the assumption that b is constant.

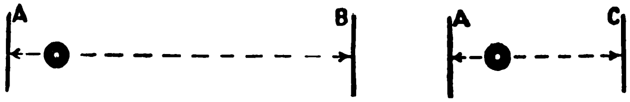

FIG. 2.—The Effect of the Size of the Molecules on the Volume of Gases.

The effect of molecular attraction.—If the molecules of a gas have appreciable cohesion or attraction for one another, they must be swerved from their rectilinear paths when they come within the sphere of one another's influence, and they must then move in curved, not in straight paths. Doubling the number of particles per unit volume will not then give exactly twice the number of impacts on the boundary walls. When the molecular attraction is marked, the product pv must be *less* than corresponds with Boyle's law. Molecular attraction deflects some of the molecules from the straight path so that they do not strike the walls of the vessel under conditions where they otherwise would, and the pressure is accordingly diminished. This appears to be the case with carbon dioxide, and most gases with a smaller apparent volume v, or a smaller value of pv, that is, a greater concentration, than corresponds with an increase of pressure as described by Boyle's law. This is illustrated by the downward slope of the pv curves, Fig. 3, for carbon dioxide below 150 atmospheres pressure. The closer the proximity of the molecules to one another, the greater will be the effect of the attractive forces between the molecules. This attractive force, which may be denoted by F, will tend to make the gas occupy a smaller volume. The effect is much the same as if the gas were subjected to the action of a greater external pressure $p+F$ than the observed or apparent pressure p of the gas. With these ideas before him, G. A. Hirn (1868) [2] proposed to use an equation of the form $(p+F)(v-b)=RT$ in place of the regular equation $pv=RT$. The assumption that the attractive force F between the molecules varies inversely as the fourth power of the distance between the molecules, leads to a/v^2 as the magnitude of the molecular attraction, F, where a is a constant which varies with the nature of the gas, and v denotes the observed volume of the gas. Granting the assumption, a/v^2 must be added to the observed pressure of the gas in order to indicate the total pressure tending to compress the gas. The magnitude of the internal or cohesive pressure a/v^2 for liquid water is nearly 11,000 atm.—a surprisingly large value which is in approximate agreement with results obtained by other independent methods of calculation.

On correcting the equation $pv=RT$ for the volume and cohesion of the molecules, J. D. van der Waals (1873) obtained the so-called **J. D. van der Waals' equation :**

$$\left(p+\frac{a}{v^2}\right)(v-b)=RT \quad . \quad . \quad . \quad . \quad (12)$$

This amended equation agrees fairly well with a number of observations of gases under large pressures, and of gases near their points of liquefaction—*e.g.* ethylene, carbon dioxide, etc. It also describes many of the properties of liquids, and of the continuous passage of a gas to the liquid condition. The constants a and b can be evaluated from observations. The numerical values of J. D. van der Waals' constants a and b for some substances are indicated in Table IV.

TABLE IV.—NUMERICAL VALUES OF J. D. VAN DER WAALS' CONSTANTS.

Substance.	*a*	*b*	Substance.	*a*	*b*
Ammonia	0·00820	0·00162	Acetylene	0·00810	0·00210
Benzene	0·03827	0·00532	Methane	0·00379	0·00160
Water	0·01173	0·00151	Carbon dioxide	0·00727	0·00192
Ethyl alcohol	0·02512	0·00385	Sulphur dioxide	0·01345	0·00251
Acetic acid	0·03737	0·00492	Nitrous oxide	0·00723	0·00189
Carbon tetrachloride	0·04184	0·00586	Nitric oxide	0·00257	0·00115
Tin tetrachloride	0·05926	0·00771	Nitrogen	0·00266	0·00176
Hydrogen phosphide	0·00953	0·00235	Oxygen	0·00266	0·00139
Hydrogen sulphide	0·00887	0·00191	Carbon monoxide	0·00274	0·00168
Hydrogen chloride	0·00704	0·00174	Argon	0·00256	0·00134
Carbon disulphide	0·02412	0·00350	Krypton	0·00460	0·00177
Cyanogen	0·01480	0·00298	Xenon	0·00823	0·00231

J. D. van der Waals (1888) found that for carbon dioxide, $R=1{\cdot}00646$; $b=0{\cdot}0023$; and $a=0{\cdot}00874$, when the unit of pressure is one atmosphere, and the unit of volume is the volume of one gram at 0° and one atmosphere pressure. With these numbers, J. D. van der Waals' equation for carbon dioxide assumes the form

$$\left(p+\frac{0\cdot00874}{v^2}\right)(v-0\cdot0023)=1\cdot00646(1+a\theta)$$

This equation may be employed for comparing the observed values for a gas which is known to deviate rather considerably from R. Boyle's simple relation. Table V has been computed from the numbers obtained by E. H. Amagat (1893) [3] at 20°.

TABLE V.—COMPARISON OF BOYLE'S AND VAN DER WAALS' EQUATIONS FOR *pv* OBSERVATIONS WITH CARBON DIOXIDE.

p (atmospheres).	*pv*.		
	Observed.	Calculated. (J. H. van der Waals' law).	Calculated. (Boyle's law).
1	1·000	1·000	1·000
50	0·680	0·678	1·000
75	0·180	0·179	1·000
100	0·228	0·226	1·000
200	0·419	0·411	1·000
500	0·938	0·936	1·000

The agreement between theory (J. D. van der Waals) and fact (observed data) is quite good. It will be seen that if the gas behaved according to the Boyle's equation, the product *pv* would have had the same constant value for all pressures. As a matter of fact, the value of *pv* first decreases and then increases for all gases except hydrogen and helium. The two corrections act in opposite ways. At first the value of *pv* is decreased by the molecular attraction, but increased to a greater extent by the finite dimensions of the molecule; the two corrections balance one another at ordinary pressures; and at low pressures, the correction for molecular attraction preponderates over that required for the volume of the molecule. The correction for the volume of the molecule is relatively large when the volume of the gas is compressed very small by a large pressure. If the numerical value of the term a/v^2 could exceed that of $RT/(v-b)$, negative pressures would appear as indicated by the dotted line in Fig. 3. This is unreal and therefore unsatisfactory, and does not appear with a second approximation to the gas equation proposed by C. Dieterici [4] in 1899. The experiments of M. Berthelot (1850) and of A. M. Worthington (1892) are sometimes quoted to demonstrate the existence of negative pressures. Here, sealed tubes, quite full of liquid, were cooled slowly, and in some cases the thick-walled tube collapsed owing to enormous tension. It may mean that the molecules of the fluid exert an attractive influence on the walls of the vessel, whereas J. D. van der Waals' equation assumes that there is no such attraction. The alleged negative external pressure is probably a myth.

The numerical values of *a* and *b* of van der Waals' equation are, in reality, not constant at different temperatures; thus, F. B. MacDougall (1916) calculated from E. H. Amagat's results for carbon dioxide:

	20°	40°	60°	80°	100°	137°
a	0·00983	0·00919	0·00852	0·00797	0·00749	0·00708
b	0·00202	0·00221	0·00227	0·00228	0·00226	0·00227

showing that *a* decreases with increasing temperatures even above the critical temperature, while *b*, if it increases at all, increases very slowly; and above the critical temperature is virtually constant and independent of temperature. There are also indications that for low pressures, *b* is not affected, but diminishes when the pressures are very large. There is a wide divergence in the values of the constant a by different methods, thus, for carbon disulphide, numbers ranging from the 1683 (15°) of H. Davies to the 3363 (0°) of J. D. van der Waals, have been reported.[5]

There are various methods for evaluating the constant a of J. D. van der Waals' equation. These methods have been examined by A. P. Mathews. They are: (1) from the surface tension; (2) from R. Eötvös rule or T. Young's rule; (3) from J. D. van der Waals' equation at the critical temperature; (4) from the latent heat of vaporization; and (5) from A. P. Mathews' formula $a=1{\cdot}249\times10^{11}M\Sigma v$, where M denotes the molecular weight, and Σv, the number of valencies per molecule.

There has been a great deal of tinkering with J. D. van der Waals' equation. Over thirty attempts have been made to modify still further the gas equation to make it better describe the behaviour of gases under wide variations of pressure and temperature. C. Dieterici (1899) has made one of the best attempts. In most cases, other terms involving special constants which have to be evaluated from the experimental numbers, have been introduced. Such equations are therefore of limited application.

C. Dieterici's gas equation.—Instead of assuming that the observed pressure of a gas should be reduced by the subtraction of a term a/v^2, as was done by J. D. van der Waals, to give his equation the form

$$\left(p+\frac{a}{v^2}\right)(v-b)=RT\text{ ; or }p=\frac{RT}{v-b}-\frac{a}{v^2}\quad\ldots\quad(13)$$

C. Dieterici (1899) assumed that the term $RT/(v-b)$ should be reduced by multiplication with a function, $e^{-a/vRT}$, always less than unity. Consequently, his equation assumed the form

$$p(v-b)=RTe^{-\frac{a}{vRT}}\text{ ; or, }p=\frac{RT}{v-b}e^{-\frac{a}{vRT}}\quad\ldots\quad(14)$$

where e represents the base of the natural logarithms.

C. Dieterici argued that in the interior of the liquid the attractive forces between the molecules are balanced; at the surface, the molecules are subjected to an unbalanced force directed inwards. Consequently, the density of the layers near the surface will decrease from the interior outwards. Only those molecules with a velocity exceeding a certain value will be able to penetrate the surface layer and exert a pressure on the containing wall: molecules moving towards the interior are assisted by the force directed inwards. If the fraction of the total number of molecules which has a velocity greater than this limiting value can be estimated, it follows that the observed pressure p will be that fraction of the interior pressure $RT/(v-b)$. From the theory of probability, if a represents the most probable speed of the molecules; and S, the speed the molecules must possess to be able just to penetrate the surface, the required fraction will be e^{-S^2/a^2}; and if V denotes the mean velocity, more exactly, the square root of the mean of the squares of the speeds, $V^2=\frac{3}{2}a^2$, or $a^2=\frac{2}{3}V^2$. If M represents the mass of a molecule and n the number of molecules, e^{-S^2/a^2} becomes $e^{-\frac{\frac{1}{2}nmS^2}{\frac{1}{3}nmV^2}}$, and from (2), $\frac{1}{3}nMV^2=RT$; and $\frac{1}{2}MnS^2$ will represent the work W done by a molecule penetrating the surface layer of molecules against the molecular forces. The previous expression thus becomes $e^{-W/RT}$. C. Dieterici then assumed that the work W is proportional to the density of the gas or $W=a/v$, where a is a constant. Whence follows equation (14) above.

The curves obtained by plotting J. D. van der Waals' and C. Dieterici's equations have the same general form, Fig. 3. Both equations reproduce the critical state very well, but Dieterici's equation agrees better with the general results of observation particularly at high pressures, where J. D. van der Waals' equation usually breaks down. At low pressures, where v is large in comparison with b, both equations give equally good results. Since, under these conditions, C. Dieterici's equation reduces to that of J. D. van der Waals. This can be shown by expanding Dieterici's equation and omitting the higher powers of v, because when v is large, these terms are negligibly small. In that case,

$$p=\frac{RT}{v-b}\left(1-\frac{a}{vRT}\right)=\frac{RT}{v-b}-\frac{a}{v(v-b)}=\frac{RT}{v-b}-\frac{a}{v^2} \quad . \quad . \quad (15)$$

since, when b is small in comparison with v, $v(v-b)$ approximates to v^2. J. D. van der Waals' equation is thus a special case of C. Dieterici's equation applicable to low pressures, just as the equation $pv=RT$ is a special case of the same equation applicable to gases, for which a and b are negligibly small in comparison with p and v.

If the simple equation $pv=RT$ be regarded as a first approximation to a true gas equation, J. D. van der Waals' equation can be regarded as a second, and C. Dieterici's as a third approximation towards a complete law. Most, if not all, the formulæ of physics and chemistry are in the earlier stages of such a process of evolution. As I have said elsewhere,

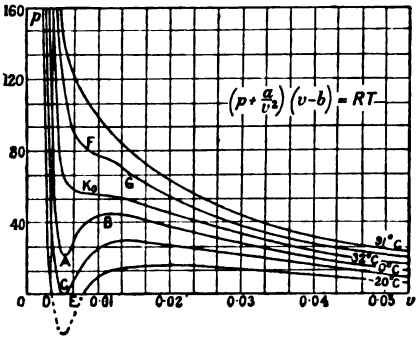

FIG. 3.—Graphs of J. D. van der Waals' Equation.

> There is a prevailing impression that once a mathematical formula has been theoretically deduced, the law embodied in the formula has been sufficiently demonstrated provided the differences between the calculated and the observed results fall within the limits of experimental error. With improved instruments, and better methods of measurement, more accurate data are from time to time available. The errors of observation being thus reduced the approximate nature of the original formula becomes more and more apparent. Ultimately the discrepancy between theory and fact becomes too great to be ignored. It is then necessary to "go over the fundamentals." New formulæ must be obtained embodying less of hypothesis, more of fact. Thus, from the first primitive guess, succeeding generations progress step by step towards a comprehensive and a complete formulation of the several laws of Nature.

§ 5. J. D. van der Waals' Theory of Corresponding States

J. D. van der Waals' equation assumes the form of an equation of the third degree in v when it is multiplied out:

$$v^3-\left(b+\frac{RT}{p}\right)v^2+\frac{a}{p}v-\frac{ab}{p}=0 \quad . \quad . \quad . \quad (16)$$

In algebra, we are taught that such an equation must have three roots real or imaginary, equal or unequal; and of the real roots, there may be one or three equal or unequal—imaginary roots have no physical meaning. Otherwise expressed, there may be one or three different volumes corresponding with certain assigned values of p and T. If there is only *one real root*, *A*, Fig. 4, the equation furnishes only one value of v for every assigned value of p. The graph for carbon dioxide above the critical temperature is an example. If the equation has *three unequal roots*, *C*, Fig. 4, there ought to be three different values of v at the given pressure and temperature, but only two of these have been realized, since the middle portion of the curve is physically unstable. The line of constant pressure cuts the theoretical curve in three places as indicated at a, b, and c, Fig. 4, but, instead of the pressure increasing to a maximum α (Fig. 4), falling to a minimum β, and then increasing indefinitely, as the volume is diminished, the pressure increases to a certain value, and then remains constant until the gas has completely condensed to a liquid. The curve $C'a$ has been prolonged a very short distance towards β by undercooling; and the curve Cc prolonged a little towards a by supersaturation. The suggestion that the dotted line, Fig. 4, be substituted for the horizontal part of Andrew's curves was made by J. Thomson in 1862. For three unequal roots, the line of constant pressure cuts the theoretical curve in three places, as indicated at a, b, c, Fig. 4; but, when there are *three equal roots*—β, Fig. 4—there is only one numerical value for v for the assigned values of p and T. This occurs at the critical temperature K.

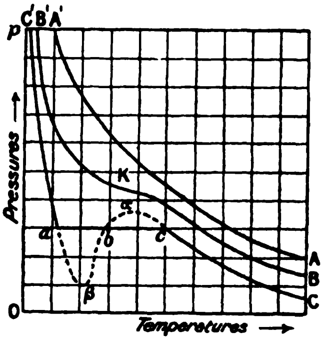

FIG. 4.—Graphs showing the Roots of J. D. van der Waals' Equation.

Let v_c, p_c, and T_c respectively denote the critical volume, critical pressure, and critical temperature; v_c will be the root of van der Waals' equation at the critical temperature, and $(v-v_c)^3=0$. Expand this equation, and the result is an identity with (16) above. Equate coefficients of like powers of v, and it follows that

$$v_c=3b\,;\ p_c=\frac{a}{27b^2}\,;\ T_c=\frac{8a}{27bR}\ . \quad . \quad . \quad . \quad (17)$$

These results enable the values of the constants a, b, and R to be calculated when the critical volume, pressure, and temperature are known, on the *assumption* that a, b, and R are constant. Corresponding values for C. Dieterici's equations are

$$v_c=2b\,;\ p_c=\frac{a}{29{\cdot}56b^2}\,;\ T_c=\frac{a}{4bR}\ . \quad . \quad . \quad . \quad (18)$$

Again, let $\mathbf{p}=p/p_c$; $\mathbf{v}=v/v_c$; and $\mathbf{T}=T/T_c$, then, by the substitution of these values in J. D. van der Waals' equation (18), there remains

$$\left(\mathbf{p}+\frac{3}{\mathbf{v}^2}\right)(3\mathbf{v}-1)=8\mathbf{T}\ . \quad . \quad . \quad . \quad (19)$$

The magnitude $\mathbf{v}$ is called the *reduced volume*; $\mathbf{p}$ the *reduced pressure*; $\mathbf{T}$ the *reduced temperature*; and (19), the *reduced equation of state*. The operation of reduction seems to have freed van der Waals' equation of specific constants peculiar to individual substances, and substituted numbers of universal application in their place. The result means that if the initial assumption be granted, different substances can exist in such states or conditions that their volume, pressure, and temperature are respectively the same fractions of their critical values. Hence, states characterized by the same values of $\mathbf{v}$, $\mathbf{p}$, and $\mathbf{T}$, were called **corresponding**

states—*übereinstimmende Züstande*—by J. D. van der Waals. This extraordinary conclusion means that **at the critical point the relation between the pressure, volume, and temperature is the same for all substances**; no matter what the substance, no matter what be the diameters of the particles, the range and magnitude of the molecular forces, or the potential energy of the particles, the same relation holds; any two of these variables being given, the third can be calculated.

J. D. van der Waals' theory of corresponding states was first regarded as being derived from the molecular theory, but it is now treated as being based on a purely empirical equation of state, like those of R. Clausius[1] and D. Berthelot, both of which were empirically devised to represent the facts more nearly than the state-equation of J. D. van der Waals. G. Meslin has shown that the theory of corresponding states follows directly from any equation of state with not more than three constants. *R. Clausius' equation of state* has four constants—namely a, b, c, R—and it gives a reduced equation with one constant λ:

$$\left(p+\frac{a}{T(v+c)^2}\right)(v-b)=RT\,;\quad\left(\mathbf{p}+\frac{1}{\mathbf{T}(\mathbf{v}+\lambda)^2}\right)(\mathbf{v}-1)=\mathbf{T}$$

If the constant c be removed, *D. Berthelot's equation of state* with three constants, and a reduced equation with no constants:

$$\left(p+\frac{a}{Tv^2}\right)(v-b)=RT\,;\quad\left(\mathbf{p}+\frac{1}{\mathbf{T}\mathbf{v}^2}\right)(\mathbf{v}-1)=\mathbf{T}$$

are obtained. P. Curie has also shown that at the critical point $(dp/dv)_T=0$, $(d^2p/dv^2)_T=0$, and any critical point so defined will serve for setting up reduced equations. For example, let p_0, v_0, and T_0 be critical points, then, from J. D. van der Waals' equation, $b=Bv_0$; $a=Ap_0v_0^2$; and $R=Cp_0v_0/T_0$, where A, B, and C represent pure numbers. Then $p/p_0=\mathbf{p}$; $v/v_0=\mathbf{v}$; and $T/T_0=\mathbf{T}$, so that

$$\left(\mathbf{p}-\frac{A}{\mathbf{v}}\right)(\mathbf{v}-B)=C\mathbf{T}$$

a reduced equation containing only numerical constants; J. D. van der Waals' form of the reduced equation is a special case of this. D. Berthelot has set up three reduced equations with special properties—in one, the unit of reference in the critical point is defined by $dp/dT=0$, where p is a maximum. As G. von Kaufmann has shown, the theory of corresponding states is quite independent of any critical point, for by assigning specific or special units for p, v, and T, for each substance, three specific constants can be eliminated from any equation of state.

S. Young[2] tested the law of corresponding states with a few substances; it seems to hold fairly well for a few groups of related compounds—hydrocarbons, esters, ketones, ethers, etc.—where the results are not disturbed by molecular association. It does not agree closely with water, the alcohols, and the fatty acids. The results with the monatomic gases argon and helium agree amongst themselves, but not with those of other groups. A few examples are indicated in Table VII. In S. Young's method the values of v_c, p_c, and T_c are measured and the different functions compared with equal values of $\mathbf{p}$ and $\mathbf{T}$. E. H. Amagat (1896) recommended a method in which no knowledge of the critical values is needed, because curves with the variables log p, log v, log T, etc. are plotted, and from the theory of corresponding states, the curves for different substances should be of identical shape and superposable by a parallel shifting of the axes. C. Raveau (1897) applied E. H. Amagat's method to ethylene and carbon dioxide. K. Meyer and D. Berthelot found that a fairly accurate correspondence of states exists if the reduced variables p/p_c, $(v-v_c)/(v_c-v_m)$, and $(T-T_c)/(T_c-T_m)$ be chosen, where T_n and v_n have specific values for each substance. G. von Kaufmann sums up the position:

Although in many cases a fairly approximate correspondence of states has been found to exist, the theory in its entirety has been proved without doubt inexact; it has not been found completely true for even a single pair of substances. There is therefore no general p, v, T-equation of state with only three specific constants. Nevertheless, a theory which is so far-reaching and fundamental as this, and which over a whole range of phenomena gives a good first approximation to the facts, will not be lightly discarded, and in the present position, attempts are being made to modify it in such a way as to bring it more into agreement with the truth.

The critical density.—P. A. Guye (1890) and S. Young (1892)[3] showed interesting consequences of combining the three equations (18). S. Young obtained $v_cp_c=\frac{3}{8}RT_c$. Let v denote the volume occupied by the substance in the gaseous state, and assume that it behaves like an ideal gas at the critical state when $vp_c=RT_c$. By division, $v_c=\frac{3}{8}v$. If d_c denotes the observed density of the gas in the critical state, and D_c the theoretical density required for an ideal gas, then, remembering that the density is the reciprocal of the volume, $d_c/D_c=\frac{8}{3}=2·67$, so that if J. D. van der Waals' equation accurately describes the behaviour of the gas in the critical state, the observed critical density of all gases ought to be 2·67 times the theoretical density of an ideal gas at the critical temperature and pressure. This is not the case. The actual results are larger, being somewhere near 3·67 for the hydrocarbons, esters, ketones, and ethers.

TABLE VI.—ILLUSTRATIONS OF THE LAW OF CORRESPONDING STATES.

Gases and vapours.	$\mathrm{v}=\frac{v}{v_c}$	$\mathrm{p}=\frac{p}{p_c}$	$\mathrm{T}=\frac{T}{T_c}$
Carbon tetrachloride	0·725	0·408	27·5
Stannic chloride	0·736	0·403	28·1
Ether	0·738	0·403	28·3
Benzene	0·728	0·407	28·3
Fluorobenzene	0·733	0·407	28·4
Ethyl alcohol	0·735	0·400	29·6
Acetic acid	0·762	0·410	25·4

	CCl_4	$SnCl_4$	CO_2	SO_2	CH_4	O_2	N_2
$\frac{d_c}{D_c}$	3·65	3·76	3·61	3·62	3·67	3·49	3·53

Abnormally high results are obtained with associated substances—*e.g.* the fatty acids and alcohols have values approximating 4 or 5. Argon has the value 2·71 (D. Berthelot, 1901), and hydrogen 2·69 (J. J. van Laar, 1904); and these gases alone approximate with any reasonable accuracy to the value required by van der Waals' hypothesis. According to C. Dieterici's values for the critical data, the critical density is 3·6945 times greater than the density of an ideal gas at the critical temperature and pressure. This is a much closer approximation to the actual results with normal substances than is obtained with the equation of J. D. van der Waals, for, according to S. Young (1892), the value of d_c/D_c is nearly 3·7 for all substances which can attain the critical state without chemical change.

Method of determining molecular weights from the critical constants.——If the pressure be expressed in atmospheres and the unit of volume be the volume occupied by a gram-molecule of the gas under normal conditions, J. D. van der Waals[4] has shown that the equation

$$\left(p+\frac{a}{v^2}\right)(v-b)=R\frac{T}{273}, \text{ becomes } (1+a)(1-b)=R\frac{T}{273}$$

so that the relative molecular volumes of the different gases at 0° and 1 atm. pressure, or the volumes of the different gases at 0° and 1 atm. which contain the same number of molecules, are proportional to

$$\frac{1}{(1+a)(1-b)},\ \frac{1}{(1+a')(1-b')},\ \ldots$$

and the volume in litres occupied by a gram-molecule of the gas under normal conditions, by Avogadro's rule, will be the same for all gases, so that $(1+a)(1-b)M/W=$a constant, where W denotes the weight of a litre of a gas under normal conditions:

$$M=\frac{22{\cdot}412W}{(1+a)(1-b)}$$

since P. A. Guye (1905) has shown Avogadro's constant to possess the same normal value 22·412 for all gases. The constants a and b vary with temperature, and Guye considers that the value of the critical constants at the temperature T can be represented by the equations:

$$a_0=a\left(\frac{T_c}{T}\right)^{\frac{3}{2}};\ b_0=b\left(1+\frac{T_c-T}{T_c}\right)\left(1-\beta\frac{p}{p}\right)$$

The numerical value of the constant $\beta=0{\cdot}0032229$ has been deduced from the critical constants, density, and molecular weight of carbon dioxide, consequently the molecular weight of the gas is given by the expression:

$$\text{Molecular weight }=\frac{22{\cdot}412W}{(1+a_0)(1+b_0)}$$

The following examples illustrate the application of the rule:

	Carbon dioxide.	Nitrous oxide.	Sulphur dioxide.	Hydrogen chloride.	Acetylene.
W . . .	1·9768	1·9774	2·9266	1·6407	1·1707
T_c . . .	303·98	311·8	428·4	325	308·25
p_c . . .	72·93	77·8	78·9	83	61·03
$a\times10^5$ . .	721	719	1345	726	879
$b\times10^5$ . .	191	185	251	180	231
$a_0\times10^5$ . .	847	878	2644	943	1055
$b_0\times10^5$ . .	161	156	255	153	207
M . . .	44·003	44·000	64·065	36·484	26·018

With gases which have a low critical temperature and which do not liquefy very readily, the correction of the constants a and b for temperature is not necessary, and

$$\text{Molecular weight }=\frac{(22{\cdot}412-mT_c)W}{(1+a)(1-b)};\text{ or }M=\frac{(22{\cdot}412-0{\cdot}0000623T_c)W}{(1+a)(1-b)}$$

is sufficiently accurate, where the value of the constant m has been fixed with respect to oxygen $=16$, at $m=0{\cdot}0000623$. For example,

	Oxygen.	Hydrogen.	Nitrogen.	Argon.	Carbon monoxide.
W . .	1·4290	0·089873	1·2507	1·7802	1·2504
T_c . .	154·2	32	128	152	133·5
$a\times10^5$.	266	28·8	275	260	284
$b\times10^5$.	139	73·7	174	138	172
M . .	32	2·0153	28·013	39·866	28·003

A. Leduc's[5] method of molecular volumes for determining the molecular or atomic weight of gases.—A. Leduc's method is related to D. Berthelot's method of limiting densities, but as experimental data it requires a knowledge of the densities and the critical constants. It is based on the theory of corresponding states. The variations of pressure p, molecular volume V, and absolute temperature T of a gas described by Boyle's and Charles' laws, are related by $pV=KT$, where K is a constant the same for all gases. All known gases deviate from this rule, and the relation is then represented by $pV'=K'T$, where K' is related with K so that $K'/K=V'/V$. Let V'/V, the ratio of the molecular volume V' of a gas to the molecular volume V of an ideal gas at the same temperature, be represented by $\phi=V'/V$. Consequently, it follows that $K'/K=\phi$, and $pV'=KT\phi$, where ϕ is variable quantity. If M denotes the molecular weight, and v the specific volume, it follows, since $Mv=V'$,

$$Mpv=KT\phi$$

For oxygen gas $M=32$; $v=v_1$; and $\phi=\phi_1$; accordingly, $32pv_1=KT\phi_1$; and by division, remembering that if D and D_1 respectively denote the densities of a given gas and oxygen, $D=1/v$ and $D_1=1/v_1$—all at the same temperature and pressure:

$$\frac{M}{32}=\frac{\phi D}{\phi_1 D_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

If $1-E$ and $1-E_1$ be respectively substituted for ϕ and ϕ_1, this equation is identical with that used in D. Berthelot's method of limiting densities.

In order to evaluate ϕ and ϕ_1, it follows that the relation for zero pressure becomes $Mp_0v_0=KT\phi_0$, and by division $pv/p_0v_0=\phi/\phi_0$. A. Leduc then assumes that ϕ_0 may be regarded as unity at a common temperature, and at an indefinitely small pressure; this means that under these conditions all gases have the same molecular volume, consequently

$$\frac{pv}{p_0v_0}=\phi$$

A. Leduc further assumes that the compressibility of a gas over a range of a few atmospheres, can be represented by the expression $E=1-pv/p_0v_0$, or

$$1-\frac{pv}{p_0v_0}=mp+np^2$$

where m and n are small constants to be determined for each gas. Accordingly, $\phi=1-mp-np^2$, and therefore

$$\phi=1-mp_c\left(\frac{p}{p_c}\right)-np_c^2\left(\frac{p}{p_c}\right)^2 \quad . \quad . \quad . \quad . \quad (2)$$

A. Leduc measures p in cm. of mercury, and p_c in atm., and he denotes the ratio p/p by e.

To evaluate the constants m and n, A. Leduc assumes that the molecular volumes of gases are equal at the same reduced temperature T/T_c, and reduced pressure, p/p_c. At the same reduced pressure, different gases at the same reduced temperature give the same values of ϕ. Consequently, the coefficients mp_c and np_c^2 must each be functions of the reduced temperature only. A. Leduc finds that within the limits of experimental error, these functions are respectively:

$$mp_c=18{\cdot}85\frac{T_c}{T}\left(2\frac{T_c^3}{T^3}-\sqrt{2}\frac{T_c^3}{T^2}+2\sqrt{2}\frac{T_c}{T}-1\right)\times10^{-4}\,;\quad np_c^2=3{\cdot}5\frac{T_c^3}{T^3}\left(\frac{T_c}{T}-1\right)\times10^{-4}$$

The results represent his experiments on compressibility very closely, excepting with ammonia, phosphine, hydrogen sulphide, and methyl ether.

In applying this method, (i) the density D of the gas at the temperature T and pressure p; and (ii), the critical pressure p_c and temperature T_c, are supposed to be known. This enables the constants m and n to be evaluated. It is then necessary to calculate ϕ from equation (2). The value of ϕ_1 for oxygen is also supposed to be known; and the required molecular weight is then calculated from (1). In practice $T=273$ and $p=1$. A comparison of some results by these different physical methods gives:

Method of	Hydrogen.	Nitrogen.	Carbon.	Chlorine.
Limiting densities . .	1·0075	14·008	12·009	35·461
Critical constants . .	1·0075	14·010	12·003	35·436

§ 6. Summary of the Kinetic Theory of Molecules

The phenomena are our data, and behind them we cannot go except in imagination.—A. SCHOPENHAUER.

The fundamental assumptions of the kinetic theory in its simplest form, can now be summarized—the term "kinetic," by the way, is derived from the Greek κινέω, I move. (1) Matter is composed of a finite number of molecules. In gases, the volume of the molecules is very small compared with the space not occupied by the molecules. At great pressures, however, the relative sizes of the molecules must be taken into consideration. (2) The molecules of a gas are in a state of rapid perpetual motion in straight lines. The molecules are continually colliding against the walls of the boundary vessel and against one another. (3) The molecules are perfectly elastic and rebound after a collision without any loss of momentum. (4) The molecules of gases do not always move quite independently of one another, since some molecules have a slight attractive force one for the other. This becomes appreciable with increasing concentrations. (5) Two gases are in thermal equilibrium when the average kinetic energies of the molecules of both gases are the same.

A. D. Risteen in his *Molecules and the Molecular Theory* (Boston, 1895), has compared the results of observation with the deductions from the kinetic theory in double columns. The following is modified from his scheme:

TABLE VII.—COMPARISON OF THE KINETIC THEORY WITH FACTS.

Results of theory.	Results of observation.
1. The molecules of a particular gas are all alike. There are special cases of dissociation and polymerization.	1. Gases are homogeneous and show no signs of settling, nor can the molecules of any particular gas in general be separated, by diffusion, into different molecules.
2. Molecules are at relatively great distances apart, and in constant motion in straight lines.	2. The compressibility, permeability, and diffusivity of gases is great. The incompressibility of gases at high pressures is supposed to be due to the abnormal crowding of the molecules.
3. In a given mass of molecules, the product pv is proportional to the average kinetic energy per molecule.	3. In a given mass of gas the product pv is proportional to the absolute temperature, etc. This includes the laws of Boyle, Dalton, and Charles.
4. The average *kinetic energy* is constant for every set of molecules in a mixture of gases.	4. So far as we can tell, the *temperature* of each constituent of a mixture of gases is the same.
5. If two sets of molecules have the same kinetic energy, and the same pressure, they contain the same number of molecules per unit volume.	5. Avogadro's hypothesis, and hence also Gay Lussac's law. This is not a result of observation, but it has been inferred independently from purely chemical phenomena.
6. Diffusion.	6 Graham's law.

Molecular magnitudes.—The following Table VIII summarizes the results of some preceding calculations for a few common gases:

TABLE VIII.—MAGNITUDES IN THE MOLECULAR WORLD.

Gas.	Molecular weight, M	Mean velocity V, at 0°, in cm. per sec.	Number of collisions per sec.	Average free path, L, at 0° and 10^6 bars cm.	Molecular diameter, d cm.	Mass of the molecules, m grm.
Hydrogen, H_2 .	2·016	$1·838 \times 10^5$	$10·6 \times 10^9$	$16·00 \times 10^{-6}$	$2·403 \times 10^{-8}$	$13·33 \times 10^{-24}$
Oxygen, O_2 .	32·00	0·461	4·7	9·05	2·975	52·78
Nitrogen, N_2 .	28·02	0·493	5·3	8·50	3·146	46·53
Argon, A . .	39·88	0·413	4·2	8·98	2·876	65·79
Water, H_2O .	18·02	0·615	6·3	8·31	2·900	29·73
Carbon dioxide, CO_2	44·00	0·393	6·5	5·56	3·335	72·59

The following [1] also represent some constants which occur in calculations:

Volume of ideal gas per gram molecule at 0°, 760 mm. .	22,412 c.c.
Number of molecules per gram molecule at 0°, 760 mm.	$6·062 \times 10^{23}$
Number of molecules per c.c. at 0° and 760 mm. . .	$2·705 \times 10^{19}$
Kinetic energy of a molecule at 0° and 10^6 dynes . .	$5·621 \times 10^{-14}$ erg
Gas constant, R, 1·987 cals. per degree, or . . .	$83·15 \times 10^6$ ergs per degree
Boltzmann's gas constant, $R/N = k$	$1·372 \times 10^{-16}$ ergs per degree

It is sometimes convenient to use a millionth of a metre, *i.e.* a thousandth of a millimetre, as a unit of smallness, and to represent this unit by the symbol μ; this unit is called a **micron.** In illustration, 0·001 mm. or 10^{-3} mm. is μ; and thus 0·01 mm. or 10^{-2} mm. will be 10μ, and 0·0001 mm. or 10^{-4} mm. will be $0·1\mu$. Similarly, the double μ or milli μ, symbolized $\mu\mu$, and called a **millimicron,** represents a thousandth part or $0·001\mu = \mu\mu$ $= 0·000001$ mm.

In every explanation of natural phenomena, said H. von Helmholtz, we are compelled to leave the sphere of sense perceptions and to pass to things which are not the objects of sense, and are defined only by abstract conceptions. It is almost the same with magnitudes in the molecular world. Most of the numbers representing the motions and magnitudes of molecules convey no meaning to the mind because they are utterly beyond the range of our comprehension, and they might almost as well be abstract conceptions. The following considerations will serve to emphasize our inability to form a clear concept of the scale of magnitudes in the world of molecules. They have been employed by several writers.[2]

> *First*, A normal human eye, at a distance of 10 inches, can see objects $\frac{1}{250}$th inch in diameter; with a good microscope objects not much smaller than $\frac{1}{50000}$ inch in diameter can be clearly seen, but this is nearly 5000 times the magnitude of the molecule of an element. It would take about 40,000,000 molecules, touching one another, to make a row an inch long. *Second*, If all the molecules in a cubic inch of a gas were laid in a row, touching one another, although they are so inconceivably small, yet they are so very numerous that they would form a line about 35,000,000 miles long, and this line would extend more than 1000 times round the earth, and this in spite of the fact that only about one-three-thousandth of the volume is actually occupied by matter, the remainder being vacuous space. *Third*, If the gas were magnified on such a scale that a molecule was an inch in diameter, each cubic foot would contain about one molecule, and a molecule would then travel about 100 feet before it collided with another. *Fourth*, It would take about 53 years, counting at the rate of three per second, 24 hours a day, to count the number of collisions—5,000,000,000—made by a molecule with its fellows every second. *Fifth*, A molecule travels at the rate of nearly a quarter of a mile per second.

If the molecules occupy only a fractional part of the space taken up by a mass of matter, it is natural to inquire : Is there absolutely nothing in the intermolecular spaces ? Students of light, heat, electricity, and magnetism say that the intermolecular space, where no ponderable matter exists, is full of " an entity of a highly rarefied nature called æther." This hypothetical medium is continually crossing the path of the student of chemical theory.

Early history of the kinetic theory.—The first inkling of the idea that many of the observed properties of matter may be explained by the motion of its constituent particles without the introduction of separate adventitious hypotheses as to the nature of matter, has been traced back to the so-called atomic theory of Leucippus (*c.* 450 B.C.), Democritus (*c.* 420 B.C.), Epicurus (*c.* 300 B.C.), and Lucretius (*c.* 80 B.C.). Francis Bacon, in his *De principiis atque originibus* (London, 1612), said :

> Almost all the ancients—Empedocles, Anaxagoras, Anaximenes, Heraclitus, and Democritus—though they differed in other respects about the first matter, agreed in this, that they set down matter as active, as having some form, as dispensing with that form, and as having the principle of motion in itself. Nor can any one think otherwise unless he plainly deserts experience.

The theory that the properties of matter are dependent on the mode of motion of the constituent particles was taken up by P. Gassend, in his *Syntagma philosophicum* (Lugduni Batavorum, 1658), where he explained the three states of matter by postulating absolutely rigid atoms moving in all directions in empty space. Robert Boyle also, in his *Considerations and Experiments touching the Origin of Qualities and Forms* (London, 1664), assumed the existence of a continued motion of the primitive atoms. As previously indicated, Robert Hooke (1678) attributed the pressure of gases to the impact of similar particles ; and the same notion occurred independently to D. Bernoulli (1738), and to T. Herapath (1821). J. P. Joule (1848) also applied the principle to calculate the average speed of the particles of a mass of hydrogen. J. P. Joule's calculation is independent of the number of particles, as well as of their direction of motion and of their mutual collisions. These ideas did not develop into a satisfactory hypothesis until R. Clausius, in 1857 and subsequent years, took into consideration the mutual impacts, and the internal rotations and vibrations which the molecules communicate to one another. R. Clausius also discussed the bearing of the internal motions of the molecules on specific heat, and he explained the comparative slowness of the process of diffusion of one gas into another in spite of the swiftness of the motions of the molecules.

In 1860, J. C. Maxwell applied the statistical method or method of averages to the distribution of velocities among the molecules of a gas, and he made the first numerical estimate of the average length of the free path of a moving molecule between two collisions. The work of A. Krönig (1856), R. Clausius (1857), J. C. Maxwell (1859), L. Boltzmann (1868), and of others played an important part in the subsequent development of the hypothesis.

The kinetic theory and the corresponding molecular theory of liquids and gases have been of great service in helping chemists to form mental pictures of many processes which would be otherwise too difficult to conceive clearly. No one pretends that the picture corresponds with reality, but it has been of great assistance in applying the method of deduction and verification. The theory has its faults; at present, it throws no light on many of the properties of gases, while the applications to liquids and solids have scarcely been touched. A great deal of work remains to be done, but most of the outstanding difficulties relate to the nature of the atoms and molecules, and do not affect the main outline of the theory. A short time back there was a school of chemists which repudiated the kinetic theory as an exhausted moribund hypothesis—for instance, C. L. Speyers rather prematurely said in his *Textbook of Physical Chemistry* (New York, 1898): "The kinetic theory is a troublesome thing, and is becoming an object of ridicule." As a matter of fact, the kinetic theory of molecules may be a troublesome thing, but it still promises to live long when our mathematicians get strong enough to wrestle with its many difficulties; few have any doubts as to the validity of the essential features of the doctrine.

§ 7. Ultramicroscopic Particles—Ultramicroscopy

The sun discovers atoms and makes them dance naked in his beams.—D. CULVERWELL.

In practice, a good microscope will not clearly resolve particles much smaller than 0·00025 mm. (0·25$\mu\mu$, or $2·5 \times 10^{-5}$ cm.) in diameter by direct illumination; with oblique illumination, using a naphthalene monobromide immersion lens, and violet light, particles 0·000012 mm. in diameter have been noted. The term **ultramicroscopic particles** is applied to granules smaller than the limits of a good microscope. The ultramicroscopic particles cannot be seen with a powerful microscope illuminated in the ordinary manner, because the light waves bend round the minute particles and enter the eye just as if the particle did not exist. If the particles be illuminated with a lateral beam of light, their very smallness enables them to scatter the light, so that their presence can be inferred from the fact that each particle is surrounded by visible diffraction rings, or halos of light, just as surely as the presence of smoke indicates fire. The motes dancing in a beam of sunlight would be invisible but for this phenomena. The diffraction rings which surround the particles in the track of a beam of sunlight make them appear as if they were self-luminous, and they are more clearly seen against a dark background.

Clear solutions with particles too small to be resolved by the most powerful microscope, appear more or less opalescent when a beam of converging light is focussed into the solution. A solution free from these particles would not produce the opalescence, and such a solution is said to be **optically empty.** This is the so-called **Tyndall's optical test.**[1] Air and gases generally, if quite free from suspended particles, are said to be optically empty because the track of a beam of light therein is invisible. Air can be made optically empty by allowing it to stand overnight in a glass box whose sides are smeared with, say, glycerol. The difficulty in removing fine particles suspended in a gas is well shown by trying to remove sulphur trioxide from air by passing air charged with this compound through a number of wash bottles charged with water for which sulphur trioxide has a great affinity. The sulphur trioxide will persist after passing slowly through half a dozen ordinary washing bottles. It is also exceedingly difficult to get a liquid optically empty so that the track of a converging beam of light in the liquid is not visible in a darkened room. Distillation and filtration will not do. If colloidal silicic acid be suspended in the water, and then precipitated by passing an electric current through the solution, or if colloidal ferric or aluminium hydroxides be precipitated in aqueous solution, the precipitate in settling catches and drags the suspended particles down; the supernatant liquid is then optically empty. Precipitates which settle in a crystalline form do not clarify the liquid in the same way as colloidal precipitates. Ordinary air must be excluded or it will again charge the liquid with suspended particles. The work of R. C. Tolman, and others, shows that for the range of particles in actual smoke (5×10^{-6} to 10^{-4} cm.) and for particles in suspension 10^{-4} cm. upwards, the Tyndall beam becomes more intense at a given concentration the greater the subdivision. W. Mecklenburg found that with particles less than 10^{-4} cm., the Tyndall beam increased in intensity with an increase in the size of particles—concentration constant.

The sensitiveness of J. Tyndall's optical test (1868) has been greatly developed by the use of the so-called **ultramicroscope** of H. Siedentopf and R. Zsigmondy.[2] In this microscope, an intense beam of light—arc light, or, better, a beam of bright sunlight—is focussed into the liquid under examination, so that the light enters the liquid at right angles to the direction in which it is viewed under the microscope. The positions of the particles then become visible as points of light against a dark background. If transmitted light be used, the eye is dazzled by the profusion of light, and it cannot distinguish the slight differences of brilliancy caused by the diffraction of light by the small particles; just as it is impossible to see the stars by daylight. The presence of particles about 6×10^{-5} or 7×10^{-5} mm. in diameter can be demonstrated by this mode of illumination. Although the *position* of the particles can be seen, their form or *shape* cannot be distinguished. The *relative sizes* of the particles can be roughly estimated from their relative brightness. The ultramicroscope is therefore a microscope in which particles are illuminated against a dark background with the strongest possible light. It does not give an image of the object in the microscopic sense of the term, but it does give proof of the existence of small particles with a refractive index different from the surrounding medium. The stronger the illumination, the smaller the particles which can be perceived, but the efficiency of the ultramicroscope is limited by the decrease in the brightness of the particles at a rate which is proportional to the sixth power of their diameter.

While the opalescence produced by Tyndall's optical test merely shows that a solution contains a number of distinct individual particles in suspension, the ultramicroscope enables the *individual* particles to be detected under conditions where the most powerful microscope would fail to reveal any sign of non-homogeneity. When viewed in the ultramicroscope, the ultramicroscopic particles appear as glittering discs of light with a dim or dark background. A solution may thus appear perfectly homogeneous when viewed under the most powerful microscope, and yet appear distinctly heterogeneous when viewed under the microscope with Tyndall's illumination.

W. Ostwald suggested that in the two-phase system, the one phase which is finely subdivided and discontinuous is called the **disperse phase**; the other phase which is usually continuous is called the **dispersion medium**; the disperse phase may also extend through the dispersion medium as a kind of reticulum or network. The **degree of dispersion** or the dispersity of a colloid refers to the state of subdivision to which the disperse phase has been carried; the dispersion medium may be I. A *gas*, and the disperse phase (*a*) a liquid (*e.g.* cloud or mist), or (*b*) a solid (*e.g.* dust or smoke); II. A *liquid* and the disperse phase (*a*) a gas (*e.g.* foam), (*b*) a liquid (*e.g.* emulsion), or (*c*) a solid (*e.g.* suspensions); III. A *solid*, and the disperse phase is then (*a*) a gas (*e.g.* solid foam and scoriæ), (*b*) a liquid (*e.g.* certain liquid inclusions and gels), or (*c*) a solid (*e.g.* certain solid mixtures). When the dispersion medium and the disperse phase are both liquids, **emulsions** are formed if the degree of dispersion is not high, and **emulsoids** if the degree of dispersion is large; while if the dispersion medium is a liquid and the disperse phase is solid, **suspensions** are formed if the dispersity is not high, and **suspensoids** if the degree of dispersion is large. The general term **dispersoids** covers both emulsoids and suspensoids. H. Siedentopf and R. Zsigmondy proposed to call dispersoids which are visible under the microscope **microns,** and those which can be seen only by the application of ultramicroscopic methods **ultramicrons** or submicrons; ultramicroscopic particles which cannot be seen by ultramicroscopic methods are called **amicrons.** The limiting sizes are as follows:

Visible under microscope—*Microns*			$0{\cdot}25\mu$, or $2{\cdot}5\times10^{-5}$ cm.
Ultramicroscopic particles	*Submicrons*	Electric arc light	$15\mu\mu$, or 15×10^{-7} cm.
		Strong sunlight	$1{\cdot}0\mu\mu$, or 10^{-7} cm.
	Amicrons		$<1{\cdot}0\mu\mu$, or $<10^{-7}$ cm.

Early in the nineteenth century, the products obtained by reducing solutions of the salts were generally regarded as solutions although several investigators believed them to be suspensions of the metals, and not solutions at all, and those formed by cathodic reduction were considered to be hydrides, although R. L. Ruhland (1815)[3] and J. C. Poggendorff (1848) believed them to be metals in a very fine state of subdivision. J. J. Berzelius (1844) said that the arsenious sulphide obtained by the action of hydrogen sulphide is for the present to be regarded rather as a suspension of transparent particles than a solution, for arsenious sulphide gradually separates out as a precipitate; similarly, H. W. F. Wackenroder (1846) found that the reaction between solutions of sulphur dioxide and hydrogen sulphide furnishes a liquid from which the suspended sulphur can be separated by thawing and freezing; but it immediately separates out in large flocks if a neutral salt of an alkali like sodium chloride be added to the acid liquid. A. Sobrero and F. Selmi (1850) also gave an elaborate account of the same suspension of sulphur, and stated that sulphur belongs to a class of substances which possess the power of dispersing and dividing themselves in a liquid without completely dissolving therein—*e.g.* soap, starch, and Prussian blue, and which F. Selmi (1844) classed together under the name *pseudo-solutions*. J. L. Gay Lussac (1810) and W. Crum (1853) noted the formation of a suspension during the hydrolysis of aluminium acetate; L. Péan de St. Gilles (1854), the hydrolysis of ferric acetate; J. J. Berzelius (1833), E. Fremy (1853), and H. Kühn (1853), the formation of a solution of silicic acid by the hydrolysis of silicon sulphide by water, and the coagulation of the solution by alkalies. Then followed T. Graham's researches on dialysis in 1861–64.

T. Graham found that substances like potassium hydroxide, potassium sulphate, sugar, and alcohol diffuse much more rapidly in aqueous solution than hydrated silicic acid, dextrin, tannin, gelatin, and albumin. He found also that the former diffuse much more rapidly than the latter through a parchment membrane. Since the slow diffusing substances are apt to occur in the gelatinous or non-crystalline form. T. Graham suggested calling them **colloids**—from κόλλα, glue; on the other hand, since the crystalline salts are typical of those substances which diffuse rapidly, T. Graham called them **crystalloids.** In illustration, potassium chloride, cane sugar, magnesium sulphate, hydrochloric acid, sodium chloride, and barium chloride are crystalloids; while albumin, gums, starch, gelatinous aluminium hydroxide, gelatinous ferric hydroxide, and gelatinous silicic acids are colloids. It must not be supposed that the colloids do not pass through the parchment at all.

T. Graham found that when the time of diffusion of hydrochloric acid—HCl—was taken as unity, the rate of diffusion of an equal quantity of sodium chloride was 2·3, cane sugar 7, egg albumen 49, and caramel 98. On account of these great differences, T. Graham proposed the useful method of separating substances in the colloidal and crystalloid states. The crystalloid is removed by diffusion through a membrane of parchment, bladder, or some similar substance. The process is called **dialysis**—from the Greek διά, through; λύω, I loosen. The operation will be understood from the following description:

> A piece of parchment or bladder is bound across one end of a glass or guttapercha hoop so as to form a kind of shallow dish, Fig. 5, narrower at the base than the open top. A mixed solution of albumin (the white of an egg) and potassium chloride in water is poured into the dish. This vessel is placed in another dish, *B*, containing distilled water. The water in the outer vessel is renewed every few hours. The dish containing the mixed solution is covered by a clock-glass to protect it from dust. In about three days, practically all the potassium chloride will have passed through the membrane into the outer vessel, while the egg albumin will remain in the inner compartment. The whole apparatus is called a **dialyzer.**

FIG. 5.—Dialyzer.

T. Graham held the opinion that the distinction between a crystalloid and colloid was due to a difference in molecular conditions, for, he said:

> Crystalloids and colloids . . . appear like different worlds of matter and give occasion to a corresponding division of chemical science. The distinction between these kinds of matter is that subsisting between the material of a mineral, and the material of an organized mass.

It is now believed that crystalloids and colloids are not different *kinds* of matter, but rather different *states* of matter. W. Ostwald emphasized the idea that we should speak rather of a colloidal state than of a colloidal substance, and that if the phase is sufficiently subdivided it is to be regarded as **colloidal phase** or **colloidal state**; and he defines *colloidal chemistry* not as the study of colloid materials but as that of the colloidal state of materials. T. Graham's classification of substances into colloids and crystalloids left the wrong impression that a colloidal substance must be amorphous, whereas it is now believed that a phase is colloidal when it is in a sufficiently fine state of subdivision whether it be crystalline or amorphous, and that every substance may appear under different circumstances either in the colloidal or in the crystalline nature of the substance concerned. P. P. von Weimarn has shown that a mere change in the concentration of the components of a reacting system suffices to precipitate a substance in either the crystalline or the colloidal states. W. D. Bancroft accordingly says that colloidal chemistry differs from ordinary chemistry through variations resulting from the increasing dispersity of one or more phases. T. Graham also distinguished between colloids in solutions and colloids in the gelatinous form, and he applied the term **sol** to the colloids when the system appeared to be liquid, and **gel** when the colloids assigned a jelly-like condition. If the one component was water, he employed the terms *hydrosol* and *hydrogel*; if alcohol, *alcosol* and *alcogel*; etc. The terms sol and gel are in fairly common use. J. Perrin (1905)[4] proposed the term **lyophile**—from λύειν, to loosen; φίλος, loving—for those systems in which there is a marked affinity between the two phases of a colloidal solution, and **lyophobe**—φόβος, fear—to the others; if the colloidal dispersion medium is water, **hydrophile** and **hydrophobe**—ὕδωρ, water—are used. If the degree of dispersion of a dispersoid can be increased or decreased by reversing the conditions which brought about the change, the dispersoid is said to be a **reversible colloid,** and if this cannot be done, an **irreversible colloid.** These terms were introduced by W. B. Hardy in 1900.

The particles which can be perceived in the ultramicroscope are more or less approximately the same order of magnitude as the molecules themselves. For instance, ultramicroscopic particles of colloidal gold, 1·7$\mu\mu$, have been measured, and, according to C. A. Lobry de Bruyn, the estimated size of a molecule of soluble starch in solution is 5$\mu\mu$; a molecule of chloroform is roughly 0·8$\mu\mu$, according to G. Jäger; a molecule of carbon dioxide approximates to 0·285$\mu\mu$; a molecule of water vapour, 0·113$\mu\mu$; and a molecule of hydrogen gas is between 0·067 and 0·159$\mu\mu$, according to an estimate of O. E. Meyer.[5] Hence particles smaller than the complex molecule of soluble starch have been perceived.

The definition of solutions.—Solutions are usually defined as "homogeneous mixtures which cannot be separated into their constituent parts by filtration." This definition forces us back to the distinction between homogeneous and heterogeneous mixtures; and this, in turn, upon the sensitiveness of the tests for homogeneity.

S. E. Linder and H. Picton [6] filtered arsenious sulphide suspensions through porous earthenware; and found that while particles over a certain size were arrested, others passed through unchanged. C. Barus tried to estimate the size of the disperse phase in a silver suspension from the pore size of the plate which just permitted filtration, and H. Bechhold elaborated the principle by preparing a graduated series of filters by impregnating filter paper, wire gauze, or fabric with a solution of collodion in acetic acid or gelatin in water, and subsequently hardening the solid. The filters for *ultrafiltration*, as it is called, were then standardized with a solution of hæmoglobin.

A solution may appear clear and homogeneous; the particles in solution may not be separable by the ordinary methods of filtration; and the substance in the solution may remain suspended an indefinite time; and yet when Tyndall's optical test is applied, an opalescence will prove that minute particles are in suspension; and the ultramicroscope will enable the particles to be recognized as distinct individuals. Perfect solutions, said T. O. Bergmann (1779), should be transparent, but there are all possible gradations between liquids carrying rapidly settling particles in suspension, and liquids which carry particles in suspension an indefinite time without settling, and in which the particles are so small that they can only just be perceived by the ultramicroscope. Consequently, if the above definition of a solution be accepted, every time the sensitiveness of the method for detecting non-homogeneity is increased, a certain number of solutions previously classed as homogeneous will probably appear heterogeneous or colloidal. This difficulty can be partially overcome by restricting the term solution, by an arbitrary convention: **Solutions are mixtures which appear clear and homogeneous with Tyndall's illumination, and which cannot be separated into their constituent parts by ordinary mechanical processes of filtration through paper or settling.**

J. W. Gibbs' concept of phase and component helps to clarify and generalize the distinction between chemical and physical action and between colloidal and true solutions. The idea underlying J. W. Gibbs' concept of a phase involves a distinction between molecular magnitudes and matter *en masse*, and it certainly holds good for matter which is homogeneous so long as it is not reduced in bulk to molecular dimensions. J. W. Gibbs' phase-concept serves as a criterion for a sharp classification of systems until the colloidal solution is reached, and then difficulties occur. In order to emphasize his opinion that the study of colloidal solutions renders it impracticable to draw even an arbitrary line between molecular and molar magnitudes, W. Ostwald advocates the use of the term **dispersoid system** in place of solution, and he applies the general term **dispersoids** in the following manner:

	Size of particles.	Examples.
Dispersoids .	Over 0·1μ	Suspension, emulsions, etc.
	Between 0·1μ and 1$\mu\mu$ . .	Colloidal solutions
	About 1$\mu\mu$ or less . . .	Molecular (and ionic) solutions

because he also believes that suspensions, colloidal and true solutions, represent varying degrees of dispersion of the solute. Although colloidal solutions are usually considered to be two-phase systems, and ordinary solutions one-phase systems, there appears to be an unbroken continuity between the heterogeneity of suspensions and the homogeneity of true solutions. Hence W. Ostwald tried to emphasize this by calling dispersoids with a degree of dispersion greater than 6×10^7 *molecular dispersoids*; and molecules may ionize—ionically disperse—to form *ionic dispersoids*. The evidence is therefore pointing to the inference that **the distinction between colloidal two-phase solutions and ordinary one-phase solutions turns on the relations between the dispersoids or solute and the solvent rather than on the size of the particles.**

Colloids have but a slight influence on the vapour pressure, freezing point, and boiling point of the dispersion medium. Indeed, when the colloid has been purified to a high degree, the colloid has no influence on these properties at all. For example, E. Paterno found that tannic and gallic acids form colloidal solutions with water and do not appreciably influence the freezing point of the solvent, but in glacial acetic acid, a true solution is formed, and the freezing point is depressed in the regular manner. The *molecular weights of colloidal solutions* have quite a different meaning from the results obtained with the so-called true solutions. Apart altogether from disturbances due to absorbed impurities, and possible hydrolytic changes, the different results obtained with systems having the same composition but varying degrees of dispersion, show that a series of progressively varying molecular weights can be obtained for one and the same substance which, in the systems with a low degree of dispersion, would approach infinity. In some cases where a change has been observed, we are by no means sure that some compounds other than the assumed colloid are not producing the change. For instance, it is highly probable that hydrolysis in aqueous solutions of sodium palmitate, or oleate, results in the formation of some sodium hydroxide. It must also be remembered that it is exceedingly difficult to get rid of impurities which are associated with colloids during their preparation. Again, said W. D. Bancroft, if the suspended colloidal particles are insoluble in the dispersion medium, there will be no change of surface tension, no osmotic pressure, and no diffusion except what is due to the Brownian movements; and conversely, if the particles are slightly soluble, there will be a slight change of surface tension, some osmotic pressure, and some diffusion other than that due to the Brownian movements.

Many attempts have been made to calculate the molecular weight of colloids from the osmotic pressure calculated in this and analogous methods, and numbers like these have been reported, Table IX, for example.

TABLE IX.—OSMOTIC PRESSURE AND MOLECULAR WEIGHTS OF COLLOIDS.

	Concentration grams per litre.	Osmotic pressure mm. of mercury.	Molecular weight.
Egg albumin	12·5	20	11,000
Gelatin	12·5	6	36,000
Starch iodide	30·0	15	34,000
Dextrin	10·0	165	1,000
Gum arabic	10·0	72	2,400

Some confusion is here prevalent because the term molecular weight is imparted to two totally different concepts. Molecular weight means something quite different in the case of gas or a solute, and in the case of a suspended particle. The molecular weight of a lump of, say, metal is not generally supposed to be high because the metal does not diffuse and is visible; why then should it be permitted to assign a high molecular weight to the finely divided metal? The mere fact of grinding cannot increase its molecular weight. This has been emphasized by W. D. Bancroft[7]:

> The molecular weight of a suspended particle, if it means anything at all, means something entirely different from the molecular weight of a solute or gas. We can determine the molecular weight of benzene approximately from the measurement of the surface

tension, but it is absurd to say that suspending fine drops of benzene in water causes the molecular weight of benzene to become . . . very large. We are talking about entirely different things in the two cases. What we mean is that liquid benzene has a molecular weight of 78, and that liquid benzene suspended in water behaves, or may behave, as if it were a dissolved substance having a . . . very large . . . molecular weight. As a matter of fact, the experiments bring out clearly the enormous difference between a solution and a suspension.

Many colloids show a small osmotic pressure, and measurements of the *osmotic pressure of colloidal solutions* have been made by W. Pfeffer,[8] H. Picton and S. E. Linder, C. E. Linebarger, etc. The results show that the osmotic pressure of most colloids is a complex function not only depending on the number of particles in unit volume but also on the degree of dispersion, and the state of the system. The theoretical investigations of A. Einstein and M. von Smoluchowsky show that the osmotic pressures—P_1 and P_2—of two equally concentrated but differently dispersed phases are inversely proportional to the cubes of the radii—r_1 and r_2—of their particles; or $P_1 : P_2 = r_2^3 : r_1^3$. Observations on the *vapour pressure of colloidal solutions* have been made by A. Smits,[9] F. Guthrie, C. Lüdeking, etc.; on the *boiling points of colloidal solutions* by F. Guthrie,[10] C. Lüdeking, etc.; and on the depression of the *freezing points of colloidal solutions* by H. F. Brown and C. H. Morris,[11] F. Krafft, etc.

The *compressibilities of colloidal solutions* have been determined by G. de Metz,[12] H. Gilbaut, etc. The compressibility of a colloidal solution is in general smaller than that of the dispersion medium, and it decreases as the concentration increases. The *specific gravities* and the *specific volumes of colloidal solutions* do not follow the mixture rule. The relations are somewhat complicated, but approach the mixture law the less the degree of dispersion of the disperse phase. W. Ostwald[13] showed that the capillary pressure causes the specific gravity of water to increase the smaller the size of the globulets—for the water in droplets 3 in diameter has a density 0·005 per cent. greater, and the droplets 0·03μ in diameter, 0·5 per cent. greater than water *en masse*. Observations have been made by G. Rose, J. P. Cholodny, etc.

The internal friction or *viscosities of colloidal solutions* is very marked. The concentrations of inorganic colloidal solutions of the metal and sulphides are small and the viscosities are but little different from that of water; the case is different with organic colloids like gelatin and albumin, and inorganic colloids like silicic acid and hydrated alumina, where the viscosity becomes relatively large such that T. Graham called the viscosimeter a *colloidoscope*. The viscosities have been measured by J. Friedländer,[14] H. W. Woudstra, etc., and the effects of changes in concentration, temperature, and age have been investigated. The effect of the addition of other substances in the solution has also been determined. A. Einstein deduced the viscosity formula $\eta = \eta_0(1 + 2{\cdot}5v)$, where v is the volume of colloidal matter per unit volume of medium. It is assumed that the volume v is not too large, that is, the concentration is not too great; the radius of the particles assumed to be rigid spheres is also supposed to be large compared with the range of molecular attraction. Values for the constant ranging from 1·5 to 4·75 have been obtained. The *surface tensions of colloidal solutions* have been measured by Lord Rayleigh,[15] G. Quincke, etc. The *diffusibility of colloidal solutions* was measured by T. Graham,[16] T. Voightländer, etc. The *dialysis of colloidal solutions* has been examined by T. Graham,[17] G. Malfitano, R. P. van Calcar, etc. The *coefficients of thermal expansion of colloidal solutions* have been investigated by H. Rodenwald.[18]

The settling of particles suspended in water.—It is well known that the finer the grain-size of a given substance the slower the settling in still water. G. G. Stokes[19] has shown that in a medium of specific gravity D', and viscosity η, the rate of settling V of a spherical grain of measurable size and of radius r and specific gravity D,

$$\text{Rate of settling, } V = \frac{2}{9} \cdot \frac{r^2 g(D - D')}{\eta}$$

where g is the gravitation constant. This formula assumes that the resistance a fluid opposes to the descent is proportional to the radius of the sphere and to the coefficient of viscosity of the fluid. E. Cunningham showed that with microscopic or ultramicroscopic particles, the resistance no longer depends exclusively on the coefficient of viscosity, and it is necessary to take into consideration resistance elements borrowed from the kinetic theory of gases; he uses the same factor as G. G. Stokes multiplied by $1+Al/r$, where l is the average length of path of the molecules of gas, and r is the radius of the spherule. Hence, the Stokes-Cunningham formula is:

$$\text{Rate of settling, } V=\frac{2}{9}\cdot\frac{gr^2(D-D')}{\eta}\left(1+\frac{Al}{r}\right)$$

The coefficient A depends on the nature of the shocks between gaseous molecules and the surface of the sphere, and it has to be evaluated experimentally, it has values ranging between 0·815 and 1·63. This formula has been verified by M. Knudsen and S. Weber, R. A. Millikan, J. Roux, M. Keehan, A. Schidlof, O. W. Silvey, etc.

A particle of radius μ settles in still water at the rate of 2·4 mm. per minute, and a particle of radius $10\mu\mu$ and specific gravity 3, settles at the rate of one mm. per month. The formula does not apply to angular grains, nor to excessively fine grains. P. Ebell found that ultramarine particles, when reduced to a very fine state of subdivision by grinding, remain suspended in water for months; O. Mühlhäuser found that similar remarks apply to carborundum powder; and some clays freed from soluble salts will remain in suspension an indefinitely long time. There is then some disturbing factor which neutralizes the action of gravity; the clue to this was given by some observations by the botanist R. Brown in 1827. He said:

> While examining the form of the pollen grains from *Clarckia pulchilla* suspended in water, . . . I observed many of them very evidently in motion. . . . Their motions were such as to satisfy me, after frequently repeated observation, that they arose neither from currents in the fluid nor from its gradual evaporation, but belonged to the particle itself . . . smallest moving particles observed and which I have termed *Active Molecules*, appear to be spherical, or nearly so, and to be between $\frac{1}{20000}$th and $\frac{1}{30000}$th of an inch in diameter (about 0·001 mm.). The molecules were not limited to organic bodies. . . . In every mineral which I could reduce to a powder, sufficiently fine to be temporarily suspended in water, I found these molecules more or less copiously, and in some cases, more particularly in siliceous crystals, the whole body submitted to examination appeared to be composed of them. . . . By reducing a drop of water to microscopic minuteness . . . by shaking or triturating water with almond oil . . . the motion of the smaller particles (of water) takes place with undiminished activity.

The bearing of R. Brown's observations on the phenomenon was not appreciated for many years. The phenomenon is named **the Brownian movement** after its discoverer R. Brown.[20] If water in which a little lycopodium—that is, the spores of the club moss—is suspended be examined under the microscope, the small particles appear to be incessantly vibrating with a slow trembling motion.

The phenomenon is demonstrated as follows: Rub a fragment of gamboge for a moment on an ordinary 3 × 1 glass slip, and place a couple of drops of water on the slip where the gamboge has been rubbed. Gently push a cover-glass up to the edge of the gamboge. The brisk motion of the particles can now be readily seen through a $\frac{1}{2}''$ objective and a dark-ground illumination; it is easy to seal up the liquid in little capillary tubules about half an inch long. These tubules can be mounted in Canada balsam under a cover-glass in the usual manner, and they are then available for showing the phenomenon at any time.

There are references to the "dancing particles of rudimentary animalcules" in the writings of some of the earlier naturalists, which show that the phenomenon had been noticed before Brown's time, but without a clear idea of the nature of the particles. Fig. 6 gives a sketch from a photograph of the Brownian movement[21] prepared by moving a photographic film at a uniform rate across the field of the microscope from left to right. Experiment has shown that the motion cannot be due to convection currents set up by small differences of temperature or pressure, to light effects, to the electrical state of the particles or of the liquid, nor indeed to any known influence outside the liquid. The cause of the motion must be sought in the liquid itself.

The kinetic theory of molecular motion seems to furnish the only admissible explanation of the phenomenon. It is supposed that, owing to the perpetual movements of the molecules of the fluid, the moving molecules are continually striking the particles, thus driving them irregularly, to and fro, up and down, in the liquid. As might be expected, the incessant movements become more and more vigorous the smaller the particles. There is a big contrast between the apparently sluggish movements of lycopodium and the vivacious motions of the ultramicroscopic particles of, say, M. Faraday's gold.[22] So much so that R. Zsigmondy once thought the two were really different phenomena. The movements of the particles of gold are described by R. Zsigmondy somewhat as follows: "The particles move with astonishing rapidity. A swarm of gnats in a sunbeam will give an idea of the motion. The particles hop, dance, and jump, and they dash together and fly away from one another so that it is difficult to get one's bearings." To this must be added the fact that if the composition of the liquid remains unchanged, the motion in the liquid seems to continue an indefinite time without ceasing, for the Brownian movements have been observed in the fluid in cavities of quartose rocks, showing that the motion has in all probability been maintained for enormous periods of time—ever since the fluid was sealed up in the rocks. By studying the movements of the fine particles of gamboge—that is, the dried latex of the *Garcinia morella*—suspended in water; and of extremely fine particles of silver dust obtained by striking an electric arc between silver poles—suspended in air; it has been proved by direct observation[23] that **the distribution of the particles, their velocities, and the frequency of their collision is the same as the kinetic theory assumes to be the case with the particles of a gas.** F. M. Exner found that particles larger than 4μ do not show the Brownian movement in water; particles smaller than 0·1μ show vigorous movements; and particles with a diameter 10$\mu\mu$ have trajectories up to about 20$\mu\mu$. The movement takes place in all fluids, though more actively the less the viscosity. J. Perrin detected it with particles suspended in the film of a soap bubble. It is just perceptible in glycerol, and very active in gases. All attempts to find an explanation of the Brownian movement outside the fluid have failed. As C. Wiener[24] stated in 1863, the agitation does not originate either in the particles themselves or in any cause external to the fluid, but must be attributed to internal movement characteristic of the fluid state; and J. Perrin adds that the apparent repose of a fluid in equilibrium is an illusion due to the imperfection of our senses; in reality the constituent particles of a fluid are in a state of spontaneous, unco-ordinated, and never-ceasing agitation. A particle of a solid suspended in a fluid is being continuously bombarded by the neighbouring molecules. W. Ramsay (1876), G. Gouy (1888), H. Siedentopf (1900), and J. Delsaulx and J. G. G. Carbonelle (1877) had a clear view of the mode in which the molecular bombardment of the fine particles suspended in a fluid can produce the Brownian movement:

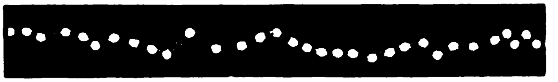

FIG. 6.—Sketch from a Photograph of the Brownian Movement (T. Svedberg, 1912).

> The internal movements of the molecules which determine the heat content of a fluid, is well able to explain the facts. . . . In the case of large surfaces, the molecular impacts which cause pressure produce no displacement of the suspended body because the resultant tends to move the body in all directions at once; but if the surface of the suspended body be smaller than the area necessary to ensure that all the irregular motions will be compensated,

> the pressures from different sides will be unequal, and continually shifting from point to point; these pressures will not be equalized by the law of averages, and their resultant being no longer zero, they will vary continuously in intensity and direction.

A. Einstein (1905) and M. von Smoluchowsky (1906) developed a quantitative theory of the phenomenon. The former showed that an emulsion diffuses like a solution, so that if x^2 denote the mean square of the projection of the displacement along a horizontal axis, the quotient x^2/t is constant when t denotes the time, so that the mean displacement is doubled when the time is increased four-fold; and increased ten times when the time is increased a hundred-fold. The quotient x^2/t is called the *activity* of the Brownian movement of the granules. A. Einstein next showed that the *coefficient of diffusion*, $\delta=\frac{1}{2}x^2/t$; and further, if N denotes Avogadro's number, the

$$\text{Coefficient of diffusion, } \delta=\frac{RT}{6N\pi r\eta}; \text{ or, Activity of movement, } \frac{x^2}{t}=\frac{RT}{3N\pi r\eta}$$

but the mean kinetic energy K of the molecules is $\frac{3}{2}RT/N$, and therefore $x^2/t=\frac{2}{9}K/\pi r\eta$. This means that the activity of the agitation (or the rate of diffusion) is proportional to the molecular energy or the absolute temperature, and inversely proportional to the viscosity and absolute temperature of the grains. This formula has been verified by L. Bancelin for sugar solutions, and for emulsions of gamboge in solutions of glycerol. V. Henri has discussed the different methods available for determining the grain size of the colloidal particles.

T. Svedberg showed that the amplitude A or the distance between the extreme and mean positions of the particle, and the period of oscillation t or the time taken by the particle to make a complete oscillation or excursion from one extreme position and back again, is related with the velocity V, by the equation $V=4A/t$. T. Svedberg found that as the amplitude increases the period of oscillation increases in such a way that $4A/t$ is nearly constant,

	Acetone.	Ethyl acetate.	Amyl acetate.	Water.	*n*-propyl alcohol.
A	3·1	2·0	1·5	1·1	0·7μ
t	0·032	0·028	0·026	0·013	0·009 sec.
$4A/t$	390	290	230	340	310

F. M. Exner showed that with particles 0·4μ in diameter, the velocity was 3·8μ per sec.; with particles 1·3μ in diameter, the velocity was 2·7μ per sec.; with particles 3μ in diameter the velocity was just perceptible, and with particles 4μ in diameter no movement was discernible; and R. Zsigmondy showed that the amplitude depends on the size of the particles; with particles 6, 10, and 35$\mu\mu$ in diameter, the amplitudes were over 10μ, 3 to 4μ, and 1 to 7μ respectively. T. Svedberg further showed that if the sizes are constant the viscosity of the medium is alone of importance; and that neither the nature of the particles nor the other properties of the medium are of importance. For any given size of particles, the amplitude is approximately inversely proportional to the viscosity of the dispersion medium.

	Acetone.	Ethyl acetate.	Amyl acetate.	Water.	*n*-propyl alcohol.
A	3·1	2·0	1·5	1·1	0·7μ
$\eta\times10^3$	3·2	4·6	5·9	10·2	22·6
$A\eta\times10^3$	9·9	9·2	8·9	11·2	15·8

J. Perrin[25] experimented on the arrangement of the particles of a colloid suspended in water under the action of gravity and its own osmotic pressure. If n and n_1 respectively denote the number of particles in unit volume at heights 0 and h; w, the mass; D, the density of the granules; D', that of the liquid; g, the gravitation constant; and P, the osmotic pressure of a single particle in unit volume, then, according to J. Perrin,

$$\log\frac{n}{n_1}=\frac{wgh}{P}\left(1-\frac{D'}{D}\right)$$

The agreement of the calculated with the observed results led J. Perrin to conclude that *the concentration of the granules in a uniform emulsion decreases in an exponential manner as a function of the height* in the same way as the barometric pressure does as a function of the height. Once this relation is established, the same equation affords a means of evaluating **Avogadro's constant,** N—for example, the number of molecules per gram-molecule of gas at 0° and 760 mm. Assuming that the pressure exerted by the particle is analogous with that as a gas obeying Boyle's law, $P=RT/N$, numbers ranging from $N=5\times10^{23}$ to 8×10^{23} were obtained —the generally accepted value determined by other independent methods is $N=6\times10^{23}$.

The perpetual agitation which is illustrated by the Brownian movement proceeds ceaselessly without external cause; it has therefore been asked if this motion contradicts the principle of the conservation of energy. The principle would be satisfied if every increment in velocity acquired by a granule is accompanied by the cooling of the liquid in its immediate vicinity, and every diminution in velocity is accompanied by local heating. J. Perrin tried to get round the difficulty by pointing out that J. C. Maxwell, W. Gibbs, and L. Boltzmann have robbed Carnot's principle of its claim to rank as an absolute truth, and reduced it to the mere expression of a very high probability. He adds that on the scale of magnitudes that are of practical interest to us, perpetual motion of the second kind is in general so insignificant that it would be foolish to take it into consideration. The impression left by this argument is that the principle is valid on the scale of magnitudes that are practical to us, but not in the realm of molecular magnitudes.

The Brownian movement is an expression of the molecular movements usually attributed to the molecules of matter. The molecular bombardment of the particles suspended in an emulsion tends to give a uniform distribution. Now, said J. Perrin, in his *Les preuves de la réalité moléculaire,*

> Let us suppose that it is possible to obtain an emulsion, with the granules all identical, an emulsion which I shall call, for shortness, *uniform*. It appeared to me at first intuitively, that the granules of such an emulsion should distribute themselves as a function of the height in the same manner as the molecules of a gas under the influence of gravity. Just as the air is more dense at sea-level than on a mountain-top, so the granules of an emulsion, whatever may be their initial distribution, will attain a permanent state where the concentration will go on diminishing as a function of the height from the lower layers, and the law of rarefaction will be the same as for the air.

J. Perrin confirmed this hypothesis with suspensions of gamboge and mastic in water; with the former, particles $0{\cdot}3\mu$ in diameter, a rise of 30μ sufficed to lower the concentration to one-tenth its value. J. Perrin found that unless the mixtures are aseptic, they may be invaded by elongated and very active protozoa, which, by stirring up the emulsion like fishes agitating the mud of a pond, much diminish the inequality of distribution between the upper and lower layers. H. Zangger[26] likewise confirmed the theory for drops of mercury; L. M. Brillouin, for emulsions of gamboge in glycerol; and B. Iljin, for emulsions of gamboge in water or castor oil, and an aqueous solution of gum arabic. B. Iljin also found that the movements of a given particle are quite independent of the movements of other particles.

A. Einstein and M. von Smoluchowsky worked out a mathematical kinetic theory of the process, and as a result of the close agreement between theory and observations, J. Perrin was led to say in his *Les atomes* (Paris, 1913), and in his *Les preuves de la réalité moléculaire* (Paris, 1909):

> The objective reality of the molecules becomes difficult to deny. At the same time, molecular movement has not been made visible. . . . The Brownian movement offers us on a different scale the faithful picture of the movement possessed, for example, by the molecules dissolved in the water of a lake which, encountering one another only rarely, change their direction and speed by virtue of the impacts with the molecules of the solvent. . . . The Brownian movement is a faithful reflection of molecular movement, better, it is a molecular movement in itself, in the same sense that the infra-red vibration is still light. From

the point of view of agitation, there is no distinction between nitrogen molecules and the visible molecules realized in the grains of an emulsion, which have a gramme molecule of the order of 100,000 tons. Thus, as we might have supposed, an emulsion is actually a miniature ponderable atmosphere; or, rather, it is an atmosphere of colossal molecules, which are actually visible. The rarefaction of this atmosphere varies with enormous rapidity, but it may nevertheless be perceived. In a world with such an atmosphere, Alpine heights might be represented by a few microns, in which case individual atmospheric molecules would be as high as hills.

In fine, **the experimental facts go very near towards establishing the validity and essential reality of the molecular kinetic theory as an explanation of the properties of matter.** In the words of E. E. Fournier d'Albe:

> We are face to face with this extraordinary situation: the molecule has ceased to be a theoretical abstraction—it has become a visible and tangible reality; for we can not only see it, but also "manipulate" it—not, indeed, with our hands, but by means of heat, and electricity, and the air pump.

Fine particles—say less than $0{\cdot}5\mu$—will remain in suspension an indefinitely long time, presumably because the Brownian movements tend to distribute the particles through the liquid against the action of gravity. If, however, enough particles agglomerate or coalesce so as to form large aggregates, settling may ensue. The aggregation, flocculation, or clotting of the fine particles and the converse dispersion, or deflocculation of aggregates is of great importance in many chemical processes, and will be discussed later—see purple of Cassius, and colloidal gold.

§ 8. The Kinetic Theory of Atoms

There are countless worlds in countless heavens each revolving about its sun.—G. BRUNO.

The curve described by a single atom is as fixed as the path of a planet, and between the two cases no other difference exists save that resulting from our ignorance.—L. MEYER.

Many philosophers—E. Kant, G. W. E. Hegel, T. S. Hunt, etc.—have laboured in vain to demonstrate by abstract reasoning that chemical combination is an interpenetration of masses or a juxtaposition of molecules. According to G. W. E. Hegel, the chemical process is either an identification of the different, or a differentiation of the identical. The characteristic mark of a chemical species or individual is homogeneity. Is this homogeneity merely relative ? Can it be truly said : *Tota in minimis existit natura ?*

Do the atoms of the molecules of a compound retain their individuality ?—It may be quite true that the properties of a compound are mainly determined by the character of the constituent elements, yet, it is not to be supposed that there is necessarily any resemblance between the properties of the elements and of their compounds. It is not yet possible for the chemist to infer *a priori*, nor explain *a posteriori* the properties of a compound from the properties of the constituent elements. For instance, no one would have suspected the peculiar properties of cyanogen from the qualities of its constituent elements carbon and nitrogen, or of sodium chloride from the constituent elements sodium and chlorine. Chemists generally consider that the atoms preserve a kind of individuality throughout their existence, and when associated with other atoms, change their habit but not their nature. The change in the habits of an atom depends entirely on its associates. For instance, the properties of a molecule of water are very different from the properties of either of the constituents hydrogen or oxygen; the atoms of oxygen are magnetic when associated together in pairs or triplets, but they are non-magnetic when compounded with many other elements; iron too is intensely magnetic, some if its compounds are also magnetic, yet there are others which are non-magnetic, and still others which are diamagnetic—*e.g.* the iron carbonyls. Although the atoms of a compound molecule do not enjoy a separate external existence, yet, *within* the molecule, the atoms are probably distinct individuals, self-contained and self-existent. As Lucretius would have expressed it, they are *solida pollentia simplicitate*, or strong in their solid singleness; but the individual properties of the atoms are not always unrecognizable in the properties of the molecules of their compounds. J. Larmor (1908) [1] has well said :

> It becomes increasingly difficult to resist the simple view that chemical combination involves an arrangement of the atoms alongside each other under steady cohesive affinity, *the properties of each atom being somewhat modified, though not essentially, by the attachment of the others:* and that the space formulæ of chemistry have more than an analogical significance. The many instances in which the physical properties of the compound molecule can be calculated additively with tolerable approximation from those of the constituent atoms, are difficult to explain otherwise.

Those qualities which depend upon the nature of the atom in the molecule are called *additive properties* when each atom exerts its own specific influence whatever its state of combination. The following is selected from the evidence which might be cited to show that the atom retains its individuality in all its migrations no matter how many of its properties might be disguised by association with other atoms: (i) The weight of an atom remains intact whatever be its associated partners. (ii) The atom emits a peculiar type of Röntgen ray when stimulated in a suitable manner, and this property can neither be changed nor disguised by association with other atoms. (iii) The absorption of Röntgen and cathode rays is an atomic property, for each atom has its own specific absorptive power which is independent of the nature of the partners, with which it may be associated. There are numerous other examples—specific heat, crystalline form, etc.—not quite so decisive.

Are the atoms of a molecule at sensible distances apart?—It is sometimes asserted that the atoms are at insensible distances apart and that the atoms of a molecule are accordingly very close together. These statements have given rise to a misconception, for if the size of the atom be taken as a standard of reference it is probable that in the molecule the distances of the atoms from one another are comparatively great. Nothing is great or small unless it be considered in relation to other things regarded as standards of comparison.

Are the atoms of a molecule at rest or in motion?—The molecules are in motion, and therefore the atoms which make up the molecules must also be in motion just as a train waiting at the station is said to be at rest, although it is moving with the earth about the sun, at a great velocity. Accordingly, the term rest here refers to the position of the atom with respect to the molecule regarded as a standard of comparison. J. B. A. Dumas (1837),[2] S. Brown (1843), and D. I. Mendeléeff (1868), like many previous philosophers—notably C. L. Berthollet (1803)—picture a complex molecule to be analogous with a kind of miniature solar system with the atoms whirling rhythmically about one another at great speeds. Like the planets and their satellites, the atoms are supposed to be "endowed with an everlasting motion." The atoms are further supposed to be held in position, and to move in definite orbits owing to their attraction for one another, just as the planets and satellites move in definite orbits owing to the action of gravitational forces. D. I. Mendeléeff, like S. Brown, was an enthusiast; he said:

> Chemically, the atoms may be likened to the heavenly bodies, the stars, sun, planets, satellites, etc. The building up of the molecules from atoms, and of substances from molecules is then conceived to resemble the building up of systems, such as the solar system, or that of twin stars, or constellations from individual bodies. This is not a simple play of words in modern chemistry, nor a mere analogy, but a reality which directs the course of all chemical research, analysis, and synthesis.

Molecular models.—M. Berthelot (1875) [3] said that a complete representation of chemical compounds must involve the notion of rotatory and vibratory movements by which each particular atom, and each group of atoms in the molecule are animated. Although many chemists have similarly expressed their belief in a kinetic theory of atoms based upon a supposed analogy between atomic and planetary systems, they would yet recoil from any attempt to represent the idea pictorially or by mechanical models; but what Lord Kelvin said of himself applies to most: "I never satisfy myself until I can make a mechanical model of a thing. If I can make a mechanical model, I can understand it." So long as we are not seduced by a prepossessing analogy, there is no harm in constructing a model or diagrammatic picture because the strength and weakness of the analogy may be then better apprehended. Following up the analogy between planetary systems and the constitution of molecules, a two-atom molecule of hydrogen, H_2; iodine, I_2; or oxygen, O_2, can be regarded as a binary star—that is, as a pair of stars—in which each atom in the molecule rapidly revolves about the other in a regular orbit. A molecule of water, H_2O, would be represented by three atoms revolving in a similar manner; ammonia, NH_3, said D. I. Mendeléeff (1889), may be represented in the simplest manner by supposing the sun, nitrogen, to be surrounded by three planets, hydrogen atoms; and a molecule of sulphuric acid, H_2SO_4, might be depicted as a complex system with a central revolving sulphur atom around which the other atoms whirl in definite orbits:

> Each orb, the smallest in its motion sings.

First would come one sulphur or two oxygen atoms representing the nucleus, SO_2, outside these would encircle two oxygen atoms each with a revolving hydrogen atom as satellite. The imaginary picture so obtained would be a kinetic model of the formula $(HO)_2{=}SO_2$. E. Frankland and F. R. Japp [4] explained the constitution of acetic acid, $CH_3.CO.OH$, in a similar manner in 1884. The chemist determines the constitution of these tiny systems by a process which G. Martin has compared with the plucking of, say, the earth and moon from the solar system, or by replacing one planet by another and observing the disturbing effects of the transposition on the whole system; for, said C. Daubeny (1850), it is probable that any of the planets in the solar system could be replaced by a ball of matter with totally different properties, provided its gravitational mass were the same, without disturbing in the least the conditions of mechanical equilibrium. A kind of orrery would therefore give a better idea of the structure of a molecule than the crude plane formulæ usually employed. By this analogy, the planets Mercury and Venus represent single atoms, the Earth, Jupiter, and Saturn with their moons represent radicles—each composed of several distinct atoms so as to form a small sub-system complete in itself. All these individuals and sub-systems are linked to one another so as to form a balanced or stable molecular system, in some respects analogous with the solar system.

Valency.—Supposing that the above speculations were to be established by unassailable evidence, that would not alter the value of graphic or constitutional formulæ. E. Molinari (1893) considered that the constitution of compounds is rather dependent upon the intramolecular movements of the atoms in relation to each other, than on the relative positions of the atoms in space; and that the so-called valency bonds denote the nature of the motion or energy of the atoms with regard to each other. Hence, so far as graphic formulæ are concerned, it really makes little difference whether the atoms are actually attached to one another, or whether they are held in position by their mutual attractions while they are revolving about a centre of stability. Indeed, some assume that the conditions of temperature, light, or electricity necessary for the formation of a stable system determine whether a given atom can form a stable system with 1, 2, 3 . . . other atoms; otherwise stated, **the valency of an element is determined by the necessity for harmonizing the peculiar motions of the combining atoms to form stable molecular systems.** When J. Dalton was asked why an atom of carbon would take up one or two atoms of oxygen, but not three or four, he replied:

> The reason I would assign is that in the state of CO_2 there are two atoms of oxygen combined with one of carbon, and a third or fourth oxygen atom, however it may be attracted by the carbon, cannot join it without repelling one or more of the atoms of oxygen already combined. The attraction of carbon is able to restrain the mutual repulsion of two atoms of oxygen but not that of three or four.

S. Brown expressed the same idea in 1843: " The conception can perhaps be made still more lucid by the counter statement in astronomy that a sun cannot be overloaded with planets." S. Brown's view of valency shows that it is not necessary to postulate a distinct force emanating from the atoms in order to explain how, say, HCl forms a stable system, while HCl_2 and H_2Cl do not form stable molecular systems. If such systems were momentarily formed, the supernumerary atoms would be immediately flung off. After trying motions and unions of every kind, the atoms no doubt fall into those favourable arrangements which can persist as stable configurations. There may, of course, be a number of different stable systems corresponding with the different stable molecules of, say, iron and chlorine, $FeCl_2$ and $FeCl_3$. L. Meyer (1884),[5] E. Molinari (1893), F. P. Venable (1899), and others have advocated similar views. The plausibility of this hypothesis, of course, is not a proof that it is true.

The energy of atoms.—Each elementary atom presumably has its own definite charge of energy. The energy possibly exists in the form of rhythmical atomic motions, so that when one atom unites with another atom, each atom possibly gives up a part of its energy or absorbs energy from some external source, so that the motions of the one atom may be co-mingled with the motions of the other atoms to form a stable molecular system. The hypothesis thus suggests a plausible explanation of selective affinity.

Selective chemical affinity.—Lucretius frequently affirmed that it was absolutely decreed from the beginning what each thing can and cannot do; and to-day it is assumed that the molecules of matter are endowed with certain peculiar qualities, for the physicist explains gravitational phenomena by investing all the molecules of matter with a *common* property which he calls **gravity,** even though he may say with Isaac Newton (1717): "Gravity is not to be taken as an essential property of bodies." The chemist too explains chemical action by endowing the atoms with a *selective* power which he calls **affinity.** Gravitation is purely a physical relation common to all molecules of all known kinds of matter, while affinity is a very specialized chemical relation characteristic of specific types of matter. The kinetic theory of selective affinity assumes with W. M. Wundt (1897) that all the qualitative properties of matter are derived from the different modes of motion assumed by the atoms; the atoms themselves are completely devoid of quality. It is supposed that when two molecules meet, they can react chemically only when the motions of the atoms of the one molecule can be co-mingled with the motions of the atoms of the other molecules, so that instead of "shattering, confounding, and dispersing" one another's motions, they move in cadence and form harmoniously working systems called molecules. Two atoms moving in unison support and sustain one another's attractions; two atoms moving in discordant periods, despite their mutual influence, cannot form a stable combination because they offer a certain resistance to conjugation. As it has been otherwise expressed, "Every atom according to its nature is always striving to get into harmonious relations with other atoms." The idea recalls Democritus' view that the atoms are attracted to one another on account of their whirling motions; paraphrasing Lucretius, "the atoms unite in all manner of ways, and thoroughly test motions and combinations of every possible kind;" consequently, it is not at all strange that the atoms have at last formed arrangements which can be maintained more or less permanently. These speculations may give the impression that chemical phenomena will be ultimately referred to fundamental mechanical laws; but we have passed in imagination beyond the region of demonstrated fact, and are dimly conscious of an illimitable expanse where hypothesis and conjecture can but wander aimlessly and blindly. Here Newton paused: "The whole frame of nature may have been wrought into various forms, at first by the immediate hand of the Creator, and ever after by the power of nature."

What makes the atoms and molecules move?—We do not know! How can matter of itself initiate motion,[6] and particularly motion in a harmoniously working system? *Ignoramus!* In the words of C. Kingsley, "Everywhere skin-deep below our boasted science we are brought up short by mystery impalpable, and by the adamantine gates of transcendental forces and incomprehensible laws." We are profoundly ignorant of the cause of the specific activities of atoms, molecules, and planets. Immortal Newton could get no further than this: "The motions which the planets now have could not spring from any natural cause." It seems as if

> Full many a secret in her sacred veil
> Hath Nature folded. She vouchsafes to knowledge
> Not every mystery, reserving much
> For human veneration, not research.—Anon. (1851).

Consequently, the kinetic theories of the Brownian movements, of atoms, of molecules, of the planetary systems, and indeed of the solar system itself, are all compelled to prescribe or postulate an initial state of motion which is self-sustained and self-regulated. Guesses at the birth-history of these motions has been whispered only by the poets. *Deus mundum ædificavit,* said Cicero; and, in the oft-quoted lines of Virgil:

> Know first, the heaven, the earth, the main,
> The moon's pale orb, the starry train,
>   Are nourished by a soul,
> A bright intelligence, whose flame
> Glows in each member of the frame,
>   And stirs the mighty whole.

§ 9. The Two Specific Heats of Gases

The kinetic theory of molecules assumes that the temperature of a gas is proportional to the average speed of translation of the moving molecules—an increase of the speed is accompanied by a rise of temperature, and conversely.

It will be remembered that specific heat is a term employed to represent the amount of heat required to raise the temperature of one gram of a substance 1°. A gas can be heated by simple compression, its specific heat then appears to be zero; but, in reality, a certain amount of energy, equivalent to the specific heat, is needed for the work of compression. Again, a gas, if it be expanded, is cooled; if the cooling effect of expansion just counterbalances the heat added to the gas, the temperature remains constant; and the specific heat appears to be indefinitely large. Here work, equivalent to the heat supplied, is performed by the expanding gas. These facts show that the condition of the gas must be stated before it is possible to define its specific heat. It is conventionally agreed that if the gas be allowed to expand during a change of temperature so that its pressure remains constant, the amount of heat required to raise the temperature of one gram-molecule of the gas 1° shall be called the **specific heat under constant pressure,** and symbolized by C_p. If the pressure be increased so that the volume remains constant when the gas is heated, the amount of heat required to raise the temperature 1° of a gram-molecule of the gas is likewise called the **specific heat under constant volume,** and symbolized C_v.

The heat imparted to a gas is not spent merely in raising the temperature of the gas; that is, in speeding up of the motions of the molecules. Energy is spent in—(1) *Augmenting the speed of the moving molecules.* The heat required actually to increase the kinetic energy of the moving molecules so as to produce a rise of temperature is the same for all gases. Let K denote this quantity. (2) *Performing external work.* Heat energy is needed to overcome the pressure of the atmosphere when the gas is allowed to expand. Call this quantity W. Since the coefficient of thermal expansion of all gases is the same, this quantity is practically constant for equal volumes or equimolecular weights. (3) *Performing internal work.* Heat energy is required to produce changes within the molecule which may alter the motions or orientation of the constituent atoms of the molecule, or raise the kinetic energy of the atoms moving with the molecule. Let ϵ denote the energy spent within the molecule per degree rise of temperature. A certain amount of energy must also be spent in overcoming the effects of intermolecular attractions. This can be neglected for the time being. Consequently, the ratio of the two specific heats may now be written, after J. J. Waterston (1845) : [1]

$$\frac{C_p}{C_v}=\frac{K+W+\epsilon}{K+\epsilon} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The specific heat of a gas at constant volume.—We have seen, (1) that $pv=\frac{1}{3}MV^2$, where M denotes the mass, and V the average velocity of the molecules. But the kinetic energy of a body of mass M moving with a velocity V is $\frac{1}{2}MV^2$; hence $pv=\frac{2}{3}\times\frac{1}{2}MV^2$; or the kinetic energy of the molecular motions is $\frac{3}{2}pv$, since $pv=RT$, the kinetic energy of molecular motion is $\frac{3}{2}RT$. If one gram-molecule of gas be heated 1°, the kinetic energy becomes $\frac{3}{2}R(T+1)$. Hence if the gas be heated 1° at constant volume, the thermal value of the increased kinetic energy is $\frac{3}{2}R(T+1)-\frac{3}{2}RT=\frac{3}{2}R$ cals. This result represents the specific heat of the gas at constant volume per gram-molecule ; or, $C_v=\frac{3}{2}R$.

The specific heat at constant pressure.—Again, if a gram-molecule of gas expands against atmospheric pressure when its temperature is raised 1°, the gas, in consequence, does work by pressing back the atmosphere, so to speak. The equivalent of this work must be supplied in the form of heat. This work is equivalent to the product of the pressure against the change in volume. Let x denote the change in volume when the gas is heated 1°, under a constant pressure ; then, $p(v+x)=R(T+1)$, and $pv=RT$. By subtraction $px=R$. This means that when a gram of gas is heated 1°, the resulting expansion against atmospheric pressure does work equivalent to R cals. ; or *the gas constant R, is numerically equal to the work done by a gas expanding against a constant atmospheric pressure, when the temperature is raised* 1°. Hence, R cals. must be added to the previous result to obtain the thermal equivalent of the energy supplied to one gram of gas in the form of heat when its temperature is raised 1°. Otherwise expressed, if one gram-molecule of gas be heated 1°, at constant pressure, an amount of heat equivalent to $\frac{3}{2}R+R=\frac{5}{2}R$ is required. This result represents the specific heat of the gas at constant pressure per gram-molecule or $C_p=\frac{5}{2}R$. In passing, it is interesting to note that *the difference between the two specific heats of a gas is numerically equal to the work done by the gas expanding against a constant atmospheric pressure when the temperature is raised* 1°, *or in symbols,*

$$C_p-C_v=R$$

a relation sometimes called **Mayer's equation,**[2] because it was used by him in 1842 to calculate the mechanical equivalent of heat, for the difference in the two specific heats represents the external work done during the expansion of 1 c.c. of air (*i.e.* 0·001293 grm.) against atmospheric pressure (*i.e.* 1,031,000 dynes per sq. cm.) when heated 1°. In Mayer's equation, when the work R is measured in calories, R is approximately 2 cals. The same value of R can be obtained another way—one gram of oxygen occupies 699·8 c.c. at standard pressure 1,013,200 dynes per sq. cm. and at 273° K. Hence, for one gram of oxygen, $R'=pv/T=2{\cdot}6\times10^6$ ergs ; and for 32 grams, or one gram-molecule, $R=2{\cdot}6\times10^6\times32=8{\cdot}3\times10^7$ ergs$=8{\cdot}3$ joules$=2$ cals. (nearly). Instead of representing gram-molecules of a gas, the specific heats C_p and C_v can be referred to one gram. In that case, R. Mayer's equation becomes $C_p-C_v=R/M$, where M denotes the molecular weight of the gas, and, for oxygen, $R/M=2\div32=0{\cdot}063$ cal.

EXAMPLES.—(1) The specific heats of oxygen at constant pressure and constant volume are respectively 0·217 and 0·155. The difference in the molecular specific heats is therefore $32(0{\cdot}217-0{\cdot}155)=2$ cals. nearly.

(2) Compute the mechanical equivalent of heat when for air $C_v=0{\cdot}1685$ and $C_p=0{\cdot}2375$. The mechanical equivalent of heat J is equal to the ratio W/Q, where Q denotes the amount of heat in calories required for performing W ergs of work. The work of

expansion when 1 c.c. of gas expands $\frac{1}{273}$ c.c. is $\frac{1}{273}\times1,013,000=w$, and the heat Q is equivalent to 0·001293(0·2375 − 0·1685) cal. Hence $J=41{\cdot}6\times10^6$ ergs per calorie.

The ratio of the two specific heats of a gas.—Returning to the ratio of the two specific heats, which is usually symbolized γ, we can now write $K=\frac{3}{2}R$, and $W=R$, or,

$$\gamma=\frac{C_p}{C_v}=\frac{\frac{5}{2}R+\epsilon}{\frac{3}{2}R+\epsilon} \quad . \quad . \quad . \quad . \quad . \quad (2$$

The magnitude of ϵ will vary with different gases, for it will naturally be related somehow with the complexity of the molecule. The greater the value of ϵ the less the value of the ratio of the two specific heats. For a monatomic gas, ϵ probably approaches zero, and the numerical value of the ratio becomes $\gamma=\frac{5}{3}$, or 1·67. The greater the complexity of the molecule, the greater the value of ϵ, and the smaller the value of the ratio of the two specific heats. This is illustrated by Table X.

TABLE X.—RATIO OF THE TWO SPECIFIC HEATS OF GASES.

Gas.	Molecule.	Atoms per molecule.	γ	Gas.	Molecule.	Atoms per molecule.	γ
Mercury . .	Hg	1	1·67	Carbon dioxide .	CO_2	3	1·31
Argon . . .	A	1	1·65	Nitrous oxide .	N_2O	3	1·31
Hydrogen . .	H_2	2	1·41	Hydrogen sulphide	H_2S	3	1·31
Nitrogen . .	N_2	2	1·41	Ammonia . .	NH_3	4	1·30
Oxygen. . .	O_2	2	1·40	Methane . .	CH_4	5	1·27
Carbon monoxide .	CO	2	1·40	Ethylene . .	C_2H_4	6	1·24
Hydrogen chloride .	HCl	2	1·39	Ethane . .	C_2H_6	8	1·18
Chlorine . .	Cl_2	2	1·32	Alcohol . .	C_2H_5OH	9	1·13
Bromine . .	Br_2	2	1·29	Benzene . .	C_6H_6	12	1·09
Iodine . . .	I_2	2	1·29	Ether . .	$C_4H_{10}O$	15	1·06
Iodine chloride .	ICl	2	1·31	Turpentine. .	$C_{10}H_{16}$	26	1·03

The effect of variations of temperature and pressure on γ.—The ratio of the two specific heats of gases decreases as the temperature rises. Thus, A. Wüllner[3] found the ratio of the specific heats of the following gases to fall as the temperature rose from 0° to 100:

γ for	Air	CO	CO_2	N_2O	NH_3	C_2H_4
0° . . .	1·4052	1·4032	1·3113	1·3106	1·3172	1·2455
100° . . .	1·4051	1·3970	1·2843	1·2745	1·2791	1·1889

and E. H. Stevens found the value for air to fall from 1·4006 at 0°, to 1·3993 at 100°, to 1·3400 at 950°; and M. Trautz obtained for water vapour saturated at 100°, γ=1·3290, and saturated at 110°, 1·3301; at 120°, 1·3129; and at 130°, 1·3119. Conversely, the ratio of the two specific heats of gases increases as the temperature falls from about 20° to −180°. For instance, M. Trautz (1913) has shown:

	Nitrogen, N_2	Carbon monoxide, CO	Oxygen, O_2	Hydrogen, H_2	Helium, He
γ from 18° to 20° . .	1·400	1·398	1·399	1·407	1·660
γ from −180° to −181°	1·468	1·472	1·447	1·597	1·673

A. Witkowsky obtained analogous results with air, and he also found that the ratio of the two specific heats increased when the pressure is augmented from 10 to 100 atm. both at 0° and at −78·5°, and attains a maximum value at −120°, as indicated in Table XI.

The ratio of the two specific heats and molecular weights.—The numbers in Table XI mean that if the ratio of the two specific heats of a gas be about 1·6, the gas will usually have one atom per molecule; with a ratio about 1·4, two atoms per molecule; and with a ratio of about 1·3, three atoms per molecule. The kinetic theory would have no explanation to offer if the value of γ were greater than $1\frac{2}{3}$; but no cases are known. There are a number of discrepancies. This must be expected owing to differences in molecular attraction, tendencies to polymerization, dissociation, etc., which affect the value of ϵ. The coloured gases—chlorine, bromine, iodine, and iodine chloride, with two atoms per molecule—give lower values than is usually obtained with the colourless diatomic molecules; and gases which are readily condensed to liquids give rather lower values than those less readily liquefied. Hence, **if the ratio of the two specific heats of a gas falls into one of these groups—1·6, 1·4, 1·3—this fact may be taken as circumstantial evidence, but not conclusive proof, that the molecule has a corresponding number of atoms per molecule.** There is, however, no unimpeachable relation connecting the specific heat of a complex molecule with the *number* of the constituent atoms which is independent of their nature. The ratio of the two specific heats of argon and the inert gases appears to be about 1·6, and hence it is supposed that the molecules of these gases are monatomic, like mercury. This means that the density ($H=2$), the molecular weight, and the atomic weight will probably have the same numerical value. Hence, the determination of the ratio of the two specific heats provides an independent method of ascertaining the number of atoms in the molecules of a gas without reference to the compounds of the element. In the case of mercury, the monatomicity of the gas has been established altogether apart from this reasoning.

TABLE XI.—THE EFFECTS OF TEMPERATURE AND PRESSURE ON THE RATIO OF THE TWO SPECIFIC HEATS OF AIR.

Temperature.	10	30	60	100
− 0°	1·43	1·44	1·53	1·60
− 60°	1·42	1·49	1·58	1·72
−100°	1·44	1·53	1·71	2·10
−120°	**1·45**	**1·56**	**1·79**	—
−140°	1·38	1·46	1·54	1·80

This subject cannot be passed by without bringing a weak step in the above reasoning into prominence. The low molecular heats of the inert gases are assumed to prove that these gases have one-atom molecules. But it is easy to see that **if little or no heat is expended in doing internal work when the temperature of a gas is raised, a gas with polyatomic molecules might be reported to have monatomic molecules.** Unlike mercury, the inert gases do not form chemical compounds, and hence the number of atoms in the molecule cannot be determined by the usual methods based upon Avogadro's hypothesis. The inference that the molecules of the inert gases are monatomic involves an assumption which is less readily granted than is the case with mercury, cadmium, etc., because these elements form volatile compounds which enable their atomic weights to be evaluated. Hydrogen at very low temperatures behaves in this respect like a monatomic gas.

§ 10. The Relation between the Two Specific Heats of a Gas and the Degree of Freedom of its Molecules

> Invisible movements, invisible particles—these and kindred assumptions have supplied the window through which the human mind has sought to spy into the inner machinery of phenomena.—T. GOMPERZ (1912).

R. Clausius [1] has shown that a value for the total heat energy contained in a gas can be obtained by assuming that the gas has been brought into its present condition by being warmed at constant volume from absolute zero to the temperature T. The density D of the gas represents the mass of the gas, and, if C_v be the specific heat at constant volume assumed for convenience not to vary with temperature, the total heat energy of the gas will be C_vDT. From (5), § 2, the kinetic energy of the translatory motions of the molecules of a gas is $\frac{3}{2}p$, a magnitude which also increases proportionally with the absolute temperature. The ratio of the total heat energy to the total kinetic energy is therefore a constant independent of temperature—provided C_v is independent of the temperature. Both magnitudes are proportional to the density D of the gas, and accordingly, the kinetic energy of the molecules of a perfect gas stands in a constant ratio to the total energy of the gas. From J. R. Mayer's equation, the kinetic energy of translatory motion is $\frac{3}{2}p=\frac{3}{2}(C_p-C_v)DT$, and accordingly, the ratio of the two forms of energy is :

$$\frac{\text{Energy of translatory motion}}{\text{Total energy}}=\frac{3(\gamma-1)}{2} \quad . \quad . \quad . \quad (3)$$

which shows that the ratio of these two forms of energy is determined by the two specific heats.

The kinetic energy of the molecules of a gas is supposed to be divided between the kinetic energy of the translatory motions, and of the various rotatory motions of the molecules. The former is sometimes called the external, and the latter the internal energy of the gas. During a collision there is probably a rapid exchange of kinetic energy between the external and internal motions. There are probably also elastic vibratory internal motions which are scarcely affected by molecular collisions, although a gain or loss of this form of internal energy may become appreciable after countless collisions. The vibratory energy may be dissipated as radiant heat, etc., and if the gas were not exposed to an external source of energy, it would be cooled by the loss of radiant vibratory energy, since the kinetic energy of the translatory and rotational motions would be gradually transformed into vibrational energy. Conversely, if a gas be exposed to a source of radiant energy, the vibrating motions are accelerated owing to the absorption of vibrational energy, and the energy so gained is but slowly converted into kinetic energy of translatory motion whereby the gas is warmed. The difficulty of heating gases by simple radiation shows that radiant energy is not rapidly absorbed by the molecules of a gas. From equation (3) it follows that if Q be the total energy of a gas, and K the kinetic energy of translatory motion, $Q-K$ represents the internal energy, or the

$$\frac{\text{Internal energy}}{\text{Total energy}}=\frac{3}{2}\left(\frac{5-3\gamma}{3}\right)=\frac{5-3\gamma}{2} \quad . \quad . \quad . \quad (4)$$

The energy of the translatory motions of the molecules has been shown to be equal to $\frac{3}{2}R$. Consequently, the ratio

$$\frac{\text{Internal energy of the molecules}}{\text{Energy of translatory motion}}=\frac{5-3\gamma}{3(\gamma-1)} \quad . \quad . \quad (5)$$

The constancy of the ratio γ for certain gases thus shows that the ratio of the internal or vibratory energy to the energy of translatory motion is likewise constant for these gases at ordinary temperatures ; or the internal energy of a gas is proportional to the kinetic energy of the gas.[2] The ratio of the vibratory to the translatory energy increases with the number of atoms in the molecule. With monatomic gases this ratio (5) is zero, and Table XII shows the value of the ratios (3) and (5) for a number of other gases as well as for ratio (5) divided by the number of atoms in the molecule.

TABLE XII.—MOLECULAR AND ATOMIC ENERGIES.

	$\frac{C_p}{C_v}=\gamma$	$\frac{\text{Kinetic energy}}{\text{Total energy}}$	$\frac{\text{Internal energy}}{\text{Kinetic energy}}$	$\frac{\text{Internal energy}}{\text{Kinetic energy}}$ per atom.

For moderate temperatures, the ratio of the molecular and atomic energies is nearly constant for diatomic molecules, but varies with temperature and other circumstances for more complex molecules. While the ratio of the two specific heats usually decreases a little with a rise of temperature, the ratio between the internal and kinetic energies, per atom, increases with a rise of temperature, and this increase appears to be the greater, the larger the number of atoms per molecule. This has been explained by assuming that some of the energy is consumed in work against the chemical affinity which hold the atoms of the molecule together.

In his *Ueber Molekularphysik* (Königsberg, 1888), F. Lindemann [3] assumes that the development of heat during chemical action consists merely in the transfer of the internal vibratory energy into translatory energy so that the products of the action possess less internal energy than before. If this be true, the internal vibratory energy of the initial products of the reaction between, say, hydrogen and chlorine must be enormously greater than the translatory energy, because of the great development of heat which occurs, and this is quite incompatible with the observed ratios of the two specific heats of the gases. Attempts [4] to correlate the specific heat ratio with the numbers of atoms in the molecule have not been very successful. J. C. Maxwell [5] sought a relation between the ratio of the two specific heats and the number of ways a system of particles is movable—*Beweglichkeitsarten*—or the so-called number of degrees of freedom of the molecules.

Degrees of freedom.—At any instant, the position of a particle compelled to oscillate to and fro on a given *straight line* is completely described by its distance from a fixed point in that line ; if the particle moves in a *plane*, its position will be described by its distance from two intersecting straight lines in that plane ; while if the particle moves in *space*, its position can be described by its distance from three fixed intersecting planes. In the first case, the particle is said to have *one degree of freedom* ; in the second, it is said to have *two degrees of freedom*, because two relations are needed to define its position, and each of the two relations can change independently of the other ; in the third case, the particle is said to have *three degrees of freedom*, because three independent relations are needed to define its position. The degree of freedom of an object is the number of facts which must be specified in order to define completely its position or state ; more precisely, **a degree of freedom is an**

independent mode in which the condition or state of a body can be altered. Consequently, the number of degrees of freedom of a particle in space cannot be less than three. If a short straight indefinitely thin rod be substituted for the particle, then, the position of the rod in space can be defined by indicating the distances of the two ends of the rod from the three intersecting planes. Hence, six relations are then used in defining the position of the rod. The rod, it is to be remembered, has a fixed definite length, and one of the six relations can be eliminated because it is related with the other five; as a result, the position of the rod can be completely defined by five independent relations. The rod is therefore said to have five degrees of freedom. If a rigid body, ABC, be fixed in space, its position can be defined by the relations of any three points, taken as the apices of a triangle drawn on the body, to the three intersecting planes of reference. Each point is defined by three relations, making nine in all; but the relation of A to B, of B to C, and of C to A are fixed distances, and hence three of the nine relations are not independent. A rigid body in space has therefore six degrees of freedom. A pair of compasses has seven degrees of freedom, but six if the joint is "ankylosed."

If a molecule has n atoms which have a definite and fixed relation with one another, the number of degrees of freedom cannot exceed $3n$. If a gas has but one atom per molecule, then the molecule will have three degrees of freedom; if two atoms at a fixed distance apart—dumb-bell fashion—five degrees of freedom; and if the atoms are so arranged such that (i) the atoms are at the apices of an imaginary triangle, there will be $3n-3=6$ degrees of freedom; (ii) if the three atoms are situated as if they were in one fixed line, there will be five degrees of freedom; and (iii) if the atoms are fixed so that two of the atoms can oscillate about a central atom, there will be $3n-2=7$ degrees of freedom. For more complex molecules, and for more complex movements, the number of degrees of freedom will be greater. The six degrees of freedom of a rigid body, free to move in space, can be resolved into three translatory movements parallel to three fixed and intersecting planes of reference, and three rotations about the same axes.

The kinetic energy of the translatory motions of the molecules of a gas is measured by the pressure, and is analogous with Helmholtz's free energy. The molecule itself, however, may be a complex system of two or more atoms capable of rotation about their centres of mass; and possibly also each is capable of rotation about its centre of mass; and possibly also each is capable of rotatory motion. The kinetic energy absorbed by the motions of this secondary system is usually called the *internal energy*, and is analogous with Helmholtz's bound energy, although a small proportion of the internal kinetic energy of gases is also vibratory or oscillatory energy.

The ratio of the two specific heats of gases makes it probable that during the collisions between the molecules, there is a constant exchange and re-distribution of the energy between the translatory and the internal energy; but for every gas, a constant ratio is preserved between the two forms of energy, namely, that portion of the energy which is manifested in the translatory motions of the molecules between their encounters, and that portion which is concerned in the rotatory and other motions. The energy distributed between each form of motion probably preserves a constant ratio to the total energy. An important assumption can now be introduced: **During the fortuitous collisions of the molecules of a gas, the total kinetic energy K is divided equally among the n degrees of freedom of the molecules,** so that the kinetic energy of translatory motion for each degree of freedom is $3K/n$; and for monatomic molecules, each with three degrees of freedom, $n=3$, the total kinetic energy is k. This hypothesis is sometimes called **Maxwell's distribution theorem,** because J. C. Maxwell (1859) applied the proposition to systems of rigid particles. L. Boltzmann (1861) extended the principle to particles which were not rigid, but which were regarded as complex systems having great numbers of degrees of freedom, and hence the hypothesis is also called **Maxwell-Boltzmann's distribution theorem.** L. Boltzmann showed that this is the most probable distribution of the energy in an aggregate of a large number of molecules, provided that all the values for the coordinates and corresponding momenta of a single molecule are equally probable. This hypothesis has been the subject of much discussion,[6] and even though the hypothesis is not now considered to be of general application, it has been an important stimulus to investigation.

Since translatory motion involves only three degrees of freedom, it follows from

Maxwell-Boltzmann's theorem, that if a molecule has n degrees of freedom, the *translatory energy* of the molecules of the gas with mean velocity V, will be equal to $3K/n$, where K is the *total kinetic energy* $\frac{1}{2}mNV^2$. Hence, the kinetic energy of the translatory motion can be written $3K/n=\frac{1}{2}mNV^2$, and since the kinetic energy, $pv=\frac{1}{3}mNV^2$, it follows, $\frac{2}{3}(\frac{1}{2}mNV^2)$, or $pv=2K/n$. The work which a gas can do when it expands adiabatically—that is, without receiving or giving out heat—is equal to its total kinetic energy, which in turn is equal to $pv/(\gamma-1)$, where γ represents the ratio of the two specific heats of the gas. Since $K(\gamma-1)=pv$ and $pv=2K/n$, it follows that by substituting for pv,

$$\gamma=1+\frac{2}{n} \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

This expression enables (i) the ratio of the two specific heats of a gas to be computed when the degree of freedom of the molecules is known; and conversely, (ii) the degree of freedom when the ratio of the two specific heats is known. The simplest possible case of a gas with monatomic molecules, each with three degrees of freedom, furnishes a gas with $\gamma=1\frac{2}{3}$. The value found for mercury by A. Kundt and E. Warburg (1876)[7] is 1·66; and the constant has the same value for members of the argon family. If the three degrees of freedom concerned in the translatory movements of a molecule between each encounter, be deducted from n, the total number of degrees of freedom, then n—3 will represent the number of degrees of freedom of the internal motions. The following table shows the result with a few gases:

TABLE XIII.—RELATION BETWEEN SPECIFIC HEATS AND DEGREES OF FREEDOM OF THE MOLECULES OF SOME GASES.

Gas.	Observed γ	n	n-3
Mercury	1·67	3·00	0·00
Helium	1·65	3·07	0·07
Oxygen	1·40	4·98	1·98
Carbon monoxide	1·41	4·94	1·94
Hydrogen chloride . .	1·39	5·06	2·06
Carbon dioxide	1·30	6·67	3·67
Carbon disulphide . .	1·24	8·40	5·40
Ethane	1·18	11·10	8·10
Carbon tetrachloride . .	1·13	15·40	12·40

With diatomic molecules, $n=5$ and $\gamma=1{\cdot}4$. This corresponds with a molecule whose shape and structure are symmetrical about one axis. Such a molecule would be formed by the union of two spherical atoms, or of two atoms not necessarily spherical, but each spherical about one axis and both axes corresponding with the axes of the molecule. This conclusion agrees with the observed values of γ for oxygen=1·4, as well as for the diatomic gases, nitrogen, hydrogen, carbon monoxide, nitric oxide, and hydrogen chloride. For superheated steam, the observed value of γ is 1·3, which virtually corresponds with a molecule with six degrees of freedom. There are some objections against a rigid application of the hypothesis:

(*a*) Intermolecular attraction has been neglected in developing the theory. With gases like steam, this attraction may reach some magnitude, and it would reduce the specific heat ratio, because instead of n, it would be necessary to substitute $n+d$ in equation (6), where d is a small positive quantity.

(*b*) If some of the molecules of a gas are dissociated, a gas with diatomic molecules would have a value of γ ranging between that appropriate for a diatomic gas with five, and that for a monatomic gas with three degrees of freedom. The gradual rise of the specific heat ratio with temperature also agrees with the assumption that a greater and greater proportion of the molecules decrease in complexity owing to dissociation with rise of temperature. The converse of this applies to molecular aggregation which would give rise to molecules with a more complex structure, and thus increase the value of n and decrease that of γ.

(*c*) If the bond which holds the atoms of a molecule together behaves as if the atoms are held together neither with perfect rigidity nor with perfect freedom, the degrees of freedom may not all have the same value, and moreover another degree of freedom would have to be added for, say, a diatomic molecule in which the atoms do not remain at an invariable distance apart. The comparison of the ratio of the two specific heats for transparent and coloured diatomic gases—Table XIV—shows that the former have values of γ in the neighbourhood of 1·4 corresponding with five degrees of freedom, while with the latter, the value of γ is 1·3, corresponding with seven degrees of freedom, and it is possible that molecular aggregation or the so-called loose-jointing of the molecules accounts for the discrepancy.

TABLE XIV.—COMPARISON OF THE RATIO OF THE SPECIFIC HEATS OF TRANSPARENT AND COLOURED GASES.

Transparent gases.				Coloured gases.			
	γ	n	n-3		γ	n	n-3
Hydrogen . .	1·40	5·0	2·1	Chlorine . .	1·33	6·1	3·1
Hydrogen chloride	1·39	5·1	2·1	Bromine . .	1·29	6·9	3·9
Hydrogen bromide	1·42	4·8	1·8	Iodine . .	1·29	6·9	3·9
Hydrogen iodide .	1·40	5·0	2·0	Iodine monochloride	1·31	6·5	3·5

(*d*) The addition of heat may also set up motions other than those described by the degrees of freedom of the molecules indicated above. Other kinds of motions may be set up by, say, a reaction with the æther as indicated by the emission of radiant energy. Even the atoms of monatomic gases may be capable of internal oscillatory motions as is made probable by the complexity of their spectra; but these motions require so small an expenditure of energy that its amount may be neglected in comparison with the kinetic energy of translatory motion Further, adds O. E. Meyer,[8]

> It does not appear impossible that the ratio $\gamma=1·67$ should be found in the case of chemically compound molecules also, if the connection of the atoms is so firm that internal motions are excluded.

Attempts to connect the values of γ or n with the number of atoms in the molecule have not been successful. A. Naumann (1867)[9] suggested that n—3 is identical with the number of atoms in the molecule; and J. J. Thomson (1893) added that only when the atoms are symmetrically arranged will n—3 be proportional to the number of atoms per molecule. J. W. Capstick (1894-5) found that the *nature* as well as the *number* of atoms is of importance. Thus, with the chloro-derivatives of methane, CH_4, J. W. Capstick found

	CH_4	CH_3Cl	CH_2Cl_2	$CHCl_3$	CCl_4
γ	1·313	1·279	1·219	1·154	1·130
n	6·4	7·2	9·0	13·0	15·4

This shows that the substitution of atoms of chlorine for atoms of hydrogen, step by step, produces a perceptible rise in the value of n, although the number of atoms remains unchanged; and K. Strecker (1881-2) pointed out that while one halogen can replace another in the hydrogen haloids without any change in value of n, the substitution of a second halogen for the hydrogen raises the value of n.

§ 11. The Molecular Heats of Gases

It follows that if n denotes the number of degrees of freedom per molecule of a gas, and if K denotes the increase in the kinetic energy when the temperature is raised from $T°$ to $T°+1°$, the total increase in the kinetic energy for N molecules will be $\frac{1}{3}nNK$. If C_v denotes the specific heat of a gas, and M the molecular weight, it follows that if the change of temperature be accompanied by no other than a change in the kinetic energy of translatory motion, $\frac{1}{3}nNK=NMC_v$, and hence, $\frac{1}{3}nK=MC_v$. From J. J. Waterston's hypothesis, if two gases be raised through the same range of temperature, the increase in the kinetic energy of each gas will be the same, and remembering that K is a constant, $MC_v=(\frac{1}{3}K)n$, which means that the product of the specific heat and the molecular weight of a gas is proportional to the number of degrees of freedom of its molecules, and equal to the product of the number of degrees of freedom of the molecules of a gas and a constant. The constant K is evaluated by substituting known values of C_v, M, and n in the equation ; and $\frac{1}{3}K$ works out to be very nearly unity, as indicated in Table XV. Accordingly,

$$\text{Molecular heat}=C_vM=n \quad . \quad . \quad . \quad . \quad (7)$$

The degrees of freedom calculated from this equation agree with those obtained for a number of gases in other ways. This relation makes the atomic heats of the monatomic gases equal to 3.

The constancy of the molecular heats over a range of different gases implies that their molecules have the same number of degrees of freedom ; and conversely, the approximate number of degrees of freedom of the molecules of a gas is given by the product of the specific heat and molecular weight. That is, **the molecular heat of a gas is almost numerically equal to the degree of freedom of its molecules,** or about one calorie per degree of freedom. The observed value for all monatomic gases excepting helium agrees with theory. The two-atom molecules with five degrees of freedom seem to behave like a rigid dumb-bell when the gas is heated, in that the possible vibratory motion of two atoms along the line joining them does not appear to represent a degree of freedom, for the motions appear to be distributed solely in two rotational and three translational movements. The results are confirmed by the molecular heats of the diatomic permanent gases. The molecular heats of chlorine and bromine are about a calorie too high for agreement with the hypothesis. This possibly corresponds with to-and-fro vibrations of the atoms along an axis joining the two atoms.

TABLE XV.—RELATION BETWEEN MOLECULAR HEATS AND DEGREES OF FREEDOM.

	Specific heat, C_v	Molecular weight, M	C_vM	Degrees of freedom, n	Constant, $\frac{1}{2}K$
Argon	0·0731	39·92	2·92	3	0·97
Mercury	0·0147	200	2·94	3	1·00
Helium	0·7465	3·96	2·95	3	0·98
Hydrogen. . . .	2·4263	2	4·85	5	0·97
Nitrogen	0·1721	28	4·82	5	0·96
Oxygen	0·1544	32	4·95	5	0·99
Carbon monoxide . .	0·1746	28	4·89	5	0·97

Ammonia . . .	0·3803	17	6·46	6	1·08
Carbon dioxide . .	0·1486	44	6·54	7	0·94

L. Boltzmann[1] expresses these results another way, the thermal capacity of a gas is equal to the product of its mass by its specific heat C_v; consequently, if w denotes the atomic weight, *i.e.* the molecular weight of a monatomic gas, the thermal capacity or the atomic heat will be wC_v. It has been shown that the mean kinetic energy of a gram-molecule of a gas is equal to $\frac{3}{2}pv$ or $\frac{3}{2}RT$, and if the gas at $-273°$ has no kinetic energy of translatory motion, the kinetic energy of a gram-molecule of the gas at 0° will be $273\ wC_v=\frac{3}{2}RT$; but $R=2$ cals. nearly; accordingly, the atomic heat of a monatomic gas per 1° will be nearly 3. This agrees with the results in Table X. In raising the temperature of a polyatomic gas from $-273°$ to 0°, intramolecular work may be done. Accordingly, if M denotes the molecular weight of the gas, MC_v will be equal to $\frac{1}{2}R(1+\epsilon)$, where ϵ denotes the fractional part of the kinetic energy which is spent in doing intramolecular work. For a diatomic gas, $\epsilon=\frac{2}{3}$, and $MC_v=5$ nearly, or the atomic heat of a diatomic gas is nearly 2·5; similarly, L. Boltzmann has shown that for triatomic gases, $\epsilon=1$, or $MC_v=6$, or $wC_v=2$ nearly.

The effect of temperature and pressure on molecular heats.—The specific heat of a gas at constant pressure, C_p, increases with a rise of temperature such that the mean specific heat C_p between 0° and $\theta°$ is $C_p=a+b\theta$; or $C_p=a+b\theta+c\theta^2$, where a, b and c are constants. E. Wiedemann's[2] value for carbon dioxide between 0° and 200° is $0·1952+0·000229\theta$; and L. Holborn and F. Henning's value between 0° and 800° is $0·0208+0·0001384\theta+0·00000005\theta^2$. H. V. Regnault thought that pressure had no effect on the thermal capacity of hydrogen, carbon dioxide, etc., but J. Joly and S. Lussana[3] have shown that the specific heat increases with increasing pressure when the temperature is constant. Thus, the value for carbon dioxide increased 38 per cent. when the pressure rose from one atm. to 41 atm. The observed results can be represented by analogous formulæ, $C_p=a+b(p-1)$ or $C_p=a+b(p-1)+c(p-1)^2$. Thus, for carbon dioxide, S. Lussana found that $C_p=0·20130+0·0019199(p-1)$. The specific heat at constant volume varies with temperature and pressure somewhat similarly to the results for the specific heat at constant pressure

W. Nernst's measurements (1911) show that the molecular heat of chlorine rises from 5·85 at 0° to 7·0 as the temperature rises to 1200°, and still another calorie higher at about 2000°. This corresponds with the addition of two new degrees of freedom. The gases with a molecular heat approaching 6 are easily dissociated, and therefore the number of degrees of freedom of molecules whose atoms are joined by strong chemical forces is less than when the atoms are united by weaker forces. The effect of temperature on the molecular heats of a few gases is further illustrated by Table XVI.

TABLE XVI.—THE EFFECT OF TEMPERATURE ON THE MOLECULAR HEATS OF GASES AT CONSTANT VOLUME.

Gas.	Theoretical value for rigid molecules.	Temperature (°C.).					
		0°	100°	300°	500°	1200°	2000°
Argon	3	2·98	2·98	2·98	2·98	2·98	2·98
Hydrogen	5	4·75	4·78	5·02	5·20	5·80	6·50
Nitrogen	5	4·90	4·93	5·17	5·35	6·00	6·70
Steam	6	5·93	5·97	6·45	6·95	8·62	13·10
Carbon dioxide	6	6·80	7·43	8·53	9·43	11·00	11·50
Ammonia	6	6·62	6·82	7·41	8·52	—	—

Similar values were obtained for oxygen, hydrogen chloride, and carbon monoxide as those indicated in the table for nitrogen; and sulphur dioxide furnished numbers similar to those for carbon dioxide. According to A. Eucken (1912),[4] the molecular heat of hydrogen falls from 5 to 3 calories as the temperature falls to —213°, and diatomic gas then behaves as if it were monatomic. At still lower temperatures, —238°, the molecular heat of hydrogen and helium at constant volume fall still lower than 3. M. Trautz (1913) has shown that the molecular heat at constant pressure decreases as the temperature diminishes from 20° to —180°. For instance,

	Nitrogen.	Carbon monoxide.	Oxygen.	Hydrogen.	Helium.
18° to 20°	6·983	7·006	6·980	6·860	4·993
—180° to —181°	7·162	7·244	7·300	5·330	4·934

The molecular heat of helium thus exhibits a positive temperature coefficient, whereas, if helium were a monatomic gas, and nothing has been overlooked, its molecular heat should not be affected by variations of temperature. The decrease with hydrogen at low temperatures is explained by M. Trautz (1913) by assuming that the hydrogen is converted into another modification with the properties of a monatomic gas whereby it loses one or more degrees of freedom. A. H. Compton (1915) made a similar assumption for solids.

§ 12. The Specific Heats of Elementary Solids—Dulong and Petit's Rule

> Les atomes de tous les corps simples ont exactement la même capacité pour la chaleur.
> —P. L. DULONG and A. T. PETIT (1819).

In 1819, P. L. Dulong and A. T. Petit published an account of their *Recherches sur quelques points importants de la théorie de la chaleur ;* [1] they found that while different substances have different capacities for heat, the atomic heats of nearly all the elements then known were the same. **Atomic heat** is a convenient term for the thermal capacity of a gram atom of an element ; it is the product of the specific heat and the atomic weight of the element. P. L. Dulong and A. T. Petit determined the specific heats of different solid elements, at constant pressure, and obtained this remarkable result : **The product of the atomic weight and the specific heat of an element has nearly always the same numerical value—Dulong and Petit's rule.** This means that the atomic heats or the thermal capacity of the atoms of the elements are approximately the same ; it requires the same amount of heat to raise every atom, no matter of what kind, one degree of temperature. The relation is usually expressed :

Atomic heat, $Cw=6$ approximately . . . (8)

where w denotes the atomic weight of the element, and C its specific heat—at constant pressure. The rule is remarkably near the truth for the solid elements at ordinary temperatures, but it fails with the gaseous elements and a very small number of solid elements. In illustration, a few examples selected at random from a list containing nearly 50 elements for which data are available, are indicated in Table XVII.

TABLE XVII.—ATOMIC HEAT OF ELEMENTS.

Element.	Specific heat.	Atomic weight.	Atomic heat.
Lithium	0·9408	6·94	6·53
Silver	0·0559	107·88	6·03
Gold	0·0304	197·2	6·25
Copper	0·0923	63·57	5·88
Bismuth	0·0305	208·0	6·34
Lead	0·0315	207·10	6·52
Aluminium . . .	0·2143	27·1	5·81
Iron	0·1098	55·85	6·12
Uranium . . .	0·0277	238·5	6·61

H. V. Regnault extended and confirmed P. L. Dulong and A. T. Petit's observation. The average value of the constant is 6·36 or 6·4. The atomic weights range from 6·94 to 238·5. and yet, when multiplied by the respective specific heats, the products are nearly constant. Rigorous agreement cannot be expected. The divergencies are too large to be accounted for by the inevitable errors of observation involved in measuring the specific heats, but the very irregularity of the divergencies leads to the view that Dulong and Petit's law approximates to a truth, and that the observed differences are due to disturbing effects which are not functions of the atomic weight. According to H. Kopp (1865) the atomic heats (determined indirectly) of the following elements in the solid state are exceptionally low :

	O	H	F	B	C	Si	S	P
Atomic heat . .	4·0	2·3	5·0	2·7	1·8	3·8	5·4	5·4

Beryllium also gives a low value. The atomic heats of the other forty elements examined by H. Kopp were nearly all in the vicinity of 6. **The elements with exceptionally low atomic heats usually form gaseous or readily volatile compounds,**

and they have small atomic weights. Of these, those which exhibit the greatest deviation usually have the smallest atomic weights, while those with the largest atomic weights approximate most nearly to the normal value. Magnesium and aluminium have small atomic weights, and though their atomic heats are considered to be normal, they are on the low side. Sodium and lithium are exceptional in possessing low atomic weights and normal atomic heats.

Attempts have been made to explain the divergencies (i) as a result of the fact that the temperatures at which the specific heats have been determined stand in a different relation to their fusion temperatures. Lead, for instance, at the temperature of boiling water, is much nearer its fusion temperature (327°) than iron is to its fusion temperature (1530°); but in the case of many elements, the specific heat does not change very much with changes of temperature not far removed from atmospheric. Another explanation assumes (ii) that the divergencies are due to differences in the configuration or orientation of the molecules or atoms of the solid elements. According to F. Richarz,[2] the fact that solid bodies with low atomic volumes—beryllium, boron, and carbon—have low values for the atomic heats shows that, on a rising temperature, the displacement of the atoms, relatively to their mutual distances apart, is large. This would make the thermal capacities of these elements more sensitive to changes of temperature than when the displacements are relatively small. This is also confirmed by the observation that the allotropic forms of an element with the smaller atomic volume or the larger specific heat have the lowest specific gravity.

The influence of pressure on atomic heats.—Measurements of the specific heats of solids, C_p, are made at a constant pressure, and the results are probably not very different from the specific heat, C_v, at constant volume at very low temperatures, but at higher temperatures the difference is significant. For instance, the observed value of C_p for silver at 100° K. is 4·86, the computed value for C_v is 4·72; and at 589° K., C_p is likewise 6·64, and C_v is 5·92. As in the case of gases, the difference between the two depends upon the amount of work required to compress the heated solid back to the volume it occupied before it was heated.

The internal energy U of compressed gases, or the heat developed during expansion without doing external work has an appreciable value, and is usually negative, and when work W is done against an external pressure p, during an expansion from a volume v_1 to v_2, $W=(v_2-v_1)p$, and, regarding the volume as constant, $dW=(v_2-v_1)dp$. Consequently, the heat Q developed during the change, follows from Helmholtz's equation, $Q=W-U=(v_2-v_1)T.dp/dT$; and the heat dQ developed during an infinitesimal change, $v_2-v_1=dv$, will be $dQ=T(dp/dT)dv$, or

$$\left(\frac{dQ}{dv}\right)_T=T\left(\frac{dp}{dT}\right)_v \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Again,[3] by the partial differentiation of Q, p, v, and T,

$$dQ=\left(\frac{dQ}{dT}\right)_v dT+\left(\frac{dQ}{dv}\right)_v dv\text{; or, }\left(\frac{dQ}{dT}\right)_p=\left(\frac{dQ}{dT}\right)_v+\left(\frac{dQ}{dv}\right)_v\frac{dv}{dT}$$

These results obtain as a purely mathematical operation like multiplication or division, and altogether apart from any meaning the symbols may have. Since dQ/dT denotes the specific heat at constant pressure or constant volume,

$$C_p-C_v=\frac{dQ}{dv}\cdot\frac{dv}{dT}\text{; or, }C_p-C_v=T\left(\frac{dp}{dT}\right)_v\frac{dv}{dT} \quad . \quad . \quad (10)$$

by substituting for dQ/dv from equation (9). E. H. Amagat applied this relation to his data on highly compressed gases, and his results with carbon dioxide at 50° are shown in Table XVIII.

TABLE XVIII.—VALUES OF $\frac{dp}{dT}\cdot\frac{dv}{dT}$ FOR CARBON DIOXIDE.

Pressure.	$\frac{dp}{dT}$	$\frac{dv}{dT}$	$\frac{dp}{dT}\cdot\frac{dv}{dT}$
50	0·265	0·0001300	0·1353
60	0·370	0·0001250	0·1815
70	0·505	0·0001428	0·2831
80	0·689	0·0001687	0·4563
90	0·960	0·0002133	0·8040
100	1·460	0·0002020	1·1105

The numbers in the last column have been divided by the mechanical equivalent of heat to convert them into gram-calories. On multiplying and dividing the right member of (10) by v_0dv, it furnishes

$$C_p-C_v=T\frac{v_0\left(\frac{1}{v_0}\cdot\frac{dv}{dT}\right)^2}{-\frac{1}{v_0}\frac{dv}{dp}} \quad . \quad . \quad . \quad . \quad (10)$$

where the coefficient of cubical expansion, $3a=dv/v_0dT$; and the compressibility, $\beta=-dv/v_0dp$, and v_0 is the volume in c.c. at 0°. These equations have been employed by M. Margules (1888), E. H. Amagat (1896), E. Grüneisen (1906), and others.[4] The preceding discussion reduces to

$$C_p-C_v=\frac{(3a)^2}{\beta}v_0T \quad . \quad . \quad . \quad . \quad . \quad (11)$$

which is a well-known relation in thermodynamics. All the magnitudes—specific heat at constant pressure, C_p; coefficient of linear expansion, a; the volume at 0°, v_0; and the coefficient of compressibility, β—, can be determined experimentally. If C_p and C_v represent the corresponding atomic heats, v_0 will represent the atomic volume; and if the unit of pressure be megadynes per sq. cm., and the unit volume is 1 c.c., the calculated values of C_p and C_v will be in mega-ergs per degree. Since $41·82\times10^6$ ergs, or 41·82 mega-ergs are equivalent to one calorie,

$$C_p-C_v=\frac{(3a)^2}{\beta}Tv_0 \text{ mega-ergs}; \quad C_p-C_v=\frac{(3a)^2v_0T}{41·82\beta} \text{ cals.}$$

The data in Table XIX were compiled by G. N. Lewis, and they show that within the limits of experimental error, the atomic heats of these elements at constant volume and 20°, are the same for all the solid elements whose atomic weights are greater than potassium. The mean of these values of the atomic heats at constant pressure (Dulong and Petit's constant) is 6·2, and at constant volume 5·9. The average deviation for the former is 0·26, and excluding the first four elements, 0·18; the average deviation for the latter is 0·15, or, excluding the first four elements, 0·09. F. Bürki found that the differences C_p-C_v for chemically related elements are nearly the same; and that for the halides of the elements of group I. in the periodic table, the requirements of H. Kopp's rule are more nearly fulfilled by C_p than by C_v.

When the coefficients of compressibility and of cubical expansion at the desired temperature are not known, the empirical expression of E. Grüneisen, $C_v=C_p-0·0214C_p^2T/T_m$, can be used when T_m denotes the melting point of the solid. Here v_0/β of (28) is assumed to be constant, and a^2 to be proportional to the atomic heat. Still further, the empirical expression of A. Magnus and F. A. Lindemann,[5] $C_v-C_p-aT^{\frac{3}{2}}$, gives results of sufficient accuracy for many purposes. The constant a is evaluated by putting $C_v=3R$ at sufficiently high temperatures.

The influence of temperature on atomic heats.—Silicon, boron, beryllium, and carbon at ordinary temperatures, have atomic heats represented respectively by 3·8, 2·7, 3·4, and 1·8. From the point of view of Dulong and Petit's rule, these numbers are low. H. F. Weber (1874) found that the atomic heats of carbon, boron, and silicon approximate closer and closer to the normal value, the higher the temperature; and A. G. Worthing has shown that the atomic heat of carbon rises to $wC_p=5{\cdot}35$ at 1200° K., and to 6·05 at 2000° K. L. F. Nilson and O. Pettersson (1880), and T. S. Humpidge (1886) obtained a similar conclusion for beryllium.[6] This is illustrated by the diagram, Fig. 7, which represents the effect of a rising temperature on the atomic heats of the elements in question. The specific heats of these elements increase with temperature until a point is reached at which they are nearly constant. W. A. Tilden's examination of the influence of temperature on atomic heats led him to conclude that *there is no one condition or set of conditions under which Dulong and Petit's rule is true for all the elements.* If carbon, boron, silicon, and beryllium be regarded as exceptional, the mean specific heats between 0° and 100° may be arbitrarily selected as a standard for the best results. E. H. and E. Griffiths suggest that the empirical relation $Cw^{0\cdot95}=4{\cdot}804$ fits the specific heats of the metals at 0° better than Dulong and Petit's rule; and by extrapolation, they infer that the atomic heats of the elements at absolute zero will have the mean value 4·813, but this induction does not fit the facts. There does not appear to be a true upper limiting value in the sense indicated by Dulong and Petit's rule, for several substances possess greater atomic heats even at 1000°; for example, A. G. Worthing has shown that while the atomic heat of tungsten at constant volume is 5·95 at moderate temperatures, the value is 6·25 at 1200° K., and 7·35 at 2400° K. As a rule the temperatures at which the elements exhibit the same atomic heats decrease as the atomic weights increase.

TABLE XIX.—THE TWO ATOMIC HEATS OF THE ELEMENTS AT 20°.

Element.	Atomic weight.	Atomic volumes, V_0	$3\alpha\times10^6$	$\beta\times10^6$	C_p-C_v	C_p	C_v
Sodium . .	23·0	23·7	15·4	72	0·5	6·9	6·4

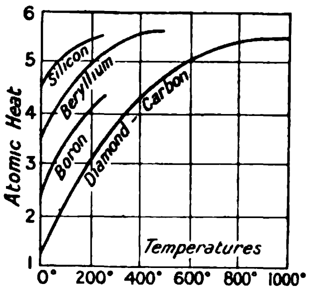

FIG. 7.—Atomic Heat Curves of Beryllium, Boron, Carbon, and Silicon.

U. Behn[7] (1898) found that there is a decrease in the atomic heats with falling temperatures, so that when the observed results are plotted, the curves appear as if they would intersect at low temperatures, but T. W. Richards and F. G. Jackson determined the specific heats of many elements between the temperature of liquid air and ordinary atmospheric temperatures, and found that with the exception of the elements of low atomic weight, they conform to Dulong and Petit's rule. Further observations[8] by W. Nernst and his co-workers, J. Dewar and H. K. Onnes, have confirmed Behn's conclusion; for while **the atomic heats of the elements with abnormally low values increase approximately to about the theoretical value with a rise of temperature, the atomic heats of all the elements converge towards zero as the temperature approaches absolute zero.** For instance, with silver:

Temperature .	−238°	−228°	−196°	−173°	−73°	−58°	−30·6°
Atomic heat .	1·58	2·47	4·07	4·86	5·78	6·01	6·64

The results with carbon (diamond), aluminium, and lead are illustrated by the graphs in the diagram, Fig. 8. H. K. Onnes and G. Holst found that the specific heat of mercury is 0·00142 between 4·26° K. and 6·48° K., and 0·000534 between 2·93° K. and 3·97° K. J. Dewar's determinations of the specific heats of fifty-three elements at temperatures between the boiling points of hydrogen and nitrogen when plotted with the atomic weights, gave a periodic curve closely resembling the atomic volume curve of L. Meyer; the specific heats at ordinary temperatures give a hyperbolic not a periodic curve—Fig. 5, Cap. VI.

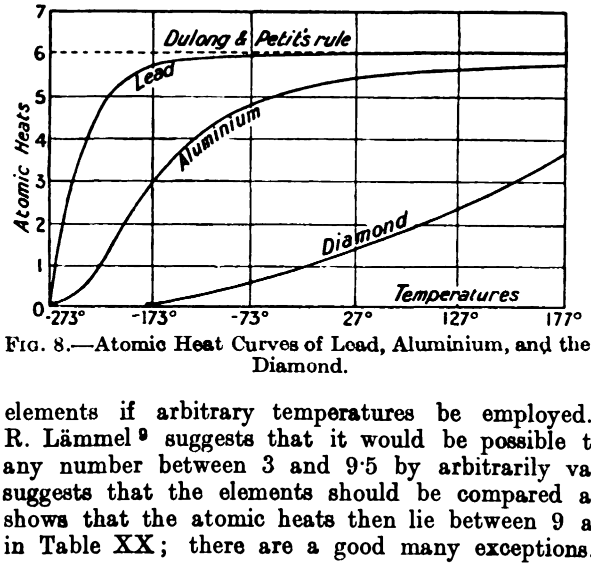

FIG. 8.—Atomic Heat Curves of Lead, Aluminium, and the Diamond.

These results make it clear that Dulong and Petit's rule is a limiting rule to which these elements approximate when the temperature is high enough, but, in virtue of the marked relation between the thermal capacity and temperature, Dulong and Petit's constant can be obtained for diverse elements if arbitrary temperatures be employed. By the same procedure, R. Lämmel[9] suggests that it would be possible to use for the atomic heat any number between 3 and 9·5 by arbitrarily varying the temperature. He suggests that the elements should be compared at their melting points and shows that the atomic heats then lie between 9 and 10 calories as indicated in Table XX; there are a good many exceptions. As a matter of fact, the

TABLE XX.—ATOMIC HEATS OF THE ELEMENTS AT THEIR MELTING POINTS.

Elements.	Atomic weight.	Melting point, T_m.	Specific heat at T_m.	Atomic heat.
Lithium . . .	7	190°	1·3	9·45

atomic heat indicates how rapidly heat, dQ/dT, is added per atom per degree rise of temperature, and a high value for this constant means that the potential energy of the molecules is being rapidly increased, possibly owing to the dissociation or approaching dissociation of complex into simpler molecules. At low temperatures where the specific heats are small, S. Pagliani (1915) has pointed out that the atomic heats of the elements at a given temperature, tend to increase with increasing atomic weight; and this is not the case at temperatures near atmospheric. The temperatures at which different elements show the same atomic heats decrease as the atomic weights become larger, presumably because usually the larger the atomic weight of the element the less is the strength of the union between the atoms.

The influence of the state of aggregation on atomic heats.—According to the kinetic theory, the heat required to raise the temperature of a body is spent (1) in raising the kinetic energy of the molecules; (2) in raising the kinetic energy of the constituent atoms—*e.g.* in doing chemical work, etc.; (3) in increasing the volume of the body against atmospheric pressure; (4) in overcoming molecular attractions, etc. The coefficient of thermal expansion of solids is small, and therefore also the work of expansion of solids against atmospheric pressure is small, but the work done against molecular cohesive forces is probably large with liquids and solids. This is illustrated by the comparative large difference in the specific heats of solid, liquid, and gaseous elements. As a rule, the specific heat of a substance in the gaseous state is less than it is in the liquid state. Thus, the specific heat of liquid alcohol is 0·5475 and for the vapour 0·4534: for ether, the numbers are respectively 0·5290 and 0·4797. The atomic heat of solid iodine is 6·9, and of the gas, 3·3; liquid bromine, 8·56, and bromine gas, 4·7. There are exceptions—for instance, the specific heat of ice is 0·500, liquid water, 1·000, and steam, 0·477; the specific heat of solid mercury is 0·0314, of the liquid, 0·0333, and of the vapour, 0·0147; the numbers for liquid and solid tin are 0·0637 and 0·0559, and for liquid and solid lead, 0·0470 and 0·0314 respectively. H. Mache[10] has worked out a demonstration that the thermal capacity of a liquid ought to be nearly double the true thermal capacity of its vapour, so that if C_v is the true thermal capacity of a vapour, the value for the corresponding liquid should be $2C_v$. This applies to a number of liquids and gases. According to J. D. van der Waals' theory, the specific heat at constant volume of any unassociated substance would be the same in the liquid and gaseous states of aggregation, but the deduction has not been tested experimentally.

The discontinuity in the atomic heat of metals at their melting point is usually positive, but, according to I. Iitaka, the magnitude is generally smaller than corresponds with the energy of one degree of freedom, *i.e.* 1 cal. In the case of lead and tin, the change is negative. In the case of these metals, therefore, it seems very probable that the molecules are not free to rotate during melting, or at least that the rotation of the molecules in the liquid state does not increase with the rise of temperature, *i.e.* these metals are to be considered as monatomic, even in the liquid state.

The difference in the specific heats of liquid and solid may not be solely determined by differences in the states of aggregation, because during the transition, the molecules may become more or less complex. This is known to be very probably the case with water. Variations in the complexity of the molecules of an element in one state of aggregation may determine differences in the atomic heats. Thus H. V. Regnault (1866)[11] found the specific heat of amorphous carbon to be 0·2609; graphitic carbon, 0·2000; and the diamond, 0·1470. R. Bunsen also found the specific heat of ordinary tin to be 0·0559 and of allotropic tin, 0·0545. No difference was observed between the specific heats of aragonite and calcite. According to F. Richarz (1893), with carbon, silicon, boron, phosphorus, sulphur, arsenic, selenium, tellurium, and tin, **the allotropic modification of an element with the smaller specific gravity has the larger specific heat—Richarz's rule**; otherwise expressed, the modification with the smaller atomic volume has the smaller specific heat. Illustrations in support of this rule are indicated in Table XXI.

TABLE XXI.—EFFECT OF SPECIFIC GRAVITY ON SPECIFIC HEAT.

Element.	Specific gravity.	Specific heat.
Carbon (diamond)	3·52	0·113 (10°)
Carbon (graphite)	2·25	0·160 (10°)
Carbon (retort)	1·89	0·204 (68°)
Boron (crystalline)	2·49	0·165 (21°)
Boron (amorphous)	2·45	0·307 (100°)
Phosphorus (red)	3·30	0·183 (51°)
Phosphorus (yellow)	1·83	0·202 (36°)
Arsenic (grey)	5·87	0·082 (100°)
Arsenic (black)	4·78	0·086 (100°)
Sulphur (rhombic)	2·06	0·173 (54°)
Sulphur (monoclinic)	1·96	0·181 (52°)
Sulphur (amorphous insoluble)	1·89	0·190 (53°)
Sulphur (amorphous soluble)	1·86	0·248 (50°)
Selenium (crystalline)	4·80	0·084 (62°)
Selenium (amorphous)	4·30	0·113 (57°)
Tellurium (crystalline)	6·30	0·048 (100°)
Tellurium (amorphous)	6·00	0·053 (100°)
Tin (white)	7·30	0·054 (21°)
Tin (grey)	5·85	0·059 (18°)

O. Richter (1913) found F. Richarz's rule applicable to binary alloys of lead and bismuth, and bismuth and tin, excepting for alloys in the vicinity of BiPb, where it is assumed the formation of the compound BiPb renders the rule inapplicable. Similar differences have been noticed with the specific heats of metals in different physical conditions—*e.g.* according to H. V. Regnault (1843), the specific heat of hard tempered steel is 0·1175, and of soft tempered steel, 0·1165; while hard bronze has a specific heat 0·0858, soft bronze has a specific heat 0·0862. Consequently, it must be inferred that the heat does important work other than merely raising the kinetic energy or temperature of the molecules; and it therefore appears strange that the relation pointed out by Dulong and Petit does not exhibit greater divergencies.

The rectification of atomic weights by Dulong and Petit's rule : $Cw = 6{\cdot}0$ to $6{\cdot}4$, where w denotes the atomic weight of the element. It will be obvious that if the specific heat of an element be known, it is possible to compute an approximate value for the atomic weight. The number so obtained may be useful in deciding between two numbers which are multiples of a common factor. The method is obviously only applicable to elements whose specific heat can be determined. In view of the variation of specific heats with temperature, the usual application of this law to the rectification of atomic weights "is a rough empirical rule, which, setting aside silicon, boron, beryllium, and carbon, is only available when the specific heats have been determined at temperatures, usually and most conveniently, between 0° and 100°." The specific heat method of fixing the atomic weights is not so much used as formerly, because so many other methods which are more exact are available.

EXAMPLES.—(1) What is the atomic weight of silver assuming that the specific heat is 0·0559? Here, $6{\cdot}0 \div 0{\cdot}0559 = 108$ nearly. This is close to the accepted value for the atomic weight of this element.

(2) Platinum chloride, on analysis, furnished 35·5 grams of chlorine per 48·6 grams of platinum. The specific heat of platinum is 0·0324, and the atomic weight is approximately $6{\cdot}0 \div 0{\cdot}0324 = 197$ nearly. Hence, since $197{\cdot}5 \div 48{\cdot}6 = 4$ nearly, it follows that if the atomic weight of chlorine is 35·5, the atomic weight of platinum must be nearly $48{\cdot}6 \times 4 = 194$.

(3) When indium was first discovered, the analysis of its chloride furnished indium, 37·8; chlorine, 35·5. The equivalent of indium is therefore 37·8. The formula of the

chlorine was thought to be $InCl_2$, and the atomic weight was accordingly represented 75·6. The specific heat of the metal was found to be 0·057. Hence, $75·6 \times 0·057 = 4·5$. If 75·6 be the correct atomic weight, the product would approximate more closely to 6, and hence it was inferred that 75·6 is not the correct atomic weight of indium; rather does the atomic weight approximate to $6 \div 0·057 = 112$ nearly. If $InCl_3$ be the formula of the chloride, the atomic weight will be $37·8 \times 3 = 113·4$, which is the number usually adopted for the atomic weight of this element.

§ 13. Molecular Heats—Neumann's and Joule's Rules

Es verhalten sich bei chemisch ähnlich zusammengesetzten Stoffen die specifischen Wärmen ungekehrt, wie die stöchiometrischen Quantitäten.—F. E. NEUMANN (1831).

The **molecular heat**, or thermal capacity of the molecules of a substance, is defined as the product of its specific heat and its molecular weight. The molecular weight of but few solids are known, and the simplest formula consistent with the valency of the component elements is provisionally regarded as representing the molecule. In the course of his *Untersuchungen über die specifische Wärme der Mineralien*,[1] in 1831, F. E. Neumann noticed that **the product of the specific heats and the molecular weights of compounds of similar composition is nearly constant—Neumann's rule.** This was confirmed by H. V. Regnault in 1841. Two illustrations of Neumann's rule for molecular heats are indicated in Table XXII.

If *R* represents the symbol of the basic element, with the RO-oxides, the constant is 11·0; with the RO_2-oxides, 14·0; with the RO_3-oxides, 18·8; with the R_2O_3-oxides, 26·9; with the RS-sulphides, 11·9; and 18·1 with the RS_2-sulphides; with the RCl-chlorides, the constant is 12·75; and 18·7 with the RCl_2-chlorides. With the RCO_3-carbonates, the constant is 21·4; and 29·1 with the R_2CO_3-carbonates. With RSO_4-sulphates the constant is 25·4; with the R_2SO_4-sulphates, 32·9; with the RNO_3-nitrates, 24·0; and with the $R(NO_3)_2$-nitrates, 38·2.

TABLE XXII.—MOLECULAR HEATS OF SOLIDS.

Carbonates.	Mol. wt.	Sp. heat.	Mol. heat.	Chloride.	Mol. wt.	Sp. heat.	Mol. heat.
$CaCO_3$	100·09	0·206	20·6	$BaCl_2$	208·29	0·090	18·7
$SrCO_3$	147·62	0·145	21·3	$SrCl_2$	158·54	0·120	19·0
$BaCO_3$	197·37	0·109	21·4	$PbCl_2$	277·02	0·066	18·3
$PbCO_3$	277·02	0·080	21·3	$HgCl_2$	270·92	0·069	19·2

J. P. Joule, in 1844, brought forward some evidence indicating that **the molecular heat of a solid compound is approximately the sum of the atomic heats of the constituent elements—Joule's rule.** Consequently, if M and C_p respectively denote the molecular weight and specific heat of the compound; $m_1, m_2, m_3, \ldots$ the atomic weights of the constituent elements; $c_1, c_2, c_3, \ldots$ the specific heats, and $n_1, n_2, n_3 \ldots$ the number of atoms of the respective elements,

$$\text{Molecular heat, } MC_p = n_1m_1c_1 + n_2m_2c_2 + n_3m_3c_3 + \ldots$$

This rule is sometimes called *Woestyn's rule*, after A. C. Woestyn (1848), and *Kopp's rule*, after H. Kopp (1865), since they each expressed the same idea by saying that **each element has the same atomic heat in compounds as it has in the free state,** so that if $a_1, a_2, a_3, \ldots$ denote the atomic heats of the respective elements,

$$\text{Molecular heat} = n_1a_1 + n_2a_2 + n_3a_3 + \ldots$$

or, if 6·4 be the atomic heat of each element, and the compound contains n atoms, the molecular heat of the compound will be approximately $6·4n$. Otherwise expressed, **the quotient obtained by dividing the molecular heat of a compound by the number of elementary atoms in one molecule is approximately equal to 6·4.** This rule was also favoured by J. J. J. Garnier and S. Cannizzaro; but H. Kopp showed that it is not universally applicable. Hydrogen, nitrogen, oxygen, fluorine, and chlorine give discordant results. There is obviously a difficulty with the carbonates. This may possibly be connected with the difficulty previously found for carbon. In the case of the lighter elements the atomic heats must be taken less than 6·4. Some atomic heats of the elements when in combination have been previously indicated. Further, if the atomic heats of all but one of the elements in a compound be known, the unknown atomic heat can be computed; thus, the atomic heat of chlorine in lead chloride is $\frac{1}{2}(18·3-6·4)=5·95$. A comparison of the results of experiment with calculations based upon Neumann's and Joule's laws is indicated in Table XXIII.

TABLE XXIII.—MOLECULAR HEATS OF SOLIDS.

Compound.	Formula.	Sp. heat.	Mol. weight.	Molecular heat.	
				Observed.	Calculated.
Mercuric chloride	$HgCl_2$	0·0689	270·92	18·67	18
Mercuric iodide	HgI_2	0·0420	253·84	19·06	18
Mercurous chloride	HgCl	0·0520	235·46	12·25	12
Mercurous iodide	HgI	0·0385	326·92	12·91	12

W. A. Tilden found the specific heats of solids show variations with temperature analogous to those exhibited by the elements; but in general, the molecular heat of a compound or alloy did not differ greatly from the sum of the atomic heats of the component at the same temperature. S. Meyer[2] has drawn attention to the fact that the additive law of mixtures is more nearly followed with molecular heats than it is with molecular volumes. A. Winkelmann found the additive law applicable to glasses; H. V. Regnault, R. Durrer, W. Spring, and L. Schüz applied it to alloys; and P. Bachmetjeff and M. Wascharoff, to amalgams. According to W. Spring, the additive rule fails with alloys of tin and lead. M. Trautz found that in the majority of cases the additive rule with the internal atomic heats, $C_v-\frac{3}{2}R$, either holds good exactly, or very approximately. J. J. J. Garnier confirmed the additive rule for hydrated salts on the assumption that the combined water has nearly the same thermal capacity as solid ice, 9·85 cals. per gram-molecule of H_2O. There are many discrepancies, as might be expected, and for the reasons stated in connection with the atomic heats of the elements.

EXAMPLES.—(1) Calculate the specific heat of solid oxygen given the specific heat of potassium chlorate, $KClO_3$, 0·194; and that of potassium chloride, 0·171. Here the molecular heat of potassium chlorate (molecular weight × specific heat) is 25·7; and of potassium chloride, 12·8. The difference $25·7-12·8=12·9$ represents the molecular heat of O_3, hence the atomic heat of oxygen will be $\frac{1}{3}$ of $12·9=4·3$. By definition, atomic weight × specific heat of solid = atomic heat of solid = 4·3. Hence, the specific heat of solid oxygen will be $4·3\div16=0·27$.

(2) The specific heat of silver chloride is 0·0911 and that of silver, 0·057: assuming the atomic weight of silver to be 107·9, what is the specific heat of solid chlorine? The molecular heat of silver chloride is 13·1, and the atomic heat of silver is 6·2. The difference $13·1-6·2=6·9$ represents the atomic heat of solid chlorine. The specific heat of solid chlorine is therefore $6·9\div107·9=0·064$.

The molecular heats can be employed to rectify the atomic weights of elements which do not form volatile compounds. Thus, the analyses of mercurous and mercuric salts indicate that the atomic weight of mercury may be 100, 200, . . . If the atomic weight be 100, the formula of mercurous chloride will be Hg_2Cl, and of mercuric chloride, HgCl; while if the atomic weight be 200, the formulæ will be those indicated in the above table. There are some discrepancies as is illustrated by the fact that E. Donath (1788) deduced the value 120 for the atomic weight of uranium from the specific heat of uranoso-uranic oxide, where C. Zimmermann's value (1881), from the observed specific heat of the metal, was twice E. Donath's value—viz. 240.

EXAMPLES.—(1) The analysis of barium chloride furnishes 35·5 parts of chlorine per 68·7 parts of barium. The specific heat of barium is 0·0465. What is the atomic weight of barium, when the atomic weight of chlorine is 35·5? The formula of barium chloride may be written Ba_xCl, where x is to be determined. The atomic weight of barium, by Dulong and Petit's rule, will be of the order $6·4\div0·0465=137$. Taking 35·5 as the atomic weight of chlorine, the fraction x must be of the order $68·7\div137=\frac{1}{2}$. Hence the formula of barium chloride is $Ba_{\frac{1}{2}}Cl$, that is, $BaCl_2$, or some multiple of this. Hence the atomic weight of barium (chlorine, 35·5) must be $2\times68·7=137·4$.

(2) The percentage composition of platinum chloride is: Platinum, 57·7; chlorine, 42·3. The specific heat of platinum is 0·0324. What is the atomic weight of platinum? Hint, see (2) in the last but one set of examples. The ratio of the constituent elements is as 48·6 : 35·5; the atomic weight is of the order 197·5; the ratio x is nearly $\frac{1}{4}$; and hence the formula of the chloride is $PtCl_4$ or some multiple of this. Hence, assuming the atomic weight of chlorine is 35·5, the atomic weight of platinum will be $4\times48·6=194·4$.

§ 14. The Meaning of Dulong and Petit's Rule

The fact that the atomic heats of all elements are approximately the same, led Dulong and Petit to infer that **the thermal capacity of all atoms is the same.** This means that every atom of a solid—no matter of what kind—requires the same amount of heat to raise its temperature 1°. J. P. Joule's rule means that **each elementary atom retains the same capacity for heat when it is combined as it had when free.** The number and kind of other atoms present and their mode of combination seem to have no influence on the numerical value of this property. The observations of Neumann and Joule indicate that **the constituent atoms of a solid compound behave as if the solid were a mechanical mixture of its component atoms, and each atom were free to vibrate independently of the others.**[1]

According to the kinetic theory, temperature is proportional to the kinetic energy of the molecules; and consequently, Dulong and Petit's rule points to a similar relation. It must be added that we can form no real conception of the "temperature of an atom" or of the "temperature of a molecule." All our conceptions of temperature are based on the properties of atoms and of molecules *en masse*. R. Clausius [2] supposes the specific heat of an element to be made up of two magnitudes (i) the heat c_v required to raise the kinetic energy of the molecules; and (ii) the heat ϵ required to perform internal work. Clausius calls c_v the true specific heat of the solid. Hence if M be the atomic weight of an element, the observed atomic heat MC is equal to $M(c_v+\epsilon)$. It is often stated that at the absolute zero of temperature, $-273°$, all atomic motion must cease. This is a mere assertion, of no intrinsic value, and probably wrong. The statement *might* be true of the translatory motion of the molecules—such that R. Clausius' Mc_v is zero —because of the convergence of the specific heats of the elements to zero as the temperature approaches absolute zero. The same fact also shows that the internal work ϵ becomes very small at absolute zero, and the fact that Dulong and Petit's rule is so nearly exact at ordinary temperatures coupled with the assumption that at the same temperature the kinetic energy of the molecules is the same, leads to the inference that when the temperature of elementary solids is raised from absolute zero, the internal work per atom is approximately the same.

W. Jankowsky [3] argued that the heat of a chemical reaction is developed for the most part by the conversion of potential energy into heat, and that at the absolute zero, the energy content of a substance is entirely potential, and that there must be an absolute upper limit or maximum temperature where the energy content of a substance consists entirely of heat.

Among the evidence which indicates that the atoms of a solid even at absolute zero, probably oscillate about a position of equilibrium, the following may be cited: (i) The low coefficient of thermal expansion of solids shows that the volume would be very little changed if the solids were cooled to absolute zero; (ii) it is not probable that solids would lose their compressibility at absolute zero; (iii) the natural frequency of the vibrations of the atoms of a solid calculated by different methods shows no signs of ceasing at absolute zero. (iv) *P. Debye's effect*, in which the intensity of the higher orders of the X-ray spectrum of crystalline solids increases as the temperature of the crystal is lowered, points in the same direction.

L. Boltzmann, in a paper *Ueber die Natur der Gasmoleküle* (1876), has shown that

the kinetic and potential energies of the molecules of a monatomic solid vibrating about a position of equilibrium are equal in magnitude. Consequently, the total energy of a vibrating system—called for convenience an *oscillator*—is shared equally between the average kinetic and potential energies, and is twice the value of either alone.[4]

This interesting result follows by considering the motion of a particle under the influence of a central attractive force moving on an orbit about its position of equilibrium. If the particle were at rest in any part of its orbit, it would tend to move to its centre of attraction, and in so doing, would acquire such a velocity that its kinetic energy would be the same as it possessed when oscillating in its former orbit. Hence, a particle oscillating about a centre of rest possesses both kinetic and potential energy, and on the average, the one is equal to the other, provided that the time average of its kinetic energy is equal to that of the potential energy. This is the case if the potential energy is zero as the particle passes through its position of equilibrium. In reality, the equipartition theorem applies only to the kinetic energy, but if the average kinetic and potential energies are equal, each will make the same contribution to the specific heat.

L. Boltzmann assumed that the atoms of a solid have natural periods of vibration, so that if a monatomic gas be in contact with a solid, the bombardment of the gaseous molecules produces a state of thermal equilibrium when the mean kinetic energy of vibratory motion of the atoms of the solid is equal to the mean kinetic energy of the translatory motions of the molecules of the gas. With a solid, the average kinetic energy of the atoms in each state will be the same; but the average kinetic energy per atom of a monatomic gas is $\frac{3}{2}KT$ per atom, hence, the sum of the kinetic and potential energy of the solid will be $2\times\frac{3}{2}KT$, or $3KT$ per atom; and if there are N atoms in a gram-atom of the solid, the total kinetic and potential energy will be $3NKT$ or $3RT$ per gram-atom, where $NK=R$ is nearly equivalent to two calories per gram-atom per degree. Accordingly, the atomic heat, wC_v, must be $3R=6$ nearly, or with a more exact value of R, 5·95. This interesting argument shows how the atomic heats of the monatomic solids are nearly twice the molecular heats of the monatomic gases; and it furnishes a brilliant deduction of Dulong and Petit's rule for solids.

The agreement between the result of Boltzmann's assumption and Dulong and Petit's observation, shows that the atoms of a monatomic solid probably vibrate so that their energy is equally divided between the kinetic and potential energy. If the oscillations of the atoms are not harmonic in character, the time averages of the kinetic and potential energies will not generally be equal. The agreement in question also shows that the opposing forces—attraction and repulsion—between the atoms just balance one another so that as two atoms approach one another the attractive forces gradually diminish, and the repulsive forces gradually increase until the latter predominate.

The discrepancies between Boltzmann's $3R$ and Dulong and Petit's constant.—There must be a flaw somewhere, because the theory does not explain (i) how the solid elements with a low atomic heat—carbon, silicon, and boron—have normal atomic heats at high enough temperatures; nor (ii) how all solids give abnormally low values at low temperatures. Many attempts have been made to explain the discrepancy between theory and fact. It may be necessary to consider:

(*a*) *The time required for the atoms to adjust themselves to a change of temperature.*—L. Boltzmann assumed that the atoms take a long time to adjust themselves to the temperature—but no corresponding variation of specific heat with temperature has been detected; and the specific heats of solids are so related with the melting points that if the specific heat changed with time, the melting point ought likewise to change. Such a phenomenon has not been observed even in the case of artificial minerals and natural minerals formed æons ago. While the translational energy may be rapidly distributed between the internal motions of a molecule during a collision, yet, if the distribution is slow, so that it becomes appreciable only after millions of collisions, the number of collisions per second is so great—a million occurs in about one-seven-thousandth of a second according to G. J. Stoney—that even when the exchange is slow, a second of time is a comparatively long interval.

(*b*) *The oscillations of the atoms are not harmonic.*—L. Boltzmann assumes that the vibrations of the atoms is harmonic; and this assumption is probably valid for most metals far from their melting points; but if the amplitudes of the vibrations of the atoms are large, oscillations may be no longer harmonic. I. Langmuir[5] has emphasized the fact that if the oscillations of the atoms are not harmonic, the time averages of the kinetic and potential energies will not be equal. The average kinetic and potential energies will be equal, only when the motion is harmonic, in which case, the restoring force acting on the atom is proportional to the displacement from the position of equilibrium. If the restoring force increases more slowly than the displacement, the potential energy will be greater than the kinetic, and from the principle of equipartition, the atomic heat will be greater than $3R$; conversely, if the restoring force increases more rapidly than the displacement, the atomic heat will be less than $3R$. The remarkable closeness of the atomic heats of the elements to the value $3R$, is taken to show that the forces to which the atoms of a solid are subjected vary approximately with the displacement of the atoms from their position of equilibrium.

There must then be both attractive and repulsive forces acting between the atoms. On the average, these opposing forces must just balance each other. As one atom approaches another the repulsive force must *gradually* increase and the attractive force decrease until the repulsive force greatly predominates. We cannot consider that the repulsive forces in solids are exerted only during collisions between atoms, for under these conditions there would be no potential energy and the atomic heat would be $\frac{3}{2}R$.

(*c*) *The congealing of molecules to more rigid systems.*—R. A. Millikan (1912)[6] considers that it may possibly be assumed that as the temperature is reduced, the atoms of the solid are frozen, so to speak, into rigid systems of continually increasing size—where each system is endowed with the kinetic energy of agitation appropriate to its temperature—before absolute zero is attained, it might be possible for the total energy of the whole mass to become that of a single molecule of the surrounding gas. C. Benedicks (1913) has also shown that the equipartition law is avoided by assuming that the solids are not always monatomic, but at low temperature form atomic complexes, which change the number of degrees of freedom. The equipartition law applies only to free atoms. However, from Joule's law, it appears probable that the rule for atomic heats applies to atoms in combination as well as free.

(*d*) Another explanation of the reduction in the atomic heats below $3R$ when the temperature is low was suggested by A. Einstein (1907). It is based on the so-called quantum theory of energy; and has been remarkably successful.

§ 15. The Quantum Theory of Energy and Dulong and Petit's Rule

> An observer who does not allow himself to be led in his work by any hypothesis, however cautious and provisional, renounces beforehand all deeper understanding of his own results.—M. Planck (1914).
>
> An attempt to imagine a universe in which action is atomic leaves the mind in a hopeless state of confusion.—J. H. Jeans (1914).

J. H. Jeans, in his *The Dynamical Theory of Gases* (Cambridge, 1904), shows that Maxwell-Boltzmann's theorem of the equipartition of energy is based upon the assumption that there is no interaction between matter and æther, whereas every ray of light which reaches the eye is evidence against the truth of the assumption. With ordinary diatomic transparent gases two (rotational) degrees of freedom appear to be directly affected by the translational motions during a collision; with the coloured gases there appear to be motions which consume energy in the production of æthereal vibrations. In 1906, M. Planck, in his *Vorlesungen über Theorie der Wärmestrahlung* (Leipzig, 1906), assumed that the interchange of energy between the æther and a vibrating atom is not a continuous process, but takes place *per saltum*—that is, discontinuously—by jumps in definite amounts $h\nu$, where ν represents the *Schwingungszahl* or the frequency of the atomic vibrations, and h is a universal constant in the same sense that e, the unit of electrical change, is a universal constant. The constant h—called **Planck's constant**—seems to be a fundamental unit which regulates and controls the ceaseless ebb and flow of energy in the world of matter. For brevity, write $\epsilon = h\nu$. This means that for any given temperature, a certain amount of energy is associated with the vibrating atom, and that this amount is a function of the vibration-frequency ν of the atom; and energy can be absorbed or emitted by a vibrating system spasmodically, and only in amounts ϵ or in integral multiples of this magnitude such as $\epsilon, 2\epsilon, 3\epsilon, \ldots$, but not in intermediate quantities, say, $\frac{1}{4}\epsilon, \frac{1}{2}\epsilon, \frac{3}{4}\epsilon, \ldots$ This virtually means, said H. Poincaré (1911),[1] that a physical system can exist only in a finite number of states, it leaps from one of these states to another without passing through a continuous series of intermediate states; and, adds M. Planck:[2]

> The continuity of all dynamical effects was formerly taken for granted as the basis of all physical theories and in close correspondence with Aristotle, was condensed in the well-known dogma—*natura non facit saltus*—nature makes no leaps. However, present-day investigation has made a considerable breach even in this venerable stronghold of physical science. This time it is the principle of thermodynamics with which that theorem has been brought into collision by new facts, and unless all signs are misleading, the days of its validity are numbered. Nature does indeed seem to make jumps—and very extraordinary ones.

The ration or unit of energy ϵ is called a **quantum**, and hence this hypothesis is called the **quantum theory of energy.** According to this remarkable hypothesis, the vibrating atoms radiate definite loads $h\nu$ of energy which, for any given vibration frequency, ν, are indivisible. M. Planck inferred that the average energy ϵ possessed by an oscillating unit, with two degrees of freedom,

$$\text{Average energy} = \frac{h\nu}{e^{\frac{h\nu}{kT}}-1}\text{; or, Average energy} = \frac{h\nu}{e^{u}-1} \quad . \quad . \quad (12)$$

per degree of freedom; and three times this value for a monatomic oscillator with three degrees of freedom instead of the average value $3kT$ per atom deduced by an application of Maxwell-Boltzmann's theorem which assumes that the evolution or absorption of energy is a continuous process. Here u is written in place of the fraction $h\nu/kT$.

M. Planck follows the theory of probability in deducing his formula; D. L. Chapman starts from J. H. van't Hoff's well-known expression $Q/RT^2 = (d \log k)/dT$. From the quantum law, if the resonators of vibration period ν are attached to the molecules of a gas, then there will be vibrators possessing amounts of energy 0, $h\nu$, $2h\nu$, . . . , but no vibrators with intermediate amounts of energy. Let the number of vibrators with 0, $h\nu$, $2h\nu$, . . . amounts of energy be respectively $n_0, n_1, n_2, \ldots n_m$. Then, from J. H. van't Hoff's rule, $mh\nu dT/kT^2=d \log (n_m/n_0)$, and by integration between T and ∞, and writing u in place of $h\nu/kT$, it follows that $n_m=n_0e^{-mu}$. Consequently, the mean energy of a vibrator is $(h\nu e^{-u}+2h\nu e^{-2u}+3h\nu e^{-3u}+ \ldots)/(1+e^{-u}+e^{-2u}+ \ldots)$, which, by division, reduces to (30) above. It might also be added that F. R. von Bichowsky[3] has shown that (i) Planck's radiation law, (ii) the quantum theory, and (iii) the equipartition law are not independent, because if any two be assumed the third will follow; and further, S. Ratnowsky has shown that if J. W. Gibb's assumption (that the free energy of a system cannot be generated until the magnitude of the co-ordinates fixing the energy of the system has reached a certain value, and is thereafter given off continuously) be made, Planck's radiation law follows directly without the assumption of the quantum hypothesis. Other attempts to establish a theory of radiation without quanta have been made by M. Brillouin, A. Byk, H. L. Callendar, and R. C. Tolman.

In one modification of the hypothesis, the oscillator is supposed to absorb energy continuously until an amount $h\nu$ has been absorbed, when it has a chance of emitting the whole of this unit. Otherwise, energy will continue being absorbed until it reaches $2h\nu$, $3h\nu$, . . . Only when the amount of energy reaches an exact multiple of $h\nu$ is the oscillator in a condition to emit the whole of its energy.[4]

It is an open question what are the receptacles of energy in a solid. As H. A. Lorentz (1913)[5] has shown, the phenomena of light make it highly probable that energy quanta can have no individual and permanent existence in the æther, and cannot be regarded as accumulations of energy in minute spaces travelling about with the velocity of light. It seems more probable that the energy of solids is localized in the elastic vibrations of the solid, and that the mean energy of an oscillator is equal to the mean energy of an æther vibration of the same frequency. No reason can be assigned why the electric charge e always acts as if it were atomic, or why electrons, each with a fractional charge—say, $\frac{1}{2}e$—do not exist; so also no reason can be assigned why energy can change only by complete quanta.

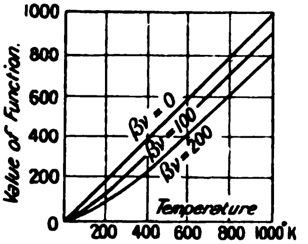

FIG. 9.—Values of the Function $\beta\nu/(e^u-1)$ at Different Temperatures.

In 1907, A. Einstein,[6] in his paper *Die Plancksche Theorie der Strahlung und die Theorie der spezifischen Wärme*, extended Planck's atomic theory of radiation to the radiation of heat. He assumed that the longer heat waves emitted and absorbed by solids are due to vibrations of the constituent atoms about a mean position of rest. A. Einstein further assumed that the energy of the solid does not reside solely in the kinetic energy of the atoms, but the vibration-frequency ν of each atom has three degrees of freedom, and the energy of these vibrations is governed by M. Planck's law, and A. Einstein thus deduced a formula analogous with that of M. Planck:

$$\text{Average energy} = 3R\frac{\beta\nu}{e^u-1} \quad . \quad . \quad . \quad . \quad (13)$$

for the energy of the vibrating atoms of a solid. If $\beta\nu$ is very small, the function is approximately $3RT$, and the expression corresponds with Dulong and Petit's law, which requires the atomic heat of monatomic solids to be proportional to the temperature. For all other values of $\beta\nu$ the function is less than $3RT$. The values of the function are plotted in Fig. 9. At any given temperature, the value of the function differs more and more from the value of T as the value of $\beta\nu$ is increased. Differentiating for dE/dT, the atomic heat, C_v, he obtained:

$$\text{Atomic heat} = 3R\frac{u^2e^u}{(e^u-1)^2} \quad . \quad . \quad . \quad . \quad (14)$$

where u, for convenience, has been written in place of $\beta\nu/T$, and β is written in place of h/k; k is the atomic gas constant represented by R/N, when R is the ordinary gas constant, and N (approximately $6·06\times10^{23}$) denotes the number of atoms per gram-atom. It will be evident that when the fraction $u=\beta\nu/T$ is very large, ν will either be very large, or T very small, and C_v will be virtually zero; and when u is small, $C_v=3R$. For example, if $\beta\nu/T$ be greater than 10, $C_v=3R\times0·004$; and if it be less than unity, C_v will be less than $3R\times0·92$. In the former case, the specific heat approaches unity, and in the latter case, C_v is nearly normal.

The numerical values of the constants *h* and *β*.—Seven different lines of argument [7] show that Planck's constant h, is equivalent to $(6·5543\pm0·0025)\times10^{-27}$ ergs per second, and is the same for all substances. For the yellow D-sodium line with a wave-length $0·5896\mu$, it follows that ν is $3\times10^{10}/0·5896\times10^{-4}$ or $5·088\times10^{14}$, so that $h\nu$ for this radiation is $6·62\times10^{-27}\times5·088\times10^{14}=33·7\times10^{-13}$ ergs per second. The numerical value of β is $4·865\times10^{-11}$.

W. Nernst and F. A. Lindemann (1911) [8] have shown that Einstein's equation is in fair agreement with their observations of specific heats at low temperatures, although discrepancies appear as the temperatures approach absolute zero; and they tried to rectify Einstein's equation by introducing a new term. So that the atomic heat C_v becomes

$$\text{Atomic heat}=\frac{3}{2}R\frac{u^2c^u}{(e^u-1)^2}+\frac{(\frac{1}{2}u)^2e^{\frac{1}{2}u}}{(e^{\frac{1}{2}u}-1)^2}\quad.\quad.\quad.\quad(15)$$

on the assumption that the solid is a mixture of oscillating atoms half of which have the vibration frequency ν and half the frequency $\frac{1}{2}\nu$. M. Planck and A. Einstein assumed that all the oscillating atoms had a frequency ν; and W. Nernst and F. A. Lindemann's assumption is a first approximation to a summation extending over an infinite number of values of ν. W. Nernst and F. A. Lindemann's equation represents the observed atomic heats of solids—aluminium, copper, silver, lead, mercury, zinc, iodine, and the diamond—down to the lowest temperatures. A few numbers selected from Nernst's tables for silver and the diamond are indicated in Table XXIV.

TABLE XXIV.—THE ATOMIC HEATS OF SILVER AND THE DIAMOND AT DIFFERENT TEMPERATURES.

Silver. $\beta\nu=221$.			Diamond. $\beta\nu=1940$.		
Temperatures.	C_p (calc.).	C_p (obs.).	Temperatures.	C_p (calc.).	C_p (obs.).
35·0	1·59	1·58	30	0·00	0·00
53·8	2·98	2·90	92	0·01	0·03
100	4·77	4·86	205	0·62	0·62
200	5·77	5·78	243	0·97	0·95
273	6·02	6·00	306	1·59	1·58
331	6·12	6·01	358	2·08	2·12
535	6·45	6·46	413	2·55	2·66
589	6·57	6·64	1169	5·41	5·45

According to the form of quantum hypothesis now under consideration, oscillating atoms cannot absorb energy unless it comes to them with a certain degree of intensity equal to $h\nu$, or some whole multiple thereof. As the temperature rises, the number of molecules which take up loads of energy from the low intensity heat waves increases rapidly in accord with the equipartition law, and the need for absorbing energy in integral multiples of $h\nu$. Molecules of chlorine and bromine begin to absorb this energy at a lower temperature than the transparent diatomic gases because (i) the bond of union between the respective atoms is weak, and their frequency ν—and consequently also their quantum $h\nu$—is small; hence (ii) the quanta or loads of energy $h\nu$ absorbed by these oscillators are correspondingly small; and (iii) the temperature at which the kinetic energy of the diatomic oscillators attain the value $h\nu$ is correspondingly low. Diatomic hydrogen molecules at a low temperature act like monatomic molecules because the rotatory motions at any given temperature correspond with a definite frequency ν, and when the energy of impact falls below this value of $h\nu$, no energy can go into these rotations, and energy is solely distributed among the three degrees of freedom corresponding with translatory motion.

The quantum hypothesis gives a qualitative explanation: (i) how the atomic heats of the elements approach zero as the temperature falls, and (ii) how abnormally low values appear at a higher temperature with the elements of low atomic weight. From measurements of atomic heats, it seems as if, as the temperature rises, different kinds of atoms can take on their normal load at different stages, the heaviest atoms take it on first, the lighter atoms last. With a given rise of temperature there is a corresponding increase in the vibratory energy of the atoms of an element, and at a sufficiently low temeprature, only a definite fraction of the atoms can take on the normal quota $h\nu$. The higher the vibration frequency ν, the higher the temperature at which energy can be absorbed. Again, other things being equal, with a falling temperature, the greater the vibration frequency ν, the sooner will atomic heats lower than $3R=6$ calories begin to appear.

Observations do not agree with the assumption that at absolute zero the atoms of hydrogen have no latent energy. Consequently, A. Einstein and O. Stern (1913)[9] have examined the hypothesis that the rotating molecules have $\frac{1}{2}h\nu$ units of energy at the absolute zero, and instead of M. Planck's expression (30), they write:

$$\text{Average energy} = \frac{h\nu}{e^u-1} - \frac{h\nu}{2} \quad . \quad . \quad . \quad . \quad (16)$$

The photoelectric effect and the emission of electrons by the action of the X-rays are also in accord with the assumption that the latent energy of the electrons on a metal is $\frac{1}{2}h\nu$ per degree of freedom. The average energy plotted according to the equipartition law, where the average energy $=kT$ per degree of freedom, is shown by the curve I, Fig. 10; according to M. Planck's formula (30), by II, Fig. 10, and according to A. Einstein and O. Stern's formula (35), by III, Fig. 10. The formula for the specific heats of gases at different temperatures derived by differentiating the above formula, agrees well with A. Eucken's observations. It might be added, however, that P. Ehrenfest (1913) obtained almost as good an agreement without their assumption. W. H. Keesom (1913) applied an argument similar to that used by P. Debye, and deduced a formula for the specific heats of gases similar to that obtained for solids. It was found generally that while the rate at which the specific heat (or the energy per degree) decreases to zero as the temperature is lowered, the total energy does not necessarily become zero at absolute zero—rather does there exist at this low temperature a latent energy whose magnitude is $\frac{1}{2}h\nu$.

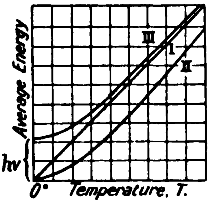

FIG. 10.—The Effect of Temperature on the Energy of Solids.

§ 16. Debye's Theory of Atomic or Specific Heats

The final object of mathematical research is a knowledge of the principles of science. —K. WEIERSTRASS.

In the solution of mathematical problems, the object of which is to represent the progress of nature, we are led by very rapid methods to results which are often overlooked, and which now and then excite our surprise by the paradoxical form in which they are presented; but when guided by simple reasoning, we return step by step over the course which was so quickly bridged by calculation, we end by perceiving the action of the principles which have given birth to these results.—R. J. HAÜY (1822).

In a paper, *Zur Theorie der spezifischen Wärmen*, P. Debye (1912)[1] argued that the whole heat energy of a solid resides in the energy of the vibrations of the constituent atoms, and that each vibration has exactly the energy allotted to it by the quantum theory, and therefore the heat vibrations are the same as light vibrations of identical frequency. He supposes that it is not likely there is only one value for the vibration frequency of an oscillating atom, and that it is more probable that a whole series of values of ν exists. It is, however, necessary to postulate an upper limit to the range of vibration frequencies, and P. Debye assumes that the number of frequencies for N atoms per unit volume cannot exceed $3N$. At the higher temperatures, where each frequency has the same average energy kT—corresponding with both kinetic and potential energy—the total energy will be $3NkT$ corresponding with Dulong and Petit's law. As the temperature is lowered, the average energy with the higher frequencies is less than with the lower frequencies, so that, when the temperature is low enough, only those atoms having vibrations of very low frequency, with $h\nu$ small, can obtain enough energy to vibrate. These low frequencies must correspond with ordinary sound vibrations, and accordingly, P. Debye identifies the thermal oscillations of the atoms with the elastic vibrations of the solid, and he shows that the maximum frequency ν for monatomic solids can be calculated from the elastic constants of the material. P. Debye utilized the quantum hypothesis and deduced an expression for the average energy of the individual frequencies:

$$\text{Atomic energy}=9R\int_0^{\frac{x}{T}} T\left(\frac{T}{x}\right)\frac{u^3du}{e^u-1}$$

By differentiating this expression for the atomic heat, C_v at constant volume, he obtained the

$$\text{Atomic heat}=3R\left\{12\left(\frac{T}{x}\right)^3\int_0^{\frac{x}{T}}\frac{u^3du}{e^u-1}-\frac{3\frac{x}{T}}{e^{\frac{x}{T}}-1}\right\}\quad . \quad . \quad (17)$$

where u is put in place of $h\nu/kT$, and x in place of $\beta\nu=h\nu/k$, so that $x/T=u$. P. Debye called x the *characteristic temperature* of the particular solid, or it can be called **Debye's constant.** Debye shows how the numerical value of x can be calculated from the elastic constants of the solid. This equation is taken to mean that **the atomic heat of a monatomic solid is a function of the ratio x/T, where x is a characteristic temperature for each substance, and is dependent upon its density and elastic constants.** The above expression cannot be integrated, but P. Debye has shown that it can be reduced to W. Nernst and F. A. Lindemann's formula by a series of approximations. At very high temperatures, when the value of x becomes very small, and the value of T/x is large, the value of the expression in brackets approximates to unity; and the atomic heat reduces to $3R$. P. Debye's equation is more complicated than the empirical relation of W. Nernst and F. A. Lindemann, but the latter is a good approximation to P. Debye's at low temperatures. For low values of T/x, P. Debye's constant x is large, and the atomic heat C_v then approximates to

$$\text{Atomic heat}=3R\times 77{\cdot}94\left(\frac{T}{x}\right)^3 \quad . \quad . \quad . \quad . \quad (18)$$

meaning that **at sufficiently low temperatures, the atomic heat varies as the third power of the absolute temperature**; or by integration, the total energy of monatomic solids near absolute zero is proportional to the fourth power of the absolute temperature. This agrees with the radiation law deduced by J. Stefan in 1879, and somewhat later by L. Boltzmann. These investigators showed that the total energy radiated by a black body is $5{\cdot}7\times10^{-5}(T^4-T_0{}^4)$ ergs per sq. cm. per second, when T represents the absolute temperature of the radiator and T_0 the absolute temperature of the body receiving the radiation.

Working from A. Einstein's (1911) relation between the elastic constants of a solid and the vibration-frequency of its atoms, P. Debye (1913) has shown that the characteristic temperature x can be calculated from the formula

$$x=35{\cdot}74\times10^{-4}w^{-\frac{1}{3}}D^{-\frac{1}{6}}\kappa^{-\frac{1}{2}}F^{-\frac{1}{3}} \quad . \quad . \quad . \quad . \quad (19)$$

where κ is the compressibility coefficient; D, the density; w, the atomic weight; and F is a function of the coefficient of linear expansion a such that

$$F=2\left(\frac{2(1+a)}{3(1-2a)}\right)^{\frac{3}{2}}+\left(\frac{1+a}{3(1-a)}\right)^{\frac{3}{2}} \quad . \quad . \quad . \quad . \quad (20)$$

Some data given by P. Debye are indicated in Table XXV. E. H. and E. Griffiths [2] found P. Debye's formula to be more accurate than any other existing

expression for reproducing their observations of the specific heats between −165° and atm. temperatures, although here, systematic divergences occur at the higher temperatures. In general, observations of the specific heats of various metals at low temperatures agree remarkably well with the values computed from Debye's formula, even though the elastic constants for evaluating $\beta\nu$ have been determined at room temperatures. According to W. H. Keesom and H. K. Onnes (1914), the specific heat of copper is 0·0396 at —258·49°; 0·1155 at —252·89°; 0·2340 at —246·63°; and 0·8700 at —232·78°, and therefore decreases more rapidly on a falling temperature than it should do according to P. Debye's third-power law.

The curve for aluminium calculated from P. Debye's formula is indicated in the diagram, Fig. 11, where the circles represent the observed specific heats. A. Eucken and F. Schwers (1913) found that Debye's third-power law holds very well for the minerals fluorspar and pyrite from about —260° to about 187°. The application of the quantum theory to the explanation of low temperature specific heats by A. Einstein and by W. Nernst and F. A. Lindemann can be regarded as preparatory to that of P. Debye. H. von Jüptner and E. Rasch[3] have suggested simpler formulæ for the change in the specific heats of solids with temperature which gave very good results, but they have no known theoretical foundation. J. H. Jeans (1914) considers that both from its complete naturalness and from its agreement with experiment, P. Debye's treatment of the specific heats of solids seems destined to be final.

Various attempts have been made to improve Debye's theory. For example, M. Born and T. von Kármán (1912), and H. Thirring (1913),[4] assume that the atoms are arranged in the solid like a space-lattice. There are probably motions of the atoms or molecules other than vibratory and translatory movements which contribute something to the specific heat. For instance, (i) the subatomic electrons may have their energy increased when a gas is raised to a high temperature, but, if so, the increment is too small to have any appreciable effect on the specific heat of a monatomic gas. A. Eucken (1914)[5] found that the value of C_v for helium is virtually constant between temperatures ranging from —256° to 2350°. Again, (ii) the molecules may have rotational movements. The rotation of atoms is illustrated by the movement of the optical axes of a crystal as a whole when the crystal is rotated in the hand. The agreement between theory and observation when the electronic and rotary movements are neglected shows that they are too small to have an appreciable influence on the specific heat—unless perchance the specific heats are determined near the melting points of the solids. J. H. Jeans (1914) considers that this is due to the circumstances that the forces opposing the rotational movements of the atoms inside the solid are so large that the corresponding vibrations are of high frequency, and so normally possess but little energy. A. E. Oxley (1914) observed that the specific heats of sodium and mercury near the melting points are in excess of the theoretical values; and E. Grüneisen (1913) argues that the forces which prevent the atoms rotating are relaxed, and then an additional term—similar to Einstein's (35)—should be added to the theoretical specific heat formula to allow for vibrations which depend upon the rotations of the atoms.

§ 17. The Kinetic Theory of Solids

> We must infer that constituent parts of all bodies are in perpetual motion.—R. WATSON (1789).
>
> Nature gives no evidence of absolute rest. All matter, so far as we can ascertain, is ever in motion, not merely in masses, as with planetary spheres, but also molecularly throughout its most intimate structure.—W. R. GROVE.

Many phenomena commonly associated with liquids and gases—vaporization, crystallization, dissolution, diffusion, chemical action, etc.—are also manifested by solids under the right conditions of temperature and pressure. The solid state is not a condition of molecular inactivity and rest. The reason why the phenomena which indicate molecular activity in solids are so often overlooked, is due to the fact that these changes are usually very slow. In solids, the translatory motion of the particles must be very greatly hampered by adjacent molecules; and, except possibly in the case of amorphous solids, it is highly probable that the forces of cohesion cause the molecules in the solid to oscillate about a fixed position of equilibrium so that their movements are restricted; and it is doubtful if the molecules change their locality in the same sense that the molecules of liquid and gases are continually moving from one part of the mass to another.

When a liquid is cooled below its freezing temperature, a certain amount of heat is evolved—latent heat of fusion—as the liquid solidifies. The solidification of a liquid must therefore be attended by a reduction in the mean kinetic energy of the molecules; and the intermolecular attractive forces then probably restrict the migrations of the molecules to oscillatory or vibratory motions about their positions of equilibrium. The low compressibility of solids, and the comparatively slow rate at which one solid diffuses into another, show that the molecules of a solid have a comparatively *low* mobility. One molecule can get away from contact with another molecule only very very slowly, if at all. Solid diffusion, however, seems to be confined to those systems in which solid solutions can be formed; raising the temperature or subjecting the system to a uniform pressure also appears to augment the speed of diffusion.[1]

The fact that many solids evaporate or sublime very slowly, shows that their molecules probably do possess a certain mobility. Thus, zinc at 370°, though still a solid, volatilizes to such an extent that a clean copper plate placed just above appears on the under side to have been coated with brass. The fact that most solids retain their shape for indefinitely long periods, unless prevented by chemical, mechanical, or physical actions, shows that the molecules of solids have a very *limited* mobility—*e.g.* some ancient jewellery appears to be the same now as when first engraved. On the other hand, a mass of pitch may be so brittle as to be readily fractured by a blow, and yet, when placed on an inclined plane, it gradually loses its shape, and, following the solicitations of gravity, begins to flow (not slide) downwards; similarly, a long glass tube or rod supported at both ends, gradually sags in the middle. The substances, glass and pitch, are therefore regarded as extremely viscous liquids. Accordingly, it is not possible to draw a sharp line of demarcation between amorphous solids and liquids.

The term **solid** is therefore ambiguous in that it has at least two meanings. Amorphous solids are frequently harder and more brittle than the same substance in the crystalline condition, and yet the amorphous state is indistinguishable from the liquid state; while a liquid can be readily distinguished from a crystalline solid, it is sometimes said that all true solids are in a crystalline state, and that amorphous solids are super-cooled liquids. This view is discussed in G. Tammann's *Kristallisieren und Schmelzen* (Leipzig, 1903). From his investigation of the structure of the co-called amorphous solids, R. Gross infers that there are probably no true amorphous solids, only crystals and liquids with varying degrees of viscosity up to the high viscosity of glasses.

The stress and strain of solids.—Many properties of solids—*e.g.* tenacity, hardness, etc.—depend on intermolecular forces and also on the grouping of the particles. In general, the particles are in stable molecular equilibrium because, like the so-called conservative system, they tend to restore any work done upon them. For instance, any displacement of the particles within the limits of elasticity produces a counter or restitutional pressure equal and opposite to the distorting stress. The effect of cohesion or the attraction of the particles of a solid for one another must also be attributed to the same molecular forces; and the cohesive forces are measured by the amount of force which must be applied in order to overcome them.

The term *stress* is applied to a force or system of forces which acts upon a body or system of bodies producing an alteration of form. The change or alteration in form which is produced by the application of a stress is called a *strain*, the magnitude of the stress is usually referred to unit area of surface across which it acts. For instance, if a bar of metal of n sq. cm. sectional area and fixed at one of its ends, sustains a load of w kilograms, uniformly distributed, the *longitudinal stress* is w/n kilograms per sq. cm.; and if a portion of the bar increases in length from 100 to 100·01 cm., and the increase be uniformly distributed over the portion lengthened, the *longitudinal strain* will be (100·01–100)/100=0·0001 cm. per sq. cm.

According to R. Hooke,[3] 1676, *ut tensio sic vis*—**strain is proportional to stress**—a relation known as **Hooke's law**. Consequently, the strain will be k times the stress, where k is a constant. The observed relations between the two variables indicate that when the stress is a compression, the curve showing the corresponding change of volume, Fig. 12, does not approach the strain-axis so rapidly as when the stress is a tension. Hence, the intensity of the force resisting compressive strains decreases more rapidly than is the case with the force resisting tensile or dilative strains.

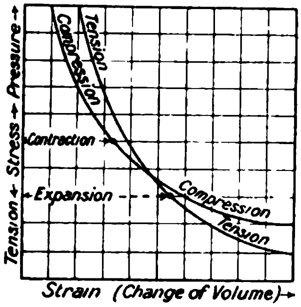

FIG. 12.—Hooke's Law.

If a body subjected to a stress experience no strain, it would, if it existed, be called a *perfectly rigid body*. There are no such bodies.[4] Consequently, every solid can sustain stress or transmit force only by suffering strain. A body is said to be *perfectly elastic* if, when subjected to a given stress at a given temperature, it experiences a definite strain which does not increase when the stress is prolonged, and which disappears completely when the stress is removed. If the form of the body be permanently altered when the stress exceeds a certain value, the body is said to be *soft* or *plastic*, and the state of the body when the (permanent) alteration is just going to take place, is called the *limit of perfect elasticity*. According to the British Standard Specification,

> The **elastic limit** is the point at which the extensions cease to be proportional to the loads. In a stress-strain diagram plotted to a large scale it is the point where the diagram ceases to be a straight line, and becomes curved. The **yield point** is the point where the extension of the bar increases without increase of load. In practice, the yield point is the load per sq. in. at which a distinctly visible increase occurs in the distance between the gauge points on the test-piece, observed by using dividers; or at which when the load is increased at a moderately fast rate there is a distinct drop of the testing machine lever, or in hydraulic machines, of the gauge finder.

If the stress, when it is maintained constant, causes a strain which increases with time, the substance is said to possess *viscosity* or to be *viscous*. According to J. C. Maxwell, a viscous material is fluid when any stress, however small, produces a constantly increasing strain , and he draws a distinction between elasticity of bulk and elasticity of shape. The latter is peculiar to solids. A body possesses elasticity of bulk or **volume elasticity,** when, on removal of the stress, it returns to its original volume, even though the form of the surface be permanently altered. Under a compressive stress, the elasticity of bulk may far exceed the elasticity of shape. According to Lord Kelvin [5]

> If we reckon by the amount of pressure, there is probably no limit to the elasticity of bulk in the direction of the increase of pressure for any solid or fluid , but whether continued augmentation produces continued diminution of bulk towards zero without limit, or whether for any or every solid or fluid, there is a limit towards which it may be reduced in bulk, but smaller than which no degree of pressure, however great, can condense it, is a question which cannot be answered in the present state of science.

The volume elasticity is also called the *cubic elasticity* or *bulk modulus*, or the *resistance to compression*, and it is represented in dynes per sq. cm.

> If other units are employed it is convenient to remember that a *megabar* is equivalent to 10^6 dynes per sq cm , or to 0 987 atm , or to 750 15 mm. of mercury at 0°, sea level, and latitude 45°. One gram per sq. cm. is equivalent to 981 dynes per sq cm

When a uniform pressure of dp dynes per sq. cm reduces the volume v of a body to $v-dv$ the **compressibility** is measured by the fractional change of volume dv/v per dyne of applied pressure per sq cm. The volume elasticity is the reciprocal of the compressibility. Hence

$$\text{Compressibility, } \beta=-\frac{\frac{dv}{v}}{dp};\quad \text{or, } \beta=-\frac{1}{v}\cdot\frac{dv}{dp}.\qquad \text{Volume elasticity } \frac{1}{\beta}=\frac{dp}{\frac{dv}{v}};\ \text{or, } \frac{1}{\beta}=-v\frac{dp}{dv}$$

where the negative sign indicates that the volume decreases as the pressure increases. The volume elasticity is therefore the quotient of a given stress p, by the strain it produces. For example, if a liquid contracts 50 millionths of its volume when subjected to a pressure of 1000 dynes per sq. cm. the modulus of elasticity is 2×10^7 dynes per sq. cm. The compressibility measures the sensitiveness of a body to changes of pressure under the specified conditions. These results apply to gases, liquids, and solids. The temperature is supposed to be constant, and the result is called the **isothermal elasticity** of the gas. If the operation be conducted adiabatically, $pv^\gamma=$a constant, and by differentiation and rearrangement of terms, $vdp/dv=\gamma p$. Hence, the **adiabatic elasticity** of a gas is γ times the pressure, where γ denotes the ratio of the two specific heats of the gas. Similarly, by differentiation of Boyle's law, $pv=$a constant, when the temperature is constant, $vdp/dv=p$. Hence, the ratio of the adiabatic and isothermal elasticities of a gas is equal to the ratio of the two specific heats of the gas.

If a solid bar, supposed perfectly elastic, be exposed to *longitudinal stress*, the ratio of the stress to strain or the *longitudinal elasticity* or the *coefficient of resistance to extension*, is called **Young's Modulus** [6]—symbolized E. The longitudinal elasticity or Young's modulus is represented in dynes per sq. cm. This constant is sometimes referred to as the *modulus of elasticity*, though this term is liable to confusion there are so many kinds of elasticity. If a wire of a sq. cm cross-sectional area be stretched by a force of F dynes, and its length changes from l to $l+dl$, Young's modulus is $lF/a\,dl$. If Young's modulus for a bar of the given material be independent of the direction in which the axis of the bar is taken, the material is said to be *isotropic*, all other materials are said to be *æolotropic*. If a bar be exposed to simple longitudinal traction, the ratio of the lateral contraction to the longitudinal extension of an isotropic elastic solid—each measured per unit of length—is called **Poisson's ratio,**[7] and symbolized σ. Thus, if the diameter of a bar under a uniform longitudinal stress changes from 10 to 9 9997 cm , the lateral contraction is 0 0003 cm , and if the longitudinal strain be 0 0001 cm , Poisson's ratio will be 0·3.

A *shear* is a particular kind of strain in which there is an extension in one direction combined with an equal compression in a perpendicular direction, as when a sphere is converted into an ellipsoid, or a square into a rhombus. The shear is measured by the tangential stress required to produce unit shear, *i e* a shear of one radian, θ, or 57 3°. The *resistance to transverse distortion*, the so-called **rigidity,** n, is therefore $n=F/\theta$ The rigidity, or *shear modulus*, is expressed in dynes per cm , for example, if a tangential stress of 10^8 dynes per sq cm deflects a steel rod through an angle of 0 7°, then $F=10^8$, and $\theta=0\ 7/57\ 3=0\ 0122$ radians ; and $n=F/\theta$, or the rigidity is $8\ 2\times10^{11}$ dynes per sq. cm. This magnitude is sometimes called the *modulus of torsion*, but this term is also applied to another concept, and is best not employed for rigidity.

The relation between the elastic constants are as follows. If β be used to denote the coefficient of compressibility ; E, Young's modulus, or the longitudinal elasticity ; n, the rigidity ; and σ, Poisson's ratio, the relations [8] between these constants for a homogeneous isotropic substance are $E=2n(1+\sigma)$; and $\beta E=3(1-2\sigma)$.

Assuming that the molecules of the different metals show a similarity in behaviour in passing from the rigidity of rest at absolute zero, to the vanishing point of rigidity at the melting point, W. Sutherland [9] found empirically that the relation between rigidity and temperature can be represented by the simple parabolic formula :

$$\frac{n}{N}=1-\left(\frac{\theta}{T}\right)^2$$

where n denotes the rigidity at the absolute temperature θ° ; N is a constant supposed to represent the rigidity at absolute zero ; and T is the absolute melting temperature of the metal. The following values of $10^{-6}N$, that is, 10^{-6} times the rigidity at absolute zero, were calculated from the observed values of n at θ° :

Cu	Ag	Au	Mg	Zn	Al	Sn	Pb	Fe	Ni	Pt
452	295	284	164	426	264	200	118	771	781	661

By plotting n/N as ordinates and θ/T as abscissæ from zero to unity in each case, a parabolic curve is obtained on which the values for the different metals fall. This result establishes the relation between the rigidity of the metals and their melting points, and according to W. Sutherland shows that " rigidity is in its essence a kinetic phenomenon almost as simple in character as the elasticity of perfect gases."

The older writers distinguished between *cohesion*—the mutual attraction of particles of the same substance—and *adhesion*—the mutual attraction of particles of different substances—but there is nothing to show that there is any distinction in kind between the two phenomena.

It is the custom to explain the cohesion of solids as an effect of intermolecular attraction. The laws of gravitational attraction explain the movements of planets at great distances, and a similar law for molecular distances served P. S. de Laplace to explain the surface tension and capillary action of liquids. Many attempts have been made to correlate the elastic constants with molecular attraction. There are difficulties in the application of the gravitational law of inverse squares to solids.

According to R. A. Fessenden's hypothesis cohesion is primarily due to the ionic charges of electricity. The magnitude of the electrical attraction can be calculated from the magnitude of the charges on the atoms, and the number of atoms per c.c. Measurements of the electro-chemical equivalent of silver show that the atoms in one c.c. of silver have a total ionic charge of about 1000 coulombs. The diameter of the silver atom approximates 10^{-4} cm. and there are about 10^{24} atoms per c.c. Consequently, the total quantity of electricity on a single atom is about 10^{-24} coulombs, or, on a single layer of atoms, 10^{-8} coulombs per sq. cm. Two adjacent layers of atoms may be regarded as two plates of a condenser 10^{-8} cm. apart and charged with 10^{-4} coulombs of electricity. Assuming the charges to act as if concentrated at the centres of the atoms, the force required to separate the two layers will be 44×10^5 dynes. According to G. Wertheim, the tensile strength of silver is 37×10^5 dynes per sq. cm., a number in fair agreement with the calculated in view of the approximations made concerning the size of the atoms.

The metals with the smallest atomic volumes usually have the greatest tensile strength. It follows that if the atoms in one rod are twice the diameter of those in another rod, and if the charges behave as if located at the centres of the atoms, then since the charge on each atom is the same, and the smaller atoms are as close again as the larger atoms, twice as much work will be required to shear the rod made of the smaller atoms through a certain angle as with the rod with the larger atoms ; there will also be twice as many atoms in the smaller rod to be sheared ; consequently, the force required to produce a given shear, *i.e.* the rigidity of the rod will vary inversely as the fourth power of the atomic diameter, or as the four-thirds power of the atomic volume.

The rigidity and Young's modulus vary with temperature, and therefore these properties can be compared only when the metals are in corresponding states.

R. A. Fessenden found empirically that Young's modulus and rigidity are approximately two-thirds the atomic volume, so that the rigidity and Young's modulus vary inversely as the square of the atomic volumes. The relation between atomic volume v and rigidity was pointed out by G. Wertheim; R. A. Fessenden plots the two curves: Rigidity, $n=28\times10^{12}v^{-2}$; and Young's modulus, $E=78\times10^{12}v^{-2}$, and found the observed values for a number of metals fall close to the values so calculated. If the attractive force between the atoms with the same charge varies inversely as the square of the distance, the attraction of the smaller atoms in a given rod will be 2^2 times as great per atom as with the larger atoms. There will also be 2^2 times as many atoms. Hence the tenacity will also vary as the four-third power of the atomic volume. Assuming the change of the tensile strength with temperature is proportional to the melting point $T°$ measured from absolute zero, R. A. Fessenden gives: Tensile strength$=0\cdot5208Tv=\frac{4}{3}$ kilograms; and, comparing the calculated results with G. Wertheim's observations, he finds that—

	Fe	Cu	Pt	Ag	Au	Al	Zn	Sn	Pb
Calc. . . .	74	48	48	29	29	18	16	5	4
Obs. . . .	65	41	35	29·6	28·5	18	15·7	3·4	2·36

W. C. Roberts-Austen has shown that the addition of a metal of small atomic volume to one of large atomic volume will increase the tensile strength of the latter provided chemical combination does not supervene.

Several have assumed that the cube root of the molecular or atomic volume v of a metallic element is proportional to the average distance r between adjacent atoms. For example, G. Wertheim[10] showed that the longitudinal elasticity, E, increases as the magnitude r decreases; and H. Tomlinson further showed that for a number of metals, the product E (grams per sq. cm.) into r^7 approximates to a constant, 1711×10^8. Hence, H. Tomlinson assumed that the modulus of longitudinal elasticity varies inversely as the seventh power of the average distance between the atoms; that is, as the seven-thirds power of the atomic volume.

If the intermolecular attraction diminishes rapidly as the molecules move apart, the more a solid is strained by a tensile stress, the less should be the force required to maintain that strain. This is in direct opposition to the observed facts. Similarly with a compressive stress: the greater the strain, the less should be the compressive strength required to maintain that strain. This also does not agree with observation. The molecules of a solid under no stress are presumably in a state of equilibrium but still rotating or oscillating about definite mean positions from which they do not depart except when constrained to do so by the application of an external force which is greater than the force or forces which determine the position of equilibrium of the vibrating molecules. A disturbance of that condition by compression appears to be opposed by *repulsion* as a restoring force. This is shown by the *elastic compressibility* of solids and liquids. By compression, the particles of a solid or liquid can be brought closer together, and the mutual repulsive forces, when developed, result in the storage of energy in the strained body which makes the particles return to their former position when the pressure is relieved. Similarly with *elastic tension*, where the separated molecules are drawn together by attraction as a restoring force when the tension is released.

The fact that a solid resists both compression and dilation, is usually taken to demonstrate the existence of an intermolecular force which changes from a repulsion at small distances to an attraction at greater distances. This means that the intermolecular force either changes instantaneously from attraction to repulsion and *vice versâ*, or else there is a neutral zone in which some or all the molecules of a solid exhibits no cohesion when a solid gradually passes from a state of compression to a state of tension. There is no evidence of such a state of neutrality. The invention of an intermolecular force which changes abruptly from attraction to repulsion is not very satisfactory. The identification of the repulsive forces with the thermal oscillations of the molecules or the resilience which attends molecular impacts,[11] leads to the assumption that the thermal oscillations do not cease at absolute zero since the elasticity at that temperature is not markedly different from what it is at ordinary temperatures.

The assumption that the attractive and repulsive forces are independent of one another is fairly old, and it was developed by G. Mie and E. Grüneisen [12] on the assumption that both forces are inversely proportional to some power of the distances of the molecules apart.

The molecules of a solid may conceivably possess axes along which the attractive forces are particularly active. In gases and liquids the molecules are in constant rotation, and the haphazard translatory motions as well as the distances between the centres is so great that the directional forces are inappreciable; but in crystals directed forces predominate. The orderly configuration of the molecules in a crystalline solid shows that the intermolecular forces are *directed forces.*

There is nothing incompatible with a law of intermolecular attraction which refers the elastic strength of a solid in tension or compression to the increasing resistance which a given configuration of the molecules offers to deformation. Under the influence of a gradually increasing compressive stress, the deformation of the molecular configuration continually increases as the particles are forced closer together, but at a certain point, allotropic or chemical change may occur so that the atoms rearrange themselves to form new molecules. This is shown very well by P. W. Bridgman and G. Tammann's experiments on the effects of pressure on single and mixed solids. When the deformation becomes too great, a form stable under the new conditions replaces the former configuration. J. C. Maxwell,[13] in an essay on the *Constitution of Bodies,* considers that the molecules of a solid oscillate about mean positions so that with certain groups of molecules, the configuration is never very different from the mean stable positions about which the oscillations occur. This will be the case even if the solid be in a state of strain provided the amplitude of the oscillations does not exceed a certain limit; if it exceeds this limit, the oscillating molecules do not return to their former configuration, but begin to oscillate about new positions of stability in which the strain is less than in the original configuration. There are probably many groups of such molecules with oscillations of different amplitude. Thus, the breaking up of any one configuration depends partly upon the magnitude of the strain on the original configuration, and partly on the amplitude of the oscillation.

§ 18. Reactions between Solids—Spring's Experiments

In W. Spring's experiments,[1] two cylinders of copper were placed end to end with clean surfaces in contact, and heated to 400° for some hours under pressure; the cylinders united together so completely that when the resulting cylinder was broken, the fracture did not pass through the jointed surfaces. The melting point of the copper was far above the temperature of the compressed metals, and thermoscopic observations have shown that the result cannot be explained by the rise of temperature due to the compression. Cylinders of aluminium, bismuth, cadmium, tin, gold, and lead behaved similarly, but the experiment was not successful with antimony and platinum; G. Spezia (1911) failed to obtain any signs of combination with a mixture of finely divided silver and copper after being a month under a uniform pressure of 8000 atm. W. Spring further reported that precipitated alumina dried at 140° appeared to flow like a liquid when subjected to a pressure of 5000 atm., but neither natural nor artificial silica showed any signs of flow. Cylinders of *different* metals were united by compression, *e.g.* with cylinders of copper and zinc, an alloy of brass, about 18 mm. thick, was formed about the plane of contact. Similar remarks apply to cylinders of iron and zinc, copper and cadmium, tin, or bismuth. Powdered metals when subjected to a pressure of about 10,000 atmospheres, gave coherent masses which appeared as if they had been fused. By repeatedly filing and compressing a mixture of bismuth, cadmium, and tin in the correct proportions, Wood's alloy was formed; similarly with Rose's alloy (lead, bismuth, and tin); mixtures of copper and zinc furnished brass; copper and tin gave bronze. The criterion for judging the formation of the alloy were "general appearance and fusibility." W. Hallock [2] showed the futility of the melting-point test because an alloy may be formed by heating the constituents to a temperature above the melting point of the alloy, but below the melting point of any single constituent. W. Rosenhain and P. A. Tucker could obtain only a conglomerate of tin and lead by compression at 35 tons per sq. in., and similar results were obtained with copper and silver by G. Spezia.[3] In agreement with G. Massing, J. Johnston and L. H. Adams say:

> Compression alone does not result in the production of true alloys. In those systems in which the metals crystallize out from the melting as pure components, there is no essential difference between the conglomerate produced by compression and that obtained by fusion. In all other systems, the immediate effect of compression is slight, and consists solely in the fact that compression brings about very intimate contact between the particles, the result of which, in turn, is the formation at the contact of a compound (if such be possible) or the promotion of diffusion (when the metals can form mixed crystals).

J. Johnston and L. H. Adams contend that in Spring's experiments the results must be attributed not to the pressure itself, but rather to the grinding stress to which the material was subjected, for W. Spring frequently speaks of his materials squirting out around the piston which did not fit the cylinder very well. For the effects recorded by W. Spring can be more simply observed by grinding the materials in a mortar; the alloys produced by W. Spring's process are agglomerates. Pressure can favour the formation of alloys by bringing into good contact metals capable of forming solid solution, this process going on very slowly by the diffusion of one metal in another. A uniform pressure can fuse only those metals whose melting points are lowered by pressure, and few metals other than bismuth satisfy this condition. On the other hand, a grinding process may produce results which are not obtained by a uniform pressure—*e.g.* calcium carbonate ground in a mortar loses a little carbon dioxide, but not if this compound is subjected to a uniform high hydrostatic pressure.

This relation between the volume of liquid and solid phases and the lowering of the melting point dT by a pressure dp, is given by Clapeyron's equation:

$$\frac{dT}{dp}=\frac{T_m}{\lambda}(v_2-v_1) \quad . \quad . \quad . \quad . \quad . \quad (1)$$

when v_2 denotes the specific volume of the liquid, v_1 that of the solid, T_m the melting point on absolute scale of temperature, and λ the latent heat of fusion. This means that a pressure acting *uniformly* on the solid and liquid phase of a single substance raises or lowers the melting point according as the process of melting is accompanied by an increase or decrease of volume.

The effect of a non-uniform pressure on solids.—The volumes of most of the silicates increase during fusion.[4] For instance, the specific gravity of a sample of fireclay was 2·627 before fusion, and after fusion 2·470. This corresponds with an expansion of about 6 per cent. Consequently an increase of pressure should raise, not lower, the fusion temperature of the clay.

It has been assumed that the latent heat of fusion λ is constant, and independent of temperature. Experiment shows that this assumption is generally valid, although G. Tammann [5] and others have discussed the possibility of the latent heat of fusion changing from a positive to a negative value. G. Tammann has also shown that since a liquid is usually more compressible than a solid, a positive value of v_2-v_1 will diminish with an increase of pressure, and, after passing through zero, will gradually assume an increasing negative value. It is not probable that the discrepancy between theory and practice is to be attributed to either of these possibilities, rather is the formula not applicable to the case under discussion. Theory assumes that the pressure is uniformly exerted in all directions, whereas the interstices between the grains of a pulverulent material would give the pressure the character of a shearing stress. The solid and liquid phases do not therefore suffer the same increase of pressure.

H. W. B. Roozeboom [6] uses the following illustration: If V_s and V_l, Figs. 13 and 14, represent the vapour pressure curves of the solid and liquid states at a pressure p, and

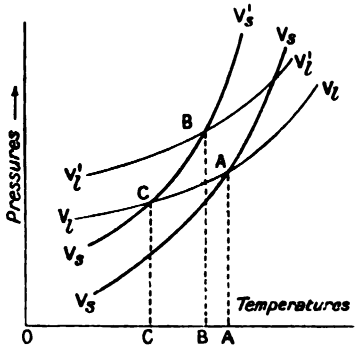

FIG. 13.

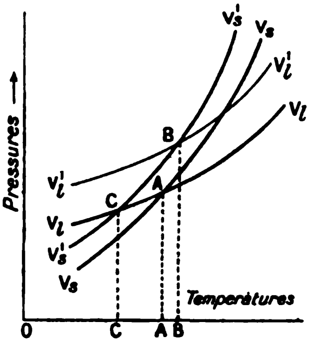

FIG. 14.

V'_s and V'_l represent the vapour pressure curves of the solid and liquid at a higher pressure, when the two phases—liquid and solid—are subjected to the same pressure, the point of intersection A of the V_s and V_l curves will represent the melting point of the substance under a pressure p; similarly, the point of intersection B of the curves V'_s and V'_l will represent the melting point of the substance under a pressure higher than p. When the solid phase alone is subjected to the increased pressure it will melt at the point of intersection C of the V_l and V'_s curves. The temperature OC is always less than OA whether OB be greater or less than OA. Consequently, *the melting point of a solid will always be lowered when the pressure acts on the solid but not on the liquid.* E. Rieke calculates that by the application of a tensile or compressive stress p, the lowering of the melting point $=vT_mp^2/2E$, where E represents the elasticity of the solid in the direction of the applied stress p; λ the latent heat of fusion; T_m the absolute melting point; and v the specific volume of the solid.

J. Johnston and L. H. Adams have shown that pressure decreases the stability of a phase which then exhibits an increased tendency to pass into another phase; otherwise expressed, pressure acting only on a solid phase increases its vapour pressure, and the solubility in a given solvent. Pressure also lowers the melting point in accordance with the relation:

$$\frac{dT_1}{dP} = -\frac{T_m}{\lambda}v_1 \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

when v_1 is the specific volume of the solid and the temperature and pressure in question. Since the quantities on the right are always positive, **the application of an excess of pressure on the solid phase alone always lowers the melting point.** If dT_1 refers to the depression of the melting point when the pressure dp acts on the solid phase alone, and dT the depression when both phases are subjected to the same pressure dp, the combination of equation (1) and (2) furnishes the relation

$$\frac{dT_1}{dT} = \frac{v_1}{v_2 - v_1}$$

meaning that the ratio of the lowering of the freezing point of the solid phase, when this alone is subjected to pressure, to that observed when the same given pressure acts on both phases, is equal to the ratio of the specific volume of the solid phase to the change of specific volume on freezing. This result shows how much the melting point is lowered when the pressure acts on the solid phase alone. For example, with a uniform pressure, the melting point of ice is lowered 0·00752 per atm., but by an unequal pressure the melting point is lowered 0·09° per atm.—*i.e.* twelve times as much. J. Johnston further estimates that if D denotes the specific gravity of the solid, T the normal melting point on the absolute scale, the lowering of the melting point is $0·0242T_m/D\lambda$ per atm. Thus, if potassium melts at 62° (*i.e.* 335° K.), and its heat of fusion is 15·7 cals., and specific gravity 0·87, its melting point will be lowered 0·59° per atmosphere unequal pressure. It is therefore important to distinguish clearly between the effect of uniform and of non-uniform pressure in all discussions on the effects of compression on solid systems; neglect to do so has given rise to some apparently contradictory statements.

Chemical action between compressed solids.—W. Spring claimed to have crystallized amorphous substances like bismuth, zinc (130°), manganese dioxide, zinc and lead sulphides, mercuric iodide, and transformed plastic or monoclinic sulphur into the rhombic varieties. These statements have been contradicted by C. Friedel, E. Jannettaz, and J. Johnston and L. H. Adams. The latter say that compression alone will not in general produce crystallization, or transform one modification of a substance into another. It is true that a uniform or nearly uniform pressure will tend to produce any reversible (enantiotropic) transformation in favour of the system with the smaller volume, but it often does not do so because the reaction velocity is very small. In irreversible (monotropic) changes, no positive statement can be made as to the influence of pressure except by empirical trials. The effects produced by uniform pressure are comparatively slight. If the pressure, uniform or non-uniform, be such as to make the substance melt at the temperature of the investigation, crystallization or recrystallization may ensue; but pressures up to 15,000 atm. do not convert calcite—sp. gr. 2·71—into the denser aragonite—sp. gr. 2·93; nor marcasite—sp. gr. 4·9—into the denser pyrites—sp. gr. 5·0—and this even at 425° under 2000 atm. pressure when the change takes place under ordinary pressures at about 450°.

W. Spring claims to have formed sulphides and arsenides of the metals by the alternate compression and filing of intimate mixtures of the metals with sulphur or arsenic respectively. C. Friedel considered that sulphides were really formed in Spring's experiments because of the change of colour, which he regarded as a more certain indication than the evolution of hydrogen sulphide when treated with hydrochloric acid, and because he found that a mixture of zinc and sulphur gave rise to the evolution of this gas. W. Hallock, however, obtained sulphides at ordinary temperatures with copper and sulphur an inch apart and with a wad of cotton wool in between. He claims that it is the vapour of sulphur which attacks the copper. The same remark applies if the sulphur is replaced by mercuric chloride. There is no reason to doubt that combination did occur even if the reactions did not go to completion, as W. Spring, judging from a microscopic examination, thought really occurred. Hence, although chemical combination no doubt occurred in these experiments—just as the trituration of two solids will sometimes induce combination—yet it does not follow that pressure, *per se*, promotes chemical action. Further examples of the chemical union of solids were reported by W. Spring to occur by compressing mixtures of sodium carbonate and barium sulphate; sodium sulphate and barium carbonate; potassium nitrate and sodium acetate; lead chloride and potassium nitrate; mercuric chloride and potassium iodide; arsenious oxide and cadmium nitrate; etc. Dry sodium nitrate and zinc chloride or sulphate react when shaken together forming zinc nitrate; the heat of the reaction decomposes part of the latter forming zinc oxide and brown vapours. T. von Hagen studied the effect of pressure on powders with the object of preparing tabloids by compression.

While chemical reaction may be favoured by close contact, by the grinding action which attends the application of pressure, and by the slow diffusion which is possible in certain systems, J. Johnston and L. H. Adams have pointed out that W. Spring's tests for chemical combination were defective. For example, the small cylinder obtained by compressing a mixture of powdered and dried anhydrous sodium carbonate and barium sulphate to 3000 atm. was pulverized and "washed completely in cold water; the insoluble residue filtered off, and analysed." W. Spring's results, therefore, show the composition of the compressed mass *after the addition of water*, but not the composition of the dry solid phases, for it is known that the system, $BaSO_4+Na_2CO_3\rightleftharpoons Na_2SO_4+BaCO_3$, when in the presence of water reaches equilibrium after the elapse of a certain time. In the case of potassium nitrate and sodium acetate, the mixture was left four months in a desiccator, and he noticed the mixture was deliquescent. The original salts do not deliquesce; hence, said W. Spring, some deliquescent potassium acetate must have been formed. Here again, the equilibrium was tested after exposure to water vapour, but there is no indication of the state of equilibrium of the dry solids. Mere trituration of the pure and dry salts in the presence of water vapour suffices to start the deliquescence.

In general, only those reversible reactions—physical or chemical—which are accompanied by a diminution in volume are favoured by an increase of pressure. The fact that substances can react in the solid state by trituration or grinding, or by the application of a non-uniform pressure, shows that the molecules of solids can be brought close enough for chemical union. The older chemists did not believe that solid substances could react chemically, and their experience is summarized in the oft-quoted phrase: *corpora non agunt nisi soluta*—substances do not react unless they are in solution. J. L. Gay Lussac combated this dogma as far back as 1846. He said:

> Il est certain, au contraire, que tous les corps solides, liquides, ou aériformes agissent les uns sur les autres, mais que, des trois états des corps, l'état solide est le moins favorable à l'exercice de l'affinité.

§ 19. The Vibration Frequency of Atoms and Molecules

> The more boldly we advance beyond experience, the broader the survey we obtain. the more surprising the facts we discover, but the greater the likelihood of one going astray.—L. BOLTZMANN (1899).

In recent years, the mathematical treatment of the theory of solids has been largely based upon the quantum theory principally in connection with the specific heats of solids, but also in connection with the co-relation of the physical properties of solids with a property called the periodic time or the vibration frequency—*Schwingungszahl*—of the atoms or molecules. W. Sutherland[1] made an attempt in 1890. He showed that if the molecules of a solid vibrate about a mean position, it can be assumed that at the melting point the vibratory motion will just break down; and the vibration frequency or the period of vibration of the elements at their melting points becomes

$$\text{Vibration frequency} \quad \nu=K\sqrt{\frac{T_m}{Mv^{\frac{2}{3}}}}$$

where K is a constant. W. Sutherland's argument is somewhat as follows:

Let a molecule or atom of mass M and mean specific heat C, be heated from absolute zero to its melting point T_m; it will receive heat MCT_m, and this will be proportional to the kinetic energy $\frac{1}{2}MV^2$ of the molecule, where V is the velocity of vibratory motion at the melting point, provided the body undergoes no expansion when heated. By Dulong and Petit's rule, MC is almost constant for the elements, and therefore V the mean velocity of the vibrations at the melting point is proportional to NT_m/M. If D denotes the density of the element, M/D will represent the molecular volume, v; and if a denotes the mean coefficient of linear expansion of the substance between absolute zero and T_m, the increase in the linear dimensions of the space occupied by the molecule when heated from zero to T_m will be $aT_mv^{\frac{1}{3}}$. This represents the length or amplitude of the vibrations just as the molecule is going to leave the vibratory state characteristic of the solid, on the assumption that the amplitude of the vibrations of the particles is augmented as the temperature rises from absolute zero to the melting point, at which temperature the amplitude becomes comparable with the distances of the molecules apart. At the melting point, the crystalline form of the solid is destroyed. Hence, the vibration frequency of the molecule at the melting point is proportional to $aT_m(M/D)^{\frac{1}{3}}/T_m/M$. Assuming that aT_m is a constant, a relation verified by E. Grüneisen,[2] it follows that if the constants be collected together the vibration frequency is proportional to $(M/D)^{\frac{1}{3}}/(T_m/M)^{\frac{1}{2}}$.

W. Sutherland estimated the relative vibration frequencies of the elements of the alkali family to be in the proportion:

Li	Na	K	Rb	Cs
0·21	0·43	0·66	0·96	1·23

i.e. approximately as 1 : 2 : 3 : 4·5 : 6 ; and for the alkaline earth metals :

Be	Mg	Ca	Sr	Be
0·35	0·70	1·04	1·62	1·88

or approximately as 1, 2, 3, 4·5, 5·3. Similarly, for other groups when data are available. Consequently, the periods of vibration of the molecules at their melting points show simple harmonic relations. Analogous results were obtained with some compounds of the elements. A precisely similar expression was obtained by F. A. Lindemann [3] for the relation between the vibration frequency, ν, and the melting point, T_m. F. A. Lindemann gave the constant the empirical value $2·06 \times 10^{12}$, which W. Nernst afterwards altered to $3·08 \times 10^{12}$. The vibration frequencies of the atoms of the solid have been determined by a number of independent methods and the average values so obtained agree fairly well with one another.

(1) *From the melting point.*—The vibration frequency ν by means of W. Sutherland's formula, with W. Nernst's constant,

$$\nu = 3·08 \times 10^{12} \sqrt{\frac{T_m}{Mv^{\frac{2}{3}}}} \text{; or, } \nu = \frac{3·08 \times 10^{12}}{v^{\frac{1}{3}}} \sqrt{\frac{T_m}{M}} \quad . \quad . \quad (1)$$

where M denotes the molecular or atomic weight ; T_m, the absolute melting temperature; and v, the atomic weight. The agreement between the observed vibration frequencies and those calculated by F. A. Lindemann's formula is very fair :

	Al	Cu	Zn	Ag	Pb	Diamond
$\nu \times 10^{-12}$ (Observed) . .	8·3	6·6	4·8	4·5	2·0	40
$\nu \times 10^{-12}$ (Calculated) . .	8·4	7·5	4·8	4·8	1·9	35

The low atomic weights and the high melting points of these elements, diamond, boron, and silicon, give these elements abnormally high vibration frequencies. Lithium has a low atomic weight, but its low melting point gives its vibration frequency a normal value. The atomic frequencies of the elements calculated from F. A. Lindemann's formula [4] are indicated in Table XXVI.

TABLE XXVI.—ATOMIC VIBRATION FREQUENCIES OF THE ELEMENTS.

Titanium . .	9·17	Vanadium .	9·26	Manganese .	8·35

The numbers are based on the assumption that the molecules of the solid are monatomic. It is also assumed that the molecular structure remains unchanged—without polymerization or dissociation—in cooling from the melting point to absolute zero. If the molecular weight changes from M to nM, the molecular volume will be increased n times. Consequently, in virtue of the terms $m^{\frac{1}{2}}$ and $v^{\frac{1}{3}}$, the frequency calculated by F. A. Lindemann's equation must be divided by $n^{\frac{1}{2}+\frac{1}{3}}$, or $n^{\frac{5}{6}}$. The molecular volume is usually computed from density determinations at ordinary temperatures; and it is assumed that the molecular volume is a constant, whereas it is not likely that the molecular volumes of a substance at absolute zero and at the melting point are the same; hence the formula probably needs a correction term for the change in the molecular volume of temperature.[5] It must also be emphasized that the constant has been evaluated empirically, and that a series of approximations have been made in the deduction of the formula. The different allotropic forms of an element may have different frequency numbers. The atomic frequencies of the elements also exhibit periodic properties, as W. Sutherland (1890) and later W. Biltz (1911) have shown. The curve, Fig. 15, recalls L. Meyer's atomic volume curve, Fig. 14, Cap. VI Thorium, manganese, tin, and tellurium do not sit on the curve. Argon and potassium occupy their anomalous position; hydrogen seems to fall with the halogens. The unique chemical character of carbon in its great capacity for forming compounds seems to correspond with its exceptionally large vibration frequency. H. S. Allen[6] has shown that if N be the atomic or Moseley's number for an element, a large proportion of the elements furnish values of the product $N\nu = na$, where n is a whole number, and a is a constant, approximately $21{\cdot}3 \times 10^{12}$; and for a few others—lithium, beryllium, sodium, magnesium, phosphorus, sulphur, potassium, arsenic, rubidium, indium, iodine, mercury—n involves fractions. E. Grüneisen

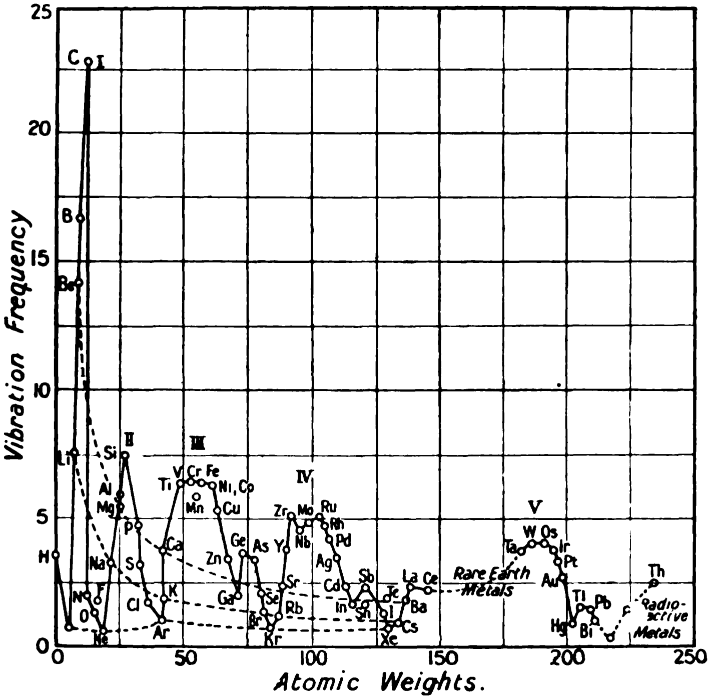

FIG. 15.—Vibration Frequencies and Atomic Weights.

found the product of the linear expansion coefficient, α, and the absolute temperature of the melting point to be a constant; H. Alterthum substituted the reciprocal of α for T_m in Sutherland and Lindemann's formula, and obtained

$$\nu=4\cdot2\times10^{11}\sqrt{\frac{1}{M\alpha v^{\frac{2}{3}}}} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The deviations of the results with this formula from others are probably due to the use of values of α determined at ordinary temperatures.

(2) *From the elastic constants of the solid.*—The relation between the natural vibration frequency ν of the atoms, the atomic weight M, the compressibility β, and the density D of a solid was computed by A. Einstein (1911) to be

$$\nu=3\cdot3\times10^{7}\sqrt{\frac{v^{\frac{1}{3}}}{M\beta}} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

showing that the forces which produce the thermal oscillations of the solid are the same in kind as those which produce elastic oscillations—*e.g.* sound waves. A. Einstein's constant was $2\cdot77\times10^7$, but the empirical value $3\cdot3\times10^7$ was found to give more satisfactory agreement with the values obtained by the preceding formula. F. A. Lindemann modified A. Einstein's formula to

$$\nu=3\cdot58\times10^{7}M^{-\frac{1}{3}}D^{-\frac{1}{6}}\beta^{-\frac{1}{2}}$$

E. Grüneisen (1912)[7] obtained a relation (4) between the coefficient of linear expansion, α; the compressibility, β; and the specific heat at constant volume, C_v, in gram calories per degree. When this relation was combined with A. Einstein's specific heat formula, an expression for the vibration frequency is obtained:

$$\nu=2\cdot92\times10^{11}\sqrt{\frac{C_v}{3\alpha v^{\frac{2}{3}}}} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

This shows a good agreement with values obtained by other methods.

(3) *From the frequencies of the longest heat waves in the dispersion spectrum.*—The natural vibration frequency ν of the atoms of the elements for any temperature can be calculated from the abnormally low specific heats. In order that the specific heat may be less than normal at ordinary temperatures—say, 27°, when $T=300$—the vibration frequency ν must lie between $6\cdot5\times10^{13}$ and $6\cdot5\times10^{12}$. Vibration frequencies of this range lie in the infra-red spectrum, and therefore all elements with abnormally low specific heats must have a value of ν in this part of the spectrum. Adapting a table from N. R. Campbell's *Modern Electrical Theory* (Cambridge, 242, 1913), it has been found

	S and P	Fl	O	Si	B	H	C
C_v . .	5·41	5·0	3·99	3·81	2·68	2·32	1·79
$\nu\times10^{-12}$.	7·1	9·1	14·3	15·0	20·0	23·1	25·0

These values of ν are in fair agreement with such observations as have been made on the absorption frequencies of the atoms in compounds of these elements. The agreement is surprising, because, as N. R. Campbell says, it might have been anticipated that the forces under which the atoms would vibrate in the compounds would be entirely different from the vibrations of these same atoms when they form part of a solid element. While the absorption bands in the infra-red probably represent the free vibrations of the atoms and not of the electrons inside the atoms, the vibrations of transparent bodies in the ultra-violet are probably contributed by the *electrons*. The spectrum shows that the vibrating atoms have many degrees of freedom, which are very important optically, but they possess such high values of ν that they do not absorb appreciable amounts (quanta) of energy when the body is heated.

According to S. Pagliani,[8] the vibration frequency ν of a molecule can be calculated from the vibration frequencies ν_1 and ν_2 of its component atoms by the formula $\nu=\frac{4}{3}(\nu_1+\nu_2)$; and it is connected with the entropy ϕ of the compound by the expression $\nu=9·6\times10^{12}\phi$.

The specific heats of compounds.—At ordinary temperatures the additive nature of the specific heat laws of F. E. Neumann, J. P. Joule, and H. Kopp show that the heat energy of the molecules is mainly derived from the vibrations of the individual atoms. At high enough temperatures, the vibrational energy of the atoms approaches the value $3RT$; but at low temperatures, W. Nernst [9] assumes that the vibrations of the molecules play a more important part than the vibrations of the atoms in the molecule. W. Nernst further assumes that the heat energy of a compound in the solid state is made up of the energy due (i) to the motions of the molecules relative to one another, and (ii) to the internal energy of the molecules owing to the vibrations of the atoms in the molecule. The first contribution is calculated by P. Debye's formula ; the second by A. Einstein's. Each calculation involves a knowledge of the characteristic vibration frequencies—the first, symbolized by ν_1, is given approximately by F. A. Lindemann's formula ; the second, symbolized by ν_2, obtained by the optical measurements of H. Rubens' residual rays—*Reststrahlen* [10]—by repeated reflexions from the surfaces of solids. It is assumed that the frequency of such infra-red radiations corresponds with the frequency of vibration of an electrically charged ion which may be identified with an atom, and that the forces which control the heat vibrations of the atoms of a solid are the same, whether specific heats or the reflexion of infra-red radiations are involved. Consequently, the specific heat of the compound will be :

$$2C_v=\frac{d(\text{Debye's function})}{dT}+\frac{d(\text{Einstein's function})}{dT}$$

According to W. Nernst, for KCl, $\beta\nu_1=166$ and $\beta\nu_2=213·5$, where $\beta=4·78\times10^{11}$. The calculated mean values of C_v at different temperatures are compared with the observed values of C_p in Table XXVI. The agreement between hypothesis and observation is good. The analogy between the results with the atoms of the elements and the molecules of compounds has led H. S. Allen to infer that

> The forces binding the atoms in the molecule are similar in character to those which bind the molecules of the solid, that is, the forces of chemical affinity are of the same nature as the forces of molecular cohesion.

TABLE XXVII.—SPECIFIC HEAT OF POTASSIUM CHLORIDE.

Temperature °K.	Internal vibrations.		Calculated $2C_v$.	Observed $2C_p$.	Difference between C_p and C_v.
	C_v from Debye's formula.	C_v from Einstein's formula.			
22·8	1·04	0·046	1·086	1·16	0·04
30·1	1·87	0·25	2·12	1·96	−0·08
48·3	3·52	1·43	4·95	5·70	0·37
70·0	4·57	2·89	7·50	7·58	0·04
235·0	5·81	5·55	11·68	11·78	0·05
550·0	5·93	5·87	12·70	13·08	0·19

It is found that if the single ions are situated at the points of the space lattice of a crystalline solid, the mean atomic weights can be substituted in the formula for calculating the frequencies. The agreement is then not nearly so good as when the residual rays of H. Rubens are assumed to be reflected from the molecules as a whole. The calculated results with mercurous chloride and with water agree with observations only when more complex molecules than HgCl and H_2O are respectively assumed.

If the values of the vibration frequencies are known, it is possible to calculate the molecular weight of elements and compounds from Lindemann's formula by substituting molecular weight and molecular volume in (33). The observed values for crystals of lead, silver, zinc, copper, aluminium, and carbon in the diamond agree with those calculated on the assumption that these elements are monatomic; with sulphur and graphitic carbon, the molecules are more complex—with sulphur probably S_8. Similarly with crystals of sodium chloride, NaCl; potassium chloride, KCl; potassium bromide, KBr; silver chloride, AgCl; lead chloride, $PbCl_2$; and benzene, C_6H_6. The molecular weights so determined agree with the formulæ usually assigned to these compounds, whereas with crystals of water, silica, and mercurous chloride, the ordinary formulæ are doubled so as to furnish H_4O_2, Si_2O_4, and Hg_2Cl_2 respectively.

The relation between the vibration frequency and the atomic heat of fusion.—If λ denotes the latent heat of fusion of a crystalline solid, and M the atomic weight, the number of calories required to melt a gram-atom of the solid will be $M\lambda$. The energy required to melt the solid may be regarded as equivalent to the work required to rupture the bonds which hold the crystal units in position, and enable the molecules to move freely amongst themselves. According to the quantum theory, the energy of a solid is the energy of the oscillators which it contains, and H. S. Allen[11] assumes that the latent heat of fusion is equivalent to the energy required to counterbalance the energy of a certain number of oscillators. The average amount of energy associated with a vibration frequency ν, at a temperature T, is $RTu/(e^u-1)$, where u is put in place of $h\nu/RT$, and h is Planck's constant, R the gas constant per gram-molecule. If c denotes the ratio of the number of oscillators to the number of atoms, there will be cN oscillators in a gram-molecule, where N denotes Avogadro's constant. The total energy of the atoms in a monatomic solid is accordingly

$$M\lambda=\frac{cNRTu}{e^u-1}\,;\ \text{or,}\ \frac{M\lambda}{NRT}=c\frac{u}{e^u-1}$$

NR is the value of the gas constant per gram-molecule, *i.e.* 1·989 calories per degree. The vibration frequencies of a number of elements are known, and consequently the values of c can be computed. H. S. Allen finds the value of c for nickel, cobalt, rubidium, sodium, potassium, iron, silver, lead, copper, and palladium to be nearly unity; for aluminium, mercury, cadmium, and platinum, 1⅓; for zinc, 1½; for tin, 1¾; and for gallium and bismuth, 2½. H. S. Allen's expression for the latent heat of fusion λ resembles H. Crompton's formula indicated in the next section. The relation of H. Crompton's formula to H. S. Allen's is seen by writing the latter

$$\frac{M\lambda}{Tc}=NR\frac{u}{e^u-1}$$

when, as H. S. Allen shows, the expression $u/(e^u-1)$ is not far from unity, the right side of the equation is approximately constant and equivalent to H. Crompton's relation. A great deal of the work which has been done with the classical doctrine of energy can now be translated into the language of the quantum theory.

§ 20. Empirical Relations between the Properties of Solids

> We cannot attain to a real theory of chemistry until we are able to connect the science by some hypothesis with a general theory of dynamics.—A. C. Brown (1874).

The kinetic theory of solids is in the earlier stages of its development in that it is based upon very imperfect knowledge and arbitrary assumptions. There have been quite a number of attempts to develop the subject.[1] The greatest success has been obtained by considering the properties of solids at low temperatures as a limiting case in the same sense that gases have been more amenable to mathematical treatment when in a rarefied condition. The amplitude of the oscillating molecules at low temperatures is probably small, and but a relatively small number are vibrating. This assumption is in conformity with the fact that many properties of solid bodies at very low temperatures are small, and vary almost proportionally with the temperature—this applies, for example, with the specific heats, coefficients of thermal expansion, the temperature coefficients of compressibility, etc., at low temperatures.

C. M. Guldberg (1868) sought to establish the relation

$$pv=RT-\beta\log\frac{v}{v_0}$$

as the **equation of state of ideal solids** in the same sense that $pv=RT$ is the equation of state of ideal gases. In C. M. Guldberg's equation, R, β, and v_0 are constants which have specific values for different substances—v_0 is considered to be the specific volume of the substance at absolute zero. It is further shown that if w denote the weight of a cubic metre of the solid; E, the modulus of elasticity; a, the coefficient of thermal expansion; and λ, the latent heat of fusion, these constants are related so that $E=wK$; $aw\beta=4240$; $\beta=4\times10^4\lambda$. The agreement between the observed values and those calculated by these relations is remarkably good, and it shows that some intimate relation probably subsists between the latent heat of fusion, the coefficient of thermal expansion, and the elasticity or compressibility of solids.

E. Grüneisen has also found empirically that the quotient of the coefficient of linear expansion, a, and the specific heat at constant pressure, C_p, of a number of metals is nearly a constant—that is, $a/C_p=$a constant; he also found empirically that the product of the atomic volume, v, and the coefficient of linear expansion, a, divided by the product of the coefficient of compressibility, β, and the atomic heat, C_v, is a constant—that is, $av/\beta C_v$ $=$a constant; and that the product of the coefficient of linear expansion, a, and the absolute melting temperature, T_m, is nearly constant—that is, $aT_m=$a constant.

R. Pictet [2] assumed that the mean values of the amplitudes of the vibrating molecules in a melting solid are always the same; that the product of the mean distances of the molecules and the coefficient of linear expansion, a, is proportional to the absolute temperature of the melting point, T_m; and that the product of all three variables is constant.

In ignorance of the absolute distances between the vibrating particles, and since the volume of a solid is proportional to the cube of the linear dimensions, the cube root of the atomic volume v may be substituted for the distances between the particles, and Pictet's rule assumes the form $aT_m v^{\frac{1}{3}}=$a constant. This rule applies very well for the heavier metals where the mean value of the constant lies between 4 and 5. The constant for aluminium is 6·6; for magnesium, 5·7; tin, 2·8; antimony, 2·2; and bismuth, 2·05, although there is some uncertainty as to the exact values of the melting points and the coefficients of expansion of some of the metals. It has been proposed to use Pictet's rule for the calculation of melting points of elements. W. Sutherland, however, found the empirical rule $aT_m M^{\frac{1}{3}}=0{\cdot}04$ to 0·05—say, 0·045—gives better results for all the metals tried, with the exception of antimony, bismuth, and tin. The rule applies to sodium, magnesium, and aluminium—iridium gives a constant 0·037.

J. W. Richards[3] found empirically that the latent heats of fusion of about 15 elements is one-third the amount of heat required to raise the metal from absolute zero to its melting point within an error of from 5 to 10 per cent. If the average atomic heat of an element between −273° and its melting point is approximately 6·4, Dulong and Petit's rule, then, the amount of heat in a gram-atom of the metal at its melting point is $6{\cdot}4T_m$. Assuming that the latent heat of fusion is one-third the total heat in the metal at its melting point, the latent heat of fusion will be one-third of $6{\cdot}4T_m$; and, from Pictet's rule, the latent heat of fusion $=9{\cdot}5/av^{\frac{1}{3}}$ cals. per gram-atom. Richards found that this agreed well with all the metals for which the necessary data were available with the exception of aluminium, *e.g.* for copper $9{\cdot}5/a\sqrt[3]{v}=3006$, and dividing by the atomic weight to get the amount per kilogram, the latent heat of fusion is 46·2—the observed value is 43·0.

H. Crompton's formula[4] is $M\lambda=1{\cdot}38T_m\Sigma v$ nearly; here M denotes the molecular weight of the solid; Σv, the sum of the valency bonds; λ, the latent heat of fusion of unit weight of the substance; and T_m is the absolute temperature of fusion. H. Crompton's formula also gives a constant ranging between 1·8 and 2·56 for a number of organic compounds, but for normal or non-associated liquids he obtained satisfactory results with $\lambda D=0{\cdot}099T_m$—the variations from the mean value of the constant 0·099 ranged from 0·080 to 0·142. He has also shown that for a series of metals the atomic heat of fusion divided by the absolute temperature of the melting point, T_m, is almost independent of the nature of the metal, for the quotient lies between 1·84 and 4·82. P. Walden obtained similar results by using the molecular heat of fusion of 33 compounds; here the quotient fell between 12·5 and 14·8 with a mean value of 13·5. If the compounds are associated in the liquid state, the constant assumes a lower value. G. Tammann, however, examined a far larger number of compounds than P. Walden, and only about a quarter fell between the limits indicated by P. Walden. P. W. Robertson,[5] also starting from Pictet's rule, obtained the expression $w\lambda/T_m\sqrt[3]{v}=$a constant, which gave better results than H. Crompton's equation for all the elements with atomic weights over 40 for which data are available. The constant ranges from 0·87 to 1·28—gallium, bismuth, and bromine gives values respectively 2·05, 1·75, 1·63. The formula also applies to compounds when w denotes the molecular weight.

E. Obach[6] found a relation between the specific inductive capacity, K, and the latent heat of evaporation λ of a number of related organic liquids, such that $\lambda/K=$a constant. From Trouton's rule, $M\lambda/T_b=$a constant, where T_b denotes the absolute boiling point, it follows that MK/T_b is also a constant, and accordingly, *the absolute boiling point of a series of related bodies is proportional to the molecular inductive capacity.* P. de Heen found the absolute boiling point at 760 mm., and the coefficient of expansion α at 0° are inversely proportional, or the product αT_b is a constant. Hence also αKM must be constant, or the coefficient of expansion at 0° is inversely proportional to the molecular inductive capacity. Accordingly, the product αKM represents P. de Heen's intermolecular work, or that part of the heat spent in physical dissociation as contrasted with heat required for chemical dissociation. The approximate proportionality between the latent heat of vaporization and the dielectric constant of a liquid observed by E. Obach,[6] was extended by P. Walden to a relation between the internal pressure and the dielectric constant. W. C. McC. Lewis, however, found that there is no direct proportionality between the cohesion or intrinsic pressure and the dielectric capacity. Although substances with a large dielectric capacity have generally a large intrinsic pressure, the relationship is rather more complex than is implied in E. Obach's or in P. Walden's rule. W. C. McC. Lewis has also shown that the approximate relation indicated by E. Obach and P. Walden follows from the assumption that the cohesion or intermolecular attraction is an electromagnetic and not an electrostatic effect. A. P. Mathews also postulated that, while the intramolecular affinity uniting the atoms in a molecule is an electrostatic effect produced by valency electrons, intermolecular cohesion is a magnetic effect produced by the valency and other electrons.

According to H. Tomlinson, if w denotes the atomic weight of an element of density D, and C_m, the thermal capacity per unit mass, then the thermal capacity

C per unit volume is $C=DC_m$; and by Dulong and Petit's rule, wC_m=constant. Since, as shown above, Er^7=constant, and r is proportional to $(w/D)^{\frac{1}{3}}$, it follows that $EC^{-\frac{7}{3}}$=a constant; this means that the cube of Young's modulus varies as the seventh power of the thermal capacity of the atoms per unit volume. It follows also that the same constant is equal to Er^7.

According to A. H. Stuart,[7] the relation between the coefficient of longitudinal elasticity E; the density D; the specific heat C_p; and the coefficient of thermal expansion α, is $C_p=4{\cdot}44\alpha E/D$; and if Dulong and Petit's rule be $C_pw=6{\cdot}25$, the atomic weight of an element is equal to $1{\cdot}41D/\alpha E$. The application to the few metals for which reliable data are available is indicated in Table XXVIII.

TABLE XXVIII.

Metal.	D	E kilograms per sq. mm.	$\alpha\times10^5$	Atomic weight.

J. D. van der Waals' equation of state for solids.—R. H. McCrea (1907)[8] tried to adapt J. D. van der Waals' equation to the solid state, but with no definite result. K. Eisenmann deduced

$$\left(p+\frac{a}{v^2}\right)\frac{v(v-b)}{b}-\frac{1}{v}\cdot\frac{h\nu}{e^{-\frac{h\nu}{kT}}-1}=kT$$

as the equation of state of solids with spherical atoms—here k is Boltzmann's constant. E. Kohl (1913) deduced a formula for the two specific heats: $C_p-C_v=3\alpha M\lambda D/(D_s-D_l)$, where α denotes the coefficient of linear expansion; M, the molecular weight; λ, the latent heat of fusion; D, the specific gravity; and D_s and D_l, the respective specific gravities of solid and liquid at the melting point. It is assumed that J. D. van der Waals' equation is applicable to the solid, and that the variation of the energy with temperature is independent of the state of aggregation. The results are not good.

I. Traube also applied J. D. van der Waals' equation to highly compressed gases and liquids by assuming that the observed volume is made up of two components: (i) the volume of the molecules; and (ii) the *co-volumes* or intermolecular spaces. I. Traube calculated the J. D. van der Waals' constants a and b of the metals by introducing two values for the volume v at two temperatures near 0°. The one value of v was obtained by making $v=w/D$, where w denotes the atomic weight, and D the density, and the other value of v was calculated from the coefficient of cubical expansion 3α. The values of a and b can be computed by substituting these values of v and T in J. D. van der Waals' equation $a(v-b)/v^2=RT$, when the external pressure is negligibly small in comparison with a/v^2. I. Traube's results are shown in Table XXIX.

TABLE XXIX.—VALUES OF J. D. VAN DER WAALS' a AND b FOR SOLID ELEMENTS.

The numbers in the last column are remarkably concordant when the heterogeneous character of the data is taken into consideration; the average of these numbers approximates to $\frac{1}{273}$. The value for carbon is exceptional. The values of $K=a/v^2$ are about one-third those obtained by T. W. Richards[9] on the assumption that the stress, P, under which a substance rests can be measured by the heat C absorbed per gram-molecule when the volume changes dv/dt. Whence $P=CdT/dv$. Accordingly, $K=\frac{1}{3}CdT/dv$; but if $K=a/v^2$, it follows from van der Waals' equation $a(v-b)/v^2=RT$, or $K(v-b)=RT$, and that

$$\frac{1}{v-b}\cdot\frac{dv}{dT}=\frac{c}{3RT}; \text{ or, } \frac{1}{v-b}\cdot\frac{dv}{dT}=\frac{1}{273}; \text{ or, } \frac{C}{3RT}=\frac{1}{273}$$

which says in words: *at a given temperature T, the coefficient of expansion of the co-volume of a solid element, or the change per unit volume of the co-volume, is in general constant, viz.* $\frac{1}{273}$. This rule applies to the metals (monatomic) and the metalloids (polyatomic), but not to the halogens. It also follows that the atomic volume is nearly $3R$ cals. at 0°, when $T=273°$.

The relation between the latent heat of fusion and the coefficient of expansion.—Again, the greater the coefficient of expansion of a metal the lower the melting point,[10] although the results may be disturbed by changes in the complexity of the molecules near the melting point. The rule is illustrated by data in Table XXIX. It has been shown that for the solid metals J. D. van der Waals' equation assumes the forms $a(v-b)/v^2=RT$, and $dv/(v-b)dT=\frac{1}{273}$; substituting the latter value of $v-b$ in the former, it follows that at 0°, when $T=273$,

$$\frac{a}{v}\left(\frac{1}{v}\cdot\frac{dv}{dT}\right)=R$$

where the term in brackets represents the change in volume which occurs per unit volume when the temperature alters 1°—*i.e.* the coefficient of cubical expansion $3a$; and the term a/v represents the internal heat of vaporization, *i.e.* the observed latent heat of vaporization less the work done in expansion against atmospheric pressure during the change of state, and

$$\text{Internal latent heat, } \lambda = \frac{a}{v} + RT \text{ ; or, } \frac{a}{v} = \lambda - RT$$

Consequently, from the preceding expression, $3(\gamma - RT)a = R$, or *the product of the internal molecular heat of vaporization, and the coefficient of cubical expansion is equal to the constant* R—this is illustrated in Table XXIX., where the product $3a(\lambda - RT)$ is approximately constant for the elements which follow Dulong and Petit's rule. H. F. Wiebe[11] assumed that the coefficient of cubical expansion $3a$ is proportional to the amount of heat required to raise an element of atomic weight w from its melting point T_m to its boiling point T_b. If C denotes the specific heat of the element, the product $Cw(T_b - T_m)$=constant, which is nearly 2·03. Again, assuming that the amount of heat required to raise the temperature from absolute zero to the melting point T_m—or the thermal energy of the atoms of an element just before it melts—is almost inversely proportional to its coefficient of expansion, a, so that the product of these two constants are approximately constant; and $wCT_m a$=a constant. Both rules apply to some families of elements, but there are many exceptions.

TABLE XXX.—RELATION BETWEEN COEFFICIENT OF EXPANSION AND INTERNAL HEAT OF VAPORIZATION.

Arsenic	0·0000174	—	—	101,700	1·8
Diamond	0·00000375	—	—	45,200	1·7

W. Spring[12] found that for a number of related isomorphous elements—iron and aluminium; cobalt and nickel; sulphur, selenium, and tellurium—the product of the increase in volume which occurs on heating the element from 0° to 100° into the atomic weight is a constant—*e.g.* for sulphur, 0·035408 × 32 = 1·2330; selenium, 0·017610 × 78 = 1·3657; tellurium, 0·010634 × 127 = 1·3505. P. de Heen also has shown that the product of the coefficient of expansion and the absolute temperature of fusion is a constant or a multiple of this constant for compounds which are chemically related, and crystallize in the same system.

The above relations are either wholly empirical, or else they are based upon quite arbitrary or empirical assumptions as to the constitution of matter. Some of them may at times be useful in making approximations when observational data are wanting. They are also instructive in revealing the probability of the near discovery of a great law which will co-relate all the so-called physical constants of the metals, and include these empiricisms as special cases of restricted application. There is another side to this. By the substitution of one or more of these various formulæ in others, it is possible to obtain an indefinitely large number of equations correlating various physical properties. The changes can also be rung with the different forms of the gas equation. Consequently, a game of permutations and combinations can be played in physical chemistry just as in organic chemistry a similar game is possible with the methyl, ethyl, propyl, . . . radicles. C. F. Schönbein[13] said:

> I regard the discovery of thousands and thousands of new organic compounds in the same light as I do the infinite number of figures which may be produced by the kaleidoscope. What would the world say of a man who should take the trouble to shake for whole years that plaything, and describe minutely all the shapes (pretty as they might be) he had obtained from his operation ?

§ 21. The Kinetic Theory of Liquids

> It must be remembered that in every dynamical investigation, what the mathematician really investigates is not the problem presented by nature, but some simplification of it. . . . For any purpose which is of use to man, the approximation arrived at by the simpler problem is sufficient, wherever the errors are of such a nature that they are not cumulative. Nevertheless, it should be clearly recognized that it is a mechanism illustrating nature, and not nature itself, that has been mathematically investigated.—G. J. STONEY (1895).

The molecules of a liquid seem to have less freedom for movement than gases, although the molecules are sufficiently mobile to allow the liquid to take up, more or less quickly, the shape of the containing vessel. The mobility of liquids is indeed their most obvious quality. It is very probable that the kinetic energy of the translatory motions of the molecules of a liquid and its vapour, at the same temperature, are equal.[1] A molecule can, in time, travel to any part of the liquid mass. The rate of diffusion of one liquid in another shows that the movements are rather slow, probably because a molecule in its travels must be continually abutting against other molecules. The number of molecules in a gram-molecule of a compound is approximately 6×10^{23}; and for a non-associated liquid, say fluobenzene with a gram-molecular volume of 91·7 c.c., the volume of the molecular domain is $1·5 \times 10^{-22}$ c.c. Consequently, the average distance between the centres of adjacent molecules is of the order 7×10^{-8} cm., which is the same order of magnitude as the diameter of the molecules. Further, while the intermolecular attraction with gases is relatively small, the attraction between the molecules of a liquid must be greater because of the closer packing. Again, approximately 1700 c.c. of steam at 100° condenses to one cubic centimetre of liquid water at the same temperature, so that the average distance between the molecules of the liquid must approximate at least to the cube root of 1700, that is, about one-twelfth of the average distance between the molecules of the gas. The slow evaporation of liquids also shows that the molecules possess a certain mobility, and that the velocities of the moving molecules are not all the same.

The resistance offered by liquids to compression is very great; a fluid can support a stress only when the stress is uniform in all directions. For example, one c.c. of water at about 10° is reduced 0·000048 c.c. per atmosphere, or each additional atmosphere pressure brings the particles $\sqrt[3]{0·000048}=0·036$, *i.e.* about one-thirtieth nearer to one another, provided the volume of the molecules remains constant. The fact that a liquid readily changes its shape but strongly resists any force tending to diminish its volume, is taken to indicate that the potential energy depends only on the mean distance between the molecules, and not on their configuration. The small variation in the volume of liquid with increasing pressure has led to the idea that the molecules are very close together. On the other hand, this result, at first sight, is not parallel with the effect of temperature on the volume of a liquid, for water at 10° will contract nearly six times as much in cooling to 4°.

P. S. de Laplace (1806)[2] assumed that the molecules of a liquid attract one another with a force which extends over a very short distance which he called the *radius or sphere of molecular attraction*. The range of this action has been shown to be nearly 5×10^{-7} cm., for many experimenters have found that cohesion is inappreciable at greater distances. It is assumed that if it were not for the relatively great intermolecular attractive forces, the molecules of a liquid would travel in approximately straight lines; as it is, they are supposed to describe curved paths.

In any given liquid, the attractive forces tending to draw the molecules closer together are balanced against the centrifugal forces or the tendency of the molecules, so to speak, to move tangentially outwards away from the curved path. This tendency to move outwards is proportional to the square of the mean velocity V of the molecules, and inversely as the radius of curvature r of the path; for, with a molecule of mass M moving on a circular path, the centrifugal force is equivalent to MV^2/r; and, if the attractive force for unit distance be F, then, for equilibrium,

$MV^2/r=Fr$. The radius of curvature is probably very small and of molecular dimensions; accordingly, the intermolecular attraction R must be proportionally great. If the speed of the molecules be reduced by cooling, the centrifugal tendency is lessened, the attractive forces predominate, and the molecules move closer together into a new position of equilibrium. Accordingly, the liquid contracts in volume; and it also becomes more viscous owing to the greater difficulty experienced by the molecules in moving away from the sphere of one another's influence against intermolecular attraction. Isothermal compression also brings the molecules closer together—this favours the inward attractive forces; but the kinetic energy of the molecule is at the same time augmented—this increases the speed of the molecules, and strengthens the centrifugal forces which make the liquid resist further compression.

The cohesive attraction of the molecules of liquids.—The resultant of the mutual attraction of molecules simulates an inward pressure which opposes a resistance to the forces tending to enlarge its volume. Consider two layers of molecules in proximity to one another; the resultant attraction of molecule for molecule will be proportional to the number of attracted and attracting molecules, that is, to the square of the number of molecules. The number of molecules in unit volume of a liquid or solid will be proportional to the density, D, so that if a be the constant of proportion, the **intermolecular attraction,** the **internal pressure,** the **cohesive pressure,** or the **intrinsic pressure,** P—as Lord Rayleigh[3] called it—will be $P=aD^2$; and if v denotes the volume occupied by one gram of the substance, $P=a/v^2$, which is the term employed for intermolecular attraction in J. D. van der Waals' equation. The relation av^{-2} also follows directly from the assumption that the molecular attraction varies inversely as the fourth power of the distance of the molecules apart. The magnitude of the intrinsic pressure for water, determined by two independent methods, is very great—approximately 11,000 atm.; carbon disulphide, 2900 atm.; ethyl alcohol, 2400 atm.; and for ethyl ether, 1300 atm. P. S. de Laplace[4] was surprised at the magnitude of his own estimate of this pressure, for he obtained what he called *une aussi prodigueuse value qui ne peut pas être admise avec vraisemblance*—approximately 10^{12} tons per sq. in. The intrinsic pressure is a measure of the cohesion of a liquid or solid, that is, it measures the force—tensile strength—required to separate one portion of a liquid from another. **Laplace's constant** K is equivalent in meaning to J. D. van der Waals' av^{-2}; and T. Young estimated that the surface tension σ of a liquid is equal to one-third the total cohesive force, P, into the radius r of the molecule, or $\sigma=\frac{1}{3}rP$.

The intrinsic pressure of liquids.—The intrinsic pressures of a liquid calculated from J. D. van der Waals' equation and from A. Dupré's relation between the internal latent heat of vaporization are somewhat discrepant. The former gives 10,500 to 11,000 atm., the latter 23,900 atm. The discrepancy has been attributed (i) to the invalidity of the assumption that the density of the liquid in the surface layer is the same as in the bulk of the liquid, and G. Bakker therefore assumes that there is a gradual decrease in density in passing from the liquid to the vapour phase; and (ii) to the assumption that the molecular forces have no temperature effect, whereas it is certain that the intrinsic pressure P decreases as the temperature rises, and W. C. McC. Lewis[5] shows that the relation between the intrinsic P pressure and temperature T probably has the form $P=a+b\log T+cT$, where a, b, and c are constants. The different expressions which have been suggested for evaluating the intrinsic pressure have been compiled by W. C. McC. Lewis.

In 1869, A. Dupré suggested that the intrinsic pressure is equal to the internal work done per unit volume of liquid against the molecular attracting forces when the molecules are drawn apart until they are outside the range of their mutual attractions. Hence, A. Dupré assumed that the work done against intrinsic pressure, P, is equal to the internal latent heat per unit volume λ, or $P=\lambda$; but W. C. McC. Lewis emphasized that this can be true only when P is independent of temperature, and that the true relation probably has the form of H. von

Helmholtz's free energy equation $P=\lambda+T(dp/dT)_v$; and H. Davies has shown that dP/dT is equal to $-4R/v_c$; to $-R/b$; or to $-14{\cdot}8p_c/T_c$, which enables P to be calculated from observed values of λ and the critical constants.

A. Dupré showed that if β denotes the coefficient of compressibility, and a the coefficient of cubical expansion, J. D. van der Waals' equation furnishes the relation $P=-Ta/\beta$, on the assumption that P is independent of the temperature. The original edition of J. D. van der Waals' thesis also showed that if v be the volume of a given mass of vapour, v_1 the volume of the same mass of liquid, a the coefficient of gaseous expansion, and β the compressibility of the liquid, then, at $\theta°$, $P^2=v(1+a\theta)/v_1\beta$, and I. Traube has applied this result to liquid and solid elements.

T. W. Richards assumed that the heat C required to raise the temperature of unit volume by the amount dT, is equivalent to the intrinsic pressure P such that $P=CdT/dv$, on the assumption that P is independent of temperature and volume. C is here the atomic heat—approximately 6. The numerical values obtained with the elements are very large. I. Traube showed that T. W. Richards' expression gives very nearly three times the values obtained by J. D. van der Waals' expression, and he therefore writes $P=\frac{1}{3}CdT/dv$. C. Benedicks also deduced the expression $P=av^{-2}$ of J. D. van der Waals' equation, and assuming that a is independent of temperature and a denotes the coefficient of cubical expansion, he found $P=R(a^{-1}+2T)v^{-1}$, or approximately $P=R/va$, which is virtually equivalent to T. W. Richards' expression only if C were put equal to R. R. H. Davies obtained the expression $P=4R/av_c$, where v_c denotes the critical volume, and a the coefficient of cubical expansion, which H. Davies found to be equal to $(2T_c-T)-1$. At absolute zero, this reduces to $P=8RT_c/v_c$.

J. D. van der Waals' equation may be written $(p+P)(v-b)=RT$, where p denotes the external and P the internal pressures, and b the limiting molecular volume at the absolute zero. Accordingly, if the small pressure p be neglected in comparison with the large pressure P, it follows that the intrinsic pressure, $P=RT/(v-b)$. C. M. Guldberg extrapolated Cailletet and Mathias' linear diameter to absolute zero, and found the densities of a number of substances at absolute zero and at the critical temperature, the ratio being practically a constant 3·75 or $b=0{\cdot}27v_c$, for substances. D. Berthelot also found for oxygen, chlorine, carbon dioxide and sulphur dioxide, carbon tetrachloride, and benzene, $b=0{\cdot}26v_c$. The results furnished by calculating the numerical value of $P=RT/(v-b)$ at 0° on these assumptions represent minimum values of P, because the values of b are not likely to be independent of temperature, since b probably increases as the temperature rises. Taking P. Walden's or S. Young's values of v_c, the molecular critical volume, $b=0{\cdot}27v_c$; and v the molecular volume at 0°, the intrinsic pressures P at 0° of 36 liquids were calculated by W. C. McC. Lewis in atm. per sq. cm.

TABLE XXXI.—INTRINSIC PRESSURES OF LIQUIDS.

	v_c	b	v	$v-b$	P
Water	50·3	13·58	18·00	4·42	5084
Methyl alcohol	117·6	31·75	39·5	7·75	2898
Ethyl alcohol	166·9	45·06	56·1	11·04	2035

Ethyl ether	281·9	76·11	100·5	34·39	1653
Stannic chloride	351·8	94·99	114·5	19·51	1135

The relation between intrinsic pressure and surface tension.—The conception of an internal, intrinsic, molecular, or cohesive pressure presupposes the existence of attractive forces between the molecules diminishing rapidly with distance.

G. N. Antonoff has deduced a relation between the surface tension and the internal pressure on the assumption that the attractive force between the molecules is electro-magnetic in nature, and that the molecules can be treated as if they were electro-magnetic doublets. If P denotes the molecular or internal pressure; σ, the surface tension; n, the number of doublets or molecules in unit volume of liquid; D, the specific gravity of the liquid; M, its molecular weight, and $1{\cdot}64\times10^{-24}$, the weight of an atom of hydrogen, then $n=1{\cdot}64\times10^{24}D/M$, and therefore $P=2\sigma n^{\frac{1}{3}}$. Hence, if the surface tension of benzene be 32 dynes per cm.; the molecular weight, 78; and the specific gravity, 0·890; then $n=6{\cdot}8\times10^{21}$, and $P=12\times10^{6}$ dynes per sq. cm., a magnitude very nearly equal to 1200 atm.

Since the surface tensions and intrinsic pressures of liquids are closely related, it follows that when the exact connection between the various physical properties of the one is known, their relations with the other follow as a matter of course. S. W. Smith [6] assumed that the surface tension σ of some liquid metals is related with the intrinsic pressure P by the empirical formula: $\sigma=200+0{\cdot}00437P$, when σ is expressed in dynes per cm., and the intrinsic pressure P in megabars—10^6 dynes—per sq. cm. P. Walden found for a number of organic liquids $P=1{\cdot}82\sigma$, when the surface tension is determined at the boiling point. Otherwise expressed, the intrinsic pressure of a liquid at its boiling point is proportional to the surface tension at the boiling point. The relation between the surface tensions or intrinsic pressure and some other physical properties of liquids is shown in S. W. Smith's Table XXXII. The elastic moduli and the other properties run parallel with the surface tensions.

TABLE XXXII.—RELATIONS BETWEEN THE PHYSICAL PROPERTIES OF SOLIDS AND SURFACE TENSION.

	Surface tension (fluid) dynes per cm. σ	Internal pressure (solid) megabars, P	Compressibility per atomic vol. per megabar, $\times10^6$	Elastic modulus.	Atomic concentration, sp. gr. ÷ atomic wt.	Hardness.

The relation between intrinsic pressure and latent heat.—J. E. Mills (1902) [7] assumes that the resultant attraction between two molecules varies as the square of the distance of the molecules apart, and is a mutual property of each pair of molecules, so that the resultant attractive force $F=km^2/r^2$, where r denotes the distance apart of the two molecules—each of mass m; and k is the attraction constant whose numerical value is dependent on the nature of each of the attracting molecules. Consequently, the assumed law of molecular attraction differs from the attraction of gravitation in being dependent on the nature of the molecules and not solely dependent on their mass. If L denotes the observed heat of vaporization; E, the work of expansion against external pressure; D_1, the density of the liquid; and D that of the vapour, J. E. Mills finds that

$$\frac{L-E}{\sqrt[3]{D_1}-\sqrt[3]{D}}=\text{Constant}$$

If a mass of liquid of volume v has n particles at a distance r apart; and if V denotes the volume of the same mass in the gaseous state when the molecules are a distance R apart, the work W expanded in tearing the molecules asunder, against the assumed intermolecular attraction, during vaporization will be

$$\int_R^r F.dr = km^2\int_R^r \frac{dr}{r^2};\text{ or, } W = km^2\left(\frac{1}{r}-\frac{1}{R}\right)$$

Again, if L denotes the observed heat of vaporization, and E represents the work spent in overcoming the external pressure of the atmosphere during vaporization, the work W required to pull apart the n molecules of mass m will be $W=nm(L-E)$. Note that v and V respectively denote the volumes of the liquid and vapour, each containing n molecules of mass m, $r=\sqrt[3]{v/n}$, and $R=\sqrt[3]{V/n}$; and that the density D_1 of the liquid is $D_1=nm/v$, and of the vapour, $D=nm/V$; substituting for D_1 and D, in the two preceding values of W; and remembering that k, m, and n are constants. Mills' expression follows at once.

The work E spent in overcoming the external pressure by altering the distance apart of the molecules is calculated from the equation $E=0{\cdot}0000318p(V-v)$ cals., where p denotes the pressure of the air in millimetres of mercury, and V and v the respective volumes before and after expansion. The values of the constant for carbon disulphide at different temperatures selected from Mills' tables are indicated in Table XXXIII.

TABLE XXXIII.—MILLS' CONSTANT FOR CARBON DISULPHIDE.

Temperature.	Density of liquid, D_1	Density of vapour, D	Latent heat, L	External work, E	Mills' constant.
0°	1·2921	0·000966	90·00	7·24	82·22
20°	1·2775	0·000350	89·06	7·48	82·38
40°	1·2321	0·0024	85·64	8·10	82·71
60°	1·2003	0·0044	82·87	8·42	82·85
80°	1·1684	0·0075	79·70	8·67	82·82
100°	1·1684	0·0120	76·14	8·85	82·61
120°	1·0997	0·0182	72·18	8·94	82·23

J. E. Mills also found that out of 435 observations on 26 different non-associated liquids over ranges of temperature, only 30 differed from the mean value of the constant for the specific substance in question by more than 2 per cent. and only four of the 30 by more than 5 per cent. The data thus support the assumption that the molecular attraction (i) is independent of the temperature; (ii) varies inversely as the square of the distance apart of the molecules; and (iii) is a constant for any particular substance.

G. N. Antonoff showed that the relation between the internal pressure and the surface tension is the same whatever be the law of attraction between the molecules. For many purposes, therefore, it is not necessary to specify the attractive forces other than that they diminish rapidly with the distance. R. D. Kleeman[8] has also shown that it is possible to obtain an infinite number of formulæ for the surface tension of a liquid, and each of these formulæ corresponds to a law of molecular attraction, so that any number of laws of attraction will give latent heat formulæ agreeing with facts. All these laws of attraction are but fragments of a general law which must contain an arbitrary function of the distance between the attracting molecules and their temperature. J. E. Mills argues that a change of temperature does not change the nature or magnitude of molecular attraction, but rather determines the orbit the molecules will follow in obedience to the attractive force. In reply to R. D. Kleeman's proof that the molecular attraction must decrease at a much greater rate with the distance of the molecules than is given by the law of inverse squares, J. E. Mills postulates a mutual absorption or cancellation of the whole or part of the attractive force when this attraction is exerted upon other particles.

W. Sutherland (1893)[9] used the hypothesis that the intermolecular attraction varies inversely as the fourth power of the distance apart of the molecules; R. D. Kleeman (1910) examined a fifth power law; A. Albertosi (1915) a sixth power law; and P. de Heen a seventh power law. The fifth power law proposed by J. C. Maxwell in 1866 was abandoned by him in 1879. Newton's gravitational law thus includes but one term in a possible series:

$$F=ar^{-2}+br^{-3}+cr^{-4}+dr^{-5}+\ldots$$

where the coefficients b, c, d, . . . are so small that they can be neglected except where r is itself small.

P. S. de Laplace's formula for the pressure P within a sphere of liquid of unit radius is $P=K+H$, where Laplace's constant K involves the intrinsic pressure, and the term H involves the surface tension. A high intrinsic pressure is accompanied by a large surface tension. The intrinsic pressure has been related with the surface tension, the coefficient of thermal expansion, molecular volume, compressibility, vapour pressure, viscosity, etc. If the attractive forces between the molecules, or the intrinsic pressure, be very great, the coefficient of thermal expansion as well as the compressibility and viscosity will be smaller than when the attractive forces are small. Similarly also the latent heat of vaporization of a liquid will be larger when the molecular attraction is great than when the molecular attraction is small. Consequently, a large latent heat, a small compressibility, a small coefficient of thermal expansion, and low viscosity should run together. This is illustrated qualitatively in Table XXXIV. An enormous number of changes have been rung with formulæ connecting the various physical properties of liquids. In a general way, it may be said that when a relation has been found to obtain between certain physical properties of a liquid over a certain range of temperature, it is almost sure to be applicable to other liquids over a similar range of temperature.[10] This probably also applies to the so-called associated liquids; for the apparent failure with these is mainly due to the use of incorrect molecular weights; with corrected molecular weights the associated liquids would also fall in line with other liquids. If the physical properties are markedly constitutive, that is, are dependent upon the inner structure of the molecule—the formulæ are not general—*e.g.* viscosity, latent heat, specific heat, surface tension. Of course every physical property is to some extent constitutive, and small deviations are found, but in view of the sparsity of accurate and comparable observational data, the general agreement just indicated is rather striking.

TABLE XXXIV.—SOME EFFECTS OF MOLECULAR ATTRACTION IN LIQUIDS.

Liquid.	Molecular latent heat, Cals.	Coefficient thermal expansion.	Compressibility.	Viscosity at 0°.

§ 22. The Surface Tension and Surface Energy of Liquids and Solids

Capillary force may be considered as the first degree of chemical affinity.—M. L'HERMITE (1855).

The molecular forces at the surface of a liquid do not produce the same effects as in the interior. In the interior of a liquid, the molecules are attracted equally in all directions, those at the surface are attracted inwards, in a direction perpendicular to the free surface. The surface tension, of course, is not the cause but rather a consequence of the internal pressure. The effect of this inward pressure is in many respects analogous with what would obtain if the surface was enveloped by an elastic membrane in a state of tension. The tension is called the **surface tension** or **surface pressure** of the liquid. For equilibrium, the surface tension of a given liquid is the same in all directions and at all points on the surface. There is a difference between the tension of the imaginary membrane and the actual tension, or inward pressure of the free surface of the liquid, in that when the surface of the liquid increases, it does so by exposing fresh particles, and not by stretching the old surface of the liquid in the sense that indiarubber would be stretched. The elastic membrane is merely an analogy to assist the mind in forming a concept of a number of different phenomena ; but it does not enable us to form a satisfactory mental picture of the distribution of the molecules in the surface film of a liquid. It is therefore convenient to regard liquids as if they were enclosed in a contractile membrane in a state of uniform tension which makes the free surface the smallest that circumstances will allow. The sphere has the smallest surface of any given mass of liquid, consequently, drops of liquid assume the form of a sphere, unless they are so large that gravitation can exert an appreciable influence, and flatten the drop to a thickened disc. The smaller the drops the more nearly do they approach perfect spheres.

EXAMPLES.—(i) Mercury globules on a flat board show the phenomena well. (ii) By suspending a drop of, say, ortho-toluidine in a 3 per cent. solution of sodium chloride large spherical drops 5 to 6 cm. diameter are easily obtained since the effect of gravity on the drop is cancelled, so to speak, because the drops are suspended in a liquid of the same density they are themselves. Similarly, (iii) soap-bubbles in air are spherical, and they would remain suspended therein and not sink if it were not for the actual weight of the film of soap solution.[1]

In the case of liquid crystals, the surface tension of the crystals tends to make them assume the form of spherical globules, but this is opposed by the special molecular force—the *Gestaltungskraft* of O. Lehmann—which makes normal crystals assume their characteristic forms. Hence, photographs show that the liquid crystals of some substances are spherical, while others have pyramidal forms with more or less rounded edges.

The pressure in the space enclosed by a spherical liquid surface.—Imagine the liquid sphere to be divided into two hemispheres by an imaginary plane. Let r be the radius of the sphere; p, the pressure at any point inside; and σ, the surface tension. The only forces acting on the hemisphere $ABCD$, Fig. 16, are (i) a thrust on the plane face ABC, due to the pressure of the liquid in the half sphere not shown in the diagram, and which is equal to the pressure $p \times$ the area of ABC, *viz.* πr^2; and (ii) the tension of the surface acting round the edge of the circle ABC, and which is equal to σ times the perimeter ABC, that is, to $\sigma.2\pi r$. These two forces are in equilibrium, and therefore balanced so that $p\pi r^2 = \sigma 2\pi r$. Hence, the pressure $p = 2\sigma/r$, that is, the pressure is inversely proportional to the radius of the sphere; it is produced by surface tension only; and is the excess of the internal over the external pressure. If a soap-bubble be in question, there are two surfaces, each of which exerts a pressure $2\sigma/r$, so that the pressure within a soap-bubble is $4\sigma/r$. The same reasoning coupled with hydrostatic pressure can be applied to gas-bubbles rising in a liquid.

FIG. 16.

A liquid boils when the bubbles of vapour formed in the interior can rise and escape at the surface. The pressure of the vapour within a bubble at a depth h below the liquid is equal to the pressure of the atmosphere plus the pressure equal to the weight of a corresponding column of liquid of height h, and $2\sigma/r$. If the pressure of the vapour within the bubble be less than this, the bubble must collapse. The smaller the bubble, the smaller the value of r, and the greater the pressure of the vapour. Hence the temperature of a liquid must be much higher to maintain small than to maintain large bubbles in equilibrium. If there are no facilities for producing bubbles which are fairly large to start with, the temperature may rise above the boiling point until a large bubble is formed—this may give rise to **bumping,** or portions of the liquid may be projected from the vessel, with explosive violence. The presence of a small piece of capillary, closed at one end, and filled with air, enables the vapour of the liquid to be formed in the interior, and fairly large bubbles to be formed at the open ends. This explains how the presence of these capillary tubes, porous earthenware, charcoal, etc., enables liquids to boil steadily without bumping.

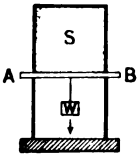

FIG. 17.—Surface Tension of Liquids.

Surface tension is evidence of the presence of cohesive forces between the molecules of a liquid. J. C. Maxwell[2] illustrated surface tension by supposing a film of liquid S, Fig. 17, to be stretched on a wire framework, and attached to a light wire AB, and a weight W. Assume the part of the wire wetted by the film is of unit length. The force exerted per unit length of the stretched film is termed the **surface tension.** It is usually more convenient to consider not the actual surface tension or force acting on the surface of the liquid, but rather the energy associated with that surface, the so-called **surface energy.** If W just supports the stretched film, the surface tension σ of the film is equal to $\frac{1}{2}W$, because there are two surfaces to the film. If the weight suffices to stretch the film a distance s, the work performed against surface tension will be the product $2\sigma s$. The potential energy of the surface of the film has therefore increased by an amount $2\sigma s$; and each side of the film has increased by an area s; hence, the increase of energy per unit area is $2\sigma s/2s = \sigma$. Hence if W denotes the surface energy per unit area, $W = \sigma$. Consequently, the surface tension of a liquid is equal to the work done in enlarging the surface of the liquid by one sq. cm., under isothermal conditions, although it is not permissible to define surface tension as the energy per unit area of the surface of a liquid. The surface tension in dynes per cm. is numerically equal to the surface energy expressed in ergs per sq. cm.; the surface tension may be expressed in dynes per cm.; in grams per cm.; or in mgrm. per mm. In converting from one system of units to another, the number of grams multiplied by 980 furnished the equivalent in dynes; and mgrm. per mm. multiplied by 9·8 changes the result into dynes per cm.

There are several more convenient methods of measuring surface tension. When a capillary tube is plunged vertically in a liquid, the surface tension inside the tube ranges over the liquid within the circumference of the *capillus* or internal bore, and the liquid rises, *A*, Fig. 18, or falls, *B*, Fig. 18, below the level of the liquid outside the tube, according as the liquid wets, *A*, Fig. 18, or does not wet, *B*, Fig. 18, the walls of the tube. The vertical component of the surface tension between the liquid and the walls of the tube at the level of the liquid within the tube acts along a ***length*** equivalent to the circumference of the internal bore, *i.e.* $2\pi r$; and at an *angle* α—called the *angle of contact*, or edge angle—between the normal to the free surface, and the tangent to the liquid surface, where it meets the solid walls. Consequently, the vertical component of the surface tension at the point of contact between liquid and solid is equivalent to $2\pi r \times \sigma \times \cos \alpha$. This is balanced by the weight of the column of liquid within the tube which is above the level of the liquid outside the tube; or, if the liquid does not wet the tube, by the column of liquid which is held back by the surface tension. If h denotes the height of this column, the volume of this liquid is $h\pi r^2$, and if D be the density of the liquid, and g the acceleration of gravity, the weight of this column of liquid is $h \times \pi r^2 \times D \times g$ dynes. When these two forces are balanced, or in equilibrium, $\sigma \times 2\pi r \times \cos \alpha = h \times \pi r^2 \times D \times g$ or $\sigma = \frac{1}{2}ghrD/\cos \alpha$ dynes, which represents the surface tension in terms of the height h of the capillary effect; the radius r of the tube; the density D of the liquid; and the constant angle α. When the contact angle is nearly 180°, cos α approaches unity, and the surface tension can be experimentally measured from the formula $\sigma = \frac{1}{2}ghrD$. Sometimes, the relation rh or $2\sigma/D$ is called the **specific cohesion** of a liquid, and it is symbolized by a^2, such that $a^2 = 2\sigma/D = rh$. For example, if the density of water is unity, and the surface tension 7·25, the value of a^2, the specific cohesion is 14·50. The surface tension can also be measured from the wave-lengths of ripples on clean surfaces;[3] from the number of drops which fall from a given orifice in a given time; etc.

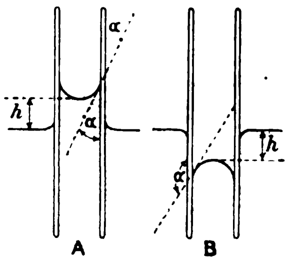

FIG. 18.—Contact Angle.

Numbers ranging from 7·13 to 7·945 mgrm. per mm. have been published for the surface tension of water at 18°; and from 39·23 to 55·78 for mercury at 20°. The surface tensions of a few liquids in dynes per cm. are:

Mercury (18°).	Water (20°).	Carbon disulphide (20°).	Chloroform (20°).	Carbon tetrachloride (20°).	Alcohol (20°).	Ether (20°).
440	75	32·7	25·68	21·6	26·3	15·9

The kinetic theory of vaporization would lead to the assumption that the properties of a liquid surface must be radically different if it is in contact with another liquid instead of its own vapour. At the boundary surface of the gas-liquid system the mean free paths of the molecules are of a very different order of magnitude, while at the surface of the liquid-liquid system, the mean free paths will be of the same order of magnitude and characteristic of each liquid. M. Planck and M. Cantor[4] believe that the surface of a liquid when in contact with another liquid retains the same properties as it had when in contact with its own vapour. Two liquids of limited solubility are in equilibrium when each liquid is saturated with the other, and D. Konovaloff showed that the saturated vapours emitted by each of the two layers of liquid have the same vapour pressure, and the same vapour composition although their own composition is very different. G. N. Antonoff believes that the surface tensions of the layers of the two liquids of limited miscibility are identical in the two contact planes. Lord Rayleigh's hypothesis led to the conclusion that the surface tension σ_{12} at the limiting surface of the two liquids with the respective surface tensions σ_1 and σ_2 when in contact with their own vapour is given by $\sqrt{\sigma_{12}}=\sqrt{\sigma_1}-\sqrt{\sigma_2}$; but G. N. Antonoff did not find this formula to agree with experiment, and he has shown that the interfacial surface tension σ_{12} is equal to the difference of the surface tensions against air of the two superposed liquids in equilibrium such that $\sigma_{12}=\sigma_1-\sigma_2$, so that two superposed liquids, of limited solubility and in equilibrium, must be regarded as solutions in the same solvent; and he also believes that they contain an equal number n of molecules per unit volume so that $n_1=n_2$, by A. Avogardo's hypothesis, for, says G. N. Antonoff, "if two solutions in the same solvent have the same freezing and boiling points, as is the case with two superposed liquids of limited solubility and in equilibrium, they must contain an equal number of molecules in unit volume." This is possible only when the molecules of the one component B form a compound with some of the molecules in the solution, and any further addition of B would not increase the number of molecules present in the solution. Hence, all properties depending on the number of molecules and not on their dimensions remain invariable.

The relation between surface tension and temperature.—According to D. I. Mendeléeff,[5] one characteristic of a perfect liquid is that its surface tension should be a linear function of its temperature, and this view was confirmed by A. L. Selby. The decrease of the surface tension with a rise of temperature is usually represented by a simple linear equation, for in most cases the surface tension σ at $\theta°$ is equal to $\sigma_0(1-a\theta)$, where σ_0 denotes the surface tension at 0°, and a is a constant characteristic of particular liquids.[6] Thus,

	Water from 0° to 70°.	Ether from 2° to 25°.	Alcohol from 5° to 72°.	Cadmium from 365° to 431°.	Lead from 389° to 498°.
a	0·0021	0·0060	0·0034	0·00042	0·00029

The ordinary linear equation $\sigma=\sigma_0(1+a\theta)$ and the parabolic equation $\sigma=\sigma_0(1+a\theta+b\theta^2)$ hold only over a very restricted range of temperatures, but they probably become very inaccurate when extrapolated far beyond the range of observation.

According to J. D. van der Waals,[7] the surface tension σ of a liquid at a temperature T, not far removed from the critical temperature T_c, is

$$\sigma=A\left(\frac{T_c-T}{T_c}\right)^{\frac{3}{2}}$$

where A is a constant independent of the temperature. At the critical temperature, both σ and $d\sigma/dT$ are zero.

Just as the kinetic energy of an ideal gas remains constant during an isothermal expansion, because the external work performed during the expansion is derived from the heat which enters the gas, so, when the surface of a liquid is stretched isothermally, the energy of the new surface is not equal merely to the mechanical work performed during the stretching, for an allowance must be made for the energy which enters or leaves the surface in the form of heat. The mechanical work performed when the surface of a liquid is increased is spent against molecular forces in bringing additional molecules within the surface-layer. If energy be expended in work against the cohesive forces during the stretching, the surface of the liquid will be cooled; and if the process be conducted isothermally, the inflow of heat will increase the surface energy; and the total surface energy will therefore be the sum of two factors; (i) The mechanical work σ performed against the intermolecular forces—with water at 0°, for example, this is equivalent to 75 ergs; and (ii) the inflow of heat—bound energy—required to maintain the temperature of the film constant during the stretching—with water at 0°, for example, this is equivalent to about 40 ergs. Lord Kelvin (1858),[8] by reasoning analogous to that employed in deducing H. von Helmholtz's equation, showed that the free energy, W, or the energy which is available for doing work, is then equal to the surface energy σ less the heat energy absorbed from the surrounding bodies, which is represented by the product of the absolute temperature and the temperature coefficient, $d\sigma/dT$, or the variation of surface tension with temperature is given by

$$W=\sigma-T\frac{d\sigma}{dT}\text{; or, }\sigma=W+T\frac{d\sigma}{dT}$$

The change of surface tension with temperature is a linear function over a considerable range of temperature, such that the surface tension σ at a temperature θ is, $\sigma=\sigma_0-b\theta$, where σ_0 and b are constants; accordingly, under these conditions, the temperature coefficient by the surface energy is a constant, or $d\sigma/dT=-b$, where the negative sign means that the surface tension decreases with increasing temperature.

P. S. de Laplace inferred that the ratio of the temperature coefficient of the surface tension and the coefficient of thermal expansion should be a constant, and this has been verified in a number of cases. For example, if σ_0 be the surface tension at 0°, and the surface tension σ at $\theta°$ is $\sigma=\sigma_0(1-a\theta)$; and if 3α be the coefficient of cubical expansion, the ratio $a/3\alpha$ is nearly constant:

	Benzene.	Alcohol.	Phenol.	Acetic acid.	Nitrobenzene.	Carbon disulphide.
σ_0	29·4	34·3	40·6	28·9	48·2	54·6
a	0.0035	0·0027	0·0029	0·0038	0·0028	0·0029
3α	0·00139	0·00124	0·00089	0·00116	0·00089	0·00121
$a/3\alpha$	2·5	2·2	3·3	3·3	3·1	2·0

Hence, the effect of temperature on the surface tension is largely an effect of the change of density. R. D. Kleeman [9] obtained the relation $\sigma=K(D_1-D)$ between the density of a liquid D_1 and of its saturated vapour D, when K is a constant dependent on the nature of the liquid. According to W. A. Kistiakowsky, at the absolute boiling point, T_b, the capillary rise a^2 in a tube of 1 mm. radium, is $a^2M=KT_b$, where M represents the molecular weight, and K is a universal constant with the same value, 0·00116 ± 0·004, for all non-associating liquids. By definition, their boiling points are proportional, and the constant $K=KT_b/MD_b{}^3$, where D_b denotes the density of the liquid at its boiling point. C. Schall found that the surface tension of liquids varies approximately as the 2⅔'s power of the density: $\sigma/D^{\frac{8}{3}}$=a constant. P. S. de Laplace's assumption that the surface density is the same as the density of the main body of the liquid failed to explain why the surface tension diminished with temperature more rapidly than the body density. By assuming that the densities of the surface film and the body of the liquid are markedly different, and that there is a corresponding difference of stress in the two regions, it will be understood how the rate of variation of surface density with temperature, as hinted at by C. Schall's rule, can be more rapid than that of the body density. This is evidenced by the heating of the upper film of liquid in a capillary tube producing a more marked effect than heating the liquid lower down. E. H. Amagat [10] also found that a stress of 3000 atm. diminishes the coefficient of thermal expansion of ether, between 0° and 50°, from 0·0017 at one atm. pressure to about one-third this value at 3000 atm. pressure. J. W. Gibbs (1876) also showed that the surface layer may be regarded as a special phase with its own characteristic density and entropy.

The relation between surface tension and compressibility.—As a rule the surface tension of highly compressible liquids is low,[11] provided there are no changes in the character of the molecules of the liquids under investigation. For example, representing the compressibility per atmosphere by β, and the surface tension by σ,

	Ether.	Acetone.	Alcohol.	Chloroform.	Benzene.	Water.	Mercury.
$\beta\times10^4$	190	121	105	103	92	48	3·83
	15·9	23·3	21·6	26·8	28·3	75	440

The product $\beta\times\sigma$ is not a constant, but, according to T. W. Richards and J. H. Mathews (1908),[12] the product of the surface tension σ of about thirty-seven organic liquids with the cube root of the fourth power of the compressibility κ, is constant. There are difficulties in comparing the compressibilities of different liquids, because the results are in part determined by the shapes of the molecules. I. Traube found that the product of the intrinsic pressure into the square root of the atomic (or molecular) compressibility is approximately constant for 14 elements in the solid state. Impurities in the metals may disturb the relation, for small traces of foreign matter may have exerted marked effect on the internal pressure.

The relation between surface tension and latent heat of vaporization.—J. J. Waterston [13] made one of the first attempts to connect the surface tension, σ, with the molecular latent heats of evaporation, $M\lambda$, and the molecular volumes, v. His expression $M\lambda=k\sigma v^{\frac{2}{3}}$—where k is a constant—is but a rough approximation, which, according to R. Eötvös, gives better results if the data for different substances are determined for corresponding states, *i.e.* at their critical temperatures, or the same temperatures reckoned downwards from the critical temperatures as zero. J. Stefan [14] has shown that the observed heat of vaporization, L, expressed in suitable units, is equal to the internal work performed in transforming the liquid into vapour; and that this, in turn, is equal to the product of the volume v of the liquid, and the difference in the internal pressure P and the vapour pressure of the liquid p. Otherwise expressed, $L=(P-p)v$. G. Bakker (1888) regards P as the internal or cohesive pressure per unit area across any section in the interior of the liquid. In that case, Pdv represents the internal work done when a liquid expands by dv; and, if the liquid changes its state so that v_0 volumes of liquid become v_1 volumes of vapour, at the same temperature, the observed latent heat will be $L=Pdv+p(v_1-v_2)$; and the internal latent heat will be $\lambda=\int Pdv$. G. Bakker further assumed that K is a function of v such that $P=Av^{-2}$, so that the internal latent heat

$$\lambda=A\int_{v_0}^{v_1}\frac{dv}{v^2};\ \lambda=A\left(\frac{1}{v_0}-\frac{1}{v_1}\right);\ \text{or, }\lambda=\frac{A}{v_0}$$

when the volume v_1 is very large compared with v_0. If A is independent of temperature the internal latent heat will be identical with av^{-2} in J. D. van der Waals' equation, and accordingly will correspond with the assumption that the molecules attract one another inversely as the fourth power of their distance apart. The values of P calculated from this relation and also from the assumption that P is equivalent to the av^{-2} of J. D. van der Waals' equation, agree in a number of cases; but G. Bakker believes that A is a function of the temperature such that $A=a-Tda/dT$. Assuming that G. Bakker's A is equal to J. D. van der Waals' a at the temperature of vaporization, the

$$\text{Latent heat of vaporization, } L=\frac{a}{v_0}+\frac{RT}{M}$$

where v_0, being small in comparison with v_1, has been neglected and $p(v_1-v_0)$ becomes pv_1; and hence if M be the molecular weight of the vapour, and Boyle-Charles' law obtains, $pv=RT/M$. Calculations [15] based on this relation do not agree very well with the observed latent heats.

P. Walden [16] has indicated a number of relations between the surface tension and the latent heat of vaporization L in calories. If L_b and L_m respectively denote the latent heats of weight; and σ_b and σ_m, the surface tensions at the boiling and melting points respectively: vaporization and fusion; v, the molecular volume; D_b and D_m, the density; M, the molecular $D_bL_b=34{\cdot}8\sigma^b$; $ML_b=3{\cdot}64v\sigma_b$; $D_mL_m=7{\cdot}2\sigma_m$, provided the liquids do not form more normal complex molecules than is indicated in the normal formula weights. D. L. Hammick gives the relation $6\sigma V/d=L$, where d denotes the molecular diameter; L the internal latent heat; and V the gram-molecular volume.

E. T. Whittaker found empirically that for about half a dozen liquids, the surface energy σ of a liquid in contact with its own vapour is proportional to the product of the internal latent heat λ and the absolute temperature T. Accordingly. $\sigma=kT\lambda$, where k is a constant which R. D. Kleeman computed to be equal to $0{\cdot}557M^{\frac{1}{3}}D_c/T_c$, when D_c and T_c respectively denote the critical density and critical temperature. E. T. Whittaker's rule is but an empirical density approximation. Several other relations between the molecular internal latent heat, $M\lambda$, and the densities of the liquid, D_1, and saturated vapour, D, have been proposed.[17] C. Dieterici (1908), for instance, suggested $M\lambda=kT \log (D_1/D)$; R. D. Kleeman and A. J. Batschinsky, $M\lambda=k_1(D_1^2-D^2)$, where k and k_1 are constants dependent on the nature of the liquid. The changes have been rung on these relations by substitutions with the various vapour pressure formulæ. R. Clausius and E. Clapeyron's equation, Trouton's relation, R. Eötvös' rule, and many other subsidiary relations have been obtained. W. C. McC. Lewis deduced a relation between the latent heat of vaporization, L, of a liquid and the product of absolute temperature, T, and the coefficient of thermal expansion a divided by the product of the density D and the coefficient of compressibility κ at constant volume, such that $L=-Ta/D\kappa$. L. Henry found this relation agrees very well with a number of observations but for the exceptional behaviour of water,[18] the alcohols, and the fatty acids, for which there is a large amount of evidence pointing to irregularities in the molecular structure.

J. D. van der Waals [19] deduced a form of Trouton's rule from his equation of state $M\lambda/T_c$ is a constant, where T_c denotes the critical temperature; and further that the latent heat of vaporization of all substances is independent of the temperature reckoned from the critical temperature. This does not agree with experiment. Several other more or less empirical relations have been obtained. Thus, P. de Heen [20] obtained from his theory of fluids $C_l-C_g=1{\cdot}333a\lambda$, when C_l and C_g respectively denote the specific heats of liquids and gas; a, the coefficient of expansion; and λ, the latent heat of vaporization; A. Nadejedine, $\lambda=kCp$, when k is a constant; C, the specific heat of the liquid; and p, the pressure under which evaporation proceeds; O. Tumlirz, $\lambda=0{\cdot}67537\gamma T/D$, which can easily be reduced to Trouton's rule.

The relation between intrinsic pressure and solubility.—P. Walden [21] has compared the intrinsic pressures of a number of liquids with their solubilities in water, and found that they run parallel with one another, for the mutual solubility of two liquids was found to be greater, the smaller the difference in their intrinsic pressures; and if this difference is very great, the two liquids are immiscible. S. W. Smith (1917) illustrates this rule by the cases of silver and gold, and of zinc and lead. The ratio of the intrinsic pressures with the former pair of metals is as 1 : 1·08, and of the latter, 1 : 2·13. The former are completely miscible, the latter only partially so.

It can be shown thermodynamically that the **specific heat** of a liquid is independent of the magnitude of the surface and that the amount of energy necessary for the production of a new surface is dependent on the temperature. This, says H. Freundlich, is because the surface energy is of a potential not a kinetic nature. P. N. Pavloff [22] found that the effect of surface tension on the **melting point** shows that very small particles have a greater surface tension and a smaller melting point than coarser-grained particles. According to P. Walden, if M denotes the molecular (or formula) weight of a substance which has a specific cohesion a_m^2 at the melting point T_m° K., then $Ma_m^2=3{\cdot}65T_m$.

The solvent powers of liquids for the indifferent gases have been found by G. Geffcken,[23] A. Ritzel, etc., to run parallel with the compressibility of the solvents. There is also a parallelism between the lowering of the compressibility and the lowering of the solubility when salts are added to water. The greater the compressibility of the solvent, the greater the amount dissolved. A. Ritzel postulates that every gas possesses what he calls a solubility pressure—*Löslichkeitsdruck*—π, for a given fluid. The solubility pressure, which favours solution, is opposed by a counter pressure which hinders solution. When the solution is saturated, the opposing pressures are balanced. If β denotes the compressibility coefficient of the liquid, S, the solubility of a given gas in the liquid, and δ the change in volume which occurs when unit volume of the liquid is saturated with gas, A. Ritzel assumes that

$$\pi=\frac{\delta S}{\kappa}\text{; or, } S=\frac{\pi\beta}{\delta}$$

meaning that the solubility is greater, the greater the solubility pressure, the greater the compressibility of the solvent, and the smaller the change in volume which occurs on solution. Without testing this equation quantitatively owing to lack of measurements of the solubility pressure, π, A. Ritzel calculates values of π, and shows qualitatively that the preceding assumptions are valid. The results for the solutions of carbon monoxide in some liquids are shown in Table XXXV.

TABLE XXXV—SOLUBILITY PRESSURE OF CARBON MONOXIDE.

Solvent.	β	δ	S	π
Acetone . . .	0·0001210	0·00211	0·238	4·15
Chloroform . . .	0·0001030	0·00224	0·206	4·48
Benzene . . .	0·0000915	0·00231	0·174	4·39
Alcohol . . .	0·0000875	0·00209	0·172	4·11

The surface tension decreases as the compressibility increases, and the solvent powers of liquids decrease as the surface tension increases. The surface tension curve for the solubility of gases in binary mixtures exhibits a maximum where the solubility curve shows a minimum; but not always conversely owing possibly to secondary disturbing effects.

Several attempts have been made to represent the surface tension of a mixture by the mixture law: $\sigma=a_1\sigma_1+a_2\sigma_2+\ldots$, where a_1, a_2, . . . denote the fractional proportions of the two liquids, so that $a_1+a_2=1$, and σ_1, σ_2, . . . their respective surface tensions. H. Rodenbeck found this rule to apply with mixtures of alcohol with water or chloroform; and chloroform with ether or petroleum. W. Sutherland[24] deduced, from the inverse fourth law of molecular attraction, the expression:

$$\frac{\sigma}{D^2}=\left(\frac{w_1\sqrt{\sigma_1}}{D_1}+\frac{w_2\sqrt{\sigma_2}}{D_2}\right)$$

where D_1 and D_2 denote the respective specific gravities of the components of the mixture; σ_1 and σ_2, the respective surface tensions: w_1 and w_2, the proportions by weight; and σ and D, the respective surface tension and specific gravity of the mixture. This is regarded as a special case of S. D. Poisson's formula $\sigma=a_1^2\sigma_1+2a_1a_2\sigma_{12}+a_2^2\sigma_2$, where σ_{12} is a characteristic constant for the interface of the superposed liquids. P. Volkmann, C. E. Linebarger, and W. H. Whatmough found the formula to be applicable in some cases, not in others.

Very little advance has been made in deducing relations between the **chemical constitution** and the surface tension of chemical compounds. D. I. Mendeléeff[25] has shown that the product of the molecular weight and the surface tension—unfortunately called the *molecular cohesion*—with certain homologous series of compounds varies proportionally with the number of CH_2 groups introduced; and that the constant $2\sigma/D$ generally varies in the same direction as the latent heat of vaporization. The substitution of hydrogen by an equivalent of oxygen or the halogens raises the coefficient. Dilute solutions have also been investigated. The surface tension of a liquid is altered when a substance is dissolved therein. In general, the inorganic salts slightly raise the surface tension of water; hydrogen chloride or bromide and ammonia lower the surface tension of water; sulphuric acid and alkali hydroxides raise the surface tension of water.

The surface tension of solutions.—In 1875, G. Quincke showed that the surface tension of aqueous solutions, σ, is a linear function of the concentration C expressed in gram-equivalents per litre, then $\sigma=\sigma_s+bC$, where b is a constant—0·1566 for sodium chloride, and 0·1666 for potassium chloride. Otherwise expressed, the so-called *molecular rise of the surface tension of solutions* defined by $(\sigma-\sigma_s)/C$, is perceptibly constant for dilute solutions.[26] G. Pann found that this proportionality does not obtain with more concentrated solutions, and E. H. Archibald connected the raising of the surface tension with the degree of ionization a of the salt in solution by the expression $\sigma-\sigma_w=a(1-a)C+baC$, where a and b are constants.

The relation between the concentration of the surface film and the body of a solution.—The distribution of the solute between the surface film and the body of the liquid is not necessarily the same. J. W. Gibbs,[27] in his classical memoir *On the equilibrium of heterogeneous substances* (1876), first showed the relation between the concentration of the surface film and the surface tension :

$$u\frac{dp}{dC}=-C\frac{d\sigma}{dC}$$

where u denotes the excess concentration in grams per sq. cm. surface over the concentration C in the body of the solution ; dp/dC denotes the coefficient of the change dp in the osmotic pressure which is attended by a change dC in the concentration. This magnitude is positive for all solutions. The coefficient $d\sigma/dC$ represents the coefficient of the change in the surface tension for a small change dC in the concentration of the solution. Since u and $d\sigma/dC$ are always opposite in sign, the surface tension will increase with concentration if the concentration of the surface film is less than in the interior of the liquid ; and conversely, for dilute solutions obeying J. H. van't Hoff's osmotic pressure formula $p=RCT$, or $dp/dC=RT$, and therefore J. W. Gibbs' relation between the amount u of solute adsorbed by a surface film and the change in the surface tension per unit change of concentration, assumes the form :

$$u=-\frac{C}{RT}\cdot\frac{d\sigma}{dC}$$

This same expression follows directly from the principle of virtual work. A surface s contains a gram-molecule of salt and the surface tension is σ, so that the surface tension is diminished $d\sigma$, when a little solute enters the surface, and the change of surface energy is $sd\sigma$. To remove this amount of solute from a volume v of the solution against the osmotic pressure p, requires the expenditure of energy vdp so that $sd\sigma+vdp=0$. If the gas law is applicable, $v=RT/p$, and therefore $d\sigma/dp=-RT/sp$; but the osmotic pressure is directly proportional to the concentration C, so that $d\sigma/dC=-RT/Cs$. Again, since s is the surface which contains a gram-molecule excess of solute, and if u denotes the excess in unit area, $u=1/s$. Hence, rearranging terms, $u=-(C/RT)(d\sigma/dC)$.

It will be observed that if $d\sigma/dC$ be positive, *i.e.* when the increase of the surface tension with increasing concentration of the solute in the film is negative, the surface will contain less solute than the body of the liquid—this is called ***negative adsorption***—and the effect of the salt in raising the surface tension of the solvent will in consequence be partially counteracted. Again, if $d\sigma/dC$ be negative, the surface tension will decrease with concentration, as is the case with many organic compounds—*e.g.* the oleates, amyl alcohol, etc.—and u will be positive, meaning that the solute will be absorbed by the surface so that the concentration of the solute in the surface film will be greater than in the body of the liquid. This is called ***positive adsorption.*** The term adsorption is usually applied to this surface layer. Consequently, ***a solute is positively adsorbed by a surface film when it lowers the surface tension of a solvent towards its own vapour, and negatively adsorbed when it raises the surface tension of the solvent.*** A small quantity of the dissolved substance can lower the surface tension of a solution to a marked degree, but a solute cannot raise the surface tension very much because in the latter case, the concentration of the solvent in the surface film will be less than in the body of the liquid, and the extreme limit is attained when the surface film is purely solvent. Here then u and $d\sigma/dC$ can possess only a small value. On the other hand, if the adsorption be positive, the whole of the dissolved substance, under suitable conditions, will be concentrated in the surface layer, and this can reduce the surface tension very much. There is a limiting case with a solution containing 0·000022 gram-molecule of salicylic acid per litre, for all the solute collects in the surface film. The concentration of the solute in the surface film has been investigated by J. von Zawidsky,[28] C. C. Benson, and S. R. Milner by producing a copious froth which has a very large surface, and comparing the concentration of the solute in the froth and in the body of the liquid. Thus, with an aqueous solution of amyl alcohol, it was found that when C for the original solution was 0·0375 gram-molecule, C for the foam was 0·0394 gram-molecule, hence $u=0·0019$ gram-molecule. Near the critical point, where $d\sigma/dC=0$, $u=0$, so that with an increase of concentration, the solute distributes itself in the interior of the liquid, and does not enrich the surface layer. W. C. McC. Lewis' results[29] did not agree with theory, and hence S. Arrhenius inferred that the phenomena of adsorption does not depend on surface tension, and that all attempts to correlate these phenomena are doomed to failure.

According to I. Traube,[30] the more a solute diminishes or increases the surface tension of a solvent, the smaller or greater is its intrinsic pressure, and the difference between the surface tensions of a solvent and a solution is a measure of the intrinsic pressure of the solution. P. Walden (1909) also showed that the greater the internal pressure, the greater the surface tension, and the greater the tendency of the molecules of a liquid to form complex aggregates; and further, that the intrinsic pressure in atmospheres is 75·3 times the surface tension of the liquid at the boiling point.

The surface energy of liquids.—The volume energy of gases is a linear function of the temperature for $d(pv)/dT=R$, where R is a constant; and in 1886, R. Eötvös, in a paper *Ueber den Zusammenhang der Oberflächenspannung der Flüssigkeiten mit ihrem Molekularvolumen,*[31] called attention to the fact that the surface energy of liquids, $d(\sigma s)/d\tau$, is likewise a function of the temperature τ measured downwards from the critical temperature, since $\sigma s=k\tau$, where k is a constant. This is **Eötvös' rule.** In illustration:

	k
Ether (6° to 120°)	0·227
Chloroform (20° to 60°)	0·230
Carbonyl sulphide (3° to 63°)	0·231
Carbon disulphide (22° to 78°)	0·237
Sulphur dioxide (2° to 60°)	0·230

W. Ramsay and J. Shields, however, have shown that a slight correction is necessary, since the line representing the product of the surface tension σ and molecular surface s has its origin about 6° below the critical temperature, Fig. 19. Consequently, $\sigma s=k(\tau-6)$. In order to make his formula apply to all liquids, R. Eötvös made the surface s such that the same number of molecules are distributed over the same surface area, and obtained what has been called the *molecular surface;* he also assumed that the molecular surface of a liquid was equal to $(Mv)^{\frac{2}{3}}$, where Mv denotes the molecular volume of the liquid, that is, that volume of the liquid which contains the same number of molecules, for if this volume were a cube, the edge would be $(Mv)^{\frac{1}{3}}$, and any face $(Mv)^{\frac{2}{3}}$. Substituting this value of s in Eötvös' formula, what W. Ostwald[1] calls the *molekulare Oberflächenenergie*—the molecular surface energy —is obtained, namely

$$\sigma(Mv)^{\frac{2}{3}}=k\tau \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where τ denotes the temperature, T, reckoned downwards from the critical temperature, T_c, that is, the difference between the critical temperature and the temperature of the experiment, $\tau=T_c-T$. The molecular surface energy, $\sigma(Mv)^{\frac{2}{3}}$, represents the work necessary to enlarge the surface of a liquid by an amount proportional to the molecular weight—the molecules being treated as spheres. The formula assumes that the distribution of the simpler and more complex molecules over the surface is the same as in the body of the liquid; this assumption is justified from the circumstance that the molecular surface energy of a mixture is the mean of those of its constituents determined at the same temperature.

W. Ramsay and J. Shields tested Eötvös' formula for about fifty liquids at temperatures ranging from −89·8° up to the critical temperature. It was found that the liquids arranged themselves into two groups when the observed data were substituted in the formula :

$$\sigma(Mv)^{\frac{2}{3}}=k(\tau-d)\ ;\ \text{or}\ \sigma(Mv)^{\frac{2}{3}}=k(T_c-T-d) \qquad . \quad . \quad (2)$$

The theory of the equations of R. Eötvös and W. Ramsay and J. Shields is somewhat as follows : Assuming that the internal attraction of the molecules varies inversely as the fourth power of their distance apart, or, what is the same thing, inversely as the volume of unit mass—specific volume—the work of expansion W from a specific volume v of liquid to a specific volume V of vapour against internal molecular forces, will be

$$\text{Internal work}=\int_V^v \frac{a}{v^2}dv\ ;\ \text{or,}\ W=a\left(\frac{1}{V}-\frac{1}{v}\right)$$

where the constant a can be calculated from the internal latent heat of vaporization of the liquid. If the internal heat of vaporization be denoted by λ, it follows that $W=\lambda$; and, since the specific volume is inversely as the density, if D_1 and D respectively denote the densities of liquid and vapour. The internal latent heat of vaporization, $\lambda=a(D_1-D)$. If the density of the vapour be negligibly small in comparison with that of the liquid, $\lambda=aD_1$, but by L. Cailletet and E. Mathias' rule, if the density of the vapour be likewise negligibly small, $D_1=a-bT$. By differentiating these two expressions with respect to T, $d\lambda/dT=adD_1/dT$; and dD_1/dT=constant, meaning that the decrease in the latent heat or the density of a liquid with temperature has a constant value for substances not too near their critical temperatures, and which do not change their chemical character with the change of temperature. Consequently, $d\lambda/dT$=a constant. Again, according to J. Stefan,[32] neglecting the influence of the vapour, a molecule passing from the interior of a liquid to the surface will escape from one-half the molecular attraction, and if it evaporates clear away from the surface, it will escape from the other half of this attraction. Consequently, the work required to bring a molecule from the interior to the surface is one-half the work required to transport a molecule from the interior of the liquid to a point outside where the attraction of the liquid is no longer sensible. The molecular surface energy $\sigma(Mv)^{\frac{2}{3}}$, or the work necessary to bring a number of molecules proportional to the molecular weight to the surface of a liquid, is therefore equal to $\frac{1}{2}\lambda$; and by differentiation of this expression with respect to T, it follows that the variation of the molecular surface energy with respect to temperature is equal to a constant, say k ; by integration, W. Ramsay and J. Shields' expression follows at once.

Returning to the results of W. Ramsay and J. Shields' experiments, in the one group—called *normal liquids*—the value of k was virtually constant, averaging 2·2—with a positive or negative deviation of 5 per cent. when the constant $d=6$. It is assumed that in normal liquids the gaseous and liquid molecules are of the same degree of complexity. If the liquid molecules were formed by the association of a number of gaseous molecules so that (i) all the molecules were associated to an equal extent ; and (ii) the degrees of the association were not altered by changes of temperature, the liquid would give constant values for the constant k ; but it is extremely unlikely that mere liquefaction would produce an equal or uniform association of the molecules, and that the degree of association would not be altered by a rise of temperature. Hence it is inferred that the so-called normal liquids are not associated. Among the normal or non-associated liquids are : Carbon disulphide, nitrogen peroxide (not the gas), silicon tetrachloride, phosphorus trichloride, phosphoryl chloride, sulphur dichloride, thionyl chloride, sulphuryl chloride, nickel tetracarbonyl, carbon tetrachloride, ethyl ether, benzene, hydrocarbons, etc.

In another group—called *associated liquids*—the value of k was not constant, but ranged between comparatively wide limits. Accordingly for these liquids $\sigma(Mv)^{\frac{2}{3}}$ varies with the temperature. Since σ and v are determined experimentally in each case, it follows that M varies with the temperature, and that the molecules must be more complex at low than at high temperatures. Assuming that the molecular weights of non-associated liquids are the same as the molecular weights of the compounds in the gaseous state, the product of the molecular weight, M, in the gaseous state, multiplied by a factor i, will give the relative molecular weight of the liquid molecules ; i of course varies with the temperature, and, for these liquids, $\sigma(iMv)^{\frac{2}{3}}=k(\tau-d)$. If k' denotes the observed value of the constant for any temperature, and $k=2{\cdot}12$, the division of the last equation by (2), gives $i^{2/3}=2{\cdot}12/k'$. Such liquids are undoubtedly associated, and have a greater molecular weight than when in the gaseous state. Among the associated liquids are water, formic, nitric, and sulphuric acids, bromine, the alcohols, organic acids, etc. The values of the constant i for acetic acid, methyl alcohol, and ethyl alcohol are respectively 3·73, 3·43, and 2·79. These numbers are probably a little high. Thus, i for water between 0° and 140° changes from 1·707 to 1·289 ; for acetic acid between 20° to 280° from 2·13 to 1·30 ; for methyl alcohol between —89·8° and 220°, from 2·65 to 1·75 ; and for ethyl alcohol, between —89·8° to 230°, from 2·03 to 1·00. The variation of $i^{2/3}$ with temperature was not allowed for, and a new formula making provision for this variation has been obtained, and the results are better.

$$\sigma(Mv)^{2/3}=\frac{k(\tau-d)}{1+e\tau} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

The revised formula includes the constants d and e, whose numerical values are dependent upon the nature of the liquid. The constants are :

	k	d	e	Critical temperature.
Methyl alcohol	1·489	4·22	0·00104	240·0
Ethyl alcohol	2·170	4·8	0·00193	243·1
Water	2·631	19·5	0·00218	358·1
Acetic acid	1·910	11·9	0·00163	321·5

The formula for computing the degree of complexity i of the molecules of the liquid now assumes the form :

$$i=\left\{\frac{2{\cdot}121}{k}(1-e\tau)\right\}^{3/2} . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

The degree of association for water thus becomes :

i	0°	20°	60°	100°	140° C.
Water . . .	1·7	1·6	1·5	1·4	1·3
Ethyl alcohol . .	2·0	1·7	1·4	1·2	1·0
Methyl alcohol . .	2·7	2·3	2·1	1·9	1·8
Acetic acid . . .	2·1	1·9	1·7	1·5	1·3

The general conclusion is that W. Ramsay and J. Shields' equation $\sigma(Mv)^{2/3}=k(\tau-d)$, where $k=2{\cdot}12$ (nearly), applies generally for substances whose chemical nature does not alter with temperature. If the expression $\sigma(Mv)^{2/3}=k\tau$ be plotted, the slope of the curve represents the value of k, and the introduction of the constant d means that the straight line starts not from the critical point, but from a point at a distance d from the critical point. The distance between the dotted and the curved line OA, Fig. 19, represents the deviation of the observations from Ramsay and Shields' rule in the vicinity of the critical temperature.

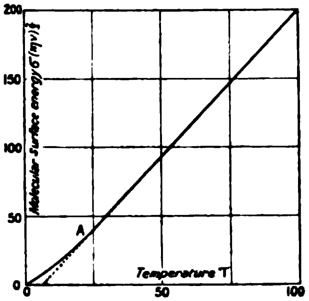

FIG. 19.—R. Eötvös' Curve for Benzene.

F. M. Jäger has measured the surface tension and molecular surface energy of about 200 organic liquids between —80° and 250°, and of about 50 inorganic substances in the molten condition between 300° and 1650°. The surface tension, σ, and the molecular surface energy, μ, of the halides of phosphorus, arsenic, antimony, and bismuth increase with the molecular weight, while the variation of μ with temperature, $d\mu/dT$, is more or less normal. With the halides of the five alkali metals the surface tension of the molten salt decreases (i) with increasing atomic weight of the halogen from fluorine to iodine, and also (ii) with increasing atomic weight of the metal. The molecular surface energy varies in an irregular manner, while $d\mu/dT$ is in all cases small. The alkali sulphates, nitrates, borates, molybdates, and tungstates were also investigated.

The association of the molecules of liquids.—The abnormal vapour densities of certain liquids at temperatures near their boiling points, led chemists—*e.g.* A. Neumann[33]—to the view that the molecules of such liquids may be formed by the coalescence or association of two or more molecules of the substance as they occur in the gaseous state, and in 1888, P. de Heen[34] developed a theory of liquids based upon the assumption that the constituent molecules of certain liquids are aggregates of the molecules as they occur in the gaseous state, so that he postulated what he called liquidogenic and gasogenic molecules. A liquid under ordinary conditions is a solution of gasogenic in the liquidogenic molecules. If a very small volume of liquid is in equilibrium with a large volume of vapour, the liquid will be saturated with gasogenic molecules and cannot furnish liquidogenic molecules to the vapour; conversely, if the volume of the liquid is large, and the vapour small, the vapour will consist largely of liquidogenic molecules. The density of a saturated vapour of a pure substance, like that of a mixture, is therefore supposed to be dependent on the relative masses of liquid and vapour phases. This is contrary to experience. Modifications of P. de Heen's theory in which the two forms of molecules are in a definite state of equilibrium have been employed to explain supposed phenomena which occur at the critical temperature of a liquid or gas, namely, that (i) the greater the proportion of liquid confined in the tube, heated to the critical temperature, the higher the critical temperature; and (ii) that the critical temperature at which a meniscus appears on cooling is lower than that obtained on heating. There is, however, considerable doubt about the accuracy of both conclusions, since the experimental errors are large, and care has not always been taken to use pure materials free from absorbed air.[35] It is generally held that the difference between the liquid and gaseous states is solely due to the greater propinquity of the molecules in the liquid state, and not to polymerization of the molecules. Nothing very definite, however, was known about this until about 1887, when W. Ramsay and S. Young[36] showed that the density of acetic acid vapour increases as the boiling point is approached; and about 1888, E. Beckmann[37] showed, by freezing-point determinations, that acetic acid and ethyl alcohol possess more complex molecules in concentrated solution than in the vaporous state; while naphthalene does not form complex molecules under the same conditions. J. T. Cundall (1891) also showed that solutions of nitrogen peroxide behave as if the molecules are more complex in solution than in the vaporous state.

§ 23. The Association or Polymerization of Liquids

> The custom of comparing all liquids in an indiscriminate fashion, in the hope of establishing general relationships has been attended with a certain degree of success, but exceptions of a very puzzling order frequently arise. One great cause of such exceptions is to be found in the fact that monomolecular and associated liquids have been indiscriminately compared one with another, when strictly speaking they are not truly comparable.—H. CROMPTON (1898).

There is much evidence indicating that the normal molecules of certain liquids, vapours, and even solids may coalesce or associate into more complex aggregates when the vapour condenses to a liquid, or even when the temperature is changed without a change in the state of aggregation, as when n molecules of a substance, A, coalesce to form one molecule, and *vice versa* : $nA\rightleftharpoons A_n$. So long as our knowledge of molecular weights was deduced from the study of vapour densities, the conclusions were strictly applicable to matter in the gaseous state only. A large number of attempts have been made to get an insight into the molecular condition of liquids and solids, and in the case of liquids, the problem now approaches within a measurable distance of a successful solution ; indeed, liquids are now classed as associated or non-associated according as the molecular weight can be represented by iM or M, where M denotes the formula-weight deduced from the vapour density, and i the factor of association.

The evidence for polymerization is based upon some irregularity in the variation of many of the physical properties of the liquids with temperature—*e.g.* heat of vaporization ; external work of evaporation ; vapour pressure curves ; molecular volumes ; molecular refraction ; densities ; viscosities ; etc. Several methods are based on the behaviour of liquids either at or near their critical points, for it will be evident that when matter is undergoing a change of state, if the molecules simultaneously alter their degree of association, the variation should be rendered apparent in a marked degree. D. Tyrer lays down the condition that any exact equation which might be employed to calculate the association factors of liquids should conform with the law of mixtures, for with partially associated liquids we are dealing with a mixture and not with an individual in the chemical sense. In the case of water, for example, we are possibly dealing with a mixture containing not one molecule but several, H_2O, $(H_2O)_2$, $(H_2O)_3$, . . . If the first three molecules have the respective molecular weights, M_1, M_2, M_3, . . . and n_1, n_2, n_3, . . . of the respective molecules be present, the mean molecular weight M of the associated liquid, $(H_2O)_i$, will be

$$iM=\frac{n_1M_1+n_2M_2+n_3M_3+\ .\ .\ .}{n_1+n_2+n_3+\ .\ .\ .}$$

and the various physical properties X_1, X_2, X_3, $+$ . . . should be functions of the right member of this equation. This applies for all mixtures whether of associated or normal liquids which have no chemical action on one another.

In 1894, P. A. Guye made a collection of evidence which furnished a number of criteria indicating the association of liquids, but much more has accumulated since then. D. Tyrer has tried a number and found them to fail when tested by the above criterion. Ten of these methods are here indicated :

(1) W. Ramsay and J. Shields' work on surface energy. Various attempts have been made to modify W. Ramsay and J. Shields' equation, thus, A. Batschinsky [1] proposed to substitute $T_c=16{\cdot}31(\eta T^3)^{2/7}/D_c^{1/7}$, where η denotes the viscosity at the absolute temperature T ; and D_c, the critical density—the density at 0° may be substituted for D_c if the constant be altered. P. Walden also says that $\sigma(Mv)=K(T_c-T-d)$ gives as good results as the equation of W. Ramsay and J. Shields.

(2) About 1890, P. A. Guye [2] found it necessary to double the ordinary molecular weights of methyl alcohol, acetic acid, and water in order to make these liquids conform with his rule that the quotient obtained by dividing the absolute critical temperature T_c, by the critical pressure p_c, is equal to the molecular refraction r multiplied by a constant which is 1·85 for most liquids, but 1·1 for associated liquids.

(3) According to S. Young and G. L. Thomas,[3] the ratio of the actual density of a liquid to the density at the critical point is 3·85 ; and with liquids assumed to be associated, the ratio appears to have a greater value—thus with some alcohols and acetic acid, the ratio ranges from 4·0 to 5·0.

(4) If the arithmetical mean of the density of a liquid and gas is not a linear function of the temperature, as indicated in L. Cailletet and E. Mathias' rule,[4] it is assumed that the liquid is associated—*e.g.* water.

(5) If the heat of vaporization rises to a maximum with rise of temperature, and then diminishes, it is assumed that complex molecules are being converted into simpler ones during the descent of the curve. W. Ramsay and S. Young [5] found this to be the case with ethyl alcohol and acetic acid. Normally, the curve shows that the heat of vaporization decreases regularly up to the critical temperature when it becomes zero.

(6) The greater value for the heat of vaporization for unit increase in volume in the case of alcohols and water corresponds with the consumption of a greater amount of internal work for the expansion against external pressure, owing to the dissociation of the complex molecules. For example, F. Trouton's rule, and G. G. Longinescu's rule.[6] G. G. Longinescu found that for non-associated liquids, $n=(T_b/100D)^2$, where T_b denotes the absolute boiling point; D, the specific gravity at 0° ; and n, the number of atoms in the molecule. In W. A. Kistiakowsky's modification of F. Trouton's rule, $a^2M/T_b=1{\cdot}14$, where a^2 denotes the capillary rise in a tube of one mm. radius, at the absolute boiling temperature T_b. For associated liquids, the constant is smaller—*e.g.* for methyl alcohol it is 0·482, and for acetic acid, 0·576.

(7) The vapour pressure curves of normal liquids do not cut one another at any point in their course, but the vapour pressure curves of associated liquids often cut across those of normal liquids.[7]

(8) The ratio of the volume of a saturated vapour at some chosen pressure to that at the critical pressure points to the association of organic acids and alcohols.[8]

(9) J. D. van der Waals' vapour pressure equation,[9] $\log p_c - \log p = f(T_c - T)/T$, where p_c and T_c denote the critical pressure and temperature respectively, and p denotes another pressure at the temperature T, gives a constant approximately 3 to 4 with most liquids, but the numerical value of f rises to 3·2–3·4 for water; 3·36–3·49 for acetic acid; 3·58–4·02 for methyl alcohol; and 3·49–3·77 for ethyl alcohol.

(10) A. E. Dunstan and F. B. Thole[10] have shown that the quotient of the viscosity by the molecular volume is nearly 60×10^{-6} for normal liquids, but for water, the fatty alcohols, and acetic acid, the fraction has more than twice its normal value.

Several other methods have been described—*e.g.* I. Traube's method of molecular volumes, the empirical formulæ of D. Tyrer, M. M. Garver, E. T. Whittaker,[11] and R. D. Kleeman, etc. Indeed, nearly every physical property which has been accurately measured—specific heats, osmotic pressures, etc.—has been related with the molecular weights.

§ 24. Thermal Effects attending the Expansion and Compression of Gases

> I use the word attraction in a general way for any endeavour of what kind so ever, made by bodies to approach to each other—whether that endeavour arise from the action of the bodies themselves, or whether it may arise from the action of the æther or of any medium whatsoever, whether corporeal or incorporeal, anyhow impelling bodies placed therein towards one another.—Isaac Newton.

In an essay *Of the cold produced by evaporating fluids, and of some other means of producing cold*, W. Cullen (1755)[1] seems to have been the first to notice that the temperature of air is decreased by rarefaction, and increased by compression; and J. Dalton (1802) made an attempt to measure the change of temperature which occurs when air is compressed or rarefied. In a general way, it has been proved that if a gas, whose molecules exert no attraction on one another, be confined in a suitable vessel, and compressed, the mechanical work employed in compressing the gas is equivalent to the product of the pressure into the change in volume. This energy is transformed into an equivalent amount of heat which raises the temperature of the gas. On the other hand, if the gas of itself expands against atmospheric pressure from a volume v to a volume v_1, the gas will be cooled because the gas itself has done a certain amount of work against atmospheric pressure p, equivalent to the product of the atmospheric pressure into the change in volume—*viz.* $p(v_1-v)$, or more accurately, $p \log (v_2/v_1)$. The phenomenon is illustrated by the time-honoured experiment in which a piece of tinder in a glass cylinder containing a little ether is ignited by suddenly compressing the piston in the cylinder.

The adiabatic expansion or compression of gases.—If the expansion of a gas against atmospheric pressure be performed slowly enough, the gas will remain at a constant temperature, and the expansion is said to be **isothermal**; the energy required to overcome the external pressure is absorbed as heat from its surroundings. On the other hand, if the walls of the containing vessel be made of some insulating material which prevents the passage of heat inwards or outwards, the energy required for the expansion is absorbed from the kinetic energy of the gas molecules themselves, and the temperature of the gas decreases. Such an operation is said to be **adiabatic,** from *a*, not; *διαβαίνειν*, to pass through, or transmit. An approximation to an adiabatic change is obtained when gases are *suddenly* expanded or *compressed,* because there is not then time for the heat to dissipate. Boyle's law describes the relation between the pressure and volume of a gas when the operation is performed isothermally; this law will not be valid for adiabatic changes. No perfectly adiabatic substance is available for measuring the relations between the adiabatic changes of volume and the pressure of a gas, but the law has been derived from several lines of reasoning, and the observed results approximate to the theoretical values. Obviously, the actual change of temperature which occurs during the adiabatic process must depend in some way on the specific heat of the gas concerned. If the thermal capacity of the gas be small, the change of temperature will be greater than if the thermal capacity be large. If γ denotes the ratio of the two specific heats of a gas, C_p/C_v, then, if k be a constant,

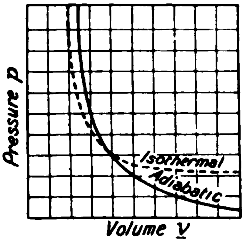

FIG. 20.—Isothermal and Adiabatic *pv*-Curves.

$$pv^{\gamma}=k\,;\ p_1v_1{}^{\gamma}=p_2v_2{}^{\gamma}$$

The dotted curve, Fig. 19, represents Boyle's law (isothermal) curve pv=constant, the other the adiabatic curve pv^{γ}=constant. If the isothermal curve passes through the point O when the volume of the gas is unity and the pressure p, it passes above the adiabatic for values of v greater than unity, and under it for values of v less than unity. By substituting the gas law, $pv=RT$, in these equations, two other equations can be obtained:

$$\left(\frac{v_1}{v_2}\right)^{\gamma-1}=\frac{T_2}{T_1}\,;\ \left(\frac{p_2}{p_1}\right)^{\frac{\gamma-1}{\gamma}}=\frac{T_2}{T_1}$$

which express the relation between the volume, pressure, and temperature of gases undergoing adiabatic changes.

These expressions—pv^{γ}=constant, etc.—can be deduced from the laws of thermodynamics, somewhat as follows: Let the temperature of unit mass of gas at a constant pressure be raised a small amount dT owing to the absorption of an amount of heat dQ, which in turn is equivalent to C_pdT when C_p is the specific heat of the gas at constant pressure; let the volume of the gas at the same time be augmented dv. The final condition of the gas can be regarded as the joint effect of two operations: (i) The temperature may be supposed to increase by an amount dT while the volume remains constant, so that heat equivalent to C_vdT is absorbed; (ii) The temperature remains constant while the volume increases by an amount dv. Let H denote what has been called the latent heat of expansion; that is, the amount of heat absorbed per unit change of volume without change of temperature; accordingly, the quantity of heat absorbed when the volume changes by a small amount dv, at a constant temperature, will be $H.dv$. Consequently, $dQ=Hdv+C_vdT$; or C_pdT

$=Hdv+C_vdT$. From Charles' law, it follows that $(v+dv)/(T+dT)=v/T$; or, $dv=(v/T)dT$; and, after substituting this value of dv in $C_pdT=H.dv+C_vdT$, dividing through by dT, it follows that $C_p-C_v=Hv/T$; or $H=(C_p-C_v)T/v$. Again, if a gas changes its volume dv under adiabatic conditions without any exchange of heat between it and its surroundings, the temperature would change by an amount dT, and dQ must be zero. Hence, $H.dv+C_vdT=0$. Substitute the above value of H in this equation; put γ for C_p/C_v; and it follows that $(\gamma-1)dv/v+dT/T=0$. This on integration gives the relation $pv^\gamma=$constant, and the other expressions follow.

The cooling (or heating) effect obtained by expanding (or compressing) gases adiabatically can be computed from these equations. Thus, air expanded adiabatically from 20° and 50 atm. to 1 atm. pressure will be cooled to −177°; and air at −60° and 50° atm. pressure will be cooled to 204° on expanding adiabatically to one atmosphere pressure. With air initially at 0°, and a final pressure of one atmosphere ($\gamma=1{\cdot}41$),

Initial pressure	50	100	200	300	400	500 atm.
Final temperature	−187·0°	−201·5°	−214·5°	−221·0°	−225·1°	−229·2°

Hence, it is possible to cool gases considerably by adiabatic expansion. By utilizing this principle, L. P. Cailletet (1877)[2] liquefied small quantities of air, oxygen, nitrogen, methane, and carbon monoxide. G. Claude (1909) has employed the principle in the continuous production of liquid air.

EXAMPLES.—(1) A litre of air at 0° expands adiabatically to two litres. Find the fall of temperature when γ for air is 1·4. Here $T_2\times2^{0\cdot4}=273$; $2^{0\cdot4}=1{\cdot}32$; hence, $T_2=207°\ K$ or −66°.

(2) If the ignition temperature of electrolytic gas be 585°, what adiabatic compression would cause the mixture to ignite if the gas were originally at 15° and atmospheric pressure? Assume that the ignition temperature is not altered by variations of pressure. Ansr. 43 atm.

The Joule-Thomson or the Joule-Kelvin effect.—No heat is developed when an ideal gas expands into a vacuum. This was established by some experiments by J. L. Gay Lussac, described in his *Essai pour déterminer les variations de température qu'eprouvet les gaz en changeant de densité* (1807); and by J. P. Joule, in his memoir, *On the changes of temperature produced by the rarefaction and condensation of air* (1845). Compressed air was allowed to expand into an evacuated vessel, and the result, as J. P. Joule expressed it, was as follows: "No change of temperature occurs when air is allowed to expand in such a way as not to develop mechanical power"; and generally, **when a gas expands without doing external work, and without taking in or giving out heat, its temperature does not change**—a statement sometimes called **Joule's law.** The first increment of gas into a vacuum will of course produce a pressure, and each successive increment supplements the pressure produced by the earlier portions. Since a gas expands indefinitely, each increment may be regarded as filling the whole space or volume v, and consequently the work done is simply $v\int dp=pv$. This is also equal to the kinetic energy of the gas. Consequently, the work done in forcing the later portions of gas into the evacuated space against the existing pressure is wholly transformed into kinetic energy. No change of temperature occurs, because the work done *by* the gas is equal to the work done *on* the gas. The case is analogous with the transmission of energy by a rod or belt whose state of strain is steady—the rod or belt transmits the impressed energy without loss; so also if gas be forced into a cylinder when the temperature and pressure are constant, the stress introduced by the entering gas is relieved by the escape of an equal amount of gas. If the gas is in a steady state, the work done by the escaping gas will be equal to the work done *on* the gas. Otherwise expressed, the work required to transform unit mass of any fluid from a place where there is a uniform pressure p_1 to another place where there is a uniform pressure p_2, is equal to $p_2v_2-p_1v_1$, where the subscripts refer to the respective states of the gas if the density of the gas is strictly proportional to the pressure in the two states, p_2v_2

$-p_1v_1=0$, and no work is done. If, however, the external pressure be diminished by internal attractions depending on the distance apart of the molecules, so that p_1v_1 is less than p_2v_2, the external work done *on* the gas is no longer equal to the external work done *by* the gas—because during expansion part of the energy is spent in doing internal work separating the molecules. The assumption made in Joule's law is that no work is performed against intermolecular attractions. However, intermolecular attractions are evidenced with most gases. The experiments of Gay Lussac and Joule[3] were not sufficiently sensitive to detect the small change of temperature which occurs when such gases expand in vacuo, so that although no external work is done by the gas, internal work is done against intermolecular attraction. The molecules are torn apart, so to speak, against the (feeble) attractive force drawing them together. This involves an expenditure of energy—work must be done—and the gas is cooled.

The work W done against intermolecular attractive forces will depend on the distance of the molecules apart. Suppose the attractive forces be such that they vary inversely as the fourth power of the distance apart of the molecules, then, when a gas expands from a volume v_1 to a volume v_2, $W=a(p_1-p_2)$, where a is a constant.

If the molecular attraction f varies inversely as the fourth power of the mean distance r_1 of the molecules apart, $f=c/r_1^4$, where c is a constant; and if the gas expands until the mean distance of the molecules apart becomes r_2, the work done against molecular attraction will be:

$$\int_{r_1}^{r_2} f.dr=c\int_{r_1}^{r_2}\frac{dr}{r^4};\quad \text{Internal work}=\frac{c}{3}\left(\frac{1}{r_1^3}-\frac{1}{r_2^3}\right)=\frac{c}{3b}\left(\frac{1}{v_1}-\frac{1}{v_2}\right)$$

since r is linear, and the volume v of the gas will therefore vary as the cube of r, so that $v_1=br_1^3$ and $v_2=br_2^3$, where b is a constant. Again, since the temperature is nearly constant, $p_1v_1=p_2v_2=$constant. Collecting the various constant terms under the symbol a, it follows that the work done against molecular attraction when the gas expands from a volume v_1 to a volume v_2 is $a(p_1-p_2)$.

Consequently, **the work done in overcoming the intermolecular attractive forces will be proportional to the difference between the initial and final pressures of the gas** (temperature constant). This result is in harmony with observations. The cooling effect actually produced when a gas expands by simple outflow in vacuo is due to the absorption of heat equivalent to this work.

In later and more delicate experiments, Lord Kelvin (W. Thomson) and J. P. Joule—1852-62—forced a steady stream of gas under a pressure slowly along a tube A, Fig. 21, in the direction of the arrows, through small orifice, O, where it expanded against the pressure p_1. To avoid eddies in the gas, a porous plug was actually used. For the sake of simplicity, suppose the tube AB has unit sectional area, and that it is made of some material which does not conduct heat away from the gas. Two phenomena occur: (1) the gas is slightly heated by friction as it passes through the orifice O; and (2) the gas is cooled as it passes through O by doing work against a pressure p_1. Suppose a piston A, Fig. 21, moves from left to right so as to drive a volume of air, v_2, at a pressure p_2, into the compartment BC. The work done *on* the gas is obviously p_2v_2. Similarly, the work done *by* the gas as it pushes the piston from, say, B to C through a distance v_1, will be p_1v_1. Hence, if the gas obeys Boyle's law, we shall have $p_1v_1=p_2v_2$, and there will be no loss in the internal kinetic energy of the gas through overcoming internal attractions, and no variation of temperature of the gas on the sides AB and BC. If, however, work be done against molecular attraction during the expansion of the gas, the work of expansion on the side BC will exceed the work of compression on the side AB. The work

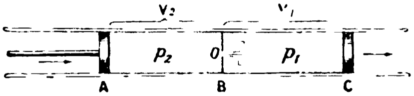

FIG. 21.—J. P. Joule and W. Thomson's Experiment.

performed when the gas expands against intermolecular attractive forces diminishes the kinetic energy of the gas, and this ceases to be sensible as heat; accordingly, the temperature of the gas is lowered owing to the loss of the kinetic energy of the molecules of the gas itself. Hence, the gas on the side *BC* will be cooled below the temperature of the gas on the side *AB*. **The change of temperature which occurs when a compressed gas expands adiabatically through a small orifice is called the Joule-Thomson effect.** In J. P. Joule and W. Thomson's experiments, the temperature of carbon dioxide, nitrogen, oxygen, and air fell about 1°; or, more exactly, the observed fall of temperature per atmosphere difference of pressure was

Air.	Carbon dioxide.	Oxygen.	Nitrogen.	Hydrogen.
0·208°	1·005°	0·253°	0·249°	—0·039°

so that the phenomenon with hydrogen is reversed, there is a rise of temperature of the gas on the side *BC*. This corresponds with Regnault's observation that the product pv increases with hydrogen above a certain temperature; if, however, the experiment be conducted at a lower temperature, hydrogen gas behaves like other gases and is cooled; and at higher temperatures, other gases behave like hydrogen.

According to J. Rose Innes,[4] the measurements of Joule and Thomson can be represented by a formula of the type: Fall of temperature$=aT^{-1}+b$, where a and b are constants such that for air, $a=141·5$, $b=0·697$; for carbon dioxide, $a=2165·0$, $b=4·98$; and for hydrogen, $a=64·1$, $b=-0·331$. In the case of hydrogen, the change of temperature will be zero when $T=194°$ K., or —79° C. This means that the Joule-Thomson effect with hydrogen will change sign from heating to cooling in the neighbourhood of —80°, and this is called the **inversion temperature.** The inversion temperature of helium is —240°.

The porous plug experiment shows that the fall of temperature which occurs when the pressure falls from p to p_1 varies very nearly in the inverse proportion to the square of the absolute temperature, and is approximately 0·25° per atmosphere; or, more exactly.

$$\text{Fall of temperature} = A\left(\frac{273}{T}\right)^2(p-p_1)$$

where T is the temperature of the gas at the initial pressure p, and p_1 the final pressure of the gas. The constant A is $+0·276°$, say $\frac{1}{4}°$ per atm. for air; $+1·388°$ for carbon dioxide; and $-0·049°$ for hydrogen. The magnitude of this constant, and accordingly also the cooling effect, is greater the more the gas deviates from the ideal gas laws—presumably because more work is done against intermolecular attractive forces.

Examples.—(1) If carbon dioxide, at 4 atm. pressure and 0°, on passing through a porous plug falls to a pressure of one atmosphere, show that the temperature falls about 4·2.

(2) If air at 0° is driven through an orifice and at the same time falls 3·6 atm. in pressure, show that the fall in temperature is 0·994°, and if the fall in pressure is 10 atm., the fall in temperature is 2·76°.

The greater the pressure, the smaller the corresponding cooling effect per atmosphere difference of pressure. Thus, E. Vogel[5] found for oxygen at 0°, and an initial pressure p, calculated for a pressure difference $p-p_1$ of one atmosphere:

p . . .	20	60	100	120	140	160 atm.
Cooling effect .	0·260°	0·225°	0·191°	0·174°	0·157°	0·139°

At about 300 atm. pressure and ordinary temperatures the cooling effect is nil.

The observed results are represented by the following modifications of Thomson's equation :

$$\text{Cooling effect} = (0{\cdot}268 - 0{\cdot}00086p)(p - p_1)\left(\frac{273}{T}\right)^2$$

The lower the temperature, the greater the cooling effect. Thus, W. P. Bradley and C. F. Hale found that when $p=204$ atm. and $p_1=1$ atm.,

Temperature .	0°	−20°	−40°	−60°	−80°	−90°
Cooling effect .	44·6°	52·1°	61·1°	72·5°	88·2°	99·2°

If external work W be performed on unit mass of gas compressing it isothermally, the intermolecular attractions will do a quantity of internal work w which will appear as heat. Hence, during an isothermal compression the total heat Q, taken from the gas, will be $Q=W+w$; and the total energy of the gas has been diminished by an amount w. Consequently, if the compressed gas be allowed to expand back to its original volume, without receiving energy from some outside source, internal work equivalent to w will have to be performed at the expense of the kinetic energy of the gas, and the temperature of the gas will accordingly fall. If w is equivalent to the heat abstracted from a gram of gas and which produces a fall of temperature $\theta°$, then if the heat be taken from half the gas, the fall of temperature will be $2\theta°$, and if from an nth part of the gas, there will be a fall of $n\theta°$.

If the specific heat of air at constant volume be 0·177, and if, for convenience, it be assumed that the specific heat is constant, it will require $210\times0{\cdot}177=37$ cals. to lower the temperature of a gram of air from 20° to −190° ; further, if the latent heat of vaporization be 50 cals. per gram, and a gram of the air at −190° be liquefied, it will require $37+50=87$ cals. to cool a gram of air from 20°, and liquefy it at −190°. According to Joule and Thomson's experiment, the expansion of a gram of compressed air will cool it $\frac{1}{4}$° per atmosphere ; if the gram of air expands from a pressure of 160 atm., it will therefore be cooled 40°. This corresponds with 7 Cals. of internal work per gram ; and accordingly, since 87 cals. of heat are required in order to cool a gram of air from 20° and to liquefy it, it follows that under ideal conditions only $\frac{1}{12}$th to $\frac{1}{13}$th of the gram of air can be liquefied by expansion from a pressure of 160 atm. when the rejected air has the same temperature as the compressed air. If m_1 and m_2 denote respectively the masses of the initial and the rejected air, then m_1-m_2 will denote the mass of air which has been liquefied during the expansion. Let W denote the external work done during isothermal compression, and w the work due to intermolecular attractions ; then, if Q_1 and Q_2 respectively denote the heat equivalents of W and w,

$$\frac{m_1}{m_2} = \frac{Q_1+Q_2}{Q_1} = \frac{W+w}{W}; \quad \therefore \quad \frac{m_1-m_2}{m_2} = \frac{w}{W}$$

This means that the ratio of the mass of liquefied air to the mass of rejected air is equal to the ratio of the work due to intermolecular attraction to the external work of isothermal compression. Since the cooling due to expansion of air from a pressure of 160 atm. is equivalent to $w=7$ cals. of internal work per gram, and the work W required for the isothermal compression of a gram of air to 160 atm. is equivalent to $W=98$ cals., it follows that $w/W=\frac{1}{14}$. This means that under ideal conditions, one-fourteenth of the work performed by the isothermal compression of air at 20° to a pressure of 160 atm., and its subsequent adiabatic expansion to the original pressure, is due to intermolecular attractions. In any system of liquefying gases by utilizing the slight cooling effect produced when internal work is done against intermolecular attractions, the test of the efficiency of the process is how near

$$\text{Maximum efficiency} = \frac{\text{Liquid obtained}}{\text{Work done}}$$

approaches the theoretical; for the air costs virtually nothing. Special refrigerants may enable a large percentage of compressed air to be liquefied; reducing the pressure for the expanded air below one atmosphere will give a bigger cooling effect, etc.; but all this requires the application of more work, and it is for the chemical engineer to find if the different factors increase or diminish the efficiency fraction.

As previously indicated, it is sometimes convenient to use an idealized gas as a limiting case or standard of comparison in the theoretical study of molecular forces, etc. Such a gas—called a perfect or ideal gas—(i) obeys Boyle's and Charles' laws for all pressures and temperatures; and (ii) it suffers no change of temperature when it is allowed to expand into an evacuated vessel. In this sense, perfection is not an objective quality of any particular gas, but it rather denotes a favourite and familiar fiction whose sole justification is that it facilitates the general investigation of the properties of gases.

§ 25. The Liquefaction of Gases

> If the earth should all of a sudden find itself placed in very cold regions, the water which now forms our rivers and seas, and probably the greater number of liquids which we know would be transformed into solid mountains and into very hard rocks. The air, according to this hypothesis, or at least a portion of the aëriform substances which compose it, would doubtless cease to exist in the condition of invisible fluids, and through the absence of a sufficient degree of heat, it would revert to the liquid state, and this change would produce new liquids of which we have no idea.—A. L. LAVOISIER (1789).

The conversion of liquids into vapours, and the reverse condensation of vapours into liquids during distillation must have attracted attention before the Christian era, and have suggested the possibility of the condensation of aëriform fluids in general. M. A. Lucanus, in his satirical *Vera historia*, written in the second century, said that the inhabitants of the moon drink air squeezed or compressed into goblets, for this operation produces a liquid like dew. There are also some poetic references to liquid air in Virgil (*c.* 50 B.C.). This, of course, does not mean that the liquid in question was known to the Greek and Roman poets.[1] Some time before the composition of air was known, H. Boerhaave, in his *Elementa chemiæ* (Lugduni Batavorum, 1732), described an attempt to condense air to the liquid state by artificial cold, although he succeeded in producing no other result than the condensation of the moisture in the air. He therefore concluded:

> We may fairly assert that the fluidity of air, in all the large compass from the most rarefied to the most compressed, remains without alteration; and that therefore it is neither capable of being solidified by the intensest cold, nor the greatest degree of compression.

John Dalton saw as clearly as A. L. Lavoisier the probable result of subjecting gases to a great enough cold and pressure. He said:

> There can scarcely be a doubt entertained respecting the reducibility of all elastic fluids of whatever kinds into liquids; and we ought not to despair of effecting it in low temperatures, and by strong pressures exerted upon the unmixed gases.

Among the early experiments there is M. van Marum's[2] liquefaction of ammonia under a pressure of about 3 atm.; L. B. G. de Morveau, and A. F. de Fourcroy and L. N. Vauquelin's liquefaction of the same gas by cooling with a freezing mixture to about —40°, and their nugatory attempt to liquefy hydrogen chloride, hydrogen sulphide, and sulphur dioxide by similar means. G. Monge and L. Clouet reported the liquefaction of sulphur dioxide by simple cooling. In some cases, the drying of the gases must have been so imperfect that the condensation of moisture or of a solution of the gas in water was mistaken for the liquefaction of gas itself.

T. Northmore's work[3] on the liquefaction of gases by compression is perhaps the most important of the earlier experiments. He succeeded in liquefying chlorine, hydrogen chloride, and sulphur dioxide. When the attempt was made with carbon dioxide, the receiver unexpectedly burst with violence. In 1823, M. Faraday[4] liquefied a number of gases by the joint effect of pressure and cold. The gases were generated in one leg of a hermetically sealed glass V-tube, and condensed by cooling with the other leg of the V-tube in a freezing mixture. The increasing pressure developed by the gas enabled sulphur dioxide, hydrogen sulphide, carbon dioxide, nitrogen monoxide, cyanogen, and ammonia to be condensed; and H. Davy likewise succeeded in condensing hydrogen chloride in this manner.

D. Colladon[5] attempted to liquefy air by confining it in a stout glass tube sealed with mercury so arranged that more mercury could be forced into the tube by hydraulic pressure. He worked at —30° and produced a pressure of 400 atm., but he did not succeed in condensing the air. M. Thilorier, in 1834, generated carbon dioxide in a wrought-iron vessel and used the increasing pressure as the gas accumulated in the vessel for its condensation in an adjacent iron vessel cooled by a freezing mixture. M. Thilorier's apparatus was therefore a kind of Faraday's tube of large capacity, and made of cast iron. One of the cylinders burst before a class, and its fragments were scattered about with tremendous force; it cut off both legs of the unfortunate operator, M. Hervy, and the injury was followed by death. This showed that cast iron was not a safe metal for the chambers of an apparatus for condensing gases under pressures. M. Thilorier succeeded in liquefying and solidifying carbon dioxide, and he also prepared a freezing mixture of solid carbon dioxide and ether which enabled a temperature of —110° to be attained. Modifications of M. Thilorier's apparatus were employed by R. Addams, J. K. Mitchell, M. Faraday, J. O. Natterer, etc.[6] In all these systems the gases were liquefied by cold and pressure acting jointly or alone. A few gases—like hydrogen, oxygen, nitrogen, air, etc.—resisted all attempts to liquefaction in this way, and the refractory gases were called **permanent gases** to distinguish them from those more condensable. The term lost its main significance when L. P. Cailletet and R. Pictet succeeded in liquefying oxygen and hydrogen about 1877, and C. von Linde succeeded in manufacturing liquid air on an industrial scale.

The success of the attempts to liquefy gases has been largely dependent upon the methods for producing great cold. About two centuries ago, 1724, G. D. Fahrenheit congratulated himself that no one could produce a lower temperature than he had done by mixing together snow and salt; and he accordingly made this temperature the zero of his thermometer—Fahrenheit's thermometer. In his wildest dreams, Fahrenheit is not likely to have imagined that temperatures 400° F. below the point he evidently thought a very creditable achievement, would, in later years, be comparatively easily attained. When, a few years afterwards, Fahrenheit succeeded in reducing the temperature a few degrees below his own zero, H. Boerhaave said that the result was incredible, and asked: " What mortal man could ever have thought of it ? " The different methods which have been used for producing low temperatures include:

(1) *Methods involving the use of freezing mixtures.*– If ice or snow be mixed

with salt and water above the eutectic temperature, the water will tend to dissolve salt, and the ice will melt and make the solution capable of dissolving more salt. If the liquid be thermally insulated, the latent heat required for the fusion of the ice is abstracted from the liquid, and the temperature falls until the solution has the eutectic composition. The temperatures obtainable by the use of mixtures of ice and salts—the so-called freezing mixtures—range as low as —55°—the eutectic temperature of calcium chloride and water. The following represent some results actually obtained with mixtures of one part of snow with

	Fall of temperature from 0° to
Sodium carbonate (cryst.)—¼th part	−2°
Potassium chloride—⅓rd part	−12°
Sodium chloride—⅓rd part	−18°
Calcium chloride (cryst.)—2 parts	−42°

(2) *Cooling by the adiabatic expansion of cold compressed gases.*—C. W. Siemens (1857), E. Solvay (1885), and F. Windhausen (1892) [7] obtained patents for producing very low temperatures by the expansion of air in a suitable cylinder, and using the cooled expanded air to cool the incoming air by a kind of recuperation of the cold.

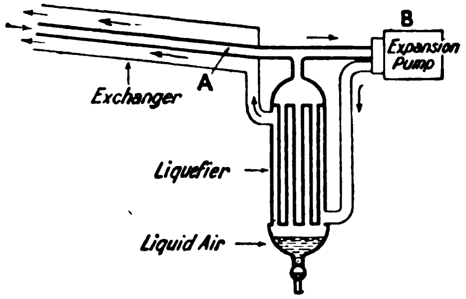

FIG. 22.—Claude's Process for the Liquefaction of Air (Diagrammatic).

In L. P. Cailletet's apparatus, gas is confined in a stout glass tube by mercury and the mercury is pumped by a hydraulic press into a suitable reservoir so as to compress the gas. L. P. Cailletet designed his apparatus so that the pressure confining the gas could be quickly relieved, in order that successive experiments could be made with the same mass of gas. By chance, on relieving the pressure under which some gaseous acetylene was confined, L. P. Cailletet noticed a thick mist—*un brouillard épais*—developed in the tube, and he at first supposed it was produced by the condensation of moisture or impurities in the gas. On testing this assumption with purified acetylene and also nitrous oxide, the sudden expansion of the compressed gas still gave the mist, and he then attributed the phenomenon to liquefaction produced by the intense cooling of the expanding gas. L. P. Cailletet then employed greater pressures with the so-called permanent gases. On Dec. 2nd, 1877, he wrote to H. St. C. Deville :

> I hasten to inform you, and you first without losing a moment, that I have liquefied this day both carbon monoxide and oxygen. I am perhaps wrong in saying liquefied, because at the temperature I obtained by evaporating sulphur dioxide, that is at —29° under 200 atm. pressure, I did not see any liquid, but a dust so dense that I was able to infer the presence of a vapour very close to its point of liquefaction.

He added that no sign of the liquid dust was detected with hydrogen treated in a similar manner, but in a later experiment the mist was obtained working from 300 atm. pressure at —28°. Cailletet's apparatus was used by J. Ogier [8] for liquefying silicomethane ; by L. Ilosvay de N. Ilosva, for liquefying carbonyl sulphide ; by J. Ansdell in studying liquid acetylene, and hydrogen chloride ; by C. Vincent and J. Chappius for methyl and ethyl chlorides, the methylamines, etc. ; by P. Hautefeuille and J. Chappius, L. Troost, and A. Ladenburg for liquid ozone. G. Claude has employed the principle for the continuous liquefaction of air.

The purified air at about 40 atm. pressure is driven through an inner tube *A*, Fig. 22, to an expansion apparatus, *B* ; and the cooled and expanded air circulates upwards about the tube A. The cooled air passes from the liquefier, about the inlet tube A, and is thence returned *viâ* A to the expansion apparatus. The compressed air in the liquefier is thus progressively cooled by the expanded gas from the pump A, until liquefaction is attained. If the temperature of the gas passing to the pump B is too low, there is but a very slight cooling of the gas, and this is aggravated by the increased specific heat of the gas at a low temperature. Consequently, the temperature of the gas entering the pump B is not allowed to fall too low. The liquefied gas is run off at the cock C. Whenever necessary, petroleum ether is used as a lubricant for low temperatures. The advantages claimed for this process are the rapid liquefaction of the air at comparatively low pressures.

(3) *Methods involving the rapid evaporation of volatile liquids.*—In 1755, W. Cullen froze water by its own rapid evaporation, and in 1862, Carré exhibited at the International Exhibition, a machine for manufacturing ice in which the cold was produced by the rapid evaporation of liquid ammonia. Ice is made by this process to-day. In 1835, M. Thilorier showed that the rapid evaporation of liquid or solid carbon dioxide mixed with ether gave a temperature of —100°, and by this means, M. Faraday obtained temperatures as low as —110°. In 1878, J. O. Natterer obtained a temperature of —140° by the rapid evaporation of a mixture of liquid carbon dioxide and nitrous oxide.

A. A. B. Bussy [9] also liquefied sulphur dioxide by cooling, and, on allowing the liquid to evaporate rapidly, produced temperatures which enabled him to liquefy chlorine and ammonia, and to solidify cyanogen. These operations introduce the work of R. Pictet.[10] In order to lessen the risk of compressing gases at enormous pressures, Pictet cooled a gas, B, below its critical temperature by the rapid evaporation of another liquefied gas, A, and used the liquefied gas B to cool a third gas, C, and so on. This is called the **cascade method of liquefying gases.** In one series of experiments, liquid sulphur dioxide was allowed to evaporate around a system of tubes containing carbon dioxide, which then liquefied under a feeble pressure; the liquid carbon dioxide was allowed to evaporate in a similar way about a tube containing oxygen. When the valve closing the tube containing the oxygen was opened, Pictet said that he noticed.oxygen escaped in the form of a transparent jet surrounded by a white cloud which he took to be solid oxygen. As a result, R. Pictet telegraphed to the French Academy of Sciences on Dec. 22nd, 1877:

> Oxygéne liquéfié aujourd'hui sous 320 atmospheres et 140° de froid par acides sulphureux et carbonique accouplés.

This telegram and L. P. Cailletet's letter to J. B. A. Dumas were read at the meeting of the French Academy on Dec. 24th, 1877. Some of R. Pictet's descriptions of liquid oxygen and also of liquid hydrogen, which he claimed to have prepared, have not been confirmed by later work. At the same meeting, J. C. Jamin pointed out that it was still necessary to assemble into a real liquid the impalpable mist which had been momentarily obtained by Pictet and Cailletet; and some time afterwards, S. von Wroblewsky pointed out that the subject required developing so that liquid oxygen could be poured as readily as liquid ethylene. He said:

> It is my conviction that the thing will be successfully carried out only when we return to R. Pictet's method, and by cycles of various liquefied gases make a cascade of temperatures whose last step will produce the stream of liquid oxygen.

S. von Wroblewsky and K. Olschewsky [11] cooled the condensing tube of an apparatus like that of L. P. Cailletet by means of ethylene evaporating under reduced pressure and cooled by solid carbon dioxide. As a result, they were able to telegraph to the French Academy on April 7th, 1883:

> Oxygéne liquéfié, completement liquide, incolore comme l'acide carbonique. Vous recevrez une note dans quelques jours.

Even here comparatively small amounts of liquid were obtained, and it was not until 1895 that C. von Linde was able to liquefy the so-called permanent gases—air and oxygen on a commercial scale. Linde's apparatus was based on quite a different principle. H. K. Onnes [12] at Leyden used the cascade process with methyl chloride, down to —90°; ethylene down to —160°; and oxygen down to —217°. This critical temperature of hydrogen and helium are so much below the lowest temperatures obtained by the evaporation of gases of higher boiling point that the cascade method is inapplicable for their condensation.

(4) *Cooling by the Joule-Thomson effect.*—When a gas, cooled by passing through a small orifice, is made to circulate around the tube leading the compressed gas to the orifice, the gas passing to the orifice is cooled, and on passing through the orifice is cooled still more. By continuing the cycle, it follows that the temperature can be reduced indefinitely low, or the gas liquefies. For example, air at —20° is cooled to —36° by expanding in the orifice from a pressure of 50 atm. to one atmosphere; if this cooled air is compressed and again expanded from —36°, the temperature drops to —54°, then to —101°, —136°, and finally —190°, when the expanding air condenses. The theory was known for almost half a century before it was realized in industrial practice. The so-called self-intensive or cumulative systems for cooling gases were elaborated by C. von Linde,[13] J. Dewar, W. Hampson, and C. E. Tripler between 1894–5.

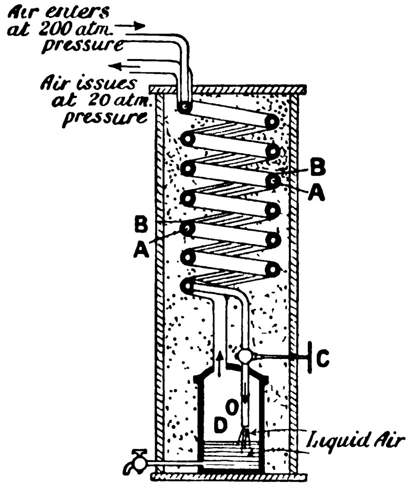

FIG. 23.—Linde's Apparatus for the Liquefaction of Air (Diagrammatic).

The idea will be understood after an examination of Fig. 23. The air to be liquefied —freed from carbon dioxide, moisture, organic matter, etc.—enters the inner tube of concentric or annular pipes, *A*, under a pressure of about 200 atm. This tube is hundreds of yards long and coiled spirally to economize space. By regulating the valve *C*, the compressed air is allowed to suddenly expand in the chamber *D* to a pressure of about 50 atm. The air thus chilled passes back through the tube *B* which surrounds the tube *A* conveying the incoming air. The latter is thus cooled still more. The gas, at 50 atm. pressure, passes along to the pumps, where it is returned with more air to the inner tube. In this manner, the incoming air at 200 atm. pressure is cooled more and more as it issues from the jet *O*. Finally, when the temperature is reduced low enough, drops of liquid air issue from the jet, and collects in the receiver. The tubes must all be packed in a non-conducting medium—wool, feathers, etc.—to protect them from the external heat. From a preceding discussion, the work required to compress a gas from atmospheric pressure to 200 atm. pressure is proportional to log 200, while the work required to compress the gas from 50 to 200 atm. is proportional to log 2. It is therefore found to be more economical and efficient to allow the gas to expand from 200 to 50 atm. pressure rather than from 200 to one atm. pressure, when the expanded gas is returned to the compressor. Several improvements on Linde's form of liquefier have been devised, but the main principles are well illustrated by the original apparatus.

In 1898, J. Dewar liquefied hydrogen by a similar method, but the gas was first cooled below its inversion temperature, —80°, in liquid air before subjecting it to the Joule-Thomson process. By evaporating liquid hydrogen under reduced pressure, a temperature of —259°, or 14° K., was obtained. The inversion temperature of helium is —240°, or 33° K., and H. K. Onnes, in 1908, succeeded in liquefying helium by cooling it below its inversion temperature in liquid hydrogen, and then cooling it still further by the Joule-Thomson process. Helium boils at 4·29° K. under atmospheric pressures; and, by evaporating liquid helium under reduced pressure, H. K. Onnes obtained a temperature 1·48° K., or —271·6°, that is, within less than two degrees of absolute zero.

Preserving liquid air.—There is a far greater difference between the temperature of liquid air (about −190°) and ordinary atmospheric air, than between the temperature of ice and boiling water. The preservation of liquid air is thus a far more difficult problem than would be involved in preventing cold water boiling away while surrounded by a steam jacket at 200°. James Dewar (1892)[14] solved the problem by keeping the liquid air in the double glass flasks with an evacuated space between the inner and outer walls. Vessels similar in principle are said to have been used by L. J. G. Violle in 1882, and by A. d'Arsonval in 1887. Glass is a poor conductor, and a vacuum is a non-conductor. Hence, the liquid in the inner vessel can receive heat only from above, and by radiation. J. Dewar also silvered the glass walls of the evacuated space so as to reduce the effects of radiant heat. Still air is a very bad conductor of heat, so that the open end of the vessel is plugged lightly with cotton wool in order to reduce the ingress of heat from outside to a minimum. In this way, liquid air is transported by rail, etc., with a surprisingly little loss. *En passant*, a similar principle is utilized in the so-called *thermos flasks*, which will not only keep the contained liquids cool, but also retard the cooling of hot liquids; and J. Dewar claimed that he utilized the principle of the vacuum vessel as an insulator in calorimetric experiments in 1874.

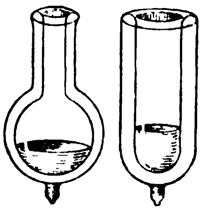

Fig. 24. — Dewar's Flasks.

§ 26. The Manufacture of Oxygen and Nitrogen from Liquid Air

When a thing is possible according to theory and only practical difficulties oppose its realization, it is infinitely probable that those difficulties are not insurmountable.—G. CLAUDE.

When liquid air evaporates, the nitrogen, boiling at —195·5°, is more volatile than the oxygen, boiling at —182·5°, and escapes first so that the gas which comes from the liquid during the earlier stages of the evaporation contains so little oxygen that it will extinguish a lighted taper; as evaporation continues the liquid becomes richer and richer in oxygen until finally almost pure oxygen separates. If oxygen gas be bubbled through liquid air (—193·5°), the bubbles of gas escaping contain 93 per cent. of nitrogen. The oxygen is condensed from the rising bubbles, and the more volatile nitrogen takes its place. For equilibrium, there is a definite relation between the composition of the liquid mixture and of the rising vapour. This has been investigated by E. C. C. Baly (1900),[1] and the results are illustrated by the curve, Fig. 25, which shows for each proportion of oxygen in the mixed liquid, the corresponding proportion in the vapour which is necessary for equilibrium. Thus, if the *liquid* contains 30 per cent. of oxygen (and 70 of nitrogen), the *vapour* will contain 10 per cent. of oxygen (and 90 of nitrogen). When oxygen is bubbled through liquid air containing 21 per cent. of oxygen (and 79 of nitrogen), then, for equilibrium, oxygen will condense and nitrogen evaporate until the vapour contains 7 per cent. of oxygen (and 93 of nitrogen). E. C. C. Baly's measurements of the percentage composition of liquid air and of the vapour in equilibrium at different temperatures are graphed in Fig. 26. A horizontal line across the curves at any assigned temperature shows the composition of liquid and vapour when in equilibrium. The composition of liquid and vapour in the rectifying columns or scrubbers of Linde's or Claude's apparatus approximate to the values indicated by these curves. These important principles must be clear before the modern method of separating oxygen and nitrogen from liquid air can be understood.

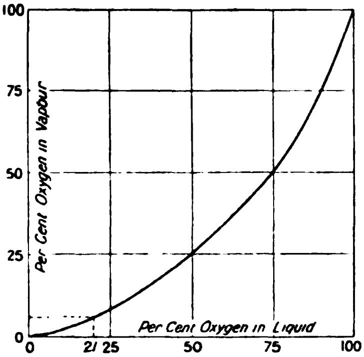

FIG. 25.—Composition of the Liquid and Vapour from Liquid Air (E. C. C. Baly).

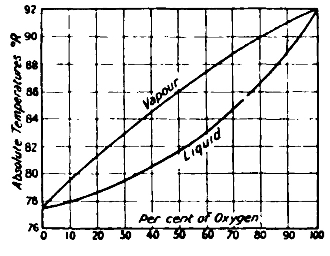

FIG. 26.—The Percentage Composition of Liquid Air in Equilibrium with its Vapour at Different Temperatures.

Linde's process.—J. Dewar noticed that when liquid air boils, the more volatile constituent—nitrogen—is given off preferentially during the first stages of the evaporation, while the residual liquid becomes progressively richer and richer in oxygen. In 1893, J. H. Parkinson[2] patented a proposal to utilize this fact for the commercial production of oxygen, but his apparatus was not satisfactory. It was not until the development of C. von Linde's process[3] in 1895 that it became practicable to manufacture oxygen from liquid air.

A diagrammatic sketch of C. von Linde's apparatus (1895) is indicated in Fig. 27. Purified air is compressed to about 200 atm., and driven along a pipe which divides at *A*, Fig. 27, into two streams and then passes down the interior tubes of a double set of annular or concentric pipes similar to the worm tube, Fig. 23. The two inner tubes finally unite into one single pipe, *B*. The air then passes through a spiral, *S*, *viâ* the regulating valve *R*, and finally streams at *C* into the collecting vessel. The action is here similar to that described in the process for the liquefaction of air, Fig. 23. After a time, the air is liquefied in the collecting vessel, about the spiral *S*. The more volatile nitrogen boils off more rapidly than the oxygen. Hence, a gas rich in nitrogen passes up one of the two annular outer pipes as indicated on the left of Fig. 27. The liquid rich in oxygen is kept at a constant level by means of the valve, and thus the rate at which the liquid air in the collecting vessel is allowed to boil is also regulated. The oxygen passes from this tube on the right of Fig. 27 along the outer annular pipe, and finally emerges from the apparatus, whence it is pumped into cylinders, etc., for use. If the valves are all properly regulated, the inrushing air is cooled by the counter currents of oxygen and nitrogen. The two latter gases pass along the tubes as indicated in the diagram. The tubes, etc., are all well insulated with non-conducting materials—feathers, wool, etc.

In the 1895 apparatus for extracting oxygen from the air, the product was not much more than 60 per cent. purity, and it was not until C. von Linde employed the rectifying tower in 1902, that a purer gas was obtained. In C. von Linde's rectifying column, there is a downward stream of liquid air which starts at about 80° K.; and an upward stream of gas which is rich in nitrogen, and which starts at about 91·5° K. The percolation of the reverse streams through the tower changes the descending current into oxygen of 98–99 per cent. purity, and the ascending current into nitrogen of 93 per cent. purity. The reason why the nitrogen is not richer than 93 per cent. purity will be clear from Fig. 26. The ascending vapours are always richer in oxygen than corresponds with the descending liquid, there is a progressive condensation of oxygen from the vapour, and an evaporation of nitrogen from the liquid, to enable that equilibrium to be established. By this process, oxygen can be obtained as pure as is commercially desired, but the escaping nitrogen contains over 7 per cent. of oxygen. The original apparatus has been much improved in recent years, principally with the object of preparing a purer nitrogen for use in the cyanamide process; but, as G. Claude has said: " We must salute in this apparatus the archetype of all the later machines, for it was the first to demonstrate that the manufacture of oxygen from liquid air is commercially possible." The rectification of the nitrogen is effected by condensing the 93 per cent. product, and rectifying it in another tower. A product with two per cent. oxygen is thus obtained. The supplementary rectification by means of a liquid rich in nitrogen was patented by R. J. Lévy and A. Helbrouner in 1903.[4]

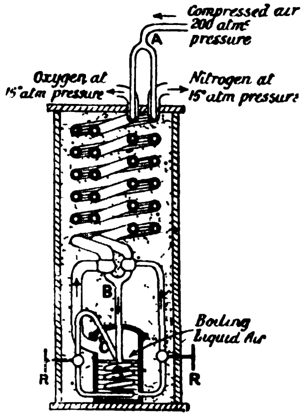

FIG. 27.—Linde's Apparatus for the Separation of Oxygen and Nitrogen from Liquid Air (Diagrammatic).

It must not be assumed that two gases which exert no chemical or physical action on one another, can be separated from a mixture without the expenditure of energy. Each gas in the mixture exerts its own partial pressure, and **the total work required to separate the components of a mixture of gases which exert no chemical or physical action on one another is equal to the sum of the work of isothermal compression of each of the constituent gases from its partial pressure in the mixture to its final pressure.** Lord Rayleigh[5] dealt with the converse problem in 1875 by showing that mechanical work is performed by the simple admixture of two gases without the exercise of chemical affinity.

G. Claude's counter-current process of rectification.—An improvement on Linde's process, by G. Claude (1903), enables practically pure oxygen and nitrogen to be obtained in a simple and effective manner. It is based on the fractional condensation of compressed air. The liquid just formed is drained back through a condenser so that it is scrubbed in contact with the gas which is being condensed. The liquid collects in two portions—one contains about 50 per cent. of oxygen, and the other is almost wholly nitrogen. The two liquids are separately rectified.

A diagrammatic sketch of Claude's apparatus is shown in Fig. 28. The cooled and purified air enters the lower part of the apparatus at a pressure of about 5 atm. and rises through a series of vertical pipes P surrounded by liquid oxygen, where it is partially liquefied. The liquid containing about 47 per cent. oxygen and 53 per cent. of nitrogen drains into the lower vessel A. The vapour which has survived condensation enters B, and then descends through a ring of pipes C arranged concentrically about the set previously described. Here all is liquefied. The liquid which ultimately collects in this vessel D is very rich in nitrogen. The pressure of the vapour in the central receptacle forces the liquid nitrogen to enter the summit of the rectifying column E, and the liquid, containing 47 per cent. of oxygen, is likewise forced to enter the rectifying column at F lower down. The pressure and rates of flow are regulated by the cocks RR'. The liquid nitrogen is 3° or 4° lower in temperature than the liquid rich in oxygen. Nitrogen evaporates from the down-streaming liquid, and oxygen condenses from the up-streaming gases. The heat supplied by the condensation of oxygen helps on the evaporation of nitrogen. Consequently, the descending liquid gets progressively richer and richer in oxygen, and the ascending gases richer in nitrogen. The liquid oxygen drains into the receptacle G, and is there evaporated by the latent heat of the gases condensing in the tubes. Finally, oxygen containing from 2 to 4 per cent. of nitrogen passes from the oxygen exit, and nitrogen containing 0·2 to 1 per cent. of oxygen escapes at the top of the rectifying column.

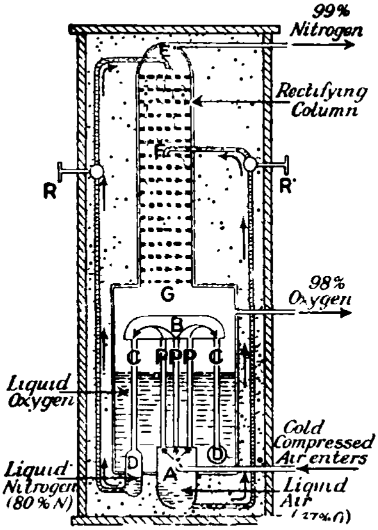

Fig. 28.—G. Claude's Apparatus for the Separation of Oxygen from Liquid Air (Diagrammatic).

These processes enable oxygen and nitrogen to be extracted from atmospheric air comparatively cheaply—one ton of coal for driving the compression apparatus is said to furnish one ton of oxygen and four tons of nitrogen. As C. von Linde has said, "the heat is eliminated from the air exclusively by the expenditure of internal work." The work required for the liquefaction of these gases is solely spent in separating the molecules of the gases from one another against their intermolecular attractions, and in compressing the gases from their partial pressure in the original mixture to their final pressure.

CHAPTER XIV

OZONE AND HYDROGEN PEROXIDE

§ 1. The Discovery of Ozone and of Hydrogen Peroxide

> In natural philosophy, no observations are trivial, no truths insignificant; that which to us is barren is often so for this reason only, that we do not sufficiently know nor sufficiently examine it.—T. BERGMANN (1779).

IN 1785, eleven years after the discovery of oxygen by J. Priestley, M. van Marum[1] said that he noticed a peculiar smell in the vicinity of electrical machines in motion, but he does not appear to have made any attempt to find the cause of the smell beyond saying that "it seems clearly to be the smell of electrical matter," and noting that the "electrical matter" has the power of acting directly on mercury. A smell, presumably similar, has been noticed from ancient times to accompany thunderbolts, and Homer has made several references to this odour in his *Odyssey* (**12.** 417; **14.** 307), and in his *Iliad* (**8.** 135; **14.** 415).[2] For a time the sulphurous smell was thought to be a popular error in which the blue lurid tint of lightning was connected with the appearance of burning sulphur, and the odour was then imagined. Now, however, there seems no reason to doubt that the peculiar odour which is sometimes perceptible during thunderstorms, and which has been likened to sulphur, is identical with the odour of ozone.

In 1782, T. Cavallo[3] referred to electrified air as the *aura electrica;* he noticed its purifying action on decaying animal and vegetable matter; and he recommended its use as a disinfectant. H. Davy, in his *Lectures on Agricultural Chemistry* (London, 6, 1826), says that

> In 1826 Dr. John Davy recognized the existence of this principle in the atmosphere and published a formula for the preparation of chemical tests to be used in its detection resembling that afterwards adopted by Schönbein.

In 1801, W. Cruickshank also mentioned that a similar odour is produced near one of the electrodes (anode) when acidulated water is electrolyzed. In 1839, C. F. Schönbein's attention was arrested by the similarity in the odour developed during the electrolysis of water and during the working of an electrical machine. The odour emitted by an electrical machine had been explained by assuming that the sensation was due solely to a peculiar action of electricity on the olfactory nerves, and not to the presence of a material substance. In a memoir, *Recherches sur la nature de l'odeur qui se manifeste dans certaines actions chimiques* (1840), C. F. Schönbein[4] claimed that the smell must be due to the formation of a definite substance to which he gave the name *ozone*—from ὄζω, I smell. He said:

> After making many fruitless experiments in order to find the relations between the smell which is developed when ordinary electricity discharges from the points of a conductor in air, and when water is decomposed by a voltaic current, I have finally arrived, not at a complete solution of the problem, but at a point where *le véritable cause de l'odeur électrique* can be recognized more or less clearly.

According to C. F. Schönbein, **ozone is a distinct form of matter with an identity of its own;** ozone is one and the same body from whatever source it be derived; for he found that the same substance was produced when an electrical machine is working; when moist air is passed over oxidizing phosphorus; and when water is electrolyzed. Hence, T. Andrews (1856) could say:

> For the first recognition of ozone and description of its properties, we are indebted to the sagacity of Schönbein, to whom the entire merit of the discovery unquestionably belongs.

Numerous investigations on ozone have proved that the gas is a condensed form of oxygen which can be symbolized by the formula O_3 when ordinary oxygen is symbolized O_2.

Hydrogen peroxide was first described by L. J. Thénard [5] in 1818 in a paper entitled *Observations sur la combinaisons nouvelles entre l'oxygène et divers acides.* The discovery was made while investigating the action of sulphuric, nitric, arsenic, phosphoric, and acetic acids on barium peroxide. He first supposed that the liquids which he obtained were *produits suroxygènés* of the different acids, but he later showed that the liquid, *eau oxygènée,* contains a super-oxide of hydrogen, which is endowed with energetic oxidizing properties, and decomposes when heated into water and oxygen. After analyzing the liquid, he concluded:

> L'eau la plus oxygènée est un bi-oxyde d'hydrogène qui contient, relativement à la même quantité d'hydrogène, deux fois autant d'oxygène que l'eau ordinaire, et que, toutes les fois que l'eau oxygènée ne contient pas cette quantité d'oxygène, elle peut être regardée comme un mélange d'eau pure et de bi·oxyde d'hydrogène.

§ 2. The Modes of Formation and Preparation of Ozone

When oxygen is heated to an elevated temperature, three endothermal reactions probably occur: (i) $3O_2=2O_3-68{\cdot}2$ Cals.; (ii) $O_2=2O-Q$ Cals.; (iii) $O_3=3O-Q_1$ Cals. Hess' principle shows that $2Q_1-3O_2+2O_3=3Q$, and when the system is in equilibrium $3O_2\rightleftharpoons 2O_3$; $O_2\rightleftharpoons 2O$; and $O_3\rightleftharpoons 3O$. In confirmation it has been shown experimentally that at about 2400°, a great part of the oxygen is dissociated into atoms or associated into molecules of ozone. The formation of ozone, O_3, from oxygen, O_2, is attended by an absorption of energy nearly equivalent to $3O_2=2O_3-68{\cdot}2$ Cals. Consequently, energy is required for the formation of ozone, and this energy must be borrowed from a foreign source, or it may be obtained whenever oxygen is developed at a low temperature by a strongly exothermic reaction. Hence, the various methods of preparing ozone have been arranged in two groups: physical and chemical—

in the former, energy is added to the oxygen directly; in the latter, indirectly. It is, however, not easy to draw a strict line of demarcation.

(1) *The formation of ozone by the action of heat.*—The reputed formation of ozone when hydrogen is burned, and when air or oxygen is passed over glowing platinum, are probably mal-observations; for example, in L. Troost and P. Hautefeuille's oft-quoted experiment (1877), ozone was said to be formed by passing oxygen through a porcelain tube heated above 1400°, but J. K. Clement (1904) [1] could find no ozone under these conditions, not even when a Nernst's filament was heated to over 2000° in oxygen. True, an odour resembling ozone could be detected, and starch and potassium iodide test-paper is coloured blue. These phenomena are a result of the formation of nitrogen oxide, not ozone; this is shown by the fact that the so-called tetra-base test-paper is coloured pale yellow characteristic of the nitrogen oxides; had ozone been present, the paper would have been coloured violet—hydrogen peroxide has no effect.

Ozone seems to be fairly stable at ordinary temperatures, although it gradually decomposes on standing. Low temperatures favour the accumulation of ozone in a system. It also appears to be fairly stable at high temperatures, while at intermediate temperatures it decomposes very rapidly. As a matter of fact, ozone is readily formed at high temperatures. There is a balanced reaction between ozone and oxygen such that the higher the temperature, the greater the proportion of ozone in equilibrium with the oxygen. W. Nernst (1913) estimates that 0·15 per cent. of ozone by weight can exist in equilibrium with oxygen at 1296°, 1·52 per cent. at 2048°, and 16·50 per cent. at 4500°. Hence, if ozone be formed at a high temperature, the hot gas must be cooled more quickly than the ozone can decompose. Ozone decomposes very much more quickly than nitric oxide, so that if both be formed at a high temperature, the latter alone is able to survive if the heated gases are not cooled with very great rapidity. This rapid cooling has been accomplished by F. Fischer and E. Brähmer (1906) by rapidly chilling the heated oxygen in various ways—*e.g.* by burning hydrogen or other substances beneath the surface of liquid air or liquid oxygen; or by plunging a glowing platinum wire or glowing Nernst's filament under the surface of liquid air; or by blowing air or oxygen against a heated Nernst's filament. After hydrogen has burned beneath the surface of liquid air for two or three minutes, the outflowing gas smells like ozone, but it does not give the ozone reaction with the tetra-base test-paper.

The liquid in the tube contains frozen nitric oxides but no hydrogen peroxide. After most of the clear liquid has evaporated, the residue gives all the reactions characteristic of ozone. This shows that nitric oxide and ozone are produced under the conditions of the experiment. Similar results were obtained by burning carbon monoxide, acetylene, hydrogen sulphide, sulphur, or charcoal, but were complicated, of course, by other products of combustion. J. K. Clement's failure to detect ozone in the products of combustion does not prove that ozone is not formed by the heat of the flame, for ozone as well as nitrogen oxide may have been formed, and the latter alone may have survived on cooling. Indeed, the blackening of a silver foil in the hydrogen, or oxy-carbon monoxide blast flame, is taken by W. Manchot (1909) to indicate the presence of ozone, since neither hydrogen peroxide nor nitrogen oxide gives this reaction. To summarize, the effect of heating air to a high temperature:

		Product.		Product.
Time of heating	Short . . .	O_3	Slow cooling	Nil
			Fast cooling	O_3
	Long . . .	O_3+NO	Slow cooling	NO
			Fast cooling	NO+O_3

When a platinum wire at 1700° is plunged beneath the surface of liquid air, ozone but no nitric oxide, is formed, presumably because the temperature required for the production of appreciable amounts of the latter is higher than for ozone. The formation of ozone is not due to the light emitted by the glowing filaments because, if the glower be placed in an evacuated quartz tube plunged in liquid air, no appreciable amount of ozone is formed in the liquid air under the conditions of the experiment so long as the quartz is cool. Nitric oxide, NO, is of course oxidized to nitrogen peroxide, NO_2, in the presence of air or ozone.

(2) *The formation of ozone by the action of ultraviolet and radioactive radiations.*—In 1894, P. Lenard [2] showed that the cathode rays which penetrated an aluminium window in a vacuum tube, ozonized the air through which they passed; but it was not made clear whether the ozone was produced by the cathode rays, or indirectly by the ultraviolet light produced by cathode rays in air. P. Lenard detected no other chemical effects by these rays. Six years later, P. Lenard showed that oxygen is ozonized by ultraviolet light of wave-length between 0·00014 mm. and 0·00019 mm., *i.e.* by rays of great refrangibility to which air is almost opaque. Air is more opaque than rock salt, fluorspar, or quartz to the most chemically active ultraviolet rays. Hence, air-spaces in the path of the rays should be avoided in designing apparatus for ozonizing oxygen by ultraviolet rays. Ozone is produced by the action of radiations of short wave-lengths on oxygen. Cathode rays and ultraviolet light rays, acting on air or oxygen, produce ozone, and this the more the lower the temperature. If liquid or solid oxygen be exposed to ultraviolet light, ozone can be detected in the oxygen obtained by subsequent evaporation. The mercury vapour or uriol lamp is commonly employed for producing ultraviolet radiations; the lamp is made of quartz, not glass, because quartz is transparent and glass is opaque to these radiations. E. Goldstein (1903) passed a discharge through a quartz Geissler's tube, and found that the air in the vicinity was strongly ozonized. If the pressure of the gas in the Geissler's tube be too large, no ozonization occurred. It was assumed that rays of ultraviolet light of small wave-length penetrated the quartz, and ozonized atmospheric oxygen. In H. N. Potter's patented process for ozonizing air, a current of air is conducted spirally about a quartz mercury vapour lamp, within a sheathing of ordinary glass. The mercury lamp gives off a copious stream of ultraviolet light.

There is no definite equilibrium ratio between the rates of formation and decomposition of ozone when air or oxygen is exposed to ultraviolet light; the amount formed increases with fall of temperature, and decreases with fall of pressure. The decomposition of ozone by ultraviolet light is very slow, but is strongly accelerated by small quantities of hydrogen which reacts thus: $H_2+O_3=H_2O+O_2$. No signs of the reaction $2O_3+H_2=H_2O_2+2O_2$ are observed when hydrogen is in excess; the main reaction is $H_2+O_3=H_2O+O_2$, and when ozone is in excess, the main reaction is $2O_3=3O_2$.

According to E. Regener (1906),[3] ozone has a maximum absorptive power for ultraviolet light of wave-length 258$\mu\mu$, and light of wave-length 200–300$\mu\mu$ converts ozone into ordinary oxygen; on the other hand, V. Schumann showed that oxygen absorbs waves below 193$\mu\mu$, and the conversion of oxygen into ozone by ultraviolet light is largely the result of exposure to light of wave-length less than 200$\mu\mu$. There is therefore an equilibrium value for the reaction $3O_2=2O_3$, which decreases with rise of temperature. E. Regener found in one set of experiments 3·4 per cent. of ozone at 20°, 3·15 at 40°, 2·7 at 54°; but the actual proportion of the two gases is also determined by the intensity of the ultraviolet light—*vide* Fig. 6.

The solar spectrum ceases abruptly at 293$\mu\mu$, from which it is inferred that light of shorter wave-length is absorbed by the atmosphere; and further, since oxygen itself does not appreciably absorb light of greater wave-length than 200$\mu\mu$, it follows that the ozone, formed by the absorption of light of wave-length below 200$\mu\mu$, is partially destroyed by light of wave-length approximately 293$\mu\mu$. This is confirmed by the spectroscopic observation that ozone gas has two well-defined absorption bands in the red part of the spectrum, and that the residual transmitted light is markedly blue. These observations are said to favour the hypothesis that the ozone in the atmosphere may have been formed by the action of the ultraviolet rays from the sun, on the oxygen in the upper regions of the atmosphere, and that ozone is formed in the upper atmosphere in sufficiently large quantities to account for the normal blue colour of the sky; this has been rendered further probable by actual determinations of the amounts of ozone in the upper atmosphere. At a mean altitude of 15·2 kilometres, for instance, J. N. Pring (1914) found a mean of $2{\cdot}1\times10^{-6}$ volumes of ozone per volume of air.

The action of the radiations from radium or other radioactive substances[4] on air or oxygen furnishes some ozone. If radium be enclosed in a tube with oxygen, ozone is formed, but not if the radioactive substance is in a separate glass vessel which in turn is placed in a tube of oxygen. The radiations from radium, polonium, etc., can produce ozone. S. C. Lind (1911)[5] showed that the amount of ozone formed by the action of α-rays on oxygen is such that one molecule of ozone is formed for two pairs of gaseous ions. F. Krüger and M. Möller found that in the passage of electrons of high velocity through gaseous oxygen, one pair of ions is concerned in the formation of each molecule of ozone.

(3) *The formation of ozone by electrolysis.*—In 1840, C. F. Schönbein[6] observed the presence of ozone in the gases evolved during the electrolysis of acidulated water and salt solutions. Ozone can generally be detected in the oxygen gas obtained during the electrolysis of acidulated water with non-oxidizable electrodes—*e.g.* gold, platinum, etc. The yield of ozone in the electrolysis of acidulated water is very small, but is increased by reducing the temperature and by increasing the current density—*i.e.* by increasing the intensity of the current or reducing the surface of the anode. By the electrolysis of sulphuric acid of a specific gravity between 1·075 and 1·1, with an anode made by imbedding platinum foil in glass and grinding away the edge so that a line of platinum 0·1 mm. broad and 11·5 mm. long, is exposed, F. Fischer and K. Bendixsohn (1909)[7] prepared oxygen containing 17 to 28 per cent. of ozone. This form of anode prevents long contact between the platinum surface and the gas. The curve, Fig. 1, shows the relation between the yield of ozone by weight and the concentration of the sulphuric acid. With a current density of 65 amps. per sq. cm., the maximum yield is obtained with an acid of specific gravity 1·1. An acid of specific gravity 1·22 has a maximum electrical conductivity, so that the best conducting acid does not give the maximum yield of ozone. Solutions of phosphoric, chromic, nitric, perchloric, or hydrofluoric acid; ammonium or potassium sulphate, potassium hydrogen carbonate; or of sodium or potassium hydroxide do not give such good yields as sulphuric acid. Platinum-iridium electrodes give the best results—lead or lead peroxide electrodes are rapidly destroyed. The cell should be immersed in water cooled to 0°, and the anode should be internally cooled by a freezing mixture to about —14°. The method of making ozone by the electrolysis of sulphuric acid is dearer than the electrical discharge process; but it is an advantage that the gas is free from nitrogen, and that the hydrogen obtained as a by-product may be utilized.

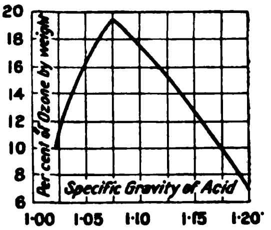

FIG. 1.—Yield of Ozone with Sulphuric Acid of Different Concentrations.

(4) *The formation of ozone by the action of an electrical discharge.*—The electrical discharge through air as dielectric produces a variety of effects: luminous, thermal, chemical, mechanical, and magnetic. In the production of ozone by the electric discharge, chemical action is alone wanted, and accordingly the conditions should be such as to keep the waste of energy expended in producing other effects as low as possible.

The relations between the current *C* and voltage *V* in a gaseous discharge are somewhat complex.[8] If the current from a positively charged point, passing through the air to the earth, be gradually increased, the voltage rises rapidly and very small currents pass as a *non-luminous or invisible discharge* which produces no chemical effects; finally, Fig. 2. there is a slight discontinuity in the voltage-current curve, and the discharge becomes luminous—*glow or silent discharge.* This is a high tension discharge of little energy. Very little electricity leaks during the so-called invisible and glow discharges. For an air-gap a few centimetres in length, there are very high voltages and small currents of a few amperes; as the voltage increases, the conductivity of the air increases, and the voltage rapidly falls, the current increases, and the so-called *brush discharge*, more luminous than the glow discharge, is developed. The appearance and nature of the brush discharge varies considerably with the conditions and the shape of the electrodes; it develops very little light and heat, and it acts almost exclusively on the oxygen—very little nitrogen is oxidized. The conditions favourable for the formation of the brush discharge are important since the production of ozone by the electrical discharge is largely the result of its work. The brush discharge is sometimes called *silent, or dark discharge.* These terms are misnomers; the brush discharge is neither silent nor dark, for it is attended by a peculiar sound, and it is coloured bluish-white. The German equivalent is *Bueschelentladung*; the French equivalents are *l'effluve électrique* and *l'aigrette électrique* according as the discharge shows a narrowed stem or is expanded fan-wise. The transition from one form of high tension discharge to another may be accompanied by sparking, where the discharge is characterized by a loud snapping noise and a yellow colour. The spark and brush discharges may be mixed. Sparking is very detrimental to the formation of ozone. At −194°, E. Briner and E. Durand (1907) [9] found that 99 per cent. of oxygen is converted into ozone with the silent discharge, and only 1 per cent. with the spark discharge; and even this was considered to be produced by the silent discharge which occurred simultaneously with the sparking.

There is another discontinuity in the voltage-amperage curve of electrical discharge as the brush discharge changes into the *electrical flame*—the precursor of the *high-tension arc.* When the arc has been established, the path of the discharge is strongly luminous, and the ratio C/V is higher than before; but instead of the voltage increasing with current, it now decreases owing to the fact that the resistance of the air-gap decreases faster than the increase of current. The high-tension arc in air at ordinary pressure corresponds with the glow-discharge in a gas at a low pressure. The electric arc is active in producing nitric oxide in air. The temperature is different in different parts of the arc and depends on the current and voltage; it approximates 2200° or 2500° in the positive column. As the current increases still further, the temperature rises, and another discontinuity occurs as the discharge passes into the *low-tension or lighting arc.* The low-tension arc is used in steel and carbide furnaces; the temperature is very high; and the electrode material is largely vaporized. The temperature with carbon electrodes is about 3500°. With a negatively charged point, the results are similar but rather less complex. If the electric discharge takes place between parallel conductivity plates, with one or both covered by a solid dielectric, the phenomenon is rather more complex. The brush discharge then changes its character, but it still retains its valuable property of converting oxygen into ozone. As a matter of fact, a series of electric sparks in oxygen will form ozone, and in air a mixture of nitrogen oxide and ozone [10]—all depends on the rate of cooling as indicated previously.

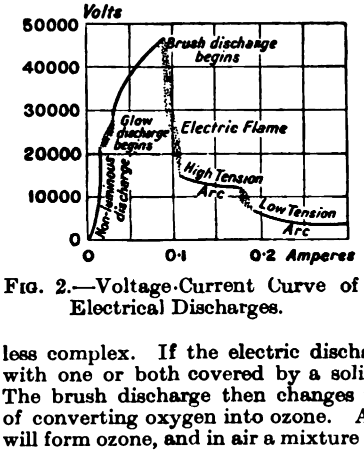

FIG. 2.—Voltage-Current Curve of Electrical Discharges.

The brush discharge is most favourable for the production of ozone.[11] In the arc and spark discharges much heat and light are developed, and energetic chemical action occurs; ozone is formed, but the nitrogen of the air also reacts with the oxygen under this stimulus. The fact that nitrogen oxides are often produced when ozone is made from atmospheric oxygen rather confused the minds of the early investigators as to the real nature of ozone, for the two products were not always clearly discriminated by the tests employed—usually, the bluing of starch and potassium iodide test-paper.

E. Warburg [12] found that under different conditions, the electrical discharge produces from 93 to 1000 times as much ozone as would have been obtained by electrolysis. One equivalent of hydrogen reduces 24 grms. of ozone, and therefore the equivalent of ozone is taken to be 24. E. Warburg and G. Leithäuser obtained between 0·003 and 0·1 grm. of ozone per coulomb, so that between 240 and 8000 coulombs are required to produce 24 grms. of ozone; these numbers are not at all equivalent to the electrochemical equivalent, 96,540 coulombs. The energy required is greater than the heat of the reaction. The highest yield of ozone, 70 grms. per kilowatt hour, is equivalent to 589 Cals. per gram-molecule—nearly 20 times the energy equivalent to the heat of the reaction. Hence it was inferred that the formation of ozone by the silent discharge is not a direct electrolytic action, but is rather a secondary effect of the ultraviolet and cathode rays generated in some profusion by this discharge. Quartz plates are virtually transparent to ultraviolet light, so that if the discharge passes inside a quartz vessel surrounded by oxygen, ozone is formed; while if under similar conditions, the discharge passes inside a glass vessel, which is almost opaque to ultraviolet rays, there is little or no ozonization of the oxygen. E. Warburg assumes that the electrons, generated by the ultraviolet and cathode rays which have a velocity as high as that required for the production of luminosity, are effective in forming ozone either directly by impact with oxygen molecules, or indirectly by the intermediate production of short æther waves.

The amount of ozone obtained per coulomb of electricity follows no known law, and it is therefore necessary to find the yield of ozone under different conditions empirically. The silent discharge has a deozonizing as well as an ozonizing effect on oxygen. The speed of the ozonization is proportional to the amount of oxygen present, and the speed of the deozonization is proportional to the amount of ozone present. In other words, the reaction follows the law of opposing reactions. If the discharge be passed an infinite time, a certain definite limiting concentration of ozone will be reached when the rate of decomposition is equal to the rate of formation of the ozone: $3O_2 \rightleftharpoons 2O_3$.

E. Warburg[13] obtained the results shown in Table I. with an apparatus containing oxygen, and fitted with a small pointed platinum wire (0·05 mm. diameter) connected to the negative pole of an electrostatic machine, and discharging on to another platinum wire (0·05 mm. diameter) connected to earth. The results show that the maximum concentration of ozone decreases as the *temperature* rises, owing to an increase in the speed of decomposition of ozone, and not to a marked reduction in the speed of formation of ozone. The spontaneous decomposition of ozone was negligibly small.

TABLE I.—MAXIMUM CONCENTRATION OF OZONE.

Temperature.	Ozone—per cent. by volume.	A constant proportional to the rate of formation.	A constant proportional to the rate of decomposition.
−71	5·74	0·0232	0·380
0	4·19	0·0219	0·503
17	3·53	0·0225	0·616
50	2·22	0·0214	0·939
93	1·23	0·0277	1·420

E. Goldstein's[14] experiment shows how a low temperature favours the formation of ozone. He introduced oxygen into an evacuated Geissler's tube until the pressure registered a few centimetres. The tube was partially immersed in liquid air, and electrical discharge passed through the tube. In about half a minute, the pressure sank to about 0·1 mm. Oxygen was again introduced until the pressure reached a few centimetres, and the process repeated again and again. In this way, E. Goldstein claimed 100 per cent. conversion of oxygen into dark blue liquid ozone.

In general, the greater the *pressure* of the gas, the greater the yield. In E. Warburg's experiments, the yield at a pressure p—between 460 and 780 mm.—was $(0·32360+0·00089p)$ times the yield at a pressure of 760 mm.—temperature between 17° and 23°. According to E. Warburg, the decrease in the yield with a rise of temperature is largely due to the decrease in the density of the oxygen.

E. Warburg's experiments further showed that the maximum concentration with a positive discharge is one-third the value obtained with a negative discharge owing to the greater ozonizing effect of the latter, while the speed of deozonization and the temperature effect is nearly the same with both a positive and a negative discharge. E. Bichat and A. Guntz (1888) [15] also testified to the greater efficacy of the negative discharge in the formation of ozone, but A. Vosmaer (1916) maintains that this is an error probably due to a reversal of the poles during the working of the electrostatic machine, so that what was thought to be the negative pole was really positive.

The yield of ozone decreases with increasing *current* up to a certain point; thus with oxygen of 98·5 per cent. purity:

Volts	7230	8800	12500
Ampères . . .	0·00000883	0·0000175	0·0000523
Ozone (grms. per coulomb)	0·0950	0·0908	0·0485

If the current be increased still more, the yield reaches a minimum, and then increases with the current. Thus, with oxygen of 96 per cent. purity:

Volts	6080	7000	9610	12510
Ampères . . .	0·00000146	0·0000219	0·0000524	0·0001307
Ozone (grms. per coulomb)	0·0423	0·0375	0·0307	0·0422

The effect of variations of temperature and pressure is complicated, because not only is the substance itself altered, but the reagent which brings about the reaction is also modified. According to A. Chassy [16] the amount of ozone formed is proportional to the *voltage*, but there is a doubt about this since it is very difficult to vary the voltage in electrical discharges through gases without at the same time varying the energy. The formation of ozone, after all, is a question of the transformation of electrical into chemical energy. The quantity of available electrical energy may be regarded as a product of the voltage and amperage, and since the voltage for a given apparatus does not change very much, the yield of ozone must depend on the amperage, and bear no special relation to the voltage.[17] The voltage can be regarded only as a force which can neither be under nor over a certain limiting value consistent with the apparatus. If the voltage be too high there is a danger of sparking through the air, or of cracking or piercing a solid dielectric. Hence, the voltage is run as high as is consistent with safety in order to keep the product—voltage × amperage—high. The yield is then large, not because the voltage is high but because a large amount of electrical energy is available. Most experiments on high-tension currents have been made with alternating currents. A higher frequency than 100 is favourable to the brush discharge. M. W. Franklin [18] says that the yield of ozone is proportional to the periodicity of the current. According to E. Warburg, the yield with an alternating current is not so good as with a direct current, but this has not been definitely accepted.

According to E. Warburg and G. Leithäuser, the presence of *water vapour* in the oxygen to be ozonized reduced the yield nearly proportional to the pressure of the water vapour.[19] With a negative discharge, a reduction of 7 mm. in the pressure of the water vapour reduced the yield to 94 per cent. of its value for dry oxygen. The effect of moisture is greater with air, and greater still with a positive discharge. The retardation with moisture is greater with oxygen than with air. E. P. Perman and R. H. Greaves also find water vapour accelerates the decomposition of ozone. Even when extreme precautions are taken to dry the gas thoroughly, W. A. Shenstone and T. A. Cundall still found that oxygen is ozonized by the silent discharge, and they also obtained a *greater* yield with moist than with the thoroughly dried gas. H. B. Baker then stated that "ozone is formed as rapidly in oxygen dried with phosphorus pentoxide as it is in the same tube when the oxygen is dried by sulphuric acid." W. A. Shenstone (1897) then showed that a high percentage of ozone is formed by the action of the silent discharge on oxygen saturated with water vapour and the ozone produced is remarkably stable; while on partially drying the gas, the percentage of ozone produced is considerably reduced, and the gas is singularly unstable." W. A. Shenstone's result has not been confirmed, and it is probably a mal-observation due to the presence of nitrogen peroxide in the dry gas, derived from the action of the discharge on slight trace of nitrogen in the oxygen gas. E. Warburg, and D. L. Chapman and H. E. Jones found that the velocity of decomposition of ozone at 100° is virtually the same whether water vapour be present or absent.

According to E. Warburg (1904), no nitrogen oxide is formed when the oxygen is mixed with 7 per cent. of nitrogen, but this is doubtful since with air, nitrogen oxides are formed. A spark discharge produces oxides of nitrogen alone; these oxides prevent the formation of ozone. A little nitrogen or hydrogen favours the production of ozone,[20] but if sparking occurs, the hydrogen unites with the oxygen—explosively if sufficient be present. According to P. Hautefeuille and J. Chappius, a little silicon tetrafluoride or hydrogen fluoride does not affect the yield of ozone; but a trace of chlorine or nitrogen oxide hinders the ozonization of oxygen.[21]

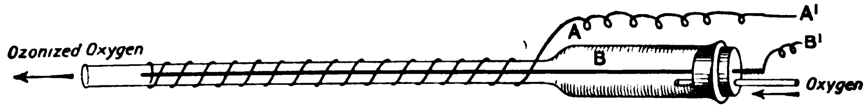

FIG. 3.—L. von Babo's *Tube Ozoniseur.*

The brush discharge may be produced from a static electric machine, from a battery of cells or a dynamo and an induction coil; or from an alternating current from a dynamo of high periodicity, and transformed up to several thousand volts. The latter is the means employed in the commercial production of ozone, while the induction coil furnishes a useful ozonizing discharge in common use for demonstrations and other purposes. L. von **Babo's ozonizer** modified by A. Houzeau,[22] is one of the oldest, and simplest. It is illustrated in Fig. 3. The discharge takes place between two platinum wires, one of which, *B*, Fig. 3, is fitted axially in the narrow tube—this wire is about one or two mm. thick and 40 cm. long; the other wire is rather thin, and is wound around the outside of the narrow tube. The ends of these wires, *A'B'*, are put in communication with the two poles of an induction coil (*G*, Fig. 4). A slow current of oxygen is passed into tube at one end; ozonized oxygen escapes at the other end. The ozonizer illustrated at *A B*, Fig. 4, is

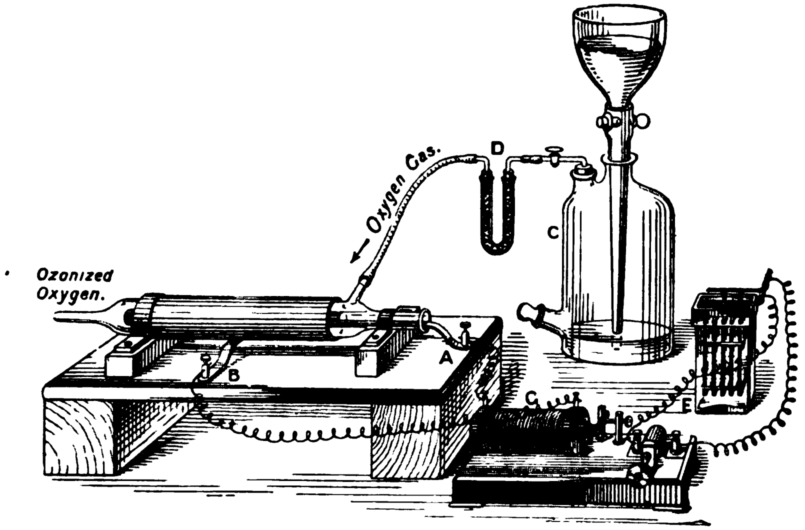

FIG. 4.—Preparation of Ozone with Siemens' Tube.

virtually the one devised by W. von Siemens (1857).[23] **Siemens' ozonizer** (or *ozonator*, or *electrizer*), as it is called, consists of two concentric tubes. The inner tube is coated on its inner surface with tinfoil in metallic contact with the terminal *A*; and the outer tube is coated on its surface with tinfoil in metallic contact with the terminal *B*. This forms the so-called *Siemens' induction tube*. The two terminals are connected with an induction coil. A slow stream of oxygen is led from the gasholder *C* through the calcium chloride drying tube *D*, and then through the annular space between the concentric tubes, and is there exposed to the action of the silent discharge of electricity, operated by the induction coil *G*, and battery *E*. Ozone is decomposed by cork and indiarubber. In consequence, these materials should not be used for any part of the ozonizer in contact with the gas. The gas issuing from the ozone tube, or ozonizer, is charged with 3 to 8 per cent. of ozone. If the oxygen contains traces of chloride, the gas should be washed in dilute alkali before drying. In some forms of ozonizer there are three concentric tubes, and cold water circulates in the inner tube while the discharge is passing so as to prevent a rise of temperature, and thus increase the yield of ozone.

The ozonizer devised by B. C. Brodie in 1872—**Brodie's ozonizer**[24]—is usually called *Berthelot's ozonizer*, though the latter designed it some years after B. C. Brodie. Here the tinfoil coatings are replaced with sulphuric acid as illustrated in Fig. 5. It consists of two concentric thin glass tubes with an annular space from 1 to 4 mm. There are inlet and egress tubes as shown. The inner tube is about 30 mm. diameter and 30–35 cm. long. This apparatus is suspended in a cylinder of water acidulated with sulphuric acid (1 : 10), and the inner tube likewise contains the same liquid. Platinum wires dip in the liquids. The wires *A* and *B* are connected with the induction coil and a slow current of oxygen is sent through the apparatus—ozonized oxygen escapes. The quantity of ozone per coulomb increases with the potential.[25] According to F. Russ, the yield of ozone with an ozonizer of vitreous quartz is but half that obtained with a glass ozonizer. The yield of ozone per kilowatt hour is greater when one electrode is not covered with an insulator (glass). The parts of the tube which do not dip in the dilute acid are covered with shellac varnish in order to prevent external sparking. The gas circulates in the annular space between the inner and outer tubes. If the gas travels through the apparatus too quickly some escapes the action of the discharge; and if too slowly, the ozone may be decomposed. About one bubble of gas per second gives good results. The cooler the vessel, the better the yield; at −23°, oxygen containing 21 per cent. of ozone can be obtained.

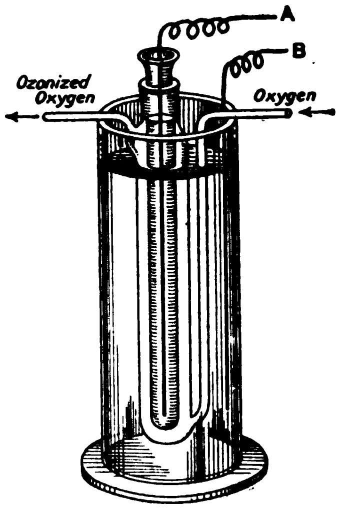

FIG. 5.—B. C. Brodie's Ozone Tube.

It will be observed that in W. von Siemens' or in M. Berthelot's ozonizer there are three dielectrics in the path of the discharge—two layers of glass, and one of gas; in L. von Babo's ozonizer there is one layer of glass, and one of gas. Neglecting the gas to be ozonized which must necessarily be present in all ozonizers, there are two types of ozonizers in use, for the ozonization of air or oxygen on a large scale: those which have dielectrics in the path of the discharge—*e.g.* E. W. von Siemens and J. G. Halske's, Abraham and Marmier's, and Linder's ozonizers[26]—and those which have no dielectric—*e.g.* A. Schneller's, A. Vosmaer's, and H. Tindal's ozonizers.[27] In the so-called *ozonair system*, a series of mica plates, covered on both sides with a metal alloy, are mounted side by side in a box. The plates serve as electrodes. Air passes into the box between the plates. It is claimed that the gauze promotes the formation of a sparkless brush discharge, and that the open arrangement of the plates suffices to keep them cool without the aid of water cooling.

Ozone is said to be produced by the violent mechanical disturbance of air[28]—say, when grinding wheels are being tested for bursting speed. This may be an effect of heat or of electrification or both. Ozone is also said to be formed during the evaporation of water. This statement may be regarded as not proven; nor is the evidence satisfactory as to the formation of ozone when water or a salt solution—*e.g.* sea water—is splashed about,[29] although these statements have been cited to explain the greater ozone content of air in the vicinity of the sea, waterworks, irrigation plants, and waterfalls; and for the bleaching of linen, etc., spread on lawns. The electrification of air by the splashing of liquids is, however, a well-known phenomenon investigated by P. Lenard,[30] Lord Kelvin, etc.

(5) *The formation of ozone in chemical reactions.*—Ozone is usually present in the oxygen obtained by low temperature exothermal reactions; but not if the temperature of the reaction be high, because the ozone, if it be formed, is at once transformed into oxygen. Potassium chlorate gives ozone-free oxygen, but if the chlorate be mixed with catalytic agents which lower the temperature of the reaction, ozone may be found in the resulting oxygen (*q.v.*). Crystallized iodic or periodic acid decomposes between 130°–135° giving off strongly ozonized oxygen; and, according to C. F. Rammelsberg,[31] aqueous solutions of periodic acid or periodates smell of ozone; but A. R. Leeds has shown that what C. F. Rammelsberg thought to be ozone is really chlorine or nitrous acid, present as an impurity in the periodate. Ozonized oxygen is also formed when many oxidizing agents are heated alone or mixed with acids. For instance, ozonized oxygen is obtained from silver peroxide (C. F. Schönbein, 1855), lead peroxide (C. F. Schönbein, 1855), and mercuric oxide (C. T. Kingzett, 1872). As previously indicated, A. R. Leeds contended that C. F. Schönbein mistook chlorine for ozone in assuming that ozonized oxygen was formed by heating these oxides—both gases affect a solution of starch and potassium iodide in the same way; but O. Brunck[32] showed that manganese dioxide, chromium, nickel, cobalt, and gold sesquioxides, silver mono- and dioxide, mercuric oxide, and chromium and uranium trioxides give ozonized oxygen if heated in an atmosphere of oxygen, but not if heated in an atmosphere free from oxygen. Ozonized oxygen is formed by the decomposition of hydrogen peroxide (A. Riche, 1860), not only with sulphuric acid, but also with dilute sulphurous acid, with finely divided metals, and with all substances[33] which stimulate the decomposition of this compound. F. Raschig also detected ozone in gas obtained by dissolving nitrogen peroxide in sulphuric acid in the lead-chamber process.[34] Ozonized oxygen is also obtained by the action of sulphuric acid on barium peroxide (A. Houzeau, 1861), sodium peroxide (C. Arnold and C. Mentzel, 1902), persulphuric acid and the persulphates (A. von Baeyer and V. Villiger, 1901, and P. Malaquin, 1911), percarbonic acid and the percarbonates (C. Arnold and C. Mentzel, 1902), perborates (S. Tanatar, 1898), per-monophosphates (J. Schmidlin and P. Massini, 1910), permanganates (G. Bertazzi, 1855), bichromates (C. Weltzien, 1867), peruranic acid (P. G. Melikoff and L. Pissarjewsky, 1897), fluovanadic compounds (P. G. Melikoff and P. Kasanezky, 1901), barium ferrate (A. Baschieri, 1906), per-pyrosulphates (W. Traube, 1909), acetone peroxide (A. von Baeyer and V. Villiger, 1900), performic acid (J. d'Ans and A. Kneip, 1915), etc.[35]

H. Moissan[36] (1891) found that when drops of water are allowed to fall into a vessel containing fluorine gas, the water is decomposed, and hydrogen fluoride and deep blue vapours of ozonized oxygen are produced. At 0°, oxygen containing up to 21 per cent. of ozone by weight was obtained. The lower the temperature of the reaction, the greater the yield of ozone. O. Ruff and F. W. Tschirch[37] obtained ozonized oxygen by the action of osmium octafluoride on soda lye. L. Gräfenberg[38] obtained ozonized oxygen by the electrolysis of hydrofluoric acid—with the 40 per cent. acid, a maximum yield of 5·2 per cent. of ozone was obtained.

E. B. R. Prideaux also electrolyzed saturated solutions of alkali fluorides, and obtained a yield never exceeding 1 per cent. of ozone.

(6) *The formation of ozone during slow oxidations.*—Ozone is formed during the slow oxidation of many substances; C. F. Schönbein [39] detected it in the atmosphere of a flask containing a couple of sticks of clean phosphorus, and J. C. G. de Marignac prepared ozonized air by aspirating atmospheric air through a flask or tube containing a few pieces of clean phosphorus partly submerged in water. According to C. F. Schönbein, one part of phosphorus converts $\frac{1}{1300}$th part of oxygen into ozone. The resulting gas should be washed to free it from phosphoric oxide. The action is very slow at the freezing point of water, but between 15° and 20°, the action is fairly quick, and at 38° but little ozone is formed; according to A. R. Leeds, the optimum temperature is 24°, but even then, the yield is very small—say about 2 mgrm. of ozone per litre of air. According to R. Engel, reducing the pressure favours the formation of ozone; thus, the action does not occur with appreciable velocity below 6°, but under reduced pressure, the action may occur at 9°. Since ozone is decomposed in contact with phosphorus, a rapid current of air is desirable. According to A. R. Leeds and R. Böttger, the addition of sulphuric acid and potassium permanganate or potassium dichromate to the water is said to increase the yield of ozone; but C. Arnold and C. Mentzel found no advantage in the use of chromic acid.

Instead of air, a mixture of oxygen and carbon dioxide can be used. J. C. G. de Marignac found that a mixture of oxygen and hydrogen sometimes exploded. Minute traces of ammonia, sulphur dioxide, nitrogen peroxide, alcohol, ether, ethylene, and ethereal oils retard the action. The liquid in the flask [40] contains phosphorous and phosphoric acids, hydrogen peroxide, and ammonium nitrite. According to C. T. Kingzett, the ratio of ozone to hydrogen peroxide formed in the reaction is 1 : 2·4; and according to A. R. Leeds, 1 : 1. The evidence is not quite satisfactory since H. McLeod failed to find hydrogen peroxide, but his tests were not very delicate.

P. Villard [41] has suggested that the oxidation of oxygen to ozone in this reaction is produced by radiations of short-wave length generated during the phosphorescence of the phosphorus. The phosphorescence of phosphorus is probably an ozonizing action; similarly, according to L. Bloch, when sulphur is heated to about 200°, the luminescence is accompanied by the formation of ozone. According to J. H. van't Hoff [42] and W. P. Jorissen, only half an atom of oxygen is available for the oxidation of oxygen to ozone per atom of phosphorus oxidized. Ozone is not formed when a substance is present capable of giving rise to the formation of hydrogen—*e.g.* hydrogen peroxide is formed by the oxidation of water when zinc, lead, etc., is substituted for the phosphorus. During the oxidation of phosphorus the ambient air becomes electrically conducting.

Many other substances also furnish ozone or activate oxygen during their oxidation. Ozone is said to be formed during the combustion of ether as well as during the combustion of hydrogen compounds generally. At any rate, the potassium iodide test indicates the formation of ozone (or hydrogen peroxide) when a spiral of hot platinum is placed above the surface of a little ether in the bottom of a beaker. The ether burns on the surface of the platinum, and the platinum remains incandescent as long as any ether remains in the beaker. The alleged formation of ozone during the evaporation of alcohol, ether, ethereal oils, hydrocarbons, etc.,[43] may be an effect of an analogous phenomenon—*autoxidation*. By exposing *p*-diacetyldiamino-stilbene-*o*-disulphonic acid, or many of its salts, in glass vessels to sunlight, the colour changes from bright yellow to reddish-brown, and the reverse change takes place in darkness. The glass cuts off the rays below 350μ wave-length. The presence of oxygen is necessary, and ozone is simultaneously formed. This may be a kind of autoxidation phenomenon.

According to C. F. Schönbein,[44] ozone is formed when turpentine, benzene, petroleum, aldehyde, coal tar, many hydrocarbons, mineral and essential oils—

eucalyptus, lavender, cinnamon, etc.—are oxidized. Acids and resinous matter are formed at the same time. There are ozonators on the market which contain an essential oil—say cinnamon oil—which slowly evaporates; they do not give ozone at all. C. Engler[45] has shown that it is not ozone which is produced by these organic compounds, but rather an unstable peroxide, or ozonide, which can act as a powerful oxidizing agent. For instance, when turpentine is agitated with a large volume of air, oxygen is absorbed, and part of the substance is oxidized, and it is this oxide which has led to the assumption that ozone is formed and dissolved by the hydrocarbon—for it can colour starch and potassium iodide test-paper blue, decolorize indigo blue, colour tincture of guaiacum blue, etc. When a 5 to 7 per cent. benzene solution of dimethylfulvene, C_8H_{10}, is agitated with air[46] for a few days, a precipitate of a peroxide, $C_8H_{10}O_4$, is formed which detonates at 120°, and which gives the usual reactions for peroxides only when a little ether, alcohol, ethyl acetate, or chloroform is present.

§ 3. The Occurrence of Ozone and Hydrogen Peroxide

According to A. Houzeau (1867), country air contains about one volume of ozone per 700,000 volumes of air; but a maximum of one part in ten millions would be nearer the mark. The maximum amount of ozone in the atmosphere is said to occur during the spring months, and to diminish gradually, reaching a minimum in winter. The air over the sea is usually, but not always, richer in ozone than air over land.[1] Ozone is absent in the air of towns and dwelling-houses, over marshes, and wherever organic matter is present. It is really extraordinary the number of determinations which have been made in order to find if the amount of ozone predominates in spring, summer, autumn, winter, or at any particular part of the day. Attempts have been made to show the effect of the electrical and hygrometric state of the atmosphere; the force and direction of the wind; the intensity of the sunlight; the geographical and geological formation of particular districts; etc. A. Houzeau himself is responsible for 4000 observations; and many others have been published. In some cases, the results are contradictory; and most of them should be discarded because much of what was formerly alleged to be ozone may not be ozone at all. This is due to the imperfection of the tests employed. For example, T. Andrews found that the oxidizing matter in the air was destroyed by heating the air to 260°. This would not be the case if the oxidizing matter was chlorine, nitrous acid or sulphur oxides; but Andrew's test does not discriminate between ozone and hydrogen peroxide. The old starch and potassium iodide test-papers did not discriminate between ozone, hydrogen peroxide, nitrogen oxide, or other oxidizing agents, hence there is some uncertainty about many of the reports of the occurrence of ozone, and more particularly those referring to the proportion of ozone in the atmosphere. For example, C. F. Schönbein gave about 0·0043 mgrm. of ozone per 100 litres of air; J. Pless and V. Pierre, 0·008 mgrm.; C. W. Zenger, 0·002 to 0·01 mgrm.; A. Houzeau, 0·0029 mgrm.; M. de Thierry, 0·0035 to 0·0094 mgrm.; and R. Lespieau, 0·00052 mgrm.[2]

The more recent determinations by E. H. Kaiser and L. McMaster, and by W. Hayhurst and J. N. Pring,[3] have satisfactorily established the presence of ozone in atmospheric air. The atmosphere of the Alps at an elevation of 6·5 kilometres contains 1·2 volumes of ozone per million parts of air; and at an altitude of 20 kilometres, 5·4 volumes per million. No hydrogen peroxide or nitrogen peroxide was detected. There is also a quite adequate explanation of the formation of atmospheric ozone. The dark electrical discharges from clouds, etc., and lightning, and the action of ultraviolet radiations from the sun must all ozonize atmospheric oxygen. W. N. Hartley[4] showed that from spectroscopic observations ozone must be a regular constituent of the upper regions of the atmosphere where it is present in larger proportions than nearer sea-level. The ozone formed in the upper regions is decomposed by oxidizable substances in the lower regions, C. Fabry and H. Buisson emphasize the fact that although the assumption that the high ozone content of the upper atmosphere is not proved, the deduction is very probable from the blue colour of the sky, and the abrupt break in the solar spectrum for rays of wave-length 293$\mu\mu$ corresponding with the break in the absorption spectrum of ozone. G. D. Liveing and J. Dewar question whether the blueness of the sky can be justly attributed to ozone because the absorption spectrum of oxygen exhibits certain bands identical with those of the solar spectrum, which K. Angström[5] found to be equally strong whether the atmosphere be wet or dry; and that daylight possesses a blue tint when observed through a 18-metre layer of oxygen compressed at 90 atm.

The presence of ozone in solution in certain spring waters has been established by R. Nasini and M. G. Levy, and C. Porlezza.[6] The spring at Fiuggi and the *aqua forte della Bagnori* of Monte Amiata, gave the qualitative reactions of ozone with starch and potassium iodide, and litmus-potassium iodide test papers; guaiacum test paper; acid-free gold chloride, manganous chloride, C. Arnold's tetramethyl base test paper; and with silver foil. At 21·50°, a litre of the water contained 0·135 c.c. of ozone in solution. It is suggested that the ozone may be due to the action of radioactive rocks, or to the autoxidation of ferrous carbonate, or to sulphur bacteria. A. Schrötter[7] (1860) reported 0·02 per cent. of ozone—identified by the smell—occluded in the blue fluorspar of Wölsendorf and Joachimsthal, but A. Houzeau and O. Loew considered this inference to be wrong because the smell attributed to ozone is retained after fluorspar has been heated to 300°. C. F. Schafhäutel attributes the smell to the presence of inclusions containing free hypochlorous acid; and J. Meyer supposes the mineral contains free fluorine as an inclusion, and this, with traces of moisture from the air, forms ozone. Reports of the presence of ozone in blood (A. Schmidt, 1862), in milk (C. Arnold, 1881), and in respired air (A. Struve, 1871) are probably wrong, and they are based only on old and fallacious tests. Some physiologists assert that the oxygen given off by green plants in light contains ozone,[8] but G. Bellucci contradicts this statement.

The occurrence of hydrogen peroxide.—There is a similar uncertainty about the alleged occurrence of hydrogen peroxide in the atmosphere and rain, snow and in dew, as in the case with early reports on the occurrence of ozone in air. C. F. Schönbein, E. Schöne,[9] and others claim hydrogen peroxide to be present in the atmosphere and in rain water; A. Houzeau[10] and L. I. de N. Ilsova say that no hydrogen peroxide is present, and the latter adds that what was thought to be hydrogen peroxide is really an oxide of nitrogen. It is too true that much of the published work does not clearly discriminate hydrogen peroxide from other oxidizing substances. In any case the amount of hydrogen peroxide must be very small—between 0·04 and 1·00 mgrm. per litre of rain water. In a year's observation at Moscow, E. Schöne reported 110 mgrm. of hydrogen peroxide in the rain and snow which fell per sq. metre. According to A. Bach,[11] when the chlorophyll of plants acts on carbon dioxide and water in sunlight, formaldehyde, CH_2O, and percarbonic acid, H_2CO_4, are formed, $3H_2CO_3=2H_2CO_4+CH_2O$; and the percarbonic acid breaks down into carbon dioxide and hydrogen peroxide, $H_2CO_4=CO_2+H_2O_2$; and the

---

latter in turn forms water and oxygen gas. A. Bach recommends the following reagent for detecting peroxides in plants : 5 c.c. of a solution of 0·03 grm. potassium dichromate and 5 drops of aniline with sufficient water to make a litre of solution. Treat 5 c.c. of the solution to be tested with one drop of a 5 per cent. solution of oxalic acid and the given reagent. A reddish-violet colour will be obtained if peroxides are present. Of 25 plants examined, 18 gave the reaction for peroxides. J. Cho (1896) obtained the coloration only where leaves were damaged. The existence of hydrogen peroxide in vegetable juices has been reported by many observers,[12] but G. Bellucci could not confirm this by the chromic acid reaction, and he attributes the results obtained to the presence of oxydases in vegetable sap. C. Wurster made similar remarks with respect to the alleged presence of hydrogen peroxide in animal fluids.[13]

§ 4. The Physical Properties of Ozone

Ozonized air has a strong characteristic smell, which reminds some people of sulphur dioxide, others of garlic, and others of chlorine. The amount of ozone which can be detected by the olfactory sense is extremely small; one part in a million parts of air can be readily perceived. Indeed, ozone can be detected by smell before starch and potassium iodide paper turns blue. If air highly charged with ozone be breathed for any length of time, it produces headache; but in minute quantities the odour is pleasing and refreshing. In large quantities, ozonized air acts as an irritant poison causing headache and coughing, and finally inflammation and death; in small quantities, ozonized air has been recommended medicinally for pulmonary complaints. According to D. Labbe and S. M. Oudin, air containing one part of ozone in 20,000 may be breathed half an hour without ill effects. L. E. Hill and M. Flack[1] say that a concentration of one part in a million irritates the respiratory tract; exposure for two hours to a concentration of 15 to 20 per million is not without risk of life. In concentrations even less than one per million, it reduces respiratory metabolism, and rapidly causes a fall of body temperature. Its beneficial effect, as popularly believed, is a myth. The irritation of the olfactory nerves may relieve the monotony of close air, and in concentrations of more than 1 per million for brief periods may be of therapeutic value by acting in appropriate cases as a sort of " blister " to the respiratory tract.

Ozone at ordinary temperatures is a gas with a pale blue **colour.** Oxygen with 10 per cent. of ozone has a blue tinge when viewed through a tube a metre long.[2] Liquid ozone is dark indigo-blue. C. F. Schönbein[3] wrote to M. Faraday (1852) to the effect that he had made experiments supporting the hypothesis that the colour of oxy-compounds is due to the contained oxygen, or to a peculiar condition of that body. To this M. Faraday replied:

> Your letter quite excites me and I trust you will establish undeniably your point. It would be a great thing to trace the state of combined oxigen by the colour of its compound, not only because it would show that the oxigen had a special state, which could in the compound produce a special result—but also because it would, as you say, make the optical effect come within the category of scientific appliances and serve the purpose of a philosophic induction and means of research, whereas it is now simply a thing to be looked at. Believing that there is nothing superfluous, or deficient, or accidental, or indifferent, in nature I agree with you in believing that colour is essentially connected with the physical condition and nature of the body possessing it, and you will be doing a very great service to philosophy if you give us a hint, however small it may seem at first, in the development, or as I may even say in the perception of this connexion.

A litre of ozone weighs 2·1445 grms. at n.p.t.; and a gram of ozone under the same conditions occupies 466·3 c.c. The **specific gravity** is 1·5 (oxygen unity), or 1·62 (air unity). P. Hautefeuille and J. Chappius (1880) liquefied ozone by gradually compressing the gas in Cailletet's apparatus, at —23°, if the compression be sudden, or without cooling, the ozone is converted into oxygen with a yellow flash. P. Hautefeuille and L. Chappius liquefied ozone under a pressure of 125 atm. at —100°; K. Olschewsky[4] under atmospheric pressure at —181°. By passing ozonized oxygen through a tube cooled by immersion in boiling liquid oxygen, or by ozonizing oxygen in a tube kept at this temperature, a solution of ozone in liquid oxygen is obtained. By allowing the liquid to boil, most of the oxygen is removed, and a deep indigo-blue, almost black, liquid remains, which is opaque in layers of 2 mm. thick. By allowing the blue liquid to vaporize, A. Ladenburg (1898) obtained a gas containing about 86 per cent. of ozone. The liquid is particularly liable to explode when it reaches the boiling point of ozone, or when it is brought in contact with oxidizable substances. According to H. Erdmann, pure liquid ozone is not explosive, and he ascribes the explosibility to the presence of highly concentrated ozone gas; he says liquid ozone is harmless, and he obtained Leidenfrost's phenomenon with a drop of the liquid on a porcelain plate. The indigo-blue vapour of ozone in a test tube explodes if a little turpentine is introduced. G. D. Liveing and J. Dewar attributed the explosion of liquid ozone at —181° to the presence of the vapour.

The **boiling point** of ozone under atmospheric pressure is —106° (K. Olzschewsky);

—116° (L. Troost); or —125° (A. Ladenburg). The ratio of the two **specific heats** C_p/C_v for ozone is 1·29 as determined[5] by extrapolation from the value 1·396 for oxygen, and the observed values of mixtures of oxygen and ozone. G. N. Lewis and M. Randall[6] say that although the heat capacity of ozone has not been accurately determined, no great error will be involved by assuming that the relation which holds good for the triatomic gases, CO_2 and SO_2, is applicable, and therefore $C_p = 7{\cdot}0 + 0{\cdot}0071T - 0{\cdot}00000186T^2$. Subtracting the heat capacity for $1\frac{1}{2}$ gram-molecules of oxygen from $C_p + 6{\cdot}50 + 0{\cdot}0010T$ leaves for the heat Q of the reaction $1\frac{1}{2}O_2 = O_3$, at constant temperature: $Q = Q_0 - 2{\cdot}75T + 0{\cdot}0028T^2 - 0{\cdot}00000062T^3$.

According to M. Berthelot (1876), the **heat of formation** of a gram-molecule of ozone, O_3, is —29·6 Cals.; —36·3 to —36·65 Cals., according to H. G. L. van der Meulen (1883); and —34·5 Cals., according to S. Jahn (1908). The reported heats of the reaction thus range from 29 to 36 Cals.; if 34,600 cals. be the best representative value, the heat of the reaction at T will be $Q = 34600 - 2{\cdot}75T + 0{\cdot}0028T^2 - 0{\cdot}00000062T^3$; and the increase in free energy $34600 + 2{\cdot}75T \log T - 0{\cdot}0028T^2 + 0{\cdot}00000031T^3 + IT$, where the integration constant I can be evaluated very crudely from F. Fischer and F. Brähmer's work, $K = p_1/p^{1{\cdot}5}$, where p_1 denotes the partial pressure of ozone, and p that of oxygen; at 2300°, $K = 0{\cdot}01$. Hence, the increase in free energy at 2300° is $-RT \log K + 21000$ cals. When this is substituted in the preceding equation $I = -22{\cdot}4$, and at 298° K. the increase in free energy is 32,400 cals.

R. Luther and H. J. K. Inglis studied the potential of the ozone electrode by means of a platinum electrode surrounded by ozone, but they were unable to determine definitely the nature of the electrode reaction; and with an iridium electrode, R. Luther obtained values differing by 0·2 volt from those with the platinum electrode. S. Jahn found the **free energy** of the decomposition of ozone, determined from measurements of the potential of the cell O_3 | electrolyte | H_2, which is 1·90 volts at 0°; and of the cell O_2 | electrolyte | H_2, which is 1·25 volts. In the former case, the free energy of the reaction is $2O_3 + 2H_2 = 2O_2 + H_2O + (4F \times 1{\cdot}90)$ joules; and in the latter case, $O_2 + 2H_2 = 2H_2O + (4F \times 1{\cdot}25)$ joules, when F denotes the electrochemical equivalent, 96,540 coulombs. By subtraction, eliminating H_2O, there remains $2O_3 - 3O_2 + (4F \times 0{\cdot}65)$ joules; or $O_3 = \frac{3}{2}O_2 + 30$ Cals. nearly.

Ozone has a high absorptive and emissive power for ultra-red heat radiations; according to J. Tyndall,[7] its absorption power is 136 times as great as oxygen. K. Angström found that there is a sharp ultra-red absorption band at 4·8μ; a feeble one at 5·8μ; an uncertain one at 6·7μ; and a strong—perhaps double—band at 9·1 to 10·0μ. The first and last occur in the solar spectrum. J. Chappius and E. Schöne found that the **absorption spectrum** of ozone shows thirteen bands and lines: (1) A narrow band of wave-length 628·5μμ in the red; (2) a very large band from 609·5 to 593·5 in the orange; (3) a very large band, 577 to 560, and (4) one at 547 to 544·5 in the yellow; (5) a large one between 535 to 527; (6) one at 508·5 to 502, and (7) one at 492·5 to 491 in the green; (8) one at 484·5 to 479, and (9) one at 470 to 468; (10) one at 464·5 to 460, and (11) at 444 in the blue. There is also one at (12) 452 and (13) one at 516. Nos. 2 and 3 are very marked; Nos. 5, 6, and 8 are less characteristic; Nos. 10 and 11 still less characteristic; Nos. 12 and 13 still less so; Nos. 1, 4, 7, 9, 12, and 13 can be recognized only under special conditions. Liquid ozone does not show any absorption bands in the visible spectrum, but there is a masking in the region at about 500μμ; there are no bands in the ultraviolet, and the absorption extends into the visible region as the concentration increases, but not so far as in the case of the gas. The absorption spectrum of the gas in the ultraviolet is so marked that, as previously indicated, W. N. Hartley supposed that in passing through the atmosphere the 293μμ radiations from the sun are suppressed. The hypothesis was confirmed by the work of E. Meyer and A. Lévy. From Lambert's law, $I = I_0 \times 10^{-al}$, when I_0 denotes the intensity of the incident energy, and I that after traversing a layer of ozone of thickness l, the absorption constant a of ozone at 0° and 760 mm. in H. Kreusler's photometer is, for light of wave-length λ, and with the centimetre as unit of length, E. Meyer found :

λ	193	200	220	240	260	280	300$\mu\mu$
a	11·7	7·8	19·2	105	126	73·4	30·3

There is thus a maximum near $\lambda=260\mu\mu$, and a minimum near $\lambda=7{\cdot}8\mu\mu$. A. Lévy estimated that the atmosphere contains $0{\cdot}7696\times10^{-6}$ per cent. of ozone by volume. The corresponding absorption can be calculated. E. Meyer found for I_0 the intensity of the incident radiant energy before it enters the atmosphere, and I, the intensity at the earth's surface, on the assumption that for $\lambda=300\mu\mu$, the intensity of the radiant energy=100,

λ	193	200	220	240	260	280	300$\mu\mu$
I_0	16·76	20·75	34·36	50·43	67·54	76·07	100
I	14·21	18·59	26·19	11·46	11·28	14·73	65·10

These curves are plotted in Fig. 6. The intensity of the radiant energy received at the earth's surface owing to absorption by ozone rapidly falls from 300$\mu\mu$ down to about 260$\mu\mu$, and then rises again. The beam of radiant energy from the sun is assumed to be directed normally to the earth's surface; in reality, the beam is more or less slanting, this could make the absorption greater than the calculated value—even if the data were otherwise correct. The absorption band commencing near $\lambda=200\mu\mu$ is probably responsible for the de-ozonizing effect of ultraviolet rays; and the rays below 170$\mu\mu$, which V. Schumann found to be entirely absorbed by a layer of air 1 mm. thick and 760 mm. pressure, are probably responsible for the formation of ozone, so that the stability of ozone is a function of the active mass of oxygen, and of the intensity of the ultraviolet rays beyond, say, 180$\mu\mu$. K. Stuchtey examined the spectrum of the luminous glow on an ozone tube.

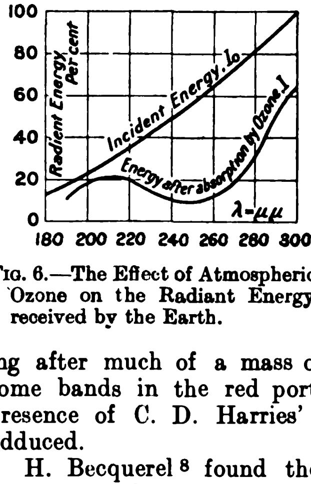

FIG. 6.—The Effect of Atmospheric Ozone on the Radiant Energy received by the Earth.

E. Ladenburg and E. Lehmann have observed a second absorption spectrum in the ozone remaining after much of a mass of liquid ozone has evaporated; this spectrum has some bands in the red portion. It has been suggested that this is due to the presence of C. D. Harries' *oxozone*—but no satisfactory proof has been yet adduced.

H. Becquerel[8] found the **specific magnetism** of ozone to be very high. M. Berthelot found that ozone is stable under the influence of sound waves.

Solubility.—H. Erdmann[9] found that liquid nitrogen dissolves ozone,[2] forming a clear sky-blue liquid. M. A. Hunter attempted to measure the molecular weight of ozone dissolved in liquid oxygen and in liquid nitrogen. The last-named solution was too explosive. He found that solutions of ozone in oxygen have a minimum boiling point, −183·3°, when 4 to 5 per cent. of ozone is present—thus :

Ozone . .	0	2	4	5	6·5	7·5 per cent.
Boiling point .	−182·8°	−182·85°	−183·3°	−183·25°	−182·75°	−182·63°

Many measurements have been made of the solubility of ozone in water. C. F. Schönbein[10] said that ozone is not perceptibly soluble in water—this statement is incorrect, since ozone is appreciably soluble in this menstruum; E. Schöne (1873) found that when ozonized oxygen is passed into distilled water, the concentration of the ozone remains constant, although about one-fourth of the ozone is decomposed; hence, H. J. K. Inglis argues that the concentration of the ozone must depend on the rate the gas is passed through the solvent, and consequently the solubility coefficient cannot be accurately determined. However, many determinations of the solubility have been attempted. According to A. Ladenburg, a litre of water at 0° dissolves 20 mgrm. of ozone; at 2°, 10 mgrm.; at 28°, 1·5 mgrm. A. Mailfert's results for the equilibrium conditions in the partition of ozone between gas and liquid are indicated in Table II.

TABLE II.—SOLUBILITY OF OZONE IN WATER.

Temperature.	Mgrm. ozone per litre solvent.	Mgrm. ozone per litre gas.	Ratio.	Temperature.	Mgrm. ozone per litre solvent.	Mgrm. ozone per litre gas.	Ratio.
0°	39·4	61·5	0·641	27°	13·9	51·4	0·270
6°	34·3	61·0	0·562	33°	7·7	39·5	0·195
11·8°	29·9	59·6	0·500	40°	4·2	37·6	0·112
13·0°	28·0	58·1	0·482	47°	2·4	31·2	0·077
15·0°	25·9	56·8	0·456	55°	0·6	19·3	0·031
19·0°	21·0	55·2	0·381	60°	0·0	12·3	0·000

The solubility decreases with a rise of temperature; and according to O. Fröhlich, increases with an increase of pressure. L. Carius reported that the absorption coefficient of ozone prepared by electrolysis is 0·834 at 1°; and for ozone prepared by the electric discharge 0·635 at 1°. A. Mailfert, E. Moufang, F. Bürger, and V. Rothmund and A. Burgstaller found that the solubility of ozone in water is augmented by the addition of acids.[11] The presence of oxidizable substances must be avoided. R. Luther and J. K. H. Inglis find that the absorption coefficient for water at 0° is 0·494; and for $\frac{1}{10}N$-H_2SO_4, at 0°, 0·487, so that the solubility appears to decrease slightly with increasing concentration of the acid; but the rate of decomposition of ozone in water increases with decreasing acid concentration. The solution of ozone in water soon decomposes, so that aqueous solutions cannot be used for the determination of the molecular weight of this gas. Solutions of ozone in $\frac{1}{10}N$-H_2SO_4 follow Henry's law. The solubility of ozone in neutral *salt solutions*—*e.g.* sodium or magnesium chloride—is in many cases greater than in water, and the solutions are more stable. B. Graf's patent for stabilizing aqueous solutions of ozone is based on this fact. The solubility diminishes in feebly *alkaline solutions*—say 0·005 and 0·00002 *N*-solutions of sodium carbonate; in concentrated solutions of the alkalies, the ozone is rapidly decomposed. No signs of the formation of hydrogen peroxide has been observed in the decomposition of acid or alkaline solutions of ozone. E. Langheld [12] recommends quinine salts for increasing the solubility and stability of aqueous solutions of ozone. Contrary to F. Jeremin's views, R. Böttger holds that oxalic acid does not make ozone solutions more stable, since it is readily oxidized by ozone. Acetaldehyde and, better still, paraldehyde have been recommended by S. Fraser for stabilizing solutions of ozone.

Ozone is apparently dissolved by *essential oils*—turpentine, thyme, cinnamon oil, etc. According to J. L. Soret,[13] these oils absorb ozone from ozonized oxygen and leave the oxygen unaffected. B. Stelzer found ozone is copiously absorbed by *fats*, C. T. Kingzett by *ethereal oils*. C. D. Harries assumes that the action is here not a true solution, but rather a case of chemical combination; addition compounds are formed called **ozonides**. According to E. Molinari (1906), unsaturated carbon compounds with a double or ethylene bond between the carbon atoms appear to absorb ozone quantitatively forming ozonides, whereas those with a triple or acetylene bond do not combine with ozone. C. D. Harries, however, does not accept E. Molinari's conclusion, since some compounds with a triple bond combine with ozone more rapidly than some with a double bond. C. D. Harries used ozonized oxygen, E. Molinari ozonized air. C. D. Harries and R. Koetschau, H. Erdmann, and F. Fischer and H. Tropsch [14] find that a blue solution is obtained when ozonized oxygen is passed into acetic acid, acetic anhydride, ethyl acetate, chloroform, or carbon tetrachloride. The colour persists for 15 to 20 hrs. with acetic acid and carbon tetrachloride, but disappears more rapidly with the other solvents. Water and formic acid do not form coloured solutions; the latter is oxidized to carbon dioxide. Carbon tetrachloride dissolves seven times as much ozone as an equal bulk of water.

The so-called *ozone water* of commerce usually contains no ozone at all. R. Böttger[15] found nitrous acid; E. A. Behrens and G. Sonntag, hypochlorous acid; C. F. Rammelsberg, L. Keutmann, H. Thoms, and C. G. Egeling, chlorine; and G. Vulpius, chloride of lime in commercial ozone water.

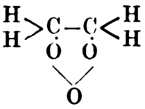
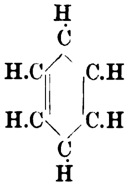
§ 5. Oxozone, Ozonides, and Oxozonides

It was thought for some time that ordinary oxygen is a compound of negative and positive oxygen, the former was called by C. F. Schönbein *ozone* and symbolized ⊕, and the latter *antozone*, symbolized ⊖; so that ordinary oxygen—ozone ⊖ +antozone ⊕. The existence of the two different forms has not been satisfactorily proved, and the term ozone is reserved for polymerized oxygen O_3, while the term antozone is not used. C. F. Schönbein used the term **ozonides** for certain peroxides which gave off ozone when decomposed; this term was then extended to certain compounds formed by the action of ozone on various derivatives of unsaturated organic compounds; and it is now applied to compounds formed by direct union with ozone, and which contain the, presumably dyad, radicle O_3. Thus, ethylene $CH_2 : CH_2$ forms *ozoethylene* or *ethylene ozonide*, $C_2H_4O_3$, where the group O_3 is thought to act as a dyad, $-O.O.O-$, or $-O:O:O-$; and benzene, C_6H_6, forms *ozobenzene*, $C_6H_6O_9$, where three dyad O_3 groups are united to the benzene. The graphic symbols of these two ozonides are considered to be respectively

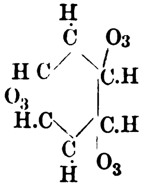
Ethylene.



Ozoethylene or ethylene ozonide.



Benzene.



Ozobenzene or benzene ozonide.

The ozonides are usually prepared by slowly passing oxygen containing 3 to 18 per cent. of ozone over the dry substance or into a solution of the substance in an inert solvent—methyl or ethyl chlorides—free from water. Solvents, like acetone, chloroform, hexane, and carbon tetrachloride, are more or less attacked by the ozone; benzene forms ozobenzene. The ozonides are usually decomposed by water, and they are often explosive.

Some evidence has been cited to show that a still more condensed form of oxygen, O_4, and called **oxozone**, is present in the residues obtained when liquid ozonized oxygen—prepared by a brush discharge of high voltage, say 8000 volts—is fractionally distilled. The alleged oxozone has not been isolated, although compounds called **oxozonides** containing the group O_4 are known; as well as ozonides with the group O_3. Thus, the hydrocarbon butylene, C_4H_8, forms both ozobutylene, $C_4H_8O_3$, and oxozobutylene, $C_4H_8O_4$. Indeed, said C. D. Harries (1911), "experimental results in ozonization lead to the conclusion that all organic compounds containing an ethylene linkage (double bond) add one molecule of ozone, and give rise to ozonides." Thus, ozone may oxidize in one of two ways: (i) One atom of oxygen per molecule of ozone is given up to the reducing agent, and the other two atoms unite to form a molecule of oxygen, and (ii) the whole molecule may unite with the reducing agent to form an ozonide.

C. D. Harries (1911)[1] claims that oxozone has an identity of its own on the following grounds: (1) The specific gravity of the gas from the last fraction of liquid ozonized oxygen to evaporate, is less than corresponds with the amount of iodine it liberates from potassium iodide. C. D. Harries takes this to mean that some O_4, as well as O_3, is present, and that the former on decomposition furnishes two atoms of oxygen: $O_4 \rightarrow O_2+2O$; and the latter, one such atom: $O_3 \rightarrow O_2+O$. This inference is not an adequate explanation of the alleged discrepancy because a mixture of the two should give the same result if determined gravimetrically as if determined iodometrically. (2) Moderately ozonized oxygen can be passed through potassium hydroxide solution or through sulphuric acid without appreciable loss of ozone, but with very concentrated ozonized oxygen or with oxygen ozonized by means of a high voltage, there is a 3 to 4 per cent. loss of ozone in the potassium hydroxide solution, and a 2 to 3 per cent. loss of ozone in the sulphuric acid. This may or may not show that there is an equilibrium condition between the ozone and the solutions in question. (3) C. D. Harries and his co-workers (1912) have shown that washed ozonized oxygen in contact with butylene, C_4H_8, produces the ozonides $C_4H_8O_3$ and the polymer $(C_4H_8O_3)_2$, while the unwashed gas produces the oxozonide $C_4H_8O_4$ and the polymer $(C_4H_8O_4)_2$. They also found that when washed ozonized oxygen is passed into a solution of tetrahydrobenzene, C_6H_{10}, in hexane, it gives the solid ozonide $C_6H_{10}O_3$, while the unwashed gas gives a mixture of the ozonide and oxozonide; and similarly, with caoutchouc, the compounds $C_{10}H_{16}O_6$ and $C_{10}H_{16}O_8$ are formed. Hence, argues C. D. Harries, the so-called ozone in ozonized oxygen with which this work was done contained about one-third of oxozone. (4) E. Ladenburg and E. Lehmann found some absorption bands in the red portion of the spectrum of liquid ozone which are only visible in the fractions remaining when three-quarters has evaporated; these bands are the first to disappear, and the pressure increases when this occurs. (5) E. Ladenburg and E. Lehmann consider that the changes of the pressure, and also of the density of liquid ozone —1·78, 1·75, 1·83—indicate the presence of a higher molecular modification of ozone. According to E. H. Riesenfeld and F. Bencker, although the reaction between potassium iodide and ozone starts instantaneously, the final equilibrium resulting in the formation of potassium hydroxide, iodide, hypoiodite, iodate, and periodate, is attained only after some days. The *oxidation number of ozone*, that is, the number of oxygen atoms consumed per gram-molecule of ozone, in a neutral solution of potassium iodide is unity; in acid solutions the oxidation number ranges from 1·0 to 2·7—it is not affected by the concentration of ozone, and increases with decreasing temperatures; and in alkaline solutions also the oxidation number increases. The greater the concentration of the ozone in the oxygen, the greater the influence of the hydroxyl ions, resulting in the formation of iodate or hydrogen peroxide. The differences observed by C. D. Harries are to be attributed to the action of the hydroxyl ions of the alkali and not to the existence of a modification of oxygen containing more than three atoms. C. D. Harries used a concentrated solution of potassium iodide and concentrated ozone, so that the oxidation number was increased by the potassium hydroxide which was formed. In conclusion, E. H. Riesenfeld and F. Bencher say that there is no evidence of the existence of a modification of ozone containing more than three atoms per molecule. To this, C. D. Harries replied that the explanation suggested by E. H. Riesenfeld and F. Bencher is wrong; a 2·5 per cent. solution of potassium iodide was used; and moreover the action of crude and washed ozone on butylene is evidence of the presence of more than one compound in ordinary ozone.

§ 6. The Chemical Properties of Ozone

Ozone slowly and spontaneously passes into ordinary oxygen at ordinary temperatures. L. von Babo[1] kept a sample for a week over concentrated sulphuric acid and found some undecomposed ozone. The gas seems to be more stable in contact with acid than with water. C. D. Harries found that ozonized oxygen lost one per cent. of ozone by bubbling through sulphuric acid. The decomposition of ozone gives ordinary oxygen, and is attended by an expansion corresponding with $2O_3$ (2 vols.) $=3O_2$ (3 vols.).[2] The speed of the spontaneous decomposition of ozone in ozonized oxygen is greater the more concentrated the ozone.[3]

The rate of the decomposition is accelerated by reducing the pressure. According to D. L. Chapman and H. E. Jones, the presence of oxygen, carbon dioxide, nitrogen, and moisture do not appreciably affect the rate of decomposition, while the presence of traces of nitrogen peroxide, chlorine, and phosphorus pentoxide accelerate the rate of decomposition. The effect of moisture has been previously discussed. Ozone is said to be decomposed by agitation with powdered glass, by passage through a long glass tube[4]—though this is doubtful—and by mere contact with certain agents:[5] finely divided platinum and other metals; silver foil; the rare earths; dioxides of manganese, lead, nickel, and cobalt; oxide of iron, silver, or copper; mercury; soda lime; etc. The ozone is converted into ordinary oxygen without decomposing the oxides. Hence, the reactions are grouped among catalytic reactions. The effect can be shown by passing ozonized air through a tube containing copper oxide and testing the issuing gas by ozone test paper. No indication of ozone is obtained. The action is probably due to the cyclic formation and decomposition of the higher oxides: with silver foil, the alternate formation and decomposition of silver oxide can be observed. According to D. L. Chapman and H. E. Clarke the effect of the surface of the glass on the decomposition of the contained ozone is so slow that even in moderately small globes, the amount of ozone destroyed on the internal surface of the vessel may be neglected in comparison with that decomposed in the interior of the gas; and that the conversion of ozone into oxygen may be regarded as a homogeneous reaction. C. F. Schönbein[6] found that if clean and dry plates of gold or platinum be placed in ozonized oxygen, the metal becomes negatively polarized, and an electric current can be obtained by connecting up these plates with plates of ordinary gold or platinum—the polarization disappears on heating the plates.

The action of heat is very peculiar, as previously discussed. In every case, the decomposition and formation of ozone by ultraviolet light, electrical discharge, and heat, a balanced reaction is involved, and the conditions of equilibrium are in accord with the law of mass action. According to S. Jahn,[7] and E. P. Perman and R. H. Greaves, the rate of decomposition varies inversely as the pressure of the oxygen; but D. L. Chapman and H. E. Jones found the velocity of decomposition not to be affected by increasing the partial pressure of the oxygen mixed with the ozone at 100°, the reaction is almost irreversible, and the rate of decomposition at 127° is bimolecular, so that if C denotes the number of gram-molecules of ozone per litre, and k is a constant, t the time, the velocity of the decomposition is $dC/dt=kC^2$; if C is unity, k represents the number of gram-molecules of ozone which would decompose in one minute if the initial concentration of the ozone were one gram per litre. E. Warburg found at 16°, $k=0{\cdot}0000492$; at 100°, $k=0{\cdot}157$; and at 126·9°, $k=1{\cdot}77$. The water had a pressure of 0·0021 mm. of mercury; when the water pressure was 0·154 mm., the velocity of decomposition was 22 per cent. faster than the results just recorded. In order to explain this result, it has been assumed that a rapid reversible change $O_3 \rightleftharpoons O_2+O$ occurs, and this is followed by a relatively slow reaction $O_3+O=2O_2$. This latter reaction is alone accessible to measurement.

The decomposition of ozone at high temperatures is accompanied by phosphorescence or **luminescence**—this is shown by holding a hot glass rod near the surface of liquid ozone (M. Beger, 1910), or by passing ozonized oxygen through a tube with a capillary opening into an evacuated vessel (J. Dewar, 1888).[8] When ozone is aspirated with a water pump, the water becomes luminous, and retains its luminosity for five or six seconds. Flasks filled with the issuing water are distinctly luminous, and when water is shaken with ozonized oxygen, the phenomenon of luminescence can be reproduced five or six times and then ceases ; it can be reproduced with the same gas if fresh water be introduced. Variations of pressure had no appreciable effect on the luminosity. If ozonized oxygen be shaken with alcohol, the luminescence is feebler but more persistent ; with benzene it is very feeble, and the ozone is absorbed or decomposed. If the water be carefully freed from organic matter it shows no luminescence even with highly concentrated ozone. The luminescence with ordinary tap water is therefore due to the action of organic matter on the ozone. According to M. Otto, the luminescence always appears on contact of ozone with organic bodies. The decomposition of ozone gives gaseous ions which discharge a charged electroscope. According to R. Schenck,[9] ozone acts on a photographic plate, and makes zinc blende, but not zinc oxide or barium platinocyanide fluorescent. These statements have also been denied ; others say the fluorescence of zinc blende is an effect which attends its oxidation to sulphate, and the action on a photographic plate is due to the chemical action of ozone on the organic matter.

Ozone is a very powerful oxidizing agent. B. C. Brodie[10] (1872) has made an interesting study of its action with different substances. Let the so-called *oxidation number* represent the number of atoms of oxygen [O] taken up by the oxidized compounds, per molecule of ozone, then

(1) If the ozone is catalytically decomposed, say by concentrated alkali lye at not too low a temperature, $2O_3=3O_2$, the oxidation number is zero, and the increase in volume is equal to half the volume of the ozone employed.

(2) If the ozone gives up one atom of oxygen per molecule, as is the case when it acts on ferrous sulphate, manganese sulphate, potassium ferrocyanide, or potassium iodide, $O_3=O_2+[O]$, and there is no change of volume. The oxidation number is unity.

(3) If the ozone gives up all three oxygen atoms to the oxidized substance as is the case with turpentine, sodium thiosulphate in neutral solution, the oxidation of sulphur dioxide : $3SO_2+O_3=3SO_3$, sodium sulphide : $Na_2S+O_3=Na_2SO_3$, and in the formation of ozonides, $O_3=[3O]$; the oxidation number is 3, and the decrease in volume is equal to the volume of the ozone.

According to E. H. Riesenfeld and T. F. Egidius (1913),[11] it is probable that the ozone does its work in one of two ways : (i) One atom of oxygen per molecule of ozone is given up to the reducing agent, and the remaining two atoms form a molecule of gaseous oxygen ; or (ii) the whole molecule may be added or coupled with the compound oxidized, as in the formation of ozonides, and the oxidation number is 3. The more complicated reactions are probably the result of a combination of these two. Thus, the reaction $2O_3=O_2+[4O]$ observed by B. C. Brodie in the oxidation of sodium thiosulphate, is a combination of $O_3=O_2+[O]$ and $O_3=[3O]$. In the oxidation of sodium thiosulphate in neutral solution, Y. Yamauchi found that the main reaction is symbolized $Na_2S_2O_3+O_3=SO_2+Na_2SO_4$, with a side reaction $Na_2S_2O_3+O_3=Na_2S_2O_6$ (sodium dithionate). In *alkaline* solutions, sodium thiosulphate seems to unite directly with ozone, forming an ozonide, $Na_2S_2O_3.O_3$ which subsequently decomposes, giving off ordinary oxygen, forming as principal products : sodium sulphate, sulphite, and dithionate—with sulphate as the end-product. Similar remarks apply to the oxidation of sulphides and sulphites. The result may be complicated by the catalytic decomposition of the ozone or of the thiosulphate ($Na_2S_2O_3=S+Na_2SO_3$) itself.

Ozone oxidizes **hydrogen** very slowly. Although C. F. Schönbein and M. Berthelot failed to obtain any evidence of combination, others[12] have found that by exposing electrolytic gas to the brush discharge—either under reduced pressure, or by diluting the gas with argon or carbon dioxide so as to avoid an explosion, or by heating the gaseous mixture—water is formed. Thus, F. Fischer and M. Wolf, by heating electrolytic gas containing ozone, for an hour, at 100°, obtained 3·7 mgrm. of water and 4·45 mgrm. at 174°. According to F. Weigert, when electrolytic gas is exposed to ultraviolet light, larger quantities of water are formed than corresponds with the ozone produced. H. Thiele says that the action is not to be ascribed to the primarily formed ozone, as in the case of other reactions in ultraviolet light.

C. F. Schönbein, G. Meissner, and L. von Babo [13] supposed that when a solution of ozone in **water** decomposes, hydrogen peroxide, H_2O_2, is formed, but many investigators—C. Engler and A. Nasse, L. Carius, E. Schöne, C. Gianetti and A. Volta, and M. Berthelot—have denied this reaction, and claim that the solution decomposes into oxygen and water. There is no reliable evidence of the alleged formation of hydrogen peroxide. The difficulty arose because of the confusion of ozone reactions with those of hydrogen peroxide, and C. Arnold and C. Mentzel, V. Rothmund and A. Burgstaller, and P. Jannasch and W. Gottschalk, have employed tests which leave no ambiguity. The latter have shown that neither hydrogen peroxide nor persulphuric acid is formed in solutions of ozone in sulphuric acid. Ozone precipitates manganese dioxide quantitatively from a solution of manganous sulphate, but if a trace of hydrogen peroxide were formed the reaction would not be quantitative since the precipitate is dissolved in the presence of that reagent. The stability of a solution of ozone decreases as the concentration of the acid decreases, but no relation between the concentration of the acid and the velocity of decomposition has been discovered. Alkaline solutions of ozone are very unstable. Colloidal platinum, copper sulphate, stannous sulphate, etc., do not accelerate the speed of decomposition of aqueous solutions of ozone. V. Rothmund also found that in $0{\cdot}01N$-acid solutions the speed of decomposition of ozone is bimolecular, and in weaker acid and in alkaline solutions the speed is between a bi- and uni-molecular process; they therefore assume that a uni-molecular reaction is superposed on a bimolecular one, and this furnishes the velocity equation $dx/dt=k_1(a-x)^2+k_2(a-x)$, where k_1 and k_2 are constants—in acid solutions the first term is the more important, and in alkaline and weakly acid solutions the second term is the more important.

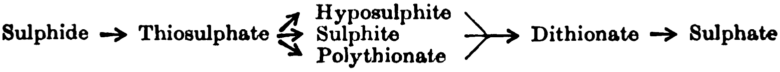
C. D. Harries found almost all ozonides react with water forming hydrogen peroxide. M. Berthelot and C. T. Kingzett also found ozonized ether, and many other substances after treatment with ozone, give hydrogen peroxide when shaken with water. The hydrogen peroxide may be formed by the autoxidation of these substances, and the ozone may act indirectly as a carrier of oxygen. C. F. Schönbein, L. von Babo, E. Schöne, A. Schmidt, etc., have reported that commercial ether nearly always contains hydrogen peroxide, and this may mean that an ozonide has been formed. Ozone and **hydrogen peroxide** react slowly: $H_2O_2+O_3=H_2O+2O_2$. H. J. K. Inglis found the reaction is catalytically accelerated by manganese salts. So slow is this reaction in aqueous solutions that C. Arnold and C. Mentzel believed the mixture to be *Beständigkeit*, and C. Engler and W. Wild [14] applied the same remarks to the gaseous mixture. It is very remarkable that the reaction between a vigorous oxidizing agent like ozone, and a reducing agent like hydrogen peroxide, should be so slow. Theoretically it might have been anticipated that $O : O : \boxed{O+H_2} : O : O \rightarrow H_2O+2O_2$ would readily occur. In concentrated solutions this is probably what happens, because, in F. Fischer and M. Wolf's experiments on the synthesis of hydrogen peroxide by the action of the brush discharge on mixtures of hydrogen and oxygen at low temperatures, it was found that a mixture with 97 per cent. of oxygen and 3 per cent. of hydrogen gave much ozone and the merest traces of hydrogen peroxide, while if these proportions were reversed, a highly concentrated form of hydrogen peroxide was obtained. It is assumed that the trace of hydrogen peroxide, in the former case, represents what has escaped decomposition in the reaction between ozone and hydrogen peroxide. V. Rothmund and A. Burgstaller measured the velocity of the reaction between hydrogen peroxide and ozone in $0{\cdot}01N$-sulphuric acid at 0°, and found that in the presence of a large proportion of hydrogen peroxide the decomposition of the ozone follows the course of a unimolecular reaction: $H_2O_2+O_3=H_2O+2O_2$; but if a less proportion of the peroxide be present, the ozone disappears more rapidly than the peroxide, and this the more the lower the ratio of peroxide to ozone. Hence it was inferred that the interaction of hydrogen peroxide and ozone is accompanied by the spontaneous decomposition of ozone, and that hydrogen peroxide catalyzes the latter reaction. According to H. McLeod (1880), if the hydrogen peroxide be in an alkaline or neutral solution, the ozone is destroyed very quickly; the reaction is slow only in acid solutions. In some cases, therefore, **ozone acts as a reducing agent.** Thus, barium peroxide is reduced to the monoxide, and hydrogen peroxide to water. When ozone is brought into contact with sodium peroxide, the two substances mutually decompose and oxygen is liberated: $O_3+Na_2O_2+H_2O=2NaOH+2O_2$.

There are very uncertain signs of the formation of a very unstable compound of ozone with **fluorine.**[15] H. Moissan postulated the possible formation of an intermediate compound of fluorine and ozone when fluorine acts on water; but O. Ruff and J. Zedner could detect no signs of such a compound by the action of fluorine on oxygen under the influence of an electric arc, or in the induction coil. G. Gallo, however, believed that he did prepare an unstable endothermal compound by the action of ozone on fluorine at low temperatures, and that above $-23°$ this compound is liable to decompose explosively. E. Comanducci claims to have converted a mixture of **chlorine** and oxygen into chlorine dioxide by treating the mixed gases in Siemens' ozonizer.[16] D. L. Chapman and P. S. McMahon found that the presence of ozone retards the photochemical action between chlorine and hydrogen. No reaction was observed with **bromine** and oxygen. C. F. Schönbein found that **iodine** is oxidized in a stream of ozonized oxygen to I_2O_3 or I_4O_9, and according to H. B. Baker and R. J. Strutt, the oxidation [17] is accompanied by an orange-coloured glow. By exposing a mixture of iodine vapour and oxygen to the brush discharge in an ozonizer, J. Ogier obtained different oxidization products in different parts of the tube. F. Fichter and F. Rohner passed 8 per cent. of ozonized oxygen into a chloroform solution of iodine, and obtained a yellowish-white oxide, I_4O_9, and the same product was obtained by the action of ozone on dry iodine. By treating a solution of iodine in acetic anhydride and concentrated sulphuric acid with ozonized oxygen, M. Beger obtained a white substance which unites with sulphuric acid forming a citron-yellow hygroscopic powder, $I_2O_3SO_3\frac{1}{2}H_2O$, analogous to the substance prepared by P. Chrétien by the action of iodine on a solution of iodic acid in sulphuric acid. Ozone decomposes all the **hydrogen haloids** with the exception of **hydrogen fluoride**: $2HCl+O_3=Cl_2+H_2O+O_2$; and E. Comanducci claims to have made hypochlorous acid by the action of ozone on **hydrogen chloride** in an ozonizer.

The action of ozone on potassium iodide.—Unlike oxygen, ozone liberates iodine from a **neutral solution** of potassium iodide, KI. This can be shown by dipping paper in a solution of potassium iodide and holding it at the exit tube of the ozonizer. The paper turns brown owing to the liberation of iodine. If a little starch be mixed with the potassium iodide, the paper will appear blue if ozone be present. The reaction is usually represented $O_3+2KI+H_2O=O_2+I_2+2KOH$. The solution is then alkaline in virtue of the potassium hydroxide. Hence, if red litmus paper be steeped in water containing a trace of potassium iodide, the moist paper, when exposed to ozonized air, will be coloured blue owing to the action of the potassium hydroxide on the red litmus. The simple equation just indicated gives no idea of the great complexity of this reaction. According to O. Brunck [18] and others, there is a slow reaction between the iodine and the potassium hydroxide which results in the formation of potassium hypoiodite, KIO, which, in consequence of another consecutive reaction, slowly forms potassium iodate, KIO_3, and iodide, $3KIO=2KI+KIO_3$. E. Péchard believes that potassium periodate is formed at an intermediate stage in the oxidation of potassium iodide by ozone, and that the periodate then reacts, $3KIO_4+2KI+3H_2O=KIO_3+2K_2H_3IO_6+I_2$, and the two constituents last symbolized react $2K_2H_3IO_6+I_2=3KIO_3+KI+3H_2O$, which form a neutral solution. Some periodate and peroxide have also been reported to be produced by a reaction between the iodide and ozone. According to J. N. Pring, the ratio of iodate and periodate to free iodide and hypoiodite increases with the amount of ozone which acts on the solution. With a dilution less than 160 parts of ozone per million of air, no iodate is formed, but only iodine and hypoiodite. If the temperature is less than —24°, and the ozone acts on the solid salt, the smallest quantity of ozone gives more iodate than free iodine and hypoiodite. If ozone acts upon an **acid solution** of potassium iodide, the result is different [19] from that which occurs with a neutral solution, for there is a side reaction resulting in the formation of hydriodic acid: $KI+HCl=HI+KCl$, in addition to the normal reaction for neutral solutions. The ozone reacts with the hydriodic acid, HI, forming hydrogen peroxide, possibly by the side reaction: $4HI+O_3=H_2O+H_2O_2+2I_2$. The resultant equation is represented: $4O_3+10HI=H_2O_2+5I_2+4H_2O+3O_2$. The hydrogen peroxide can be detected with titanium sulphate which gives a yellow coloration. It therefore follows that a gram-molecule of ozone gives more iodine in an acid than in a neutral solution. According to G. Lechner (1911), an **alkaline solution** of potassium iodide reacts with ozone forming potassium iodate, KIO_3, thus $KI+O_3=KIO_3$. If the mixed solution of iodine and iodate be acidified, iodine is liberated: $KIO_3+5KI+3H_2SO_4 =3K_2SO_4+3H_2O+3I_2$. The free iodine can then be determined by titration with a standard solution of sodium thiosulphate. In this way, E. Czako (1912) has shown that it is possible to determine 0·00002 grm. of ozone in 100 c.c. of ozonized air. According to C. Engler and A. Nasse, dry ozone and dry potassium iodide do not react. H. Riesenfeld and F. Bencker found that ozone has no action on neutral or acid solutions of potassium iodate, but it oxidizes alkaline solutions to periodate; and it is without action on potassium periodate—*vide* oxozone.

The white mist—*ozone fog*—produced when ozone acts on iodides, sulphur dioxide, etc., was thought by C. Meissner to be the antozone of C. F. Schönbein. V. Rothmund [20] noted that analogous fogs are produced in many other reactions—*e.g.* ammonium chloride fogs, fogs from fuming acids, fogs produced by the action of radium emanation on sulphur, carbon disulphide, etc.—and that it is caused by water in which a small quantity of the products of the reaction are dissolved. The fogs with ozone are produced only when the reducing agent is of a volatile nature and the reaction products are soluble in water. The size of the mist spheres were found to be practically the same in a number of very different reactions, and from their rate of subsidence they are approximately 10^{-4} cm. in diameter.

The reports which have been published to the effect that **sulphur** is not attacked by ozone are probably based on experiments in which the concentration of the ozone was very small. E. Pollacci [21] has shown that at ordinary temperatures sulphur is oxidized by ozone, but not by oxygen; and H. B. Baker and R. J. Strutt observed that a blue luminescence is obtained when ozonized oxygen is passed over sulphur. A. Malfert supposed that sulphur dioxide is formed if moisture be excluded; sulphuric acid if moisture be present; and alkali sulphates if alkalies be present. T. Weyl obtained sulphuric acid by leading ozonized oxygen into hot water with finely divided sulphur in suspension, but there were no signs of oxidation if oxygen alone be used. A. Stock and K. Friederici also found that sulphur dissolved in carbon tetrachloride was oxidized by ozone to sulphur dioxide. C. D. Harries looks upon sulphur trioxide as a kind of ozonide, SO_3. **Hydrogen sulphide** is oxidized by ozone to sulphur. and D. Helbig found that hydrogen sulphide can be oxidized to sulphur when passed into a solution of potassium permanganate and sulphuric acid, which furnishes ozonized oxygen. **Sulphur dioxide** and **sulphurous acid** are oxidized to sulphur trioxide and sulphuric acid respectively: $3SO_2+O_3 =3SO_3$. P. V. Langlois and L. S. Thomassin, and E. H. Riesenfeld have suggested technical processes for the oxidation of sulphur dioxide based on this reaction. With the same object in view, A. Reynoso and B. Hunt proposed to pass electric sparks through a strongly compressed mixture of sulphur dioxide and air at a low temperature. A. Borchers assumes that an ozonide, $(SO_2)_3O_3$, is first formed as an intermediate product which decomposes into $3SO_3$. The action of ozone on **sodium sulphide,** hydrosulphide, or polysulphide; **sodium thiosulphate**, sodium sulphate, and sodium bisulphite, gives sodium sulphate as an end-product when an excess of the oxidizing agent is used; when the ozone is not in excess, intermediate products are formed. With sodium sulphide, E. H. Riesenfeld and T. F. Egidius detected the intermediate products:



Ozone is dissolved by **sulphuric acid**; and some unknown change occurs, for J. Brand and L. Gräfenberg found that the sulphuric acid possesses oxidizing properties—*e.g.* it blues starch and potassium iodide test paper. These qualities are not lost by boiling, or by leading air through the liquid. The titanic acid reaction for hydrogen peroxide does not occur. The presence of platinum sponge favours the oxidation.

The solution gives a similar precipitate with acetone as does Caro's acid, but, according to J. Brand and L. Gräfenberg, neither persulphuric nor Caro's acid appears to be present.[22] The electrical conductivity of the dilute acid seems to be lowered by the presence of the unknown oxidizing substance which is present, and which some have supposed to be an unknown **ozonic acid.** Persulphuric acid has not yet been formed by oxidizing **sulphuric acid** with ozone. M. Berthelot obtained a persulphuric anhydride by subjecting a mixture of sulphur dioxide and oxygen to the brush discharge, and J. Schmidlin and P. Massini obtained persulphuric acid by treating the product of the action of ozone on **sulphur trioxide** or fuming sulphuric acid and with water. The presence of sulphur trioxide seems to be necessary, since no persulphuric acid is obtained with sulphuric acid alone. It is thought that the reaction involves the formation of sulphur heptoxide as an intermediate product. The salts of persulphuric acid with concentrated sulphuric acid give ozonized oxygen. **Selenium** and **tellurium,** like sulphur, are oxidized by ozone. Attempts by J. Jannek and J. Meyer to make pure selenium dioxide and selenium trioxide by this method have not yet been successful.

It has not been definitely proved that ozone can react directly with **nitrogen.** L. Carius and M. Berthelot[23] said not. C. F. Schönbein stated that a mixture of ozonized oxygen and nitrogen furnishes calcium nitrate with lime water, but M. Berthelot says that the nitrate was due to an impurity in the lime water, and that nitrates or nitrogen oxide may be produced as a by-product in the formation of ozone by the phosphorus process. However, there is no doubt that, as shown by J. Chappius and P. Hautefeuille, nitrogen is oxidized when air is exposed to the brush discharge in the ordinary method of preparing ozone;[24] but, as E. Fonrobert remarks, this does not prove that ozone can react with nitrogen. C. Montanari obtained no signs of the oxidation of nitrogen by leading a mixture of nitrogen and ozonized oxygen over platinized lime. The chemically active variety of nitrogen obtained by R. J. Strutt[25] by the action of a spark discharge on nitrogen gives no trace of nitrogen oxide after it has been mixed with ozone, and cooled with liquid air, but T. M. Lowry has shown that air which has been subjected to the brush discharge and afterwards sparked gives a greater yield of nitrogen oxides than when the air supply has not been previously ozonized. Hence, it is inferred that in the sparking the nitrogen in the air is converted into a form which enables it to unite rapidly with the ozone. **Nitric oxide** once formed can be oxidized to a higher oxide, which is decomposed by ozone to oxygen and nitric oxide.[26] While two volumes of nitric oxide and one volume of oxygen unite to form nitrogen peroxide, the reaction is not complete if the oxygen employed be previously ozonized—this may be due to the direct retarding action of ozone, or to the destruction by ozone of some catalytic agent necessary for the reaction between nitric oxide and oxygen. Ozone oxidizes **nitrogen trioxide** to the tetroxide, and **nitrogen tetroxide** to the pentoxide; in aqueous solution, nitrous acid is first formed and then nitric acid. The reaction is very much faster with ozone than with oxygen.[27] D. Helbig obtained a volatile substance by the action of ozone on nitrogen trioxide at the temperature of liquid air;

it is possible an ozonide, N_2O_6, identical with E. Müller's nitrogen hexoxide. The oxidation of the tetroxide to the pentoxide by ozone has been recommended as a method of making nitric anhydride.[28]

L. Carius, and L. I. de N. Ilosva failed to obtain evidence of any combination between dry **ammonia** and ozone; but G. Baumert and C. F. Schönbein [29] noted the formation of a cloud immediately moisture was added, and the ammonia was oxidized to ammonium nitrite and nitrate. L. Carius reported that some hydrogen peroxide was formed at the same time: $2NH_3+4O_3=NH_4NO_2+H_2O_2+4O_2$; and $NH_4NO_2+H_2O_2=NH_4NO_3+H_2O$. If the gases are very dilute, the reaction is so slow that it is not thought the occurrence of ammonium nitrite and nitrate in the atmosphere can be explained by the oxidation of ammoniacal products by atmospheric ozone. D. Helbig reported the oxidation of ammonia with incandescence when the gas is passed over a mixture of potassium permanganate and sulphuric acid; while P. Jannasch and W. Gottschalk found a cloud is formed by leading ozone into aqueous ammonia, and the cloud condenses to a white film on the walls of the vessel. E. Warburg also obtained a very marked contraction by exposing a mixture of ammonia and oxygen to ultraviolet rays. A. W. Browne and F. F. S. Netterly [30] reported that if ozone be passed into a boiling alkaline solution of **hydrazine sulphate,** a small quantity of azoimide, HN_3, but no ammonia, NH_3, was formed.

Dry yellow and red **phosphorus** are oxidized to phosphorus pentoxide by ozone; if water is present phosphorous acid is first formed and afterwards phosphoric acid. Ozone oxidizes **arsenic** in presence of water to arsenic acid, but **antimony** is not so easily oxidized, and C. F. Schönbein (1847) proposed to distinguish the two latter elements by this reaction. J. Schmidlin and P. Massini[31] tried to convert **phosphorus pentoxide** into a higher state of oxidation by means of ozone, but without result. **Arsenious oxide** is oxidized quantitatively to arsenic acid by ozone, and C. F. Schönbein [32] proposed to determine ozone by the reaction: $As_2O_3+2O_3=As_2O_5+2O_2$, but Y. Yamauchi found that one gram of ozone oxidized 2·14 grms. of arsenic trioxide while theoretically 2·06 grms. passes into the pentoxide. **Phosphine** and **arsine** are immediately decomposed by ozone; and A. Stock and W. Siebert found that **stibine** at —90° explodes in contact with ozone. A solution of ozone in liquid oxygen does not attack solid stibine, but as the temperature is allowed to rise slowly an explosion occurs. According to A. Besson,[33] ozone in sunlight acts on **phosphorus trichloride** forming the oxychloride; with **phosphorus tribromide,** the pentabromide and trioxide are formed, but no oxybromide; and with **arsenic trichloride,** at 50°, chlorine is liberated and arsenic oxide formed. **Phosphorous iodide** is decomposed with the liberation of iodine and the formation of complex oxyiodide. Ozonized oxygen has no action in the cold on solutions of **phosphorus pentachloride or pentabromide** in carbon tetrachloride. A. Stock and K. Friederici [34] find that when solutions of phosphorus trisulphide, P_4S_3, are treated with ozone a yellowish-white oxysulphide, $P_4S_3O_4$, which with further treatment forms $P_4S_3O_7$, is precipitated.

Ozone is destroyed by **carbon,** the smell disappears, but no oxidation has been detected. A. R. Leeds and F. Baumann stated that ozone oxidizes **carbon monoxide,** while according to I. Remsen and M. S. Southworth, and E. H. Keiser,[35] ozone does not oxidize this gas, but the negative results are possibly due to the use of ozone of too great dilution. M. Berthelot has shown that there is a kind of equilibrium between ozone and carbon monoxide since a mixture of the two gases in the brush discharge forms about 90 per cent. carbon dioxide, while carbon dioxide is partially decomposed under similar conditions into carbon monoxide and ozone. E. Goldstein found that when sparks were passed through a Geissler's tube filled with oxygen and carbon monoxide, at the temperature of liquid air, the spectrum of carbon monoxide gradually disappeared. R. Clausmann exposed a mixture of ozonized oxygen and carbon monoxide in sunlight for eight days and found 2·83 parts of carbon dioxide were formed, in darkness only 0·88 part was formed. J. Thiele also exposed a similar mixture to ultraviolet radiations and obtained small quantities of carbon dioxide. According to W. A. Jones and C. E. Waters,[36] the oxidizing power of ozonized oxygen on carbon monoxide is greater the higher the temperature, and the greater the concentration of the ozone. The action is appreciable in the cold if the concentration of the ozone be high. A. Besson and L. Fournier[37] converted **silicochloroform** into a volatile oxychloride, Si_2Cl_6O, by the action of ozone.

With the exception of **gold** and the metals of the **platinum** family, moist ozone oxidizes all the metals which have been tried—copper, **iron,** nickel, etc. In some cases the metals require heating at ordinary temperatures. Copper, nickel, and tin withstand the gas fairly well; **aluminium, zinc, brass,** and lead are quickly corroded. Iron is not so readily oxidized if the carbon-free metal be alloyed with chromium, and the use of **ferrochromium** containing 25 per cent. of chromium has been patented[38] for chemical apparatus required to resist the fumes of ozone or nitric oxide. A coating of shellac varnish as well as many of the acid-proof paints of the graphite or asphalt type protects the metals quite well. Silver and lead form the higher oxides. If the gas and metal be thoroughly dried, C. F. Schönbein[39] found that in many cases no reaction occurs; the presence of moisture is necessary to start the oxidation. C. F. Schönbein found that similar remarks apply to the action of ozone on several other substances—metal sulphides, iodides, manganese and lead salts, potassium cyanide, organic colouring agents, etc. W. Manchot and W. Kampschulte hold that dry ozone can react with the metals forming ozonides under certain conditions. These ozonides are usually very unstable and only a very small quantity is formed.' If, however, water be present, or the system be heated, the ozonide is formed in greater proportions and decomposed into the metal oxide and oxygen.

The many analogies between ozone and sulphur suggest the hypothesis that ozone and sulphur dioxide, SO_2, are related as indicated in the respective graphic formulæ $O=O=O$, and $O=S=O$; and that just as sulphur dioxide is the anhydride of sulphurous acid, so is ozone the anhydride of an **ozonic or ozonous acid.** Although ozonic acid is unknown, it is supposed that the well-known potassium tetroxide, K_2O_4—that is, $K_2O.O_3$—is the corresponding salt analogous with potassium sulphite, say $K_2O.SO_2$. The argument, though very feeble, has been pushed still further. C. F. Schönbein (1844) found that when ozone is passed through an aqueous solution of, say, 40 per cent. potassium hydroxide, something is formed which gives a blue coloration with a mixture of potassium iodide and starch; and A. von Baeyer and V. Villiger (1902)[40] showed that if the potash lye be strongly cooled, the ozone forms an orange-brown solution, and the colour disappears when the lye is removed from the freezing mixture. In these experiments, it was assumed that *ozonsäures Kalium*—**potassium ozonate**—is formed, and that the salt is more stable at low temperatures than it is at ordinary temperatures. A. von Baeyer and V. Villiger also obtained a coloured product with solid potassium hydroxide. Similar results were obtained with the other four **alkali hydroxides,** and the stability of the product decreased with decreasing atomic weight in passing from cæsium to lithium. Indications of the formation of an analogous unstable product were obtained with dry liquid ammonia.[41] Again, according to L. Gräfenberg, the **hydroxides of the alkaline earths** form coloured peroxidized compounds; when ozone is passed into lime water under the same conditions, a granular precipitate is formed which does not colour a mixture of potassium iodide and starch blue; but does so if it be acidified. The acidified liquid does not smell of ozone. The corresponding product with magnesium hydroxide is not coloured.

It is further assumed, without proof, that potassium tetroxide and potassium ozonate are the same, and hence, ozonic acid, H_2O_4, is regarded as a **hydrate of ozone,** O_3H_2O, or $(HO)_2O_2$, *i.e.* $(HO)_2=O=O$ by analogy with the corresponding sulphur compound, $(HO)_2=S=O$. Against this assumption it has been urged: (1) Ozonized oxygen led through water does not make the liquid appreciably more conducting, electrically, which it probably would do if traces of an acid were formed; and (2) no appreciable difference has been detected in the solubility of ozone in water and in normal acids—if an acid were formed in water, the solubility in that menstruum would probably be the greater. The latter argument has not much weight.

W. A. Shenstone and J. T. Cundall found that although dried ozone is destroyed by mercury, the metal is not attacked as it is by imperfectly dried ozone. The action of ozone on **mercury** is superficial.[42] Put a globule of mercury in a small flask, pass ozonized air into the flask and shake the globule of mercury about. The mercury loses its lustre, and spreads a film over the walls of the flask. The globule of mercury is restored when the film is shaken up with water. According to W. Manchot and W. Kampschulte, the mercury is but slightly attacked at ordinary temperatures by oxygen with 1·5 per cent. of ozone by volume; at 55°, a brown film is formed which becomes deeper and deeper in colour as the temperature is raised, and attains a maximum at 180° to 190°. The surface of the mercury then acquires a deep steel-blue colour and begins to develop a brown vapour. At higher temperatures the action becomes less marked; at 238°, only a yellow film is perceptible, and at 250° there is no apparent action. There appears to be a higher oxide, or an ozonide of mercury formed in this reaction, but the product has not been isolated. Polished **silver** foil is attacked by moist ozone, and, according to A. Volta,[43] negatively polarized; dry ozone also polarizes the metal, and the ozone is at the same time decomposed. If a piece of silver foil cleaned with silver sand be heated in a Bunsen's burner for a moment, and while still warm, held in a stream of ozonized air, the silver is browned or blackened, owing, it is said, to the formation of a higher oxide of silver. E. Frémy recommended the reaction as a test for ozone, but A. Houzeau considered it not sufficiently delicate. Ozone can be recognized by its smell long before the silver is coloured. If the silver is dirtied by contact with the fingers the test is not so good. If the surface of the silver be not specially purified it will be darkened by ozone at the ordinary temperature. Thus, if a plate which has once been blackened be strongly heated, the colour disappears, but the plate is blackened by ozone at ordinary temperatures, owing, it is supposed, to the presence of a trace of undecomposed oxide; similarly, a plate which has been dipped in dilute nitric acid, washed, and dried, is blackened at ordinary temperatures. Scouring the plate with sand destroys its activity at ordinary temperatures. Minute traces of the oxides of the heavy metals—*e.g.* nickel, cobalt, lead, chromium or iron oxide—or the platinum metals—*e.g.* ruthenium, palladium, or platinum—act as catalytic oxygen carriers and enable the silver to be blackened by—say, 0·2 per cent. of ozone—at ordinary temperatures. To clean the metal surface, it is washed a few times with benzene, polished with moist sand, and rubbed with a clean dry cloth. The sensitiveness gradually diminishes when the plate is kept. Ozone produces a white iridescent film on a clean silver plate at 100°; a steel blue film at 154°; a pronounced blackening between 220° and 240°; this is an optimum temperature since at higher temperatures the effect becomes more and more feeble, until at 450° no change can be observed—*vide* silver.

Copper is attacked by ozone, but reactions analogous with those presented by mercury have not been observed because air itself oxidizes the heated metal. As in the case of mercury, W. Manchot found that molten **tin** at 500° is attacked by ozonized air (1 per cent. of ozone). Ozonized air slowly attacks metallic **lead** forming a layer of brown dioxide; in the presence of water, A. R. Leeds found that lead hydroxide is formed, W. Manchot observed only a slight reaction on lead at 100°, with rising temperatures the attack is more marked; at 227°, the metal is steel-blue like silver; at 385° it is brownish-blue and the action cannot then be distinguished from that of ordinary oxygen. **Nickel** is not perceptibly attacked by ozone at 240°; at 300° a yellow film is formed; at 415° the film is golden yellow. This change occurs more quickly with ozonized oxygen than it does with ordinary oxygen; at higher temperatures, the difference is inappreciable. The action of ozone on **silver sulphide** is very slow; **cobalt and nickel sulphides** first form sulphites and then the dioxides; **lead, manganese, and palladium sulphides** give the dioxides and sulphuric acid without the intermediate formation of the sulphite being perceptible; and **gold sulphide** gives metallic gold.

Ozone oxidizes **mercurous salts** to the mercuric state:[44] $2HgNO_3+O_3=HgO+Hg(NO_3)_2+O_2$; mercurous chloride or bromide also forms some oxyhalide. Similarly **thallous salts** are oxidized to thallic salts; and at the same time the colour turns brown; this was proposed as a test for ozone by R. Böttger (1865) and E. Schöne (1879). According to Y. Yamauchi, the reaction, $2TlOH+2O_3=Tl_2O_3+H_2O+2O_2$, is quantitative. Ozone precipitates dark-brown lead dioxide from solutions of **lead salts,** slowly in neutral solutions, rapidly in basic solutions; hence, basic lead acetate test papers have been recommended as a test for ozone. Ozone converts dark-brown lead sulphide into white lead sulphate: $PbS+4O_3=PbSO_4+4O_2$. This can be shown by holding a strip of paper which has been steeped in a solution of lead acetate and browned by hydrogen sulphide, in a stream of ozonized oxygen or ozonized air. Many other sulphides—copper, antimony, zinc, cadmium—behave in a similar manner. Attempts by L. Moser to oxidize **cupric salt** solutions by the action of ozone on neutral or alkaline, hot or cold, solutions have given no result. Ozone acts on Fehling's solution like chlorine or hypochlorites. Feebly acid solutions of **bismuth nitrate** gave P. Jannasch and W. Gottschalk no precipitate, but alkaline solutions are coloured yellow or brown. C. F. Schönbein and A. W. Williamson represented the oxidation of **stannous chloride** to stannic chloride by the equation: $3SnCl_2+6HCl+3O_3=3SnCl_4+3H_2O+3O_2$; but Y. Yamauchi has shown that the relation between the ozone and the stannous chloride oxidized corresponds with $3SnCl_2+6HCl+O_3=3SnCl_4+3H_2O$. This latter equation is unusual in that the whole of the oxygen of ozone is consumed by the oxidation.

The action of ozone on **manganous salts** is peculiar, and is largely determined by the concentration and acidity of the solution. With *neutral* solutions, a brown precipitate of **manganese dioxide** is formed; paper soaked in a solution of manganous sulphate and dried was recommended by D. Huizinga as a test for ozone; and paper similarly made with manganous chloride was recommended by C. Engler and W. Wild. The test papers are not very sensitive. A solution of manganous sulphate can be used in place of ink, and the writing is turned brown by exposure to ozone owing to the formation of a brown manganese dioxide. C. F. Schönbein wrote M. Faraday a letter to this effect, soon after he had discovered ozone. According to L. Maquenne, in *feebly acid* solutions of manganous sulphate, the solution which remains after the separation of the manganese dioxide has a rose-pink colour, and this is the more intense, the greater the acidity of the solution, until, with 10 per cent. of sulphuric acid, no dioxide is precipitated, and the manganese is converted into **permanganate**. Ozone does not carry the oxidation further. If the concentration of the acid exceeds 30 per cent., **manganic sulphate,** not a permanganate. is formed. The greater the concentration of the manganous sulphate, the more the sulphuric acid required. Analogous results are obtained with manganous nitrate and nitric acid, and with hydrochloric acid and manganous chloride. The fact that the higher manganese oxides give ozone, led O. Brunck, as we have seen, to postulate an ozonide structure for these compounds, and the conversion of the lower mangansese salts into the higher oxides, by ozone, is taken to confirm this. P. Jannasch and W. Gottschalk[45] have studied the use of ozone as a reagent for the qualitative detection and the gravimetric precipitation of manganese salts in analysis. Colourless glass, in which the colour of the iron salts has been bleached by manganese oxide, is slowly coloured violet by exposure to ozone or to ultraviolet rays. According to F. Fischer, this transformation does not occur so readily in the near sea-level, as on high mountains where the ozone and the ultraviolet rays of the sun are more prevalent.

Ozone oxidizes **ferrous salts** to ferric salts[46] in neutral and acid solutions. The reaction, according to R. Luther and H. J. K. Inglis is in accord with $2Fe(NH_4)_2(SO_4)_2+O_3=Fe_2O(SO_4)_2+2(NH_4)_2SO_4+O_2$, but Y. Yamauchi found rather more ferrous iron was oxidized than corresponds with this equation, and hence he inferred that some of the oxygen also does work in oxidation. **Ferrocyanides** are oxidized to ferricyanides. **Potassium carbonyl ferrocyanide,** $K_3FeCOCy_5$, is not oxidized to the ferri-salt by ozone. In alkaline solutions **ferri-salts** are oxidized to ferrates by ozone: $Fe_2O_3+O_3+2H_2O=2H_2FeO_4$, which suggests an ozonide structure for the ferrates. P. Jannasch and W. Gottschalk could not oxidize **nickel nitrate** solutions by ozone, but **cobalt sulphate** gave a dark-brown precipitate. Cobalt and nickel sulphides or hydroxides are immediately oxidized to the peroxide—the sulphur of the sulphide forms sulphuric acid. Ozone oxidizes **chromic salts** to chromates or dichromates, but it does not carry the oxidation further.

Ozone precipitates gold from acid-free solutions of **gold chloride** or colours the solutions dark-violet. This was therefore recommended as a test for ozone by R. Böttger.[47] Ozone precipitates palladium dioxide from **palladium salt** solutions, and it forms complex salts, palladiates, in alkaline solutions. E. Schneider recommended palladous chloride for making test papers for ozone. The reaction is usually represented by the equation: $H_2PdCl_4+4H_2O+O_3=Pd(OH)_4+4HCl+H_2O+O_2$.

Ozone rapidly corrodes **rubber** and rubber compounds; concentrated ozone will eat through rubber tubing in a few moments; **cork** withstands dilute ozone for a short time, but its use should be avoided. Ozone attacks many organic compounds in the cold. **Methane** gives formaldehyde and formic acid; ethylene forms acetaldehyde and acetic acid; **ethylene** reacts explosively, giving carbon and water; **alcohol** forms aldehyde and acetic acid; ether forms aldehyde and acetic acid and a syrupy liquid **ethyl peroxide.** $(C_2H_5)_2O_2$, which is explosive, and which forms alcohol and hydrogen peroxide with water. **Nitroglycerol, dynamite, nitrogen chloride,** and **nitrogen iodide** explode in an atmosphere rich in ozone. **Benzene** forms formic, acetic, oxalic, and other acids as well as a white gelatinous explosive compound called **ozobenzene.** The **phenols** are slowly attacked; **aniline** forms ozobenzene, etc. The **vegetable colours** are quickly bleached by ozone—indigo blue forms colourless isatine. Tincture of guaiacum is coloured blue by ozone. The two last-named reactions have been used as tests for ozone. The colouring matter of blood as well as the albumins are destroyed by ozone.

The uses of ozone.—Ozone is used for the purification of water. Its function is to oxidize the organic matter, and sterilize the water. So satisfactory is the ozone treatment in the sterilization of water that it is declared by recognized authorities: "The purification of drinking water has ceased to be a problem." Water of average quality can be satisfactorily treated with ozonized air containing one part of ozone per million, and the cost of treatment lies between 4*s*. 0*d*. and 8*s*. 0*d*. for 1,000,000 gallons per hour. There are not far from 100 ozone water-plants giving satisfactory results. Ozonized air is also used in ventilation. The ozone treatment of air is not intended to supplant ventilation, but is to supplement it, by providing an agent which destroys bad odours, and the feeling of closeness experienced when a number of people are in a confined space. The concentration of the ozone for this purpose should be smaller than can be recognized by smell—say less than a milligram per cubic metre. Ozone or galvanized air, said Leuch, in 1849, is a most powerful bleaching agent. It is now used for bleaching purposes particularly for paper pulp; starch; oils; and for oxidizing oil in the manufacture of linoleum, etc. H. de la Coux[48] has given a long list of possible applications, but many have been reported failures on trial—sometimes because the ozone has been wrongly applied, *e.g.* in too concentrated a form for bleaching certain textiles; and sometimes because some unexpected complication has arisen, *e.g.* in bleaching flour where the taste is affected, and in bleaching dextrine and glue where the adhesive properties are impaired by ozone bleaching. The industrial applications have stimulated inventors, and accordingly, a number of fairly efficient ozonizers have been placed on the market. In most of these, a high tension alternating electric discharge is sent across a space through which the air to be ozonized passes.

§ 7. The Constitution of Ozone

The nature of ozone was the subject of much discussion soon after C. F. Schönbein had established the individuality of the gas. At first, C. F. Schönbein seems to have thought the gas was a new elementary body which belonged to the same class of electronegative elements as chlorine and bromine; later on, he suggested that it may be an elementary substance which, when united with hydrogen, forms the nitrogen of the atmosphere.[1] Henry Cavendish had proved, in 1784, that nitrates are produced when electric sparks pass through air; and L. Rivier and L. R. de Fallenberg (1845) showed that nitrous acid is formed during the oxidation of phosphorus. Nitrous acid like ozone colours starch paper blue; it was at first supposed that the reactions ascribed by C. F. Schönbein to ozone were really produced by traces of nitrous acid. Ozone can be produced under conditions where no nitrogen is present; consequently, it follows that **ozone contains no nitrogen.** Oxygen is an invariable antecedent when ozone is formed, and an invariable consequent when ozone is decomposed.

Is ozone a condensed form of oxygen or an oxide of hydrogen?—About 1845, J. C. G. de Marignac and A. de la Rive showed that moist silver, when exposed to ozone, forms a silver oxide, and that potassium iodide—KI—can be oxidized by ozone to potassium iodate—KIO_3; but there is never any sign of the formation of any nitrogen compound. This narrowed the question, for it appeared that ozone is either (1) a form of matter identical with oxygen—J. C. G. de Marignac and A. de la Rive (1845); or (2) oxidized water, that is, a peroxide of hydrogen—C. F. Schönbein and A. W. Williamson (1845). On the one hand, J. C. G. de Marignac and A. de la Rive, in their memoir, *Sur la production et la nature de l'ozone*,[2] showed that ozone can be obtained by the electrolysis of water free from nitrogen, and that ozone containing nothing but oxygen must be an allotropic form of that element. This conclusion was supported by J. J. Berzelius. On the other hand, C. F. Schönbein (1847) contended that ozone is a higher oxide of hydrogen than L. J. Thénard's *bioxyde d'hydrogène*. This view was supported by A. W. Williamson because he obtained water by passing ozonized oxygen over heated copper oxide. A. W. Williamson's gas was obtained by electrolysis. E. Frémy and E. Becquerel demonstrated in their memoir, *Recherches électrochimque sur les propriétés des corps électrisés*, that pure oxygen can be converted into ozone by the prolonged action of electricity; they also found the ozone to be absorbed by mercury or by potassium iodide, as fast as it was produced. G. Baumert then suggested that the ozone obtained by the electrolysis of acidulated water is different from that obtained by the electrical discharge in oxygen, or by the action of phosphorus on moist oxygen, because the electrolytic ozone always contains hydrogen and the other form of ozone contains nothing but oxygen. In 1856, in a paper, *On the constitution and properties of ozone*, T. Andrews showed that the difficulty with electrolytic ozone was due to the presence of impurities in the gas, and if proper precautions be taken :

> No gaseous compound having the composition of a peroxide of hydrogen is formed during the electrolysis of water; and that ozone, from whatever source derived, is one and the same body, having identical properties and the same constitution, and is not a compound body, but oxygen in an altered or allotropic condition.

About this time, ozone was variously styled *nascent oxygen*, implying that it was oxygen in an atomic condition ; *active oxygen* or *erregter Sauerstoff*, in reference to its great chemical activity ; and *polarized oxygen* or *electrisierten Sauerstoff*.

The hydrogen oxide theory was not given up until 1860, when T. Andrews and P. G. Tait[3] proved in their paper, *On the Volumetric relations of ozone*, that if an electric discharge—brush or spark—be passed through pure dry oxygen, a contraction occurs amounting to about one-twelfth of the original volume. The oxygen was sealed in a tube, shaped as indicated in Fig. 7, *Q*, and subjected to the brush discharge, *via* the platinum wires sealed into the glass. In T. Andrews and P. G. Tait's experiment the contraction in volume was measured by attaching to the tubes a small manometer, *a* and *b*, charged with concentrated sulphuric acid. A duplicate tube, *Q*, Fig. 8, containing air was treated along with the tube containing the oxygen, *R*, Fig. 7, so that any changes due to variations of pressure or temperature during the experiment could be corrected. The tubes, during the experiment, were placed in a water tank as indicated in Fig. 8, to keep the temperature uniform. When ozonized oxygen is heated to 270°, and allowed to cool, the original volume of oxygen is obtained ; and when a thin glass bulb, *c*, Fig. 7, *R*, of potassium iodide is sealed in the tube along with the oxygen, and after ozonization, broken by shaking the bulb against a piece of glass tubing *d*, iodine is liberated without any perceptible change in volume. If the gas which has been treated with potassium iodide be heated to 270° as before, no change in volume can be detected. Hence, T. Andrews and P. G. Tait concluded that **ozone is a condensed form of oxygen.** This statement, however, gives no information about the weight of oxygen in a given volume of ozone, *i.e.* the number of atoms in the molecule of ozone.

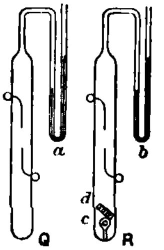

FIG. 7.—Andrews and Tait's Ozone Tubes.

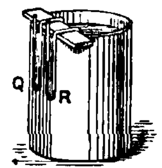

FIG. 8.—Andrews and Tait's Experiment.

The absence of hydrogen in ozone was further confirmed by A. Houzeau (1866), L. von Babo (1863) and by J. L. Soret (1863)[4] in an experiment in which ozone was thoroughly dried, and then decomposed by heat. No trace of any compound of hydrogen—*e.g.* water—could be detected in the products of decomposition. Hence, it is inferred that **ozone is not a compound of hydrogen with oxygen ; ozone contains nothing but oxygen ;** it is a kind of oxidized oxygen. A similar experiment was made by C. F. Schönbein in 1849, but its importance does not appear to have been appreciated at that time.

Ozone is a form of oxygen in which three volumes of oxygen are condensed to two volumes.—Since the volume of ozonized oxygen undergoes no change when mixed with a solution of potassium iodide, it is inferred that the oxidation of potassium iodide can only be effected by so much oxygen in ozone as has been condensed with ordinary oxygen to form ozone. This excess of oxygen is absorbed by the solution of potassium iodide, and the ordinary oxygen which remains has the same volume as the ozone present before the action of the potassium iodide. Hence, no new contraction occurs with potassium iodide. In symbols, the formula for ozone is O_{2+n}. T. Andrews and P. G. Tait did not determine the numerical value of n. The formula for ozone might be O_3, O_4, O_5, . . . The special difficulty involved in this determination arises from the fact that ozone cannot be obtained free from oxygen; and, accordingly, the regular methods of determining the molecular weights—vapour density, etc.—cannot be applied. W. Odling (1861)[5] proposed to take the simplest possible formula, O_3, thus assuming that three volumes of oxygen are condensed to form two volumes of ozone; he said:

> If we consider ozone to be a compound of oxygen with oxygen, and the contraction to be consequent upon their combinations, then, if one portion of this combined or contracted oxygen were absorbed by the reagent, the other portion would be set free, and by its liberation might expand to the volume of the whole. Thus, if we suppose three volumes of oxygen to be condensed by their mutual combination into two volumes, then on absorbing one-third of this combined oxygen by mercury, the remaining two-thirds would be set free and consequently expand to their normal bulk, or two volumes:

$$\overset{-}{O}\overset{+}{O}\overset{-}{O}+\overset{+}{Hg_2}=\overset{+}{Hg_2}\overset{-}{O}+\overset{+}{O}\overset{-}{O}$$

Interpreting this assumption in the light of Avogadro's rule:

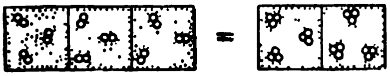

FIG. 9.—3 Volumes of Oxygen give 2 Volumes of Ozone.

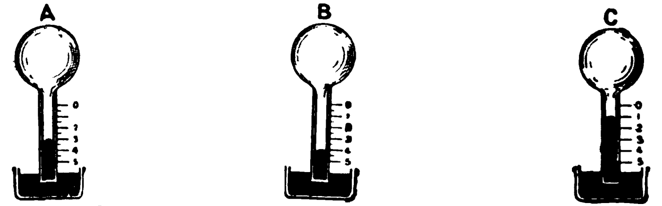
This beautiful hypothesis, said C. W. Heaton (1868), although accounting perfectly for all known facts, is yet but a probability. One link in the chain of evidence is lacking. True, J. Tyndall[6] inferred that ozone contains more atoms per molecule than does ordinary oxygen because the former has much greater absorptive power for heat than the latter; but the missing link was not supplied until J. L. Soret described some happily devised experiments in his memoir, *Recherches sur la densité de l'ozone* (1866).

J. L. Soret's experiments.—J. L. Soret (1866)[7] took advantage of the fact, known to C. F. Schönbein, that essential oils absorb ozone without absorbing any marked quantity of oxygen. Hence a sample of ozonized oxygen was introduced into two flasks, A, Fig. 10, and A_1. The vessel A was heated so as to decompose the ozone. The gas now occupied a greater volume than before—B, Fig. 10. The expansion was measured when the gas had cooled to its former temperature. The vessel A_1, containing the same mixture of ozonized oxygen, was treated with cinnamon oil; the contraction due to the removal of ozone was measured—C. J. L. Soret (1866) found the following data with measured volumes of a given sample of ozonized oxygen:



(A) Ozonized oxygen.

(B) After the ozone has been converted into oxygen by heat.

(C) After removal of ozone with cinnamon oil.

FIG. 10.—Soret's Experiments with Ozone (Diagrammatic).

Expansion after heating	3·45 c.c.
Contraction after treatment with cinnamon oil . .	6 90 c.c.

Consequently, the ozonized oxygen contained 6·90 c.c. of ozone; and 6·90 c.c. of ozone becomes 10·35 c.c. of ordinary oxygen when heated; or 2 c.c. of ozone becomes 3 c.c. of oxygen. In another set of experiments:

Contraction after treatment with turpentine oil . . .	8·0 c.c.
Oxygen absorbed by treatment with potassium iodide . .	3·9 c.c.

Hence 8·0 c.c. of gas gave up 3·9 c.c. of oxygen to potassium iodide solution without change of volume. This means that 8 c.c. of ozone is equivalent to 8·0–3·9 c.c. of oxygen within the limits of experimental error. L. von Babo and C. E. Claus,[8] in 1863, also found the decrease in the volume of oxygen on ozonization to be equal to the volume of oxygen calculated from the quantity of iodine liberated by the action of the ozone on potassium iodide. Hence, it was inferred that **three volumes of oxygen produce two volumes of ozone.**

J. L. Soret's work was rather crude, but, in 1872, B. C. Brodie[9] repeated the experiments with cinnamon oil, turpentine, and stannous chloride in such a way that the above conclusion was the only possible interpretation of the experiment. A. Ladenburg[10] extended J. L. Soret's work to a mixture containing a large proportion of ozone, and calculated the relative density of ozone—assumed unknown—from the density of a sample of ozonized oxygen, and the amount of iodine liberated by the gas when in contact with potassium iodide, taken in conjunction with the fact that the gas undergoes no change in volume during the reaction. A. Ladenburg tacitly assumed that a molecule of iodine is liberated by a molecule of ozone. The argument is accordingly fallacious because if the molecule of ozone be represented by O_2+nO, each molecule of ozone will liberate n molecules of iodine. The excess of the density of ozonized oxygen over that of pure oxygen represents the weight of oxygen available for the liberation of iodine, and this is not necessarily dependent on the molecular weight of ozone.

EXAMPLE.—If 100 c.c. of ozonized oxygen are converted into oxygen by passage through a hot tube, what was the composition of the original mixture if 110 c.c. of oxygen remained? The mixture contained x c.c. of ozone, and $(100-x)$ c.c. of oxygen, and since x volumes of ozone yield $\frac{3}{2}x$ c.c. of oxygen, the original mixture contained the equivalent of $\frac{3}{2}x+(100-x)=110$ c.c. of oxygen. Hence, $x=20$, or the mixture contained 20 per cent. of ozone and 80 per cent. of oxygen.

M. Otto (1897)[11] determined the density of ozone by weighing a bulb filled with oxygen, and again when filled with ozonized oxygen. The increase in weight gave the weight of the active oxygen in ozone. The amount of ozone was determined by means of an acidified solution of potassium iodide. A. Ladenburg (1901) measured the total volume of ozone by absorption with turpentine. The mean of A. Ladenburg's five determinations was 47·78—with 45·3 and 50·4 as extreme values. J. L. Soret (1867) confirmed his determination of the molecular weight of ozone by assuming T. Graham's relation between the speed of the diffusion of a gas and its density. He allowed vessels of chlorine and oxygen to be in communication for a given time; and likewise vessels of ozonized oxygen and oxygen. The amounts of chlorine and ozone which diffused in a given time were as 0·227 : 0·271. Consequently, if the density of chlorine is 2·49, and D, the density of the ozone, air unity, by Graham's law, $D:2{\cdot}49=(0{\cdot}227)^2:(0{\cdot}271)^2$; hence, D is nearly 1·5. A. Ladenburg obtained the density 1·3698 by Schilling's apparatus. All these numbers are in accord with a molecular weight 48 (oxygen 32) for ozone.

The frequent formation of dimeric (doubled) ozonides at low temperatures, suggested to C. D. Harries the possibility that ozone may be itself dimeric, $(O_3)_2$; at low temperatures and monomeric, O_3, at higher temperatures: $(O_3)_2 \rightleftharpoons 2O_3$; nitrogen peroxide behaves similarly, $(NO_2)_2 \rightleftharpoons 2NO_2$.

Newth's experiment.—Many neat ways of illustrating the volume relations of oxygen and ozone have been devised.[12] G. S. Newth's apparatus (1896), slightly modified, consists of two concentric tubes, Fig. 11. The inner tube has a hollow stopper ground to fit the outer tube ; it contains dilute sulphuric acid. The inner tube has two little projections, *A*, and the outer tube has three projections, *B*, in such a position that a sealed thin glass tube containing cinnamon oil can be broken, when desired, by twisting the stopper of the inner tube. The outer tube is fitted with a three-way cock, *D*, connected with a manometer charged with concentrated sulphuric acid. The apparatus is placed in a cylinder containing, say, ice and water. The annular space between the two tubes is filled with oxygen, *via* the cocks *E* and *D*. The manometer is then put in communication with the annular space between the two tubes. Note the level of liquid in the manometer. Pass a current from an induction coil, so as to ozonize the oxygen sufficiently to give, say, a one-centimetre contraction on the manometer. Note the contraction. Give the stopper a twist so as to break the glass tube containing the cinnamon oil; the contraction which occurs will be twice the former contraction, namely 2 cm. more. It may be advisable to level the liquid in the manometer, after the first contraction, by admitting either air or oxygen, before breaking the capillary tube. The same or a similar apparatus can be employed for showing the contraction which occurs when ozone is treated with potassium iodide by using a tube *C* with this substance in place of cinnamon oil.

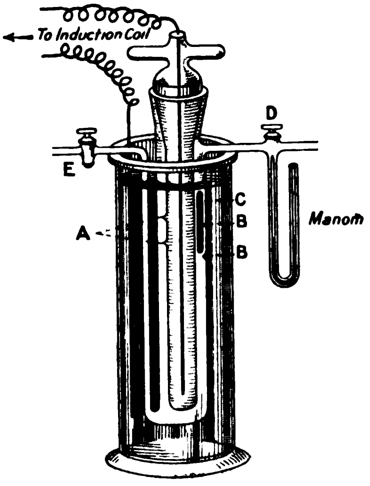


Fig. 11.—Newth's Apparatus (Modified).

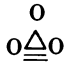
The graphic or constitutional formula of ozone.—If it be assumed that all three atoms of oxygen are bivalent, the only possible formula for ozone is the ring structure indicated in formula I. Owing to the peculiar oxidizing qualities of the odd oxygen atom, some consider that the three oxygen atoms cannot

I

II

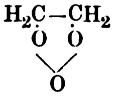
III



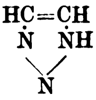
IV

V

be symmetrically placed in the molecule, and this has given rise to other suggestions. For example, M. Traube[13] assumes that two of the oxygen atoms in the ozone molecule are tervalent and one bivalent, as indicated in formula II. The evidence for the tervalency of oxygen is very weak since there are few compounds in which such an assumption can be accepted ; nor does it correspond with the position of oxygen in the periodic system. A. Angeli has drawn attention to the relationship between ozone, O_3, and azoimide, N_3H ; both compounds are endothermal, explosive, poisonous, and react with unsaturated compounds forming addition products—ozone gives ozonides ; azoimide gives triazoles :



Ozonide.



Triazole.

From observations on the molecular refraction of hydrogen peroxide, J. W. Brühl[14] inferred that this compound contains quadrivalent oxygen, and he also assumed that ozone has one or more quadrivalent oxygen atoms as illustrated in formulæ III to V ; J. W. Brühl favoured formula IV or V. Formula V is related to I in the symmetrical arrangement of its atoms. J. W. Brühl favoured IV, but gave no particularly strong evidence in its support. It will be observed that even though one atom in the ozone molecule appears to behave differently from the others, this does not prove a dissymmetrical molecule, for the trinity is possibly unstable because it is overloaded with atoms, and as soon as *any one* atom has been ejected, the remaining pair is stable. On this hypothesis the greater chemical activity of the odd oxygen atom is not due to its being oriented differently from the other two, but rather to the molecule containing one atom too many for stability.

There is no objection to the assumed quadrivalency of oxygen. In fact, it is highly probable that oxygen, like its companions—sulphur, selenium, and tellurium—in the periodic system can be bi-, quadri-, or sexi-valent. O. Wolkowicz[15] concludes that ozone has the constitution O=O=O, indicated in formula III, by analogy with sulphur dioxide O=S=O. This would make ozone the anhydride of ozonous acid, H_2O_4, analogous with sulphurous acid, H_2SO_3; and the so-called tetroxides —*e.g.* K_2O_4—analogous to the sulphites:

$\begin{matrix}O\\O\end{matrix}\!\gg O$

Ozone.

$\begin{matrix}O\\O\end{matrix}\!\gg O<\begin{matrix}K\\OK\end{matrix}$

Potassium ozonate.

$\begin{matrix}O\\O\end{matrix}\!\gg S$

Sulphur dioxide.

$\begin{matrix}O\\O\end{matrix}\!\gg S<\begin{matrix}K\\OK\end{matrix}$

Potassium sulphite.

Both series of salts reduce the permanganates. There is no decisive evidence in favour of any one formula for ozone. The question cannot be answered by far-fetched analogies, or by pen- and paper-abstractions. Accordingly, the graphic or structural formula for ozone is still *sub judice*.

The quadrivalency of oxygen.—The idea that oxygen may be quadrivalent was suggested by A. Naquet[16] in 1864 because of the analogy between oxygen and the elements of the sulphur family—sulphur, selenium, and tellurium—where the compounds SCl_4, $SeCl_4$, TeI_4, etc., show that these elements are quadrivalent. Two years later H. Buff applied the idea to hydrogen and barium dioxides, for he explained the composition of these compounds by the formulæ $H_2=O=O$ and $Ba=O=O$ respectively. A. W. Williamson (1869) suggested that oxygen is quadrivalent in carbon monoxide, $C\equiv O$; and about the same time, S. M. Jörgensen assumed that in virtue of the quadrivalency of oxygen in water, the H_2O-group can act as a bivalent radicle analogous to the bivalency of the NH_3-group—nitrogen quinquevalent. J. Thomsen (1873) also explained the constitution of periodic acid, by assuming that oxygen is quadrivalent, and S. M. Jörgensen's idea was employed by W. A. Tilden (1876) to explain the constitution of crystallized zinc sulphate, $ZnSO_4.7H_2O$; and by A. Wurtz (1879), the constitution of potassium magnesium sulphate, $K_2Mg(SO_4)_2$.

The investigation of C. Friedel,[17] in 1875, on the compounds of methyl ether, $(CH_3)_2O$, with hydrogen chloride, sulphur dioxide, SO_2, methyl iodide, CH_3I, established the existence of a series of compounds:

$\begin{matrix}CH_3\\CH_3\end{matrix}\!>O$

$\begin{matrix}CH_3\\CH_3\end{matrix}\!>O<\begin{matrix}H\\Cl\end{matrix}$

$\begin{matrix}CH_3\\CH_3\end{matrix}\!>O=S\ll\begin{matrix}O\\O\end{matrix}$

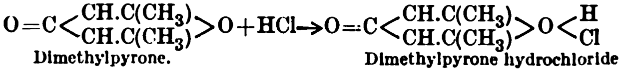
$\begin{matrix}CH_3\\CH_3\end{matrix}\!>O<\begin{matrix}CH_3\\I\end{matrix}$

in which it appears highly probable that in addition to the two ordinary valencies of oxygen, two others are wakened into activity. In an analogous manner, A. A. T. Cahours found that methyl sulphide, $(CH_3)_2S$, reacts with methyl iodide, CH_3I, to form a compound—trimethylsulphonium iodide with quadrivalent sulphur, $(CH_3)_2S.CH_3I$,

$\begin{matrix}CH_3\\CH_3\end{matrix}\!>S$

$\begin{matrix}CH_3\\CH_3\end{matrix}\!>S<\begin{matrix}CH_3\\I\end{matrix}$

The oxygen compounds are called **oxonium salts** on account of their analogy with **ammonium salts,** say ammonium chloride, H_4NCl, formed by the direct coupling of ammonia, NH_3, and hydrogen chloride, HCl. Instead of C. Friedel's formula for the hydrochloride, A. Wurtz suggested the alternative $(CH_3)_2O : Cl{\cdot}H$, where the oxygen is still quadrivalent and the chlorine tervalent. C. Friedel cited Rose's quadrantoxides, Ag_4O and Cu_4O, as further evidence of a quadrivalent oxygen. In 1888, J. F. Heyes,[18] like H. Buff, in 1866, argued that one of the oxygen atoms in the dioxides of barium, lead, manganese, etc., corresponds with quadrivalent oxygen, and he attributed the ready polymerization of the aldehydes, cyanates, and metaphosphates to the presence of oxygen potentially quadrivalent. J. F. Heyes also referred the formation of compounds with water of crystallization to the same cause. A great number of organic compounds have been discovered in which the most satisfactory formulæ are based on the quadrivalency of oxygen.[19] In 1899, J. N. Collie and T. Tickle[20] showed that hydrochloric acid unites with dimethylpyrone forming dimethylpyrone hydrochloride:



$$O{=}C{<}\begin{matrix}CH.C(CH_3)\\CH.C(CH_3)\end{matrix}{>}O+HCl\rightarrow O{=}C{<}\begin{matrix}CH.C(CH_3)\\CH.C(CH_3)\end{matrix}{>}O{<}\begin{matrix}H\\Cl\end{matrix}$$

Dimethylpyrone. Dimethylpyrone hydrochloride.

This compound acts as an easily dissociated salt of a strong base and a weak acid; it contains a quadrivalent oxygen atom which must play a similar part to that of the nitrogen atom in the salts of dimethylpyridone, and this quadrivalent oxygen

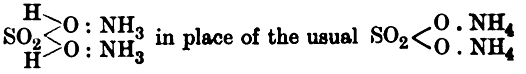
$$O{=}C{<}\begin{matrix}CH.C(CH_3)\\CH.C(CH_3)\end{matrix}{>}N{-}H$$

imparts a basic character to the salts in question. By analogy with ammonium, phosphonium, sulphonium, and iodonium bases, he supposed these salts to be derivatives of an hypothetical **oxonium hydroxide,** $H_3O.OH$. A. von Baeyer and V. Villiger (1901)[21] further argued that the simple oxygen atom, in every form in which it appears in organic chemistry, can form salts with the proper acids under suitable conditions. While a few oxygen compounds give well-characterized salts with the simpler acids, it is usually better and surer to work with the complex acids—*e.g.* hydroferricyanic, hydroferrocyanic, hydrocobalticyanic, phosphotungstic, chloroplatinic, or, above all, perchloric acid. In these salts there is usually little room for doubting the interpretation of their constitution based upon the quadrivalency of oxygen. The same influences which increase or diminish the basicity of nitrogen similarly affect the basicity of oxygen, and also, but to a limited extent, the basicity of sulphur:

NH_3, base	OH_2, neutral	SH_2, acid
$N(C_2H_5)_3$, strong base	$O(C_2H_5)_2$, weak, base unknown	$S(C_2H_5)_2$, neutral
$N(C_2H_5)_4$, OH, very strong base		$S(C_2H_5)_3OH$, base

The entrance of a positive alkyl radicle group renders the oxygen of neutral water basic although this is not the case with negative groups like phenyl, C_6H_5—*e.g.* in triphenylamine, $N(C_6H_5)_3$, the basic character of ammonia has virtually disappeared. Oxygen is an amphoteric element in that it can form both acids and bases. The base-forming qualities of oxygen are comparable with those of nitrogen, phosphorus, sulphur, and iodine, for when united with certain base-forming organic groups, the resulting compound has well-defined basic qualities. Oxygen has not so strong a tendency as nitrogen to pass from a lower to a higher valency.

When the tendency of oxygen to act as a quadrivalent element was generally recognized, and chemists ceased to be restricted to a bivalent oxygen, many compounds previously represented by graphic formula with oxygen bivalent were remodelled on the assumption of the higher valency. For example, following A. W. Williamson's suggestion that oxygen is quadrivalent in carbon monoxide, F. Goldschmidt (1904)[22] used the formula $R{-}C\equiv O{-}OH$ in place of $R{-}CO{-}OH$ for the organic acids and esters; and for ammonium sulphate, J. C. Cain (1904) used:



$$SO_2{<}\begin{matrix}{}^{H}{>}O:NH_3\\{}_{H}{>}O:NH_3\end{matrix}\text{ in place of the usual }SO_2{<}\begin{matrix}O.NH_4\\O.NH_4\end{matrix}$$

Ammonium hydroxide[23] is also regarded as a compound $H_3N:OH_2$ rather than the usual $H_4N.OH$.

E. H. Archibald and D. McIntosh (1904)[24] studied the compounds formed by the liquid hydrogen halides with ether or acetone, and assumed that the valency of oxygen increases as the temperature diminishes. While ethyl oxide, $(C_2H_5)_2O$, forms a compound $(C_2H_5)_2O.HI$ with hydrogen iodide, HI, analogous with the oxonium salts, where the oxygen is quadrivalent, they assume that oxygen is sexivalent in $C_3H_7OH.2HBr$, and dodecavalent in the compound $C_3H_7OH.5HCl$. There is here no reason for assuming these abnormally high valencies for oxygen if the halogen be taken tervalent. J. I. Kanonnikoff (1901) thought that the spectrometric constants of certain organic compounds containing oxygen better agreed with sexivalent oxygen than with either quadri- or bi-valent oxygen; and F. Flavitzky[25] used sexivalent oxygen atoms to explain the union of water of crystallization of a salt. If the tendency of water to crystallize in union with salts as water of crystallization is to be ascribed to the tendency of oxygen to pass from the bi- to the quadrivalent condition, other substances, built on the water type with bivalent oxygen, might be expected to act in a similar manner. Examples are common. Methyl alcohol, $CH_3.OH$, unites with calcium chloride as alcohol of crystallization to form $CaCl_2.4CH_3OH$. Similarly, the unsaturated character of the oxygen in water, H_2O, and of nitrogen in ammonia, NH_3, is employed to explain how ammonia and water are frequently interchangeable in chemical compounds; thus, $CuSO_4.5H_2O$ and $CuSO_4.5NH_3$, etc.

§ 8. The Modes of Formation and Preparation of Hydrogen Peroxide

At first sight hydrogen peroxide, H_2O_2, is related to water much as ozone is related to oxygen; while the latter can be regarded as oxidized oxygen, so the former can be regarded as oxidized water. Consequently, the term *eau oxygènée*, applied to this compound by its discoverer L. J. Thénard in 1818, is singularly appropriate. Just as ozone is obtained from oxygen by the expenditure of energy equivalent to 30 Cals. per gram-molecule of O_3, so is hydrogen peroxide formed from water by the expenditure of 21·5 Cals. per gram-molecule of H_2O_2. As in the case of ozone, the various methods of preparing hydrogen peroxide may be classed as physical or chemical—in the one case, energy is added in the form of heat, electricity, or ultra-violet radiations; and in the other case, energy is added indirectly or through the mediation of a chemical reaction.

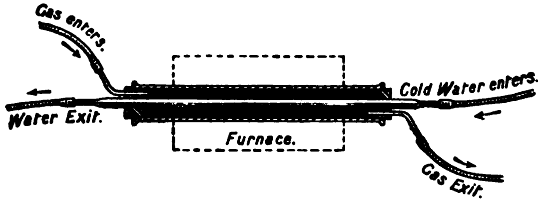

FIG. 12.—Deville's Tube Chaud et Froid.

(1) *The formation of hydrogen peroxide by the action of heat.*—Hydrogen peroxide can be formed by passing a current of moist oxygen through a tube at about 2000° and rapidly chilling the issuing gases. In **H. St. C. Deville's**[1] **hot and cold tube**—*tube chaud et froid*—method of conducting the experiment, a narrow silver or platinum tube is kept cool by a current of cold water. This tube is placed in the centre of a porcelain tube, Fig. 12. A current of gas is placed along the annular space between the two tubes. This arrangement is placed in a furnace so that the gas is heated to a very high temperature. The products of decomposition are suddenly chilled by the cold tube and partially prevented from recombining as they are carried out of the hot zone. The products of many high temperature reactions can thus be examined at ordinary temperatures. According to W. Nernst, the formation of hydrogen peroxide cannot be observed by passing a mixture of steam and oxygen through a hot platinum or iridium tube and cooling the products rapidly, presumably because of the extremely rapid rate of decomposition which W. Nernst found to be nearly the same as with ozone. The formation and decomposition of hydrogen peroxide is a balanced reaction $2H_2O+O_2 \rightleftharpoons 2H_2O_2$; and W. Nernst (1905) estimates that the percentage amount of hydrogen peroxide which can coexist in equilibrium with steam and oxygen under 0·1 atm. pressure, at different temperatures, is as follows:

Temperature . . .	650°	867°	1220°	1881°	2511°
Per cent. of hydrogen peroxide .	0·00036	0·0032	0·028	0·24	0·66

Hence, the rate of cooling must be exceedingly fast if hydrogen peroxide formed at a high temperature is to survive undecomposed. For example, W. Nernst prepared hydrogen peroxide by spraying water on to a glowing Nernst's filament, F. Fischer and O. Ringe made it by passing steam, at 40 mm. of mercury pressure, through a tube of fused magnesia nearly white hot. A large block tin condenser was placed as near as possible to the hottest zone. The condensed liquid contained 0·0045 per cent. of hydrogen peroxide. The magnesia tube was 0·6 mm. diameter, and the yield was very much reduced with tubes 0·3 mm. or 1·0 mm. diameter. F. Fischer and O. Ringe also obtained hydrogen peroxide by blowing steam from a sloping quartz capillary tube into a flame of hydrogen 4 to 6 cm. in height. The jet of steam, at 7 mm. pressure, was between 4 to 6 mm. from the flame, and so directed that the products were driven into the neck of a tin condenser. Although the condensation was incomplete owing to the velocity of the gaseous stream, 0·067 per cent. of hydrogen peroxide was found in the condensed liquid.

(2) *The formation of hydrogen peroxide by exposure to ultraviolet radiations.*—Water confined in a quartz vessel, permeable to ultraviolet rays, is decomposed by exposure to ultraviolet radiant energy furnished by a mercury lamp; hydrogen and hydrogen peroxide are formed: $2H_2O = H_2O_2 + H_2$; and, according to K. V. Charitschkoff,[2] hydrogen peroxide can be detected in water, with a little oxygen in solution, which has been exposed to bright sunlight at 9°–22° for 12 days; at 19°–31°, after 8 days; and at 20°–41°, after 7 days. If the oxygen be replaced by air, no hydrogen peroxide was observed. According to A. Tian (1915),[3] ultraviolet rays of short wave-length (λ2500–3000) decompose solutions of hydrogen peroxide at a measurable rate, but water is decomposed only by the rays in the extreme ultraviolet (less than λ1900). The water is decomposed in accord with the reversible reaction: $2H_2O = H_2O_2 + H_2$; the hydrogen peroxide is subsequently decomposed in accord with the equation $H_2O_2 = H_2O + O$; and after the lapse of sufficient time, the hydrogen and oxygen evolved by these two reactions are in the proportions which would occur if the water alone were directly decomposed into its elements. If the water contains dissolved oxygen it may unite with the hydrogen evolved in the primary reaction and form hydrogen peroxide, some of the dissolved oxygen forms ozone which in turn reacts with the hydrogen peroxide. No reaction between water and ozone has been observed under the influence of ultraviolet light. The conditions which favour the formation of hydrogen peroxide are (i) the use of ultraviolet light rich in rays of very short wave-length; (ii) the exposure of thin layers of water; and (iii) eliminating the conditions which favour the decomposition of hydrogen peroxide. Radioactive barium bromide produced a negative result in darkness, but a positive result in light, hence K. V. Charitschkoff assumes that it is not the radium emanation *per se* which produces the hydrogen peroxide, but that the radium salt acts as a catalytic agent.

(3) *The formation of hydrogen peroxide by electrolysis.*—The water which collects about the anode or positive electrode during the electrolysis of water acidulated with sulphuric acid possesses oxidizing properties which are usually attributed to the presence of hydrogen peroxide.[4] The formation of hydrogen peroxide by electrolysis is favoured by high acid concentration, low temperature, strong current, and small electrode surface. Its formation is prevented if the acid be dilute and the temperature exceeds 60°. According to M. Traube,[5] hydrogen peroxide is formed in small quantities at the cathode, not the anode, during the electrolysis of aqueous solutions, provided oxygen is bubbled about the cathode from which hydrogen is being evolved during the electrolysis of dilute sulphuric acid. If air or oxygen be carefully excluded from the cathode, no hydrogen peroxide is formed. According to M. Traube, this shows that hydrogen peroxide can be regarded as an intermediate product in the reduction of oxygen, where the end-product is water. Indeed, M. Traube draws the extraordinary conclusion that *hydrogen peroxide is always a product of the reduction of molecular oxygen, and is never produced by the oxidation of water.* M. Traube (1887) explains the formation of hydrogen peroxide by the electrolysis of water by assuming that the hydrogen liberated at the cathode immediately unites with the oxygen of the air to form the compound in question, and that this compound is reduced to water by the further action of hydrogen. F. Richarz,[6] on the contrary, shows that hydrogen peroxide is also formed at the anode, and assumes with M. Berthelot that persulphuric acid is primarily formed during the electrolysis of water acidulated with sulphuric acid, and hydrogen

peroxide is formed by the secondary reaction between the water and the acid. Persulphuric acid appears during the electrolysis of sulphuric acid more concentrated than $H_2SO_4.2H_2O$; and when this acid reacts with water, a certain amount of hydrogen peroxide is formed. According to M. Traube, if a plate of hydrogenized palladium be used as anode, the oxygen developed is absorbed without forming a trace of hydrogen peroxide.

(4) *The formation of hydrogen peroxide by the electric discharge.*—Although W. Nernst[7] failed to obtain hydrogen peroxide by passing a stream of electric sparks through a mixture of steam and oxygen, F. Fischer and O. Ringe found that hydrogen peroxide is formed under these conditions provided the stream of gas passes quickly enough to allow the escaping gases to be rapidly cooled. W. Nernst, however, did find that if electric sparks are passed through liquid water, hydrogen peroxide is formed, for the rate of cooling is then fast enough to prevent its complete decomposition.

When a mixture of hydrogen and oxygen is exposed to a brush electrical discharge, while the gas is passing through a U-tube cooled by liquid air, a yield of about 2·5 per cent. of hydrogen peroxide is obtained, but none is formed if the experiment be conducted at ordinary temperatures. The mixed gases must be under reduced pressure—say 3 cm. of mercury—to prevent explosion. At ordinary pressures when the mixed gases contain less than about 5 per cent. or more than 95 per cent. hydrogen, a yield of 87 per cent. has been obtained at the temperature of liquid air; and at 22°, a yield of 6·4 per cent. resulted. F. Fischer and O. Ringe obtained traces of hydrogen peroxide by subjecting steam to the brush discharge of an ozonizer at a temperature of 130°, so as to prevent the condensation of water within the instrument. Better results were obtained with a mixture of steam and oxygen or air. Hydrogen peroxide is also formed when the Tesla brush discharge,[8] or the discharge in an ozonizer, is passed through a mixture of oxygen and water vapour at pressures between 385 and 770 mm.; no hydrogen peroxide was observed with water vapour alone; and nitrogen oxides are simultaneously produced if moist air be used in place of moist oxygen. Hydrogen peroxide is also said to be formed by blowing moist air against a spark or arc discharge—this may be purely a temperature effect.

(5) *The formation of hydrogen peroxide during oxidation processes.*—Both hydrogen peroxide and ozone have been detected in the flame of burning hydrogen by O. Loew (1870) and by W. Manchot (1909). The latter considers that these substances do not take part in the processes of combustion, but are an effect of the high temperature of the flame. Hydrogen peroxide is produced during the explosion of hydrogen with an excess of oxygen,[9] and it has been recognized among the products of various types of combustion in air—*e.g.* hydrogen, carbon monoxide, cyanogen, etc.[10] Since the temperature of the hydrogen flame exceeds 2000°, it is natural to expect that this flame will contain appreciable amounts of hydrogen peroxide; and this was demonstrated by M. Traube, who allowed a jet of burning hydrogen to impinge on the surface of cold water in which ice was floating or on ice itself, and detected the hydrogen peroxide in the water. M. Traube thus obtained an aqueous solution containing 0·74 per cent. of hydrogen peroxide. This compound has also been reported in the water produced during the combustion of hydrogen in air; in the flames of alcohol, ether, coal gas, or carbon disulphide.

It might be asked why no trace of hydrogen peroxide was detected by F. Fischer and F. Brähmer (1906) in the products obtained when hydrogen, etc., is burned under liquid air (*vide supra*). It is supposed that the formation of ozone is preceded by the dissociation $O_2 \rightleftharpoons O+O$; that the speeds of formation of ozone and hydrogen peroxide are approximately equal, and therefore in the presence of a large excess of oxygen, more atoms of oxygen will be oxidized to ozone than water molecules to hydrogen peroxide; and further, that at the moment of cooling the ozone reacts with the relatively small quantity of hydrogen peroxide—$O_3+H_2O_2 \rightarrow H_2O+2O_2$. Hydrogen peroxide is formed when ozonized oxygen or air is passed through water on the surface of which a little ether floats. If a little water is placed in a beaker containing ether, and the latter is burnt by placing a spiral of hot platinum wire just over the surface of the liquid, hydrogen peroxide can be detected in the water after all the ether has burnt away. It is supposed that the ozone first produced forms a peroxide with the ether and that this is decomposed by the water forming ether and hydrogen peroxide. According to this view, the ether acts as a catalytic agent. K. V. Charitschkoff and M. Ambardanoff[11] reported the formation of hydrogen peroxide in water containing oxygen, during exposure to bright sunlight.[12]

According to A. Richardson, hydrogen peroxide is produced by exposing urine to direct sunlight, and also by exposing ether, amyl alcohol, and certain organic acids—*e.g.* oxalic acid—to sunlight. W. R. Dunstan and T. S. Dymond, however, were unable to detect hydrogen peroxide in pure ether—dry or moistened with water—after exposure to sunlight. Some specimens of less pure ether—*e.g.* methylated ether—did develop hydrogen peroxide in light. Hydrogen peroxide is also formed when turpentine or other oils containing terpenes are oxidized by air or ozone in the presence of water. C. T. Kingzett (1878) claims to have made a solution of hydrogen peroxide of 2-vol. strength in this way. Moist bone-black, when exposed to air and light, rapidly forms appreciable quantities of hydrogen peroxide.

Hydrogen peroxide is often formed when metals, and particularly their amalgams, are slowly oxidized in the presence of water—*e.g.* by shaking zinc amalgam with water—a better yield is said to be obtained if an alkaline earth be present. Hydrogen peroxide, says M. Traube (1893),[13] is formed only when the oxidation is effected by ordinary oxygen; oxidizing agents, other than ozone, do not give rise to this compound—*e.g.* hydrogen peroxide is obtained when finely divided zinc, magnesium, aluminium are shaken with water, but not if all traces of free oxygen are excluded. In 1859 E. von Gorup-Besanez[14] reported that an oxidizing substance, probably hydrogen peroxide, is formed during the evaporation of water, but N. Smith could detect this compound only when the evaporation took place in the presence of the metal zinc. When zinc, copper, or lead is shaken up with air and dilute sulphuric acid (1 : 55), the reactions symbolized: $Zn+2H_2O+O_2=Zn(OH)_2+H_2O_2$; and $Zn(OH)_2+H_2SO_4=ZnSO_4+2H_2O$ occur. It will be observed that twice as much oxygen is required for the oxidation process as is actually consumed in oxidizing the zinc: $Zn+O_2=ZnO+O$; $H_2O+O=H_2O_2$. One half of the oxygen is said to be used in the primary process and the other half in the secondary reaction. The reaction is a concurrent or side reaction, but since half a molecule of oxygen is used in each, the two concurrent reactions are not independent of one another. This particular type of reaction is known as **auto-oxidation.** There is a considerable difference of opinion as to the mechanism of auto-oxidation. The oxygen used in the secondary reaction—formation of hydrogen peroxide—is said to be " rendered active " by the primary reaction. The formation of ozone during the oxidation of phosphorus is another example. W. R. Dunstan, H. A. D. Jowett, and E. Goulding[15] consider that hydrogen peroxide is an intermediate stage in the rusting of iron.

In certain cases, if a substance undergoing slow oxidation at ordinary temperature be mixed with another substance which is not oxidized when alone, both substances are simultaneously oxidized. This phenomenon was noticed by C. F. Schönbein[16] in 1858. For example, (1) Ozone is formed during the oxidation of phosphorus; (ii) hydrogen peroxide is formed during the oxidation of zinc, lead, etc.; (iii) indigo blue is simultaneously oxidized to colourless isatin when benzaldehyde or turpentine is oxidized; sodium arsenite is likewise oxidized in the presence of oxidizing sodium sulphite, etc.

That part of the oxygen which unites with the substance undergoing oxidation is sometimes called **bound oxygen,** while the oxygen which is consumed in the formation of ozone, hydrogen peroxide, is called **active oxygen,** and the oxygen is said to be *activated* or *rendered active* during the process of oxidation. C. Engler calls the substance undergoing oxidation the *autoxidizer*, and the substance which unites simultaneously with the active oxygen, the *acceptor*.

C. F. Schönbein still further demonstrated that just so much oxygen is rendered active as is consumed by the oxidizing substance; or, in all slow oxidations the same amount of oxygen is required for the oxidation of the substance as is consumed in the formation of hydrogen peroxide from water, ozone from oxygen, etc. The hydrogen peroxide is generally decomposed into water and oxygen, so that an exact proof of the above deduction can be obtained only under favourable conditions.

C. F. Schönbein obtained a confirmation of the hypothesis by the slow oxidation of lead amalgam in the presence of dilute sulphuric acid. Almost the same amount of oxygen was rendered active in the form of hydrogen peroxide, as is used in the formation of lead sulphate. Similar results were obtained by M. Traube in the oxidation of zinc in the presence of water, whereby zinc hydroxide and hydrogen peroxide are formed in equi-molecular proportions. The reaction was symbolized:

$$Zn+\begin{matrix}HOH\\HOH\end{matrix}+\begin{matrix}O\\\ddot{O}\end{matrix}=Zn<\begin{matrix}OH\\OH\end{matrix}+\begin{matrix}HO\\HO\end{matrix}$$

C. F. Schönbein's observation has also been verified by J. H. van't Hoff, W. P. Jorissen, and by C. Engler and his co-workers.[17]

(6) *The formation of hydrogen peroxide in chemical reactions.*—If a peroxide, MO_2, be treated with such an acid that the base radicle is precipitated as a salt of the acid, hydrogen peroxide will remain in solution. For example, if concentrated sulphuric acid be allowed to react with barium peroxide, ozonized oxygen is evolved; if the acid is of moderate concentration, ordinary oxygen gas is evolved: $2BaO_2+2H_2SO_4=2BaSO_4+2H_2O+O_2$; while if dilute acid be used, hydrogen peroxide is formed: $BaO_2+H_2SO_4=BaSO_4+H_2O_2$. Barium peroxide is the usual starting point for the preparation of hydrogen peroxide; for example, in one process:

> Gradually add barium peroxide to ice-cold water through which a stream of carbon dioxide is passing. The insoluble barium carbonate is precipitated, and a dilute aqueous solution of hydrogen peroxide remains: $BaO_2+CO_2+H_2O=BaCO_3+H_2O_2$. If an excess of carbon dioxide be used, the yield of hydrogen peroxide is low and an insoluble barium percarbonate, $BaCO_4$, is precipitated.[18]

In the modifications of this process, the barium peroxide is mixed with a little ice-cold water and gradually added to ice-cold dilute hydrochloric,[19] sulphuric,[20] hydrofluosilicic acid,[21] hydrofluoric,[22] or phosphoric acid.[23] A barium salt—chloride, sulphate, fluosilicate, or phosphate—and hydrogen peroxide are formed. In the first case, the barium chloride is soluble. It can be removed by adding just sufficient silver sulphate to precipitate insoluble barium sulphate and silver chloride: $BaCl_2+Ag_2SO_4=BaSO_4+2AgCl$. This method is mainly of historical interest, because L. J. Thénard employed a similar process when he discovered hydrogen peroxide in 1818. The process with sulphuric acid, as employed by R. Wolffenstein, is as follows:

> Gradually add barium peroxide, suspended in a little water, to a mixture of equal volumes of water and sulphuric acid (cooled by a freezing mixture of ice and salt) until the solution is just barely acid. If too much barium peroxide has been added, a little more sulphuric acid is needed. Keep the solution in a freezing mixture for about a day. Filter off the insoluble matter, and evaporate the liquid on a water-bath, at about 70°, in a smooth platinum or porcelain basin until signs of effervescence appear. This will occur when the solution contains about 45 per cent. of hydrogen peroxide. Cool the solution quickly. Concentrated solutions soon decompose if they are not kept cold.

By treating a cold aqueous solution of sodium peroxide with dilute and cold hydrochloric acid, a solution of hydrogen peroxide in sodium chloride is obtained: $Na_2O_2+2HCl=2NaCl+H_2O_2$—hydrofluoric acid has been recommended in place of hydrochloric acid; and by treating potassium peroxide with tartaric acid in the cold, an aqueous solution of hydrogen peroxide contaminated with a little potassium tartrate is obtained. Most of the potassium tartrate separates from the cold solution. Hydrofluosilicic acid and potassium peroxide has been recommended.[24]

A. von Baeyer and V. Villiger, G. Adolph and A. Pietzsch, and L. Löwenstein found that if persulphates [25] be treated with dilute acids hydrogen peroxide is obtained; R. Wolffenstein and E. Merck used percarbonates; and F. Jaubert found that if a mixture of a perborate with an equivalent amount of a dry solid organic or inorganic acid, or an acid salt be moistened with water, hydrogen peroxide is formed. Hydrogen peroxide is prepared commercially from potassium persulphate or persulphuric acid.

The concentration of solutions of hydrogen peroxide.—The concentration of solutions of hydrogen peroxide has been effected in many ways. A 3 per cent. solution of hydrogen peroxide, which is free from alkaline compounds, from traces of salts of the heavy metals, and from suspended solids, can be concentrated on the water-bath at 75° to a 50·7 per cent. solution with a loss of about 36 per cent., and to a 66·6 per cent. solution with a loss of about 72 per cent. Further concentration by evaporation is impracticable because of the decomposition. The solution can also be further concentrated by evaporation over concentrated sulphuric acid **in vacuo,** or rather under reduced pressure until one volume of the liquid gives 475 volumes of oxygen gas.

By agitating the liquid with 10 to 12 times its volume of ether, decanting off the ethereal liquid, and removing the ether by evaporation on a water-bath, a 73·8 per cent. solution can be obtained from a 48 per cent. aqueous solution.[26] A. Houzeau concentrated dilute solutions by freezing out the water; and by this means M. Hanriot obtained a residual liquid such that one volume of liquid gave 70 volumes of oxygen.

The fractional distillation of hydrogen peroxide.—A solution of hydrogen peroxide decomposes rapidly when heated to 100°—even if the solution be dilute—hence, for a long time, the concentration of an aqueous solution of hydrogen peroxide by fractional distillation was thought to be impracticable. M. Hanriot (1885) concentrated the liquid by distillation under reduced pressure, and obtained a liquid of such a concentration that one volume furnished 267 volumes of oxygen. In 1894, R. Wolffenstein discovered that anhydrous hydrogen peroxide can be readily distilled under reduced pressure without undue decomposition; and it also can be distilled at temperatures below 85° in a very rapid stream of an inert gas. W. Spring observed a violent explosion in concentrating hydrogen peroxide by vacuum distillation.

The aqueous solution, containing about 45 per cent. of hydrogen peroxide, can be distilled under reduced pressure in the following manner. Fit up the apparatus indicated in Fig. 13. Transfer the solution to a round-bottomed, thick-walled litre flask *A*, fitted with a receiver *B*, and a thermometer *T* passing through a one-hole rubber stopper. The receiver *B* is placed over a funnel so that cold water can be sprayed on the receiver, and run off to the sink through rubber tubing attached to the stem of the funnel. The side neck of the receiver is connected, by pressure tubing, with a manometer; which in turn is connected with a 3-way stop-cock *E*, a water trap *G*, and a filter pump *D*. The flask *A* is heated by an oil bath *F*, and Bunsen's burner. When the manometer shows a pressure of about 15 mm. and the thermometer a temperature between 35° and 40°, a dilute aqueous solution of hydrogen peroxide in water distils into the receiver. The temperature rises gradually to about 70°, when a very concentrated solution of hydrogen peroxide remains in the distilling flask *A*. Further concentration is best effected by placing a beaker containing some of the hydrogen peroxide solution in a mixture of solid carbon dioxide and ether. The whole mass freezes. Drop a little of the frozen solid into a portion of the concentrated hydrogen peroxide solution. At between −8° to −10° small needle-shaped crystals separate. Drain away the mother liquid from the crystals; melt the crystals and cool the mass, so that another crop of crystals is obtained. Repeat the operations. The solution remaining in the distilling flask will serve for most experiments where concentrated solutions of hydrogen peroxide are required. If desired, it can be concentrated a little more by evaporation over sulphuric acid under reduced pressure.

Concentrated hydrogen peroxide begins to attack the glass distilling flask at about 80°. R. Wolffenstein, by fractional distillation, obtained a solution of 90 per cent. hydrogen peroxide at 81°–85° at 68 mm. pressure; and by repeatedly redistilling the product he got a liquid containing 99 per cent. of hydrogen peroxide and boiling at 84°–85° C. at 68 mm. pressure.

§ 9. The Physical Properties of Hydrogen Peroxide

Hydrogen peroxide is a viscid transparent liquid which does not wet solids so easily as water. In thick layers, it has a blue **colour**; and a metre long column has the same tint as a 1·8 metre long column of water. There is always a greenish tinge along with the blue, and W. Spring[1] attributes this to the presence of minute bubbles of oxygen. The **specific gravity** is 1·453, according to L. J. Thénard; 1·4996, according to W. Spring; and, according to J. W. Brühl,[2] 1·4584 at 0°, 1·4375 at 2°, and 1·4378 at 20°, referred to water at 4°. J. W. Brühl says that the specific gravity is *das scharfste Kriterium* of the purity and dryness since the smallest amount of water reduces the specific gravity in a marked degree, thus, the presence of 0·52 per cent. of water lowers the value of this constant to 1·4094 (0°); and a 45·9 per cent. solution, according to H. T. Calvert, has a specific gravity 1·144. I. Traube has investigated the molecular volume of hydrogen peroxide. The liquid has no smell; the vapour has a smell recalling that of nitric acid. Dilute solutions have a bitter metallic taste. When a drop of the liquid peroxide comes in contact with the skin, it forms a white blister. According to W. Spring, the **surface tension** of the liquid of specific gravity 1·4996 is 3·5374 (10°), when water at the same temperature has the value 7·750.

According to J. L. Thénard, the liquid does not freeze at 30°, but it freezes in a mixture of ether and solid carbon dioxide, and if a trace of the solid is put into the liquid cooled to —8° to —10°, transparent needle-like prisms are formed; the recrystallized peroxide has the **melting point** —2°; hydrogen peroxide evaporates slowly at ordinary temperatures and pressures, and he has studied the volatility of aqueous solutions of hydrogen peroxide at different temperatures. The **boiling point** of the anhydrous liquid at different pressures is

	21	29	33	38	44	47	68 mm.
Boiling point . .	62·8°	69·7°	73·7°	76·7°	79·7°	80·2°	84·85°

H. C. Jones, J. Barnes, and E. P. Hyde[3] have measured the lowering of the freezing points of solutions of various acids and salts in hydrogen peroxide and found this solvent to have a greater ionizing power than water, *vide infra*. The **specific heat** of hydrogen peroxide calculated[4] by W. Spring from the specific heat of the 34·25 per cent. solution is 0·6208—this number is to be regarded as an upper limit since other numbers are obtained with more dilute solutions.

M. Berthelot, J. Thomsen, and R. de Forcrand[5] have published thermochemical data for this compound, from which it follows that the **heat of formation** $H_2O_{liq.}+O_{gas}=H_2O_{2liq.}-22{\cdot}16$ Cals.; and $H_{2gas}+O_{2gas}=H_2O_{2liq.}+46{\cdot}84$ Cals. R. de Forcrand found that freshly distilled solutions of hydrogen peroxide with the composition and formula indicated below have the heats of solution:

Per cent. H_2O_2	35·31	42·66	55·16	65·38	85·93
$H_2O_2+nH_2O$, when $n=$.	3·46	2·53	1·54	1·00	0·3
Heats of solution . . .	0·071	0·093	0·099	0·310	0·403 Cal.

By extrapolation the **heat of solution** of the anhydrous peroxide: $H_2O_{2liq.}+Aq.=H_2O_{2solution}+0{\cdot}46$ Cal. The solution is distinctly acid; the **heat of neutralization** is 2·70 Cals.

The oxidation potential of the oxygen electrode is diminished by the addition of hydrogen peroxide. Attempts to measure the electrode potential by W. Nernst, F. Haber and S. Grinberg give material for calculating a value for the free energy of hydrogen peroxide, but, as with ozone, G. N. Lewis and M. Randall believe that there is no satisfactory evidence that the electromotive force is due to a single definite reversible reaction, and they calculated a value for the free energy from the dissociation pressure of barium dioxide and the equilibrium between hydrated barium dioxide and water. The **free energy** of the reaction $H_{2aq.}+O_{2aq.}=H_2O_{2aq.}$ at 298° K. is —30,970 cals. for the formation of the HO_2' ion on the assumption that hydrogen peroxide in solution is an acid which ionizes $H_2O_2=H^{\cdot}+HO_2'$; G. N. Lewis and M. Randall give $\frac{1}{2}H_2+O_2=HO_2'$; for the free energy of the reaction $H_2O_{2aq.}=H_2O_{liq.}+\frac{1}{2}O_2$, which measures the tendency of aqueous hydrogen peroxide to decompose, they give at 298° K. —25,650 cals. W. Nernst from e.m.f. measurements obtained —17,100 cals., a difference of 8500 cals. For the **heat of vaporization** $H_2O_{2liq.}=H_2O_{2gas}$, calculated from J. W. Brühl's and R. Wolffenstein's measurements of the vapour pressure of pure hydrogen peroxide, G. N. Lewis and M. Randall find 12,300 cals. per gram-molecule, or the free energy at 298° K. is 3500 cals. The same calculation makes the vapour pressure of hydrogen peroxide at 25° to be 2·1 mm.; the boiling point, 144°; and Trouton's constant, 29·5. This high value shows that hydrogen peroxide is a very abnormal liquid. If F. M. Raoult's laws of ideal solutions were followed by aqueous hydrogen peroxide, the vapour pressure of hydrogen peroxide would be $2{\cdot}1/56{\cdot}5=0{\cdot}037$ mm., but W. Nernst's distillation experiments give about one-fourth or one-fifth the value corresponding with F. M. Raoult's law. If this value be approximately 0·01 mm., the free energy of the reaction $H_2O_{2aq.}=H_2O_{2gas}$ at 298° K. is $RT\log(760/0{\cdot}01)=6700$ cals.; for $H_2+O_2=H_2O_{2liq.}$ at 298° K., —27,770 cals.; and for $H_2+O_2=H_2O_{2gas}$, at 298° K., —24,270 cals. From the heat of vaporization, and J. Thomsen's and R. de Forcrand's thermochemical data, the heat of the reaction at 291° K. is —32,600 cals.

G. N. Lewis and M. Randall assume that the thermal capacity of hydrogen peroxide may, as a first approximation, be taken as being the same as that of the tetratomic gas NH_3, and accordingly $C_p=7{\cdot}5+0{\cdot}0042T$; this in conjunction with $C_p=6{\cdot}5+0{\cdot}0009T$ for hydrogen, and $C_p=6{\cdot}5+0{\cdot}0010T$ for oxygen, gives the free energy of hydrogen peroxide, $H_2+O_2=H_2O_{2gas}$ as $-31{,}100+5{\cdot}5T\log T-0{\cdot}00115T^2-8{\cdot}08T$, when the integration constant is evaluated from the free energy at 291° K. From this equation it would appear to be impossible to obtain spontaneously appreciable amounts of hydrogen peroxide from the two elemental constituents at a temperature below 1000°. The free energy of the reaction $H_2O_{gas}+\frac{1}{2}O_2=H_2O_{2gas}$ was also found to be $26{,}310+4{\cdot}56T\log T-0{\cdot}0028T^2+0{\cdot}00000027T^3-11{\cdot}80T$. From this equation, the pressure of hydrogen peroxide in equilibrium with water vapour at atmospheric pressure is 10^{-7} atm. at 2000° K., and 3×10^{-6} atm. at 3000° K. The experiment of M. Traube in which a considerable yield of H_2O_2 is obtained by the rapid cooling of an oxyhydrogen flame cannot, therefore, be explained by assuming that H_2O_2 is largely present in the gases in the hottest portion of the oxyhydrogen flame. It must be explained rather by assuming that in the colder parts of the flame, probably between 500° and 1000° C., hydrogen and oxygen combine directly to form hydrogen peroxide.

Thermochemistry of hydrogen peroxide.—While the formation of a gram-molecule of liquid water from hydrogen and oxygen is attended by the *evolution* of 68·4 Cals., the oxidation of water to hydrogen peroxide in aqueous solution would be attended by an *absorption* of 23·1 Cals., and consequently, it is not to be expected that this compound will be formed during the combustion of hydrogen in oxygen—except possibly by arresting the reaction under special conditions on the assumption that hydrogen and oxygen first formed hydrogen peroxide as a transient intermediate product, before forming water. To prepare hydrogen peroxide an indirect process is employed. Oxygen unites with barium oxide with the evolution of 5·9 Cals. per molecule of barium peroxide, BaO_2, and this compound in turn is decomposed by hydrochloric acid with the evolution of 11·0 Cals. Again, in the remarkable reaction whereby hydrogen peroxide reacts with silver oxide forming water, silver, and oxygen, $H_2O_2+Ag_2O \rightarrow 2Ag+H_2O+O_2$, one school of chemists says that the attraction of oxygen atoms for one another in the two different compounds upsets the unstable silver oxide and hydrogen peroxide; but since the heat of formation of silver oxide is 3·5 Cals., and of hydrogen peroxide, 11·2 Cals., the reaction will evolve 7·7 Cals., an amount sufficient to account for the reaction apart from any alleged molecular attraction. Still further, the powerful oxidizing effects produced by hydrogen peroxide have been attributed to the effects of nascent oxygen in the atomic condition. There is no particular need for this assumption because, when hydrogen peroxide decomposes into water and oxygen: $2H_2O_2=2H_2O+O_2$ $+44·8$ Cals., the heat evolved by the reaction, if confined to the products of the reaction, would suffice to raise the temperature nearly 1000°, and this amply suffices to explain the marked oxidizing properties of hydrogen peroxide over those of oxygen. The superior oxidizing properties of ozone can be explained in a similar manner.

The **index of refraction**[6] (20·4°) is 1·40379 for the Li-line; 1·40421 for the H_α-line; 1·40624 for the Na-line; 1·41100 for the H_β-line; and 1·41494 for the H_γ-line. According to J. W. Brühl, the specific refraction by Lorentz and Lorenz's formula is 0·1708 for the H_α-line and 0·1742 for the H_γ-line; the specific dispersion is therefore 0·0039. According to P. Drude and H. T. Calvert, the **dielectric constant** of the anhydrous peroxide is 92·8 when the value for water is 81. This high value for the dielectric constant indicates that hydrogen peroxide is a very abnormal liquid. J. Dewar and J. A. Fleming investigated the effect of temperature on the dielectric constant. H. T. Calvert observed that hydrogen peroxide did not present the so-called anomalous electrical absorption.

L. J. Thénard found that when hydrogen peroxide is electrolyzed, it decomposes like water with hydrogen at the negative and oxygen at the positive pole, but the proportion of oxygen is much greater than with water. M. Berthelot, E. Schöne, M. Hanriot, and S. Tanatar found that with feeble currents and concentrated solutions, the hydrogen peroxide is reduced by the hydrogen at the cathode, and no gas is there given off, while oxygen is given off at the anode: $2H_2O_2=2H_2O+O_2$. The specific **electrical conductivity** of a 4·5 per cent. solution is $2·89\times10^8$. H. C. Jones, J. Barnes, and E. P. Hyde[7] could not determine the electrical conductivity of aqueous solutions because they could find no satisfactory material for the electrodes which would resist chemical action. H. C. Jones and his co-workers found that the *salts*, potassium chloride, sodium nitrate, potassium nitrate, etc., lower the freezing point of solutions of hydrogen peroxide less than they do water, possibly because of the formation of compounds analogous with $KF.H_2O_2$, $Na_2SO_4.9H_2O.H_2O_2$, etc., isolated by S. Tanatar; while *acids*, like sulphuric, oxalic, or acetic acid, lower the freezing point of solutions of hydrogen peroxide more than they do water, presumably because hydrogen peroxide has a stronger ionizing power than water. The action of *bases* on hydrogen peroxide, studied by G. Bredig and H. T. Calvert, is analogous with the action of an acid on a base, for peroxides are formed: $2NaOH+3H_2O_2=Na_2O_4+4H_2O$, and it therefore follows that hydrogen peroxide has acid properties; indeed, G. Carrara and A. Bringhenti believe that it is a monobasic acid which ionizes in solution $H_2O_2 \rightleftharpoons H^{\cdot}+HO_2'$.

Solubility.—Hydrogen peroxide dissolves in *water* in all proportions. According to J. W. Brühl, it is insoluble in *petroleum ether*,[8] and exerts no chemical action on that menstruum. When aqueous solutions are shaken out repeatedly with ether much of the hydrogen peroxide can be extracted. An ethereal solution of hydrogen peroxide is more stable than the aqueous solution. The strength of aqueous solutions is represented commercially by the number of volumes of oxygen which 100 c.c. of the solution will furnish on decomposition. Thus 100 c.c. of a real 10-*volume solution* should give 10 times its own volume of oxygen when decomposed; as a matter of fact, a 3 per cent. solution of hydrogen peroxide by weight is very nearly a 10-volume solution; a 5 per cent. hydrogen peroxide solution is nearly 20-volume strength, and so on. The most concentrated solution on the market is called *perhydrol*, and it contains about 30 per cent. of hydrogen peroxide corresponding with a concentration of 100 volumes. There is some ambiguity in this mode of expressing the concentration of the solutions, because if the solution be decomposed by potassium permanganate, $2KMnO_4+5H_2O_2+3H_2SO_4=5O_2+2MnSO_4+K_2SO_4+8H_2O$, half the oxygen comes from the permanganate, and in that sense, a 10-volume solution would furnish but five volumes of oxygen derived from the peroxide, and five from the permanganate. In addition to perhydrol, there is also on the market a 3 per cent. solution intended for general purposes, and a purer 3 per cent. solution for medicinal purposes. Besides, there is the so-called *solid hydrogen peroxide*—known in commerce as *hyperol*—a white crystalline product containing equimolecular parts of urea and hydrogen peroxide, which is made[9] by dissolving urea in perhydrol; it furnishes a solution of hydrogen peroxide when treated with citric or other acids.

The **coefficient of distribution** between water and *ether* at 17·5° is, according to K. Osikoff and S. Popoff,

Volume of ether : volume of water	0·5	1	2	5	7	9	10
Con. in ether · Conc. in water .	0·0575	0·0596	0·050	0·060	0·074	0·070	0·072

The presence of sodium chloride has no influence on the coefficient, but sodium and potassium carbonates lower the solubility of the peroxide in ether.[10] Hydrogen peroxide is soluble in many organic solvents.[11] The partition coefficient (concentration in solvent: concentration in water) for *ethyl acetate* is 1:215; *nitrobenzene*, 1:200; *acetophenone*, 7:4; *amyl acetate*, 1:8; *ethyl isovalerianate*, 1:40; *isoamyl propionate*, 1:12; *chloroform*, 1:600; *benzene*, 1:200; *isobutyl alcohol*, 1:3; *propyl formate*, 1:8; *isobutyl butyrate*, 1:50; *propyl butyrate*, 1:30; *phenol* (25°), 1:45; *aniline* (25°), 1:4; and *quinoline* (25°), 1:0·276. Quinoline is thus a very good solvent for hydrogen peroxide, and when equal volumes of quinoline and an aqueous solution are agitated together, the quinoline layer contains more than half the peroxide.

§ 10. Quantitative Application of the Law of Mass Action

> Chemical phenomena must be treated as if they were problems in mechanics.—L. MEYER (1868).

I. Kant[1] has said that in every department of physical science there is only so much science as there is mathematics; and as our knowledge of natural phenomena grows more clear and precise, so does it become more and more possible to employ mathematical methods. Owing to the absence of all mathematical treatment in chemical phenomena in his time, I. Kant denied to chemistry the name of science.

The most simple type of chemical reaction is one in which individual molecules are involved in the change; more complex reactions are concerned with the mutual action of two or more molecules. For example, in the decomposition of nickel carbonyl, $Ni(CO)_4 \rightarrow Ni + 4CO$, the individual molecules of nickel carbonyl are independently concerned in the change—this type of reaction is called a *unimolecular reaction*; with a reaction of the type, $H_2O + COCl_2 \rightarrow 2HCl + CO_2$, the mutual action of two molecules is necessary for the reaction, and this is accordingly called a *bimolecular reaction*; and in the formation of ozone, $3O_2 \rightarrow 2O_3$, the mutual action of three molecules of oxygen is necessary and this is accordingly called a *termolecular reaction*. The back reaction, in the preceding bimolecular reaction, is $CO_2 + 2HCl \rightarrow COCl_2 + H_2O$, which is a termolecular reaction. The terms uni-, bi-, ter-, and multi-molecular, or what is equivalent, mono-, di-, tri-, poly-molecular reaction, were introduced by J. H. van't Hoff[2] to indicate the number of molecules concerned in a reaction. Reactions involving more than two molecules are not very common. This is easily understood if we assume that bimolecular reactions are caused by the collision of two molecules, termolecular reactions by the simultaneous collision of three molecules, etc. The probability of a simultaneous collision between three molecules is very much less than between two molecules, and the greater the number of molecules taking part in a given transformation, the more likely is the reaction to proceed by some other path than by the simultaneous collision of a large number of reacting molecules.

The decomposition of hydrogen peroxide in light.—A solution of hydrogen peroxide decomposes when it is exposed in a quartz vessel to the rays of light from a mercury lamp. The decomposition ceases when the light is extinguished. If the amounts of hydrogen peroxide in the solution exposed for various periods of time be determined, the rate of decomposition can be calculated. It is found that if a represents the initial concentration of the solution expressed in gram-molecules per litre, and x the amount decomposed at the time t, the solution will then contain $a-x$ gram-molecules of the compound in question. Let L. Wilhelmy's hypothesis, *op. cit.*, be now tested. The velocity of the reaction at any time t must be equal to $k(a-x)$. If the symbol dx be employed to denote the amount of peroxide decomposed in the minute interval of time dt, the velocity of the reaction, the amount of substance decomposed in unit time, at the moment t, will be represented by

$$\frac{dx}{dt}=k(a-x)\,;\quad \therefore\ \frac{1}{t}\log\frac{a}{a-x}=k \quad . \quad . \quad . \quad (1)$$

The passage from the equation on the left to that on the right involves a very simple mathematical operation. The expression $a\div t(a-x)$ measured at different intervals of time must be a constant, k, if the reaction progresses so that only *one molecule* of hydrogen peroxide is concerned in the process $H_2O_2 \rightarrow H_2O+O$. Selecting a few measurements by J. H. Mathews and H. A. Curtis (1914),[3] we get

Time (t)	0	100	160	220	310	432
H_2O_2 per cent. (x) . . .	1·58	1·06	0·83	0·63	0·44	0·26
k	0·0040	0·0041	0·0042	0·0041	—	0·0042

The values of k are computed by the substitution of $a=1{\cdot}58$, and the corresponding values of x and t in the second of the above equations. The constancy of the different values of k is quite consistent with the hypothesis. However, suppose that the decomposition were to be represented by the usual equation, $2H_2O_2 \rightarrow 2H_2O+O_2$, implying that *two molecules* of hydrogen peroxide mutually react producing water and oxygen molecules. Then the velocity of the reaction must be represented by

$$\frac{dx}{dt}=k_1(a-x)(a-x)\,;\quad \therefore\ \frac{1}{t}\cdot\frac{x}{a(a-x)}=k_1 \quad . \quad . \quad . \quad (2)$$

With the same data as before, the values of k_1 are no longer even approximately constant. Hence, it is inferred that the decomposition of hydrogen peroxide in light is a unimolecular reaction, $H_2O_2 \rightarrow H_2O+O$, and not really a bimolecular reaction, $2H_2O_2 \rightarrow 2H_2O+O_2$, even though the last-named equation is conventionally used to represent the process in order that attention may be focussed on the initial and end products of the reaction. The unimolecular reaction is slow enough to be readily measured. The atoms of oxygen from two different molecules of hydrogen peroxide unite to form molecular oxygen, $O+O=O_2$, far too quickly to influence the measurement of the unimolecular change. This may be illustrated[4] by the following analogy :

> The time occupied in the transmission of a telegraphic message depends both on the rate of transmission along the conducting wire, and on the rate of progress of the messenger who delivers the telegram ; but it is obviously this last slower rate that is of really practical importance in determining the time of transmission.

Hence the following rule : *If a chemical reaction takes place in two stages, one of which is considerably faster than the other, the observed order of the whole reaction will be determined by the order of slower change.*

The decomposition of hydrogen peroxide in contact with platinum.—It has been found by G. Bredig and M. von Berneck (1900)[5] that while the catalytic decomposition of dilute solutions of hydrogen peroxide—say below $\frac{1}{50}$th gram-molecule per litre—by colloidal platinum is undoubtedly unimolecular, $H_2O_2 \rightarrow H_2O+O$, more concentrated solutions—say above the ½ gram-molecule per litre—decompose bimolecularly, $2H_2O_2 \rightarrow 2H_2O+O_2$; and that with intermediate concentrations, both types of reaction prevail. For instance, with a concentration of 0·0034 gram-molecule of hydrogen peroxide per litre, G. Dyer and A. B. Dale (1913)[6] find the following values of the constant k :

Unimolecular reaction . .	0·014	0·016	0·015	0·013	0·015	0·015
Bimolecular reaction . .	0·0036	0·0047	0·0048	0·0052	0·0073	0·0090

The constancy of the values of k in the first case is satisfactory, but not in the second case. Hence it is inferred that the decomposition of hydrogen peroxide by colloidal platinum is a uni- not a bi-molecular reaction. Again, with a concentration of 0·145 gram-molecules of hydrogen peroxide per litre, the values of the constant k are :

Unimolecular reaction . .	0·0075	0·0068	0·0062	0·0057	0·0051	0·0054
Bimolecular reaction . .	0·0015	0·0015	0·0015	0·0015	0·0014	0·0016

Here the fluctuations in the value of the so-called constant show that the decomposition of the hydrogen peroxide is undoubtedly a bi- and not a uni-molecular process. The decomposition of hydrogen peroxide by heat similarly follows the bimolecular law. To summarize, the decomposition of hydrogen peroxide in light, and when stimulated by colloidal platinum in dilute solutions, is a unimolecular process ; and when decomposed by heat, or by colloidal platinum in concentrated solutions, it is a bimolecular process. It has also been found that the velocity of the photochemical decomposition of hydrogen peroxide is proportional to the radiant energy absorbed. The energy absorbed during the decomposition of a gram-molecule of hydrogen peroxide is nearly equal to that given out by the decomposition of the substance in darkness.

The decomposition of steam by red-hot iron.—Let the method just developed be applied to the reaction of steam on red-hot iron previously described ; and let C_0, C_1, C_2, C_3 respectively denote the concentrations of the iron, steam, hydrogen, and iron oxide at any time t.

$$\underset{C_0}{3\mathrm{Fe}}+\underset{C_1}{4\mathrm{H_2O}}=\underset{C_2}{4\mathrm{H_2}}+\underset{C_3}{\mathrm{Fe_3O_4}}$$

From Guldberg and Waage's law, the velocity of the decomposition of steam will be proportional to the product of the concentrations of each of the reacting molecules. There are presumably three molecules of iron and four of steam. Hence, the velocity of the decomposition of steam$=kC_0{}^3C_1{}^4$; and, similarly, the velocity of the oxidation of hydrogen$=k'C_2{}^4C_3$. The condition of equilibrium when these two velocities are equal must therefore be $kC_0{}^3C_1{}^4=k'C_2{}^4C_3$. The condition of equilibrium, however, is independent of the concentrations of the two solids ; and hence, $kC_0{}^3$ must be a constant number, say k_1 ; and likewise, $k'C_3$ must be another constant number, say k_2. The condition of equilibrium can accordingly be written $k_1C_1{}^4=k_2C_2{}^4$. The concentrations of the two gases, hydrogen and steam, must be proportional to their partial pressures p_1 and p_2 respectively. Accordingly, the preceding equation can be written :

$$\frac{p_1}{p_2}=\text{Constant}$$

since the fourth root of a constant is itself constant. In an experiment by G. Preuner (1904),[7] at 200°, when the partial pressure of steam p_1 was 4·6 mm. of mercury, that of hydrogen was 95·9. Hence, the value of the constant is nearly 0·048. In another experiment at the same temperature, the partial pressure of hydrogen p_1 was 195·3, then that of steam p_2 must have been $0·048\times195·3=9·3$—the observed value was 9·7. The value of the constant at 440° was 0·176 ; at 900°, 0·69 ; at 1025°, 0·78 ; and at 1150°, 0·86, showing that the ratio of steam : hydrogen approaches unity with a rise of temperature.

Examples.—(1) If p_1 denotes the partial pressure of steam, p_2 that of hydrogen, and p_3 that of oxygen, show that if k is a constant, then, for the reaction $2H_2O\rightleftharpoons2H_2+O_2$, $p_2{}^2p_3=kp_1{}^2$.

(2) When barium peroxide is heated, it decomposes : $2BaO_2\rightleftharpoons2BaO+O_2$. Show that for any given temperature, $p=$constant, where p denotes the partial pressure of oxygen.

§ 11. The Chemical Properties of Hydrogen Peroxide

Solutions of hydrogen peroxide are not very stable, and readily decompose into oxygen and water. Similar remarks apply to the anhydrous peroxide. If the liquids are free from other substances they are moderately stable at ordinary temperatures. J. W. Brühl[1] found that after anhydrous peroxide had been kept 50 days protected from atmospheric dust, it had lost only one-half per cent. of peroxide by decomposition. According to R. Wolffenstein, aqueous solutions keep very well if they are free from alkaline substances, salts of the heavy metals, and from particles of alumina and silica. R. Böttger, M. Berthelot, and P. Sabatier found that the presence of acids increases the stability of aqueous solutions. A 3 per cent. solution suffered no appreciable change after it had been kept for a year. The fact was well known to L. J. Thénard, who considered that the acid combines chemically with hydrogen peroxide. He said:

> With phosphoric, sulphuric, hydrochloric, hydrofluoric, nitric, oxalic, citric, and acetic acids hydrogen peroxide forms compounds in which it is less easily decomposable than when alone. In these compounds, the acid was at first regarded as existing in a higher state of oxidation. The comparatively weak carbonic and boracic acids do not give stability to peroxide of hydrogen. . . . The evolution of oxygen gas from these mixtures takes place less easily and more slowly than from the pure peroxide of hydrogen; but when the acid is neutralized by an alkali, the former facility of decomposition is restored. The greater the quantity of acid mixed with the peroxide, the more does the affinity of the acid for that compound interfere with its decomposition by elevation of temperature, or by contact with most of the bodies mentioned below. If any of the acids just enumerated be added to hydrogen peroxide which has begun to evolve gas, the escape of gas ceases; it recommences at a higher temperature, but the whole of the oxygen is not driven off, even by half an hour's boiling. It is remarkable that although gold decomposes the pure peroxide much more rapidly than bismuth does, yet the quantity of acid required to stop the action of the gold is smaller than that which must be added to prevent the action of the bismuth. Hydrogen peroxide brought into a state of effervescence by gold, palladium, or rhodium, is restored to tranquillity by the addition of a single drop of dilute sulphuric acid.

L. J. Thénard also knew that alkaline solutions do not keep very well. G. Lemoine attributes the retarding effects of acids to their affinity for water which counteracts the catalytic action of the water; he attributes the accelerating effects of the caustic alkalies to the cyclic formation and decomposition of alkali peroxides. Hydrogen peroxide solutions corrode glass vessels faster than water, and the liquid becomes alkaline. Hydrogen peroxide is for preference kept in paraffin or paraffin-lined glass bottles, or in quartz-glass vessels. The rate of decomposition of solutions of hydrogen peroxide prepared with ordinary tap-water is said by W. Clayton to be fifty times the rate with highly purified water.

A little platinum black dropped into the solution may cause an explosion; in any case, it causes rapid decomposition. Similar remarks apply to finely divided gold, silver, and similar metals, as well as to powdered manganese dioxide. The action appears to be catalytic since the manganese dioxide, etc., remains at the end of the action unchanged in composition.[2]

J. L. Thénard's classical observations on the action of various substances on *eau oxygénée* are worth quoting:

> Substances which induce the evolution of oxygen without themselves undergoing any alteration:—A violent action occurs with charcoal (forming carbon dioxide), silver, gold, platinum, palladium, rhodium, iridium, and osmium. The action is the more vigorous

the finer the state of subdivision of the metal. A moderate action occurs with mercury, lead filings, powdered bismuth, and powdered manganese. The action is slight with copper, nickel, cobalt, and cadmium. A violent reaction occurs with manganese dioxide, manganese and cobalt sesquioxides, and lead monoxide. The reaction is moderate with ferric, potassium, sodium, magnesium, and nickel hydroxides. The reaction is mild with ferric, nickel, copper, bismuth and magnesium oxides; and feeble with the magnetic oxide of iron, and with uranium, titanium, cerium, and zinc oxides, and the hydrated dioxides of calcium, strontium, and barium. The reaction is very feeble with sodium carbonate, potassium hydrogen carbonate, manganous, zinc, ferrous, and copper sulphates; with potassium, sodium, barium, calcium, antimony, ammonium, and manganous chlorides; and with manganous, copper, mercurous, and silver nitrates. The fibrin of blood acts violently.

Substances which induce the evolution of oxygen but at the same time give up their own oxygen by reduction:—The oxides of platinum, gold, silver, and mercury are reduced to the metallic state; lead dioxide and red lead are reduced to lead monoxide. The action is in all cases violent.

Substances which allow some of the oxygen of the peroxide to escape as a gas and themselves absorb the remainder of the gas to form oxides:—Examples are—selenium forms selenic acid; arsenic or arsenious oxide forms arsenic acid; molybdenum, molybdic acid; tungsten, tungstic acid; and chromium, chromic acid. The metals potassium and sodium are violently oxidized; zinc forms zinc oxide; barium hydroxide forms barium dioxide; copper oxide forms a yellow peroxide; manganic oxide forms manganese dioxide; cobalt and iron monoxides form sesquioxides. The sulphides of arsenic, molybdenum, antimony, lead, iron, and copper are vigorously oxidized to sulphates; bismuth and stannic sulphides are slowly converted into sulphates; mercury and silver sulphides are not oxidized; and barium iodide probably forms the iodate.

The following oxides take the whole of the oxygen they require from hydrogen peroxide without liberating any gas—sulphur dioxide forms the trioxide; hydrosulphuric acid gives water, sulphur, and a little sulphuric acid; hydriodic acid forms iodine and water; the peroxides are precipitated from lime, strontia, or baryta water; and stannous oxide forms stannic oxide.

No action was observed with antimony; tellurium; tin; iron; alumina; silica; tungstic acid; chromium sesquioxide; antimonious and antimonic oxides; stannic oxide; sodium phosphate; potassium, sodium, calcium, barium, or strontium sulphate; alum; turbite; potassium chlorate; potassium, sodium, barium, strontium, or lead nitrate; zinc, stannic, or mercuric chloride; white of egg—liquid or coagulated; glue; and urea.

Hydrogen peroxide is not decomposed perceptibly faster with organic substances like potassium oxalate or acetate, alcohol, camphor, olive oil, sandarac, woody fibre, starch, gum, sugar, mannite, and indigo than when it is alone, but in some cases, the gas evolved is mixed with carbon dioxide—*e.g.* with starch or sugar.

J. H. Walton and D. O. Jones[3] found that the metal salts which catalytically decompose hydrogen peroxide in aqueous solutions, act similarly if amyl alcohol, amyl acetate, isobutyl alcohol, or quinoline be substituted for water. The reaction with manganese acetate in a solution of quinoline with 2 per cent. of water is bimolecular, and unimolecular if the quinoline be saturated with water. A small trace of some of the extremely finely divided metals—colloidal platinum, colloidal gold, etc.—can accelerate the decomposition of an indefinitely large amount of the peroxide. The action, though different, has been compared with that of yeast on a solution of sugar, and these colloidal metal solutions have been styled **inorganic ferments.** According to G. Bredig, a gram-atom of *colloidal platinum* diluted to approximately 70 million litres, can distinctly accelerate the decomposition of more than a million times this amount of hydrogen peroxide. The reaction in neutral and acid solutions is unimolecular, and is irreversible and complete, $H_2O_2=H_2O+O$, not $2H_2O_2=2H_2O+O_2$; with organic ferments, the reactions are not usually complete. Under similar circumstances, in alkaline solutions, one gram-atom of colloidal manganese diluted to 10,000,000 litres; colloidal cobalt or copper to one million litres; and colloidal lead to 100,000 litres, can act in a similar way; since their action is more or less retarded or paralyzed by traces of certain other substances, so that the inorganic ferments are said to be **poisoned** by these agents.[4] The catalysis of hydrogen peroxide by colloidal platinum, and the poisoning of the catalyst has been studied by G. Bredig and his co-workers, J. H. Kastle and A. S. Loevenhart, E. H. Neilson and O. H. Brown, etc. The following act as poisons in retarding the activity of colloidal platinum: arsine, phosphine, phosphorus, carbon disulphide, mercuric chloride, sulphide, or cyanide; hydrocyanic acid; cyanogen iodide; bromine; iodine; hydrogen sulphide; sodium thiosulphate, nitrate, and sulphite; carbon monoxide; aniline; hydroxylamine; hydrochloric acid; oxalic acid; arsenious acid; phosphorous acid; nitrous acid; hydrofluoric acid; amyl nitrite; pyrogallol; nitrobenzene; and ammonium chloride and fluoride. The decomposition is accelerated by hydrazine, dilute nitric acid, and formic acid; and it is not affected by potassium chlorate, ethyl alcohol, amyl alcohol, ether, glycerol, turpentine, and chloroform. G. Phragmén studied the effect of sodium phosphate and of the hydroxide on the decomposition of hydrogen peroxide.

G. Bredig and W. Reinders investigated the influence of *colloidal gold* on the decomposition of hydrogen peroxide in alkaline solutions, and the poisoning of the catalytic agent by potassium chloride, sodium phosphate, potassium cyanide, sodium sulphide, thiosulphate, and sulphite. Mercuric chloride stimulates the activity of the catalyst probably because that salt is reduced to colloidal mercury, which itself acts catalytically. In feebly alkaline solutions, the effect of 0·0003 mgrm. of colloidal gold is perceptible per c.c. of solution. G. Bredig and his co-workers have investigated the action of *colloidal palladium* under similar conditions. The catalytic agent is activated by hydrogen. Hydrogen cyanide, hydrogen sulphide, arsine, iodine, and mercuric chloride act as poisons; while carbon monoxide acts first as a positive and then as a negative catalyst. G. A. Brossa investigated the catalytic action of *colloidal iridium;* F. Ageno, *colloidal boron;* and G. Bredig and A. Marck, *colloidal manganese dioxide.* C. Doelter investigated the effect of a number of *minerals;* G. Lemoine, the effect of *wood charcoal;* and E. B. Spaer, the effect of *pressure* on the decomposition of hydrogen peroxide.

The decomposition of hydrogen peroxide by *blood, hæmoglobin, animal* or *plant extracts*, etc., has been studied by A. Béchamp, G. Senter, etc.[5] F. L. Usher and J. H. Priestley, A. Heffter, J. Dewitz, K. Togami, and E. J. Lesser[6] have studied the catalysis of *enzymes;* A. Bach, by yeast *catalase;* H. van Laer, by *diastase;* A. Renard, by *milk;* and J. J. Ford, by *starch.* In a general way, the agents which retard the activity of colloidal platinum also retard the activity of protoplasmic catalysts, but not all those which retard the activity of the latter interfere with the activity of the former.

Charcoal or magnesium mixed with a trace of manganese dioxide ignites immediately in contact with hydrogen peroxide. With finely powdered iron or lead, hydrogen peroxide remains quiescent, but if a trace of manganese dioxide be present, the iron burns. A few drops of liquid hydrogen peroxide on a piece of cotton wool will make the cotton inflame, although the peroxide can be filtered through gun-cotton. Similar results are obtained with aqueous solutions of hydrogen peroxide, but the action is much less vigorous. Rough surfaces have a disturbing effect on the stability of hydrogen peroxide—a concentrated solution is decomposed when poured on a ground-glass surface. W. Clayton (1916) considers that the chief factor in the decomposition of aqueous solutions of hydrogen peroxide is colloidal organic matter; he doubts if the nature of the surface of the vessel is really so active as is generally supposed; and he further attributes the observed effects to variations in the amount of colloidal organic matter which is present. The presence of small quantities of some substances[7]—*e.g.* alcohol, glycerol, ether, naphthalene, sodium pyrophosphate, oxalic acid, pyrogallol, acetanilide (1 : 2000); magnesium silicate; etc.—act as preservatives and make the solutions more stable, and these agents have been called **anticatalysts** or **negative catalysts.** The use of many of these preservatives has been patented. The use of sodium or calcium chloride as a preservative is preferred to sulphuric or phosphoric acid for medicinal hydrogen peroxide.[8] Light is a factor in the decomposition of hydrogen peroxide; an eight per cent. solution was decomposed completely after ten months' exposure, while a similar solution in darkness was but little affected.[9] H. Thiele found that exposure to ultraviolet light from a mercury lamp hastened the decomposition.[10] H. A. Curtis also showed that the oxidizing power of hydrogen peroxide, as manifested in bleaching dyes, is hastened in a similar manner. The effect cannot be duplicated by substituting oxygen for hydrogen peroxide so that the result is not due to the formation of ozone. The presence of radium bromide increases the speed of decomposition of the peroxide.[11] The compound is also decomposed when heated.

The chemical reactions with hydrogen peroxide fall into five types:

(1) The hydrogen peroxide is decomposed and the second compound is *reduced*. With permanganates, for example, both substances are simultaneously reduced, and the resulting oxygen comes from both the permanganate and the peroxide.

(2) The hydrogen peroxide is decomposed, and the second compound is *oxidized* by the oxygen derived from the peroxide, as was the case with ozone. Sulphur dioxide, for instance, changes into sulphuric acid. There are numerous other similar oxidations.

(3) Certain acids form special addition products with the hydrogen peroxide, thus sulphuric acid gives persulphuric acid; molybdic acid, permolybdic acid; chromic acid, perchromic acid; etc.

(4) Certain bases may react by double decomposition whereby the hydrogen or part of the hydrogen of the peroxide is replaced by a metal. In this case, the hydrogen peroxide has the character of an acid.

(5) Hydrogen peroxide unites with many organic and inorganic salts much in the way of water of crystallization, and it is then called hydrogen peroxide of crystallization,[12] *e.g.* $NH_4CrO_5.H_2O_2$; $(NH_4)_2SO_4.H_2O_2$.

H. A. Curtis has shown that the oxidizing power of hydrogen peroxide, as manifested in the bleaching of dyes, is increased by exposing the reaction mixture to light of short wave-lengths. This effect cannot be duplicated by substituting oxygen for hydrogen peroxide in the reaction mixture, indicating that the result is not due to formation of ozone.

Concentrated solutions of hydrogen peroxide in **water** form [13] a crystalline **monohydrate,** $H_2O_2.H_2O$, and **dihydrate,** $H_2O_2.2H_2O$. For the action of ozone on hydrogen peroxide, *vide* ozone.

The halogens, **chlorine, bromine,** and iodine, act slightly on hydrogen peroxide solutions producing the haloid acids and oxygen,[14] *e.g.* E. Schöne gives with chlorine, $H_2O.O+OH_2+Cl_2=2HCl+O_2+H_2O$; or $H_2O_2+Cl_2=2HCl+O_2$. C. F. Schönbein found that bromine gives oxygen, and hydrogen bromide. **Iodine,** in the presence of alkali carbonates, is transformed into hydrogen iodide. E. Lenssen found that **hydrogen chloride** gives oxygen and the free halogen or chloric acid and water; **hydrogen bromide** or iodide gives oxygen the free halogen. The affinity of the halogen acids for hydrogen peroxide varies as the affinity of the halogen for oxygen.[15] The reaction depends on the order of mixing. If **hydriodic acid** be added to the peroxide the reaction is more energetic than if the peroxide is added to the acid; the reverse obtains with the other haloid acids. It is probable the peroxide first liberates the haloid acids from the haloid salts and then decomposes the acid. According to J. Brode,[16] ferrous or cupric sulphate and molybdenum or tungsten trioxide accelerate the decomposition of hydriodic acid catalytically. The presence of acids affects the reaction with the different catalytic agents in a different way. Copper sulphate alone is not very active, but it stimulates the catalytic effects of ferrous sulphate. Molybdenum and tungsten trioxides act more vigorously than ferrous sulphate. **Hypochlorous acid** is reduced by hydrogen peroxide, $H_2O_2+HOCl=H_2O+HCl+O_2$; chloride of lime reacts similarly, the reaction is quantitative; one molecule of oxygen is obtained for each molecule of hydrogen peroxide employed. Hence, the reaction can be employed for the quantitative determination of either hydrogen peroxide or chloride of lime.[17] Hydrogen peroxide has no action on the alkali **chlorates** or **perchlorates** or perchloric acid; the periodates and periodic acid are reduced to iodates or iodic acid respectively. The **iodates** decompose hydrogen peroxide catalytically without themselves being affected by this agent. **Bromic acid** is reduced to bromine and hydrobromic acid with the liberation of oxygen. According to S. Tanatar,[18] **potassium fluoride** forms monoclinic prisms, KF,H_2O_2. According to C. F. Schönbein, **potassium iodide** in alkaline solution forms free iodine and potassium hydroxide, $2KI+H_2O_2=2KOH+I_2$; so also, in *acid solutions*, or in the presence of ferrous sulphate. In the decomposition of iodides by hydrogen peroxide in acid solution, the liberated iodine may oxidize to iodic acid if the iodine be kept in solution by the addition of, say, hydriodic acid. The reaction takes place only in the presence of hydrochloric or hydrobromic acid. V. Auger (1911) represents the course of the reaction by the equations: $2HCl+H_2O_2=2H_2O+Cl_2$; $I_2+3Cl_2=2ICl_3$; $5ICl_3+9H_2O\rightleftharpoons3HIO_3+I_2+15HCl$. According to G. Meissner,[19] in *neutral solutions*, potassium iodide is not decomposed, but the peroxide is decomposed catalytically. E. Schöne represents the reaction by a set of quite imaginary equations: With a feebly acid solution, iodine is liberated, the liquid becomes alkaline, and oxygen is evolved. The alkaline reaction disappears in a few days and the coloration by the free iodine decreases. E. Péchard assumes that an iodate and a periodate are formed as intermediate products, but **periodates** are at once reduced to iodates by hydrogen peroxide; and iodates and perchlorates have no action on hydrogen peroxide. More probably, a hypoiodite is the intermediate product: $H_2O_2+KI=H_2O+KIO$; $KIO+H_2O_2=KI+H_2O+O_2$. The corresponding **alkali chlorides** and **alkali bromides** are very slowly attacked in a similar manner.

According to V. Auger, the **sodium periodate**, $Na_2H_3IO_6$, is very slowly decomposed by hydrogen peroxide forming sodium iodate, and liberating more oxygen than corresponds with the equation because of the catalytic decomposition of the peroxide. S. Tanatar found acid or alkaline solutions of periodic acid are reduced to iodic acid in acid or alkaline solutions, while iodic acid is stable; but V. Auger found that the results with **periodic acid** vary according to the conditions with dilute solutions, the acid is quickly and completely reduced to iodic acid, with the separation of very little iodine. In concentrated solutions the reaction is incomplete and much iodine is formed. Cold solutions of hydrogen peroxide decompose solutions with less than 0·6 per cent. of **iodic acid** and iodine is set free; if over 0·8 per cent. of iodic acid is present the solution remains colourless, owing to the fact that the reaction $I_2+5H_2O_2=2HIO_3+4H_2O$ proceeds faster than $2HIO_3+5H_2O_2=I_2+6H_2O+5O_2$. According to S. Tanatar, hydrogen peroxide has no action on acid or alkaline solutions of **perchloric acid** or **chloric acid**; and **bromic acid** is reduced to hydrogen bromide with a little bromine, and the hydrogen bromide is oxidized by the peroxide.

According to M. Kleinstück, **silver chloride** suspended in a solution of potassium hydroxide is quickly reduced by hydrogen peroxide: $2AgCl+H_2O_2+2KOH=2Ag+O_2+2KCl+2H_2O$. A. P. H. Trivelli has studied the action of hydrogen peroxide on silver subbromide. H. T. Calvert[20] found that hydrogen peroxide acts in darkness on a photographic plate as if it had been exposed to light, and it is thought that the activity of certain metals and organic compounds in darkness on photographic plates, observed by W. J. Russell, is due to the formation of hydrogen peroxide by the action of moisture on these substances. L. Graetz found that the effect produced by hydrogen peroxide is not prevented by shielding the plate with paper, ebonite, or metal foil. O. Dony-Henault investigated the hypothesis that a kind of radioactivity is induced during the decomposition of hydrogen peroxide into water and oxygen. The activity is lessened by lowering the temperature; it is not accelerated by platinum foil, although this metal accelerates the decomposition of the peroxide; additions of sulphuric acid, alcohol, or dilute alkalies decrease the effect. J. Precht and C. Otsuki do not believe that the photographic activity of hydrogen peroxide is a radiation phenomenon at all; rather it is a consequence of the direct reducing action of the vapour of hydrogen peroxide on the gelatinized silver bromide of the plate. M. Padoa found that if a substance capable of decomposing hydrogen peroxide, *e.g.* platinum black, or manganese dioxide—be inserted between the peroxide and the photographic plate, no action occurs.

Hydrogen peroxide oxidizes **selenium** with the formation of selenic acid. Colloidal **tellurium** is attacked by dilute solutions of the peroxide, while the crystalline element reacts but slowly with 60 per cent. peroxide at 100°.[21] According to T. Fairley, the oxidizing power of hydrogen peroxide is singularly dormant in the case of pure **hydrogen sulphide,** for if alkaline or other salts be absent, the two substances may remain in contact a considerable time with no more decomposition than would have occurred with a solution of hydrogen peroxide alone. Hydrogen sulphide, however, is very slowly oxidized with the deposition of sulphur and the formation of sulphuric acid; but the decomposition is very swift with **hydrogen selenide.**[22] **Sulphurous acid** is oxidized to sulphuric acid, but according to L. Marino, selenious acid is not oxidized; the **sulphides, hyposulphites,** and **tetrathionates** are also oxidized to sulphates. A. Gutbier found that **tellurium** and **tellurium dioxide,** in alkaline solutions, are oxidized [23] to telluric acid, H_2TeO_4. Concentrated **sulphuric acid** forms Caro's acid, $HO.OSO_3H$; and when the latter is treated with water, it forms hydrogen peroxide and sulphuric acid.[24] Hydrogen peroxide transforms **nitrous acid** quantitatively into nitric acid; [25] **nitric oxide,** NO, furnishes a product which blues starch and potassium iodide paper very quickly, and hence, said C. F. Schönbein, the product cannot be nitric acid; and it is thought to be a compound of the two components. **Ammonia** is quickly oxidized to the nitrite and nitrate. If hydrogen peroxide be added to a large excess of ammonia dissolved in ether, and the solution cooled to —48°, a crystalline deposit of $(NH_4)_2O_2.H_2O$ is formed; the crystals rapidly decompose at ordinary temperatures.[26] Hydroxylamine hydrochloride at 50° forms some nitric acid, and gives off a mixture of nitrogen and oxygen.[27] **Hydroxylamine sulphate,** $(NH_2OH)_2H_2SO_4$, is quantitatively oxidized by hydrogen peroxide at 40°: $(NH_2OH)_2.H_2SO_4+6H_2O_2=H_2SO_4+2HNO_3+8H_2O$; in alkaline solutions, nitrous and nitric oxides, nitrous and nitric acid are formed.[28] According to T. Weyl, hydrogen peroxide solutions—6 to 30 per cent.—at 60°, convert yellow **phosphorus** into phosphine, phosphorous and phosphoric acids. The peroxide acts more vigorously on Schenck's phosphorus. The reaction has been represented [29] by the equations: $3H_2O_2+2P=2P(OH)_3$, followed by $4P(OH)_3=PH_3+3PO(OH)_3$.

Arsenic furnishes arsenic acid without giving off oxygen. F. Raschig found that **antimony sulphide** dissolves in an ammoniacal solution of hydrogen peroxide forming ammonium antimoniate and ammonium sulphate.[30] With **bismuth nitrate** in a warm, slightly alkaline solution, K. Hasebrock reported that hydrogen peroxide gives yellowish-brown bismuthic anhydride; bismuthous hydroxide gives the same product.[31] K. Hasebrock found that the reaction is quantitative.

Some **metals** which appear to be either insoluble or but sparingly soluble in acids often dissolve in the cold dilute acid if hydrogen peroxide be present.[32] With hydrochloric acid, the action is due to the generation of free chlorine, and accordingly all the metals, except those which form insoluble chlorides, are dissolved. Thus, T. Fairley found that a mixed solution of ferric chloride and hydrogen peroxide dissolves **gold,** and adds that the dissolution is accelerated by heat, and is sometimes followed by a reprecipitation of the gold. With dilute sulphuric acid, **copper,** silver, mercury, **nickel,** and **bismuth** are soluble in the presence of hydrogen peroxide, while **tin, lead,** gold, **platinum,** and **antimony** are not attacked. A mixture of glacial acetic acid with hydrogen peroxide dissolves copper, silver, lead, mercury, and bismuth in the cold, but has no action on tin, nickel, gold, and platinum. T. Fairley says that gold dissolves readily in a mixed solution of potassium cyanide and hydrogen peroxide, but only at the surface of a solution of the potassium cyanide alone. The presence of hydrogen peroxide also hinders the precipitation of gold by ferrous sulphate or oxalic acid. C. Weltzien found **magnesium** slowly reacts with hydrogen peroxide, forming an alkaline liquid, which on evaporation gives a white mass soluble in water, and which is probably magnesium hydroxide;

likewise also with **aluminium.** H. B. Baker and L. H. Parker found the reaction with sodium amalgam is faster with a solution of hydrogen peroxide than with water. There is probably a peroxidation as indicated below. According to S. Droste, a 3 per cent. solution of hydrogen peroxide slowly dissolves aluminium; 250 c.c. dissolved 0·2 grm. of the metal in 45 days, forming white insoluble aluminium hydroxide, $Al(OH)_3.H_2O$; the soluble or colloidal hydroxide does not appear to be formed. T. Okaya has studied the rhythmic decomposition of hydrogen peroxide by **mercury** (*q.v.*).

Powdered **silver** is a powerful catalytic agent in the decomposition of hydrogen peroxide. L. J. Thénard found that in the presence of nitric acid silver oxide is partly reduced and partly dissolved. According to M. Berthelot, there is a cyclic series of reactions in which the metal is alternately peroxidized and reduced.[33] Silver, Ag_2O, is reduced to metallic silver by a reaction which B. C. Brodie symbolizes: $H_2O_2+Ag_2O \rightarrow 2Ag+H_2O+O_2$, so that half the oxygen is derived from the silver oxide and half from the hydrogen peroxide. M. Berthelot has shown that metallic silver is not exclusively formed, since some of the reduced silver is peroxidized. W. Manchot, and A. von Baeyer and V. Villiger have studied the action of hydrogen peroxide on silver. The finely divided silver, formed during the reaction between silver oxide and hydrogen peroxide, acts catalytically on the latter, so that a mixture of an excess of hydrogen peroxide on metallic silver always gives off more oxygen than is represented by the above equation, and there is no need for assuming the formation of a silver peroxide. The catalytic action of finely divided silver, gold, platinum is most vigorous in alkaline solutions, weakest in acid solutions; and intermediate in neutral solutions. T. Fairley assumes that unstable oxides are formed in alkaline solutions, and more stable salts are formed in acid solutions. Hence, most metals dissolve in dilute acids in the presence of hydrogen peroxide. According to E. Mulder, the action of hydrogen peroxide on silver oxide, dioxide, carbonate, nitrate, and peroxynitrate, is catalytic. **Gold oxide** is similarly reduced: $Au_2O_3+3H_2O_2 \rightarrow 2Au+3H_2O+3O_2$. Curiously enough, in these reactions the reducing agent is itself reduced; usually the reducing agent is oxidized during the reduction.

A series of peroxides are formed with solutions of the hydroxides or salts of the alkalies, alkaline earths, or metals. These reactions show that hydrogen peroxide behaves like a monobasic or a dibasic acid. V. Macri noted that when ammonia is added to hydrogen peroxide in the presence of calcium chloride, calcium dioxide, CaO_2, is precipitated. Hydrogen peroxide is decomposed catalytically by **carbon;** there is no appreciable oxidation; a mixture of carbon, magnesium, and manganese dioxide takes fire in hydrogen peroxide. O. Masson[34] found that **potassium cyanide** at ordinary temperatures gives potassium cyanate, potassium carbonate, and ammonium carbonate. No oxygen is given off so long as any potassium cyanide remains unoxidized. With **titanium** salts[35] hydrogen peroxide gives an orange-yellow coloration supposed to be due to the formation of pertitanic anhydride, TiO_3, by a reaction symbolized: $TiO_2+H_2O_2=H_2O+TiO_3$. In alkaline solutions, salts of the type $Na_2O.TiO_3.3H_2O$ are formed. The particular tint depends upon the amount of titanium present, and hence the reaction is used for the determination of the amount of titanium in various materials. The tint of a solution containing an unknown amount of titanium is compared with that of similar solutions containing a known quantity of titanium; and the amount in the unknown solution determined by simple rule of three. The reaction is also used as a test for hydrogen peroxide. It is said that one part of titanium in 1800 parts of water gives a deep yellow coloration, and one part in 180,000 a light yellow coloration. **Cerium** and **vanadium** salts give a brick-red coloration; **molybdenum** salts, the intense yellow of permolybdic acid—$H_2Mo_2O_8$; **uranium** salts, a bluish coloration due to the formation of peruranic acid, $UO_4(H_2O_2)_2$; in alkaline solutions yellow peruranates are formed. With **tungsten** salts, pertungstates are obtained in a similar way. J. R. Cain and J. C. Hostetter find that **vanadic acid** is reduced by hydrogen peroxide. **Zirconia** and **cerium oxide** give peroxides analogous to pertitanic oxide; and **thorium oxide** [36] gives a peroxide Th_2O_7. **Lead monoxide** is converted into the puce-coloured dioxide, PbO_2, by an alkaline solution of peroxide, and the **lead dioxide** is then decomposed forming the monoxide.[37] Lead dioxide, obtained when red lead is digested with dilute nitric acid, dissolves very slowly, but if a few drops of hydrogen peroxide be added, all the lead dioxide dissolves in a few moments. The lead dioxide is reduced to lead monoxide by the hydrogen peroxide, $PbO_2+H_2O_2=PbO+H_2O+O_2$, and the product dissolves immediately in the dilute acid. This method is generally employed to hasten the solution of red lead in dilute acid prior to analysis. **Thallium oxides** behave similarly. C. F. Schönbein found that thallium is oxidized to $TlO(OH)$; with an excess of hydrogen peroxide, the oxidation products are oxygen, water, and thallous hydroxide. The latter is not affected by hydrogen peroxide. **Mercuric oxide** is reduced to mercurous oxide in alkaline solutions. G. Bredig and A. Antropoff [38] obtained an explosive peroxidized compound, HgO_2, by the action of hydrogen peroxide on mercuric oxide; copper sulphide forms the sulphate. The precipitation of oxides by hydrogen peroxide from alkaline or ammoniacal solutions of copper, silver, mercury, and bismuth salts, with the evolution of oxygen, is the basis of several processes for the separation of a number of metals from one another by W. R. E. Hodgkinson and A. H. Coote, etc. C. F. Schönbein found **cupric hydroxide** changes from blue to green when treated with hydrogen peroxide, and forms an unstable peroxide, H_2CuO_3; [39] on the contrary, in alkaline solutions, **cupric salts** are reduced to cuprous salts.[40] **Stannous salts** are oxidized to stannic salts without loss of oxygen. In neutral or acid solutions **ferrous salts** are oxidized to ferric salts; and in alkaline solutions ferric hydroxide and alkaline ferrates are reduced to ferrous salts. Ferric salts are not affected. H. Colin and A. Sénéchal have studied the action of ferric chloride on hydrogen peroxide. Alkaline solutions of **potassium ferricyanide** were reported by E. Lenssen to be reduced to the ferrocyanide, $2K_3FeCy_6+2KOH+H_2O_2=2K_4FeCy_6+2H_2O+O_2$, and ferrocyanides to be oxidized to ferricyanides. C. Weltzien said the opposite is true. J. Quincke recommends a process based on the reduction of ferricyanide to ferrocyanide for the volumetric determination of hydrogen peroxide, or of potassium ferricyanide. In neutral or acid solutions, the reaction is reversed, and **potassium ferrocyanide** is oxidized to the ferricyanide. M. Prud'homme [41] assumes that when solutions of potassium ferricyanide and hydroxide are boiled, equilibrium is attained in the reversible reaction, $2K_3FeCy_6+2KOH=2K_4FeCy_6+H_2O_2$, because (i) potassium ferricyanide and hydroxide are formed when a solution of hydrogen peroxide is added to one of the ferrocyanide; (ii) the addition of an excess of hydrogen peroxide to a solution of potassium ferricyanide and sodium hydroxide forms the ferrocyanide with the evolution of oxygen; and (iii) indigotin is bleached more rapidly by hydrogen peroxide in the presence of alkali hydroxide than in acid solutions. E. S. Barralet, C. F. Schönbein, E. Schöne, and W. Wobbe have examined the sensitiveness of the reaction as a test for hydrogen peroxide. According to T. Bayley, in alkaline solutions, **cobaltous hydroxide** forms a black peroxide; **nickel hydroxide** is not changed, but the sesquioxide forms nickelous hydroxide, with the evolution of oxygen. G. Watson has studied the action of hydrogen peroxide on ammoniacal solutions of nickel sulphate. **Iron sulphide** forms the sulphate; **molybdenum sulphide** forms sulphuric and molybdic acids; brown **lead sulphide** forms the white sulphate; **bismuth sulphide** and **tin sulphide** are only attacked slightly; **mercury and silver sulphides** are still less attacked. Metallic **iron** is but slightly attacked,[42] **tungsten** and **molybdenum** respectively form tungsten and molybdenum trioxides. According to V. Macri, hydrogen peroxide prevents the precipitation of ammonium phosphomolybdate when solutions of ammonium molybdate and phosphoric acid are mixed. B. Kuriloff and W. Städel found that **zinc oxide** is but slightly attacked; **zinc hydroxide** is peroxidized.[43] Similarly with **magnesium hydroxide** and with **cadmium hydroxide.** The **oxides of yttrium, didymium, lanthanum, and samarium** furnish oxides approximating R_4O_9. With alkaline solutions, hydrogen peroxide transforms the **chromic oxides**[44] into chromates; with neutral or acid solutions of chromic acid, H_2CrO_4, hydrogen peroxide forms a blue solution which immediately begins to decompose with the evolution of oxygen. The solutions of both hydrogen peroxide and of chromic acid are comparatively stable in the cold; when mixed they simultaneously decompose—half the oxygen comes from the peroxide and half from the chromic acid. It is therefore inferred that an unstable compound of both is formed—possibly $3H_2O_2.2CrO_3$—which breaks up with the evolution of oxygen leaving behind chromic sesquioxide, Cr_2O_3, which immediately dissolves in the acid solution. The transient intermediate compound has been isolated by operating at a low temperature. The blue-coloured peroxide, whatever it be, is much more soluble and stable in ethereal than in aqueous solutions, so that if a solution of chromic acid and hydrogen peroxide in a test-tube be shaken with ether, a blue ethereal solution of the peroxide will float on the surface of the aqueous layer. The compound decomposes when the ether is evaporated. This reaction is used for the detection of chromates. Add hydrogen peroxide to the neutral or alkaline solutions containing a chromate, and then acidify with dilute sulphuric acid. The presence of a chromate is indicated by a blue coloration. If but small quantities of chromate be present, shake up the solution with 2 or 3 c.c. of ether. The separation of a blue ethereal layer indicates chromic acid. The necessary modification of the process for the detection of hydrogen peroxide will be obvious. It is said that this method will indicate one part of hydrogen peroxide in 80,000 parts of water. If chromic acid be added to the solution of hydrogen peroxide mixed with hydrogen sulphide, V. Macri found that the latter makes no difference to the reaction.

The action of hydrogen peroxide on manganese compounds.—Hydrogen peroxide transforms manganous hydroxide in neutral or alkaline solutions into the dioxide which catalytically decomposes the hydrogen peroxide; if the solution is acid, manganese dioxide is reduced to manganous oxide: $MnO_2+H_2O_2+2HCl=MnCl_2+O_2+2H_2O$. The reducing action of the hydrogen peroxide is only apparent. According to B. C. Brodie (1872),[45] the oxides of silver, manganese, etc., have an atom of oxygen which is readily disengaged from its combination. Similarly, hydrogen peroxide readily parts with its odd atom of oxygen. Consequently, the atom of oxygen in hydrogen peroxide is supposed to *oxidize* the odd oxygen atom in the metallic peroxide. According to C. Weltzien, a *neutral solution* of potassium permanganate is reduced to potassium hydroxide and hydrated manganese dioxide, which catalytically decomposes the peroxide. In the presence of sulphuric or nitric acid, the peroxide reduces the permanganate to a manganous salt: $5H_2O_2+2KMnO_4+3H_2SO_4=2MnSO_4+K_2SO_4+8H_2O+5O_2$, so that the solution of potassium permanganate, acidified with sulphuric acid, is rapidly reduced and decolorized by hydrogen peroxide. The reaction is quantitative and is used in the volumetric determination of hydrogen peroxide.

According to C. F. Schönbein, the presence of a millionth part of hydrogen peroxide in a solution can be detected by its decolorizing action. Consequently, if an acidified solution, containing a known amount of potassium permanganate, be run from a burette into a known volume of a solution of hydrogen peroxide until the pink colour of the permanganate is no longer discharged, it follows, from the equation, that every two molecules of $KMnO_4$ correspond with five molecules of H_2O_2; or 2×158 (the approximate molecular weight of $KMnO_4$) grams of potassium permanganate correspond with 5×34 (the approximate molecular weight of H_2O_2) grams of hydrogen peroxide; otherwise expressed, *one gram of potassium permanganate represents* 0·5382 *gram of hydrogen peroxide.*

EXAMPLE.—45 c.c. of a standard solution of potassium permanganate containing 20 grams of $KMnO_4$ per litre were decolorized by 25 c.c. of a solution of hydrogen peroxide. What amount of H_2O_2 is present in a litre of the hydrogen peroxide? Here 1000 c.c. of the standard solution contain 20 grams of $KMnO_4$; hence, 1 c.c. contains 0·02 gram; or 45 c.c. contain 0·9 gram; but from the equation, one gram of $KMnO_4$ represents 0·5382 gram of H_2O_2; hence, 25 c.c. of hydrogen peroxide has 0·5382 × 0·9 = 0·4844 gram of H_2O_2. Hence, a litre will have 19·4 grams of H_2O_2.

Less permanganate is required for titrating a mixture of hydrogen peroxide and sulphuric acid than if a mixture of permanganate and sulphuric acid is used for titrating hydrogen peroxide alone. According to T. M. Lowry and J. H. West, this is due to the formation of persulphuric acid when sulphuric and hydrogen peroxide are mixed together, and the slowness of the reaction between persulphuric acid and potassium permanganate.

Higher hydrogen peroxides.—M. Berthelot (1880)[46] noticed that when potassium permanganate is titrated with hydrogen peroxide at a low temperature, say 12°, the permanganate is decolorized without liberating oxygen, and hence he concluded that this is due to the formation of a compound H_2O_3, or, as A. Bach suggests, H_2O_4, which is stable only at low temperatures. For instance, with hydrogen peroxide, H_2O_2, one gram-molecule of oxygen is liberated for every molecule of the peroxide decomposed: $2KMnO_4+5H_2O_2+3H_2SO_4=K_2SO_4+2MnSO_4+8H_2O+5O_2$; with hydrogen tetroxide, if it exists, and if it reacts in an analogous manner, each molecule requires just as much potassium permanganate as hydrogen peroxide, but twice as much oxygen would be liberated: $2KMnO_4+5H_2O_4+3H_2SO_4=K_2SO_4+2MnSO_4+8H_2O+10O_2$. Similar remarks would apply to Berthelot's hypothetical H_2O_3. According to A. Bach (1897),[47] also, the oxidation products of nascent hydrogen from palladium hydride oxidize indigo solutions more rapidly than hydrogen peroxide, and he therefore inferred that a higher peroxide than H_2O_2 is formed during the slow oxidation of hydrogen. Again, there is nothing to show that the rubidium and potassium tetroxides have the respective formulæ: Rb_2O_4 and K_2O_4; analysis alone gives a percentage composition corresponding with RO_2 and KO_2; but, just as sodium peroxide is represented by the formula Na_2O_2 on account of its relation to hydrogen peroxide, known to have a molecular formula H_2O_2, so the peroxides of rubidium and potassium are assumed to be derivatives of a hypothetical hydrogen peroxide, H_2O_4.

A. Bach (1900) sought for the supposed higher hydrogen peroxides (1) in the oxidation products of nascent hydrogen; (2) in the product derived from the action of dilute acids on sodium peroxide, Na_2O_2; and (3) on potassium tetroxide, K_2O_4; and (4) in the oxidation product of Caro's acid on potassium permanganate. It was found that the corresponding amounts of oxygen obtained from each of these products by the permanganate titration is:

Hydrogen peroxide.	(1) Oxidation products of nascent hydrogen.	(2) Sodium peroxide.	(3) Potassium tetroxide.	(4) Caro's acid.
1	1·07	1·17	1·28	1·65

These results might be caused by the presence of hydrogen trioxide, H_2O_3, or hydrogen tetroxide, H_2O_4. A. M. Clover (1903) failed to verify A. Bach's conclusion. During the permanganate titration of A. Bach, the reaction, $2KMnO_4+3H_2SO_4+5H_2O_2=K_2SO_4+2MnSO_4+8H_2O+5O_2$ occurs, and the hydrogen in the solution can be estimated from (1) the amount of standard permanganate used in the titration, or (2) from the volume of oxygen evolved. Bach found from 25 to 34 per cent. more oxygen was evolved than corresponded with the permanganate required for the titration, and he concluded that a higher peroxide than H_2O_2 must have been present in the solution. H. E. Armstrong (1900) and W. Ramsay (1901)[48] tried to explain Bach's results by assuming that hydrogen peroxide was consumed in a secondary reaction—namely, the formation of persulphuric acid, or Caro's acid, by the interaction of hydrogen peroxide with the sulphuric acid in the solution; but A. von Baeyer and V. Villiger (1900) showed that neither Caro's acid nor persulphuric acid rapidly affected potassium permanganate, so that titration with permanganate does not give the strength of a solution of hydrogen peroxide in sulphuric acid; more peroxide is present than is represented by the amount of permanganate consumed. This criticism cannot be valid because in his permanganate titrations,

A. Bach does not appear to have used sufficient acid, and some manganese dioxide was in consequence precipitated ; this acted catalytically, decomposed the hydrogen peroxide remaining in the solution with the evolution of oxygen ; hence, more oxygen gas was formed than corresponded with the hydrogen peroxide actually decomposed by the permanganate. This conclusion is confirmed (i) by the results obtained when sufficient acid is present to keep the manganese oxide in solution, and (ii) solutions of sodium peroxide also give an excess of oxygen if an insufficient amount of acid is present during the titration. At present, therefore, the evidence in support of the higher hydrogen peroxides is not satisfactory.

According to M. Kleinstück,[49] **carbonyl chloride** and **phenyl carbonate** react with alkaline hydrogen peroxide, and so does a saturated solution of potassium hydrogen carbonate in a pressure bottle at 100°. The distillate obtained by passing steam into the product reduces ammoniacal silver oxide, and is therefore said to contain formaldehyde, H.COH. M. Kleinstück therefore suggests that possibly the assimilation of **carbon dioxide** by plants proceeds : $2H_2CO_3+2H_2O_2=2H.COH+2H_2O+3O_2$. Hydrogen peroxide oxidizes many organic compounds particularly in the presence of an inorganic salt as catalytic agent—*e.g.* it converts **sugars** into ozones, and **benzene** into phenol in the presence of ferrous sulphate ; many organic **alkaloids** are converted into new crystalline bases which are often coloured ; thus **quinine** turns lemon-yellow ; **nicotine,** blood-red ; etc. With **potassium cyanide** it forms potassium cyanate, $KCy+H_2O_2=KCyO+H_2O$, and according to H. Cook, ammonia and potassium formate are simultaneously produced. The **monohydric alcohols** are not attacked, but the **polyhydric alcohols**—glycol, glycerol, mannite, etc.—are oxidized to the corresponding aldehydes, particularly in presence of ferrous sulphate. **Oxalic acid** is converted into carbon dioxide ; **tannin, gallic acid,** and **pyrogallol** are not browned by hydrogen peroxide ; **indigo** solution is slowly bleached, and more rapidly if ferrous sulphate is present. Tincture of **guaiacum** is turned blue. **White of egg** in a solution of lactic acid, and the **serum** of blood, become insoluble at 40°. **Fibrin** and **blood** act catalytically on the decomposition of hydrogen peroxide.

The uses of hydrogen peroxide.—Hydrogen peroxide bleaches many organic colouring agents—*e.g.* litmus and indigo solutions. Dilute solutions of hydrogen peroxide are used for bleaching silk, feathers, straw, hair, ivory, teeth, etc., where more violent bleaching agents—*e.g.* chlorine—would injure the material. Instead of hydrogen peroxide an acidified solution of sodium peroxide is sometimes employed. The actions are similar. Since the products of the decomposition of hydrogen peroxide—water and oxygen—are harmless, it is also used medicinally as an antiseptic, etc. Numerous mixtures of hydrogen peroxide with disinfectants have been registered, and they are sold under various trade names—*e.g. perhydrol, dioxogen, hydrozone, glycozone, pyrozone, peroxal,* etc. M. Pettenkofer's proposal is to use hydrogen peroxide for cleaning oil paintings which have been darkened by the action of hydrogen sulphide—sometimes present in the air of towns—upon the lead compounds in the paint. The brownish-black coloured lead sulphide is transformed into white lead sulphate. According to reports, the treatment is sometimes satisfactory and sometimes it spoils the picture. Ethereal solutions of hydrogen peroxide are used in photography for intensifying negatives. Hydrogen peroxide is also used in analytical work for the oxidation of sulphites to sulphates ; arsenites to arsenates ; chromic salts to chromates ; ferrous to ferric salts ; nitrites to nitrates ; etc.

§ 12 The Qualitative and Quantitative Determination of Ozone and Hydrogen Peroxide

The detection of ozone and hydrogen peroxide is complicated by the fact that while many reagents produce marked colorations with these two substances, yet other substances like nitrogen peroxide, chlorine, and bromine give similar colorations, so that the results with this group of reagents are merely characteristic of an oxidizing gas.

In 1842, C. F. Schönbein [1] used test papers soaked in a solution of starch and potassium iodide ; these are coloured blue by ozone. The iodine must be free from iodate or a blue colour will be obtained by the carbon dioxide which decomposes the iodate.[2] Even in the absence of iodates, the blue coloration is produced by other oxidizing agents—chlorine, nitrous acid, vapours of ethereal oils, hydrogen peroxide, etc.[3] Ozone with potassium iodide gives potassium hydroxide and iodine, and it is the latter which gives the blue coloration with starch. Attention has been directed to mixing reagents with the potassium iodide which are sensitive to the alkali instead of the iodine. Thus, A. Houzeau (1868) [4] made test papers by soaking them in a mixture of potassium iodide and wine-red litmus. These papers are coloured blue by ozone, ammonia, etc. A. R. Leeds recommended phenolphthaleïn in place of litmus ; C. Arnold and C. Mentzel tried rosolic acid, and also fluoresceïn. The former gives a red colour with ozone, the latter, with black paper, gives a green fluorescence. Neither chlorine nor nitrogen oxide gives the red with rosolic acid. While it is possible to prepare an ozone paper in this way which is not affected by chlorine or nitrogen oxide, hydrogen peroxide gives the same reactions as ozone.[5] This remark also applies to the substitution of cadmium or zinc iodide in place of potassium iodide. Nevertheless, the methods in use for the determination of ozone and hydrogen peroxide are based on the action of these agents upon a neutral solution of potassium iodide. The results are satisfactory provided other oxidizing agents are absent.

In the quantitative determination of ozone, a known volume of air is drawn through such a neutral solution of potassium iodide, when the ozone liberates iodine : $O_3+2KI+H_2O=O_2+I_2+2KOH$. The liberated iodine is determined by acidifying the solution, and titrating with standard sodium thiosulphate, $Na_2S_2O_3.5H_2O$. The reaction is symbolized : $I_2+2Na_2S_2O_3=2NaI+Na_2S_4O_6$; and accordingly, every gram-molecule of sodium thiosulphate corresponds with a gram-atom of iodine, which in turn corresponds with half a gram-molecule of ozone.

EXAMPLE.—Assuming that $\frac{1}{10}N$ sodium thiosulphate solution contains the $\frac{1}{20}$th gram-molecule of the crystallized salt, $Na_2S_2O_3.5H_2O$, per litre, the above equations show that

1000 c.c. of this solution must be equivalent to $\frac{1}{40}$th of a gram-molecule of ozone, that is, 1·2 grms. of ozone. If therefore the ozone in 100 c.c. of air, at n.p.t., ultimately required 4·9 c.c. of $\frac{1}{10}N$ sodium thiosulphate, there were present 4·9 × 0·0012=0·0059 grm. of ozone. A gram of ozone at n.p.t. occupies about 466·7 c.c. Hence 100 c.c. of ozonized air contained 466·7 × 0·0059=2·7 c.c., *i.e.* the air contained 2·2 per cent. of ozone.

The old method of estimating ozone in, say, the atmosphere was to expose ozone test papers for a definite time to the air and compare the resulting tint with a standard scale of colours obtained with air containing known quantities of ozone. Since other oxidizing substances, likely to be present in air, produce similar reactions, it is a moot question whether the large number of ozone determinations which have been made really represent ozone, hydrogen peroxide, nitrogen oxides, or chlorine. The blackening of the silver foil by ozone, as already indicated, is not a sufficiently delicate test. The tests dependent on the reduction of various metal salts—gold, thallium, lead, manganese, and palladium—do not distinguish between ozone, hydrogen peroxide, or other oxidizing or reducing agents.

Numerous organic substances have been proposed at various times for the detection of ozone and of hydrogen peroxide. For instance, tincture of guaiacum was recommended for hydrogen peroxide by C. F. Schönbein.[6] The reagent is more sensitive if a little malt extract, or diastase, be used in conjunction with the tincture.[7] C. F. Schönbein claimed that one part of hydrogen peroxide in two million parts of atmospheric air can be detected by the blue colour which is obtained, and according to E. Schöne, the reagent can be made over 20 times more delicate than this. If the diastase be not used, the coloration is produced by many other oxidizing agents—nitrous acid, ozone, chlorine, etc.—but with diastase, E. Schöne claims that the mixture forms *ein sehr charakterisches und empfindliches Reagens auf Wasserstoffperoxyd.* The bleaching of blue indigo solution, used as a test for ozone by C. F. Schönbein, is not characteristic. C. Wurster[8] recommended dimethyl- or tetramethyl-*p*-phenylenediamine, particularly the latter, as a distinctive reagent for ozone, and test papers prepared with this reagent have been called *tetra-paper*, or *tetra-base-paper.* The claims, however, are not justified since hydrogen peroxide, chlorine, nitrous acid, etc., also colour the reagent. Many other reagents have been proposed[9]—for example, a naphthylamine or azoamidonaphthylaminebenzolsulphonic acid by L. I. de N. Ilosva; and the aniline dye, ursol *D*, by G. V. Chlopin. According to G. Erlwein and T. Weyl (1898) a freshly prepared solution of from 0·1 to 0·2 grm. of metaphenylenediamine hydrochloride in 90 c.c. of water containing 100 c.c. of a 5 per cent. solution of sodium hydroxide develops a yellowish-brown or red in a few seconds, if but 0·00008 grm. of ozone be present; oxygen alone acts very slowly, while nitrous acid and hydrogen peroxide give no coloration. According to C. Arnold and C. Mentzel (1902), however, all oxidizing gases give yellow colours with this reagent.

In their investigation, *Ueber alte und neue Reaktionen des Ozons*, C. Arnold and C. Mentzel propose the use of test papers soaked in an alcoholic solution of tetramethyl di-para-diamidodiphenylmethane, a name abbreviated to *tetramethyl base*. This substance is not to be confounded with the tetra-base of C. Wurster. Paper soaked in this reagent is called *tetramethyl base test paper.* The colour is not affected by hydrogen peroxide but is turned pale violet with ozone; blue, with chlorine and bromine; and from straw yellow to pale dirty brown with nitrous acid. According to F. Fischer and H. Marx, the tetramethyl base test papers should be used moist. If dry test papers are used, the results are misleading—*e.g.* ozone gives a yellow colour. C. Arnold and C. Mentzel also found that a saturated alcoholic solution of benzidine furnishes a reagent which is coloured brown by ozone; blue by bromine, chlorine, and nitrous acid; while hydrogen peroxide, hydrogen sulphide, ammonia, ammonium sulphide, and hydrocyanic acid give no result. If copper sulphate be present hydrogen peroxide and hydrocyanic acid give a blue coloration. According to K. V. Charitschkoff (1909), the pink-coloured paper obtained by soaking filter paper in a benzene solution of cobalt naphthalate is coloured olive-green by hydrogen peroxide (0·03 per cent.), but not by ozone.

The two most characteristic reactions for hydrogen peroxide are the chromic acid-ether test which C. F. Schönbein found sensitive enough to detect one part of the peroxide in 20,000 parts of liquid; and the yellow coloration of a solution of titanic sulphate which E. Schöne found to be sensitive to one part of hydrogen peroxide in 1,000,000; L. I. de N. Ilosva gives a sensitiveness of 1 : 90,000. *The most characteristic and reliable test for hydrogen peroxide is titanium sulphate; and guaiacum tincture with malt extract is the most sensitive.* E. H. Kaiser and L. McMaster (1908)[10] report that a brown solution containing a mixture of ferric chloride and potassium ferricyanide is coloured blue or green by hydrogen peroxide according to the amount of the peroxide present. Ozone and nitrogen peroxide do not reduce the ferricyanide to ferrocyanide—nitrogen peroxide alone produces a blue coloration with ferric chloride. This test is not so characteristic since sulphur dioxide, etc., reduce the ferricyanide. According to C. F. Schönbein, it is sensitive enough to show the presence of one part of hydrogen peroxide in four million parts of solution.

The reactions of the more interesting distinguishing tests with ozone, hydrogen peroxide, chlorine and nitrogen peroxide are summarized in Table III.

TABLE III.—DISTINGUISHING TESTS FOR HYDROGEN PEROXIDE, AND OZONE.

Reagent.	Ozone.	Hydrogen peroxide.	Chlorine.	Nitrogen peroxide.
KI and starch	Blue	Blue	Blue	Blue
Indigo solution	Bleached	Bleached	Bleached	Bleached
Litmus solution	Bleached	Bleached	Bleached	Bleached
Clean silver foil	Blackened	Nil	White film	No change
Mercury bead	Tail on glass	Nil	White	No change
CrO_3 and ether	Nil	Blue	Nil	Nil
Titanic acid	Nil	Yellow	Nil	Nil
Tetramethyl base	Violet	Nil	Blue	Yellow to brown
$KMnO_4$ solution	Unchanged	Decolorized	Decolorized	Decolorized

C. Engler and W. Wild (1896)[11] state that if a mixture of ozone and hydrogen peroxide be passed through a concentrated solution of chromic acid, the hydrogen peroxide is alone decomposed, the ozone is not affected. H. McLeod used a mixture of sodium bicarbonate, potassium dichromate, and sulphuric acid for arresting hydrogen peroxide, but not ozone. According to E. H. Kaiser and L. McMaster, nitric oxide is also arrested at the same time; and they find that if a mixture of ozone, hydrogen peroxide, chlorine, and nitrous oxide be passed through a solution of potassium permanganate, ozone alone escapes unchanged, and it will react with starch and potassium iodide in the usual way.

The general methods employed for the quantitative determination of hydrogen peroxide in solutions are: (1) *Gasometric*, from the volume of gas given off when the solutions are decomposed; (2) *Iodometric*, the amount of iodine liberated from solutions of potassium iodide; and (3) *Oxidation*, the mutual decomposition of hydrogen peroxide and potassium permanganate, in the presence of sulphuric acid.

The general methods available for the quantitative determination of ozone are: (1) *Gravimetric*, by precipitation of thallic oxide from solutions of thallous salts; and (2) *Iodometric*, from the amount of iodine liberated from solutions of potassium iodide.

§ 13. The Composition and Constitution of Hydrogen Peroxide

> Rational chemical formulæ are a kind of contracted equation ; a compound may have several rational formulæ and that one is best which expresses the greatest number of reactions.—C. GERHARDT (1856).

In spite of the fact that the composition and molecular weight of hydrogen peroxide have been determined ; in spite of the simplicity of the resulting formula, H_2O_2 ; and in spite of the many ingenious (sometimes far-fetched) arguments which have been deduced from experiments made to determine the relative disposition of its component atoms, the constitution of this compound has not been yet established by unequivocal experiments.

The empirical formula.—L. J. Thénard (1818) introduced a weighed amount of the peroxide in a small vial into a graduated cylinder over mercury. The vial was broken and its contents decomposed either by introducing manganese dioxide, or by heat; 17 parts of hydrogen peroxide by weight gave nearly 8 parts by weight of oxygen, and $17-8=9$ parts by weight of water. Otherwise expressed, 34 parts of hydrogen peroxide give 18 parts of water and 16 parts of oxygen. Hence, the peroxide contains hydrogen and oxygen in the proportion of 2 atoms of oxygen. The simplest formula for hydrogen peroxide is therefore HO. There is here nothing to show whether HO or some multiple of HO, say, H_nO_n, is the proper formula for the compound, since the latter has the same percentage composition as the former.

The molecular formula of hydrogen peroxide.—The instability of hydrogen peroxide prevents a determination of its vapour density being made in the regular manner. The molecular weight has been determined by the freezing-point method.[1] The result is nearly 34. This agrees with the formula H_2O_2—the generally accepted value.

The constitutional or graphic formula of hydrogen peroxide.—The evidence for the constitution of hydrogen peroxide deduced from its reactions, or from the reactions of the analogous peroxides, is somewhat ambiguous because different lines of argument lead to different conclusions in spite of very positive assertions in favour of particular formulæ. One group of evidence favours the formula HO.OH with both oxygen atoms bivalent; another group favours HO : OH with both oxygen atoms quadrivalent; and still a third group favours $H_2 : O : O$ with one oxygen atom bi- and the other quadri-valent. The two formulæ HO.OH and HO ⁝ OH are similar in type, and with our present knowledge, it does not matter very much which be favoured; the evidence for HO : OH against HO.OH is mainly physical, and special weight was given to the former by J. W. Brühl (1895). M. Traube (1893) has also argued for a similar constitution. A. Bach (1900), following C. T. Kingzett (1882), favours $H_2{=}O{=}O$; and a similar type of formula has been advocated in order to emphasize the analogy between hydrogen peroxide —assumed to be $H_2{=}O{=}O$—and ozone—assumed to be $O{=}O{=}O$. When two lines of arguments lead to two independent formulæ, each of which seems highly probable if the other be ignored, some one is almost sure to suggest that both formulæ are right, and that one formula represents the equilibrium state under one set of conditions, and likewise also for the other formula under another set of conditions. There is thus a labile intra-molecular change from one form to the other: $H_2{=}O{=}O \rightleftharpoons HO \vdots OH$. This type of chemical change has been called *tautomerism*. O. Mumm (1907)[2] has assumed that hydrogen peroxide is an illustration of the phenomenon; and E. Bose suggested in 1901, that hydrogen peroxide can exist in two different forms in one of which it acts as an oxidizing agent, and in the other as a reducing agent. Otherwise expressed, an acid solution favours the $H_2{=}O{=}O$ formula, and an alkaline solution the $HO{=}OH$ formula.

1. *Evidence for HO—OH or H.O.O.H.*—L. Carius (1863) noticed that ethylene, C_2H_4, unites directly with hydrogen peroxide to form *sehr klein Mengen* of ethylene glycol, $C_2H_4(OH)_2$, presumably by the equation:

$$\begin{array}{l}H_2{=}C\\ H_2{=}\overset{|}{C}\end{array}+\begin{array}{l}OH\\ OH\end{array}\rightarrow\begin{array}{l}H_2{=}C{-}OH\\ H_2{=}\overset{|}{C}{-}OH\end{array}$$

This does not conclusively prove that the constitutional formula is HO.OH since the glycols are similarly formed by oxidizing one of the olefine series (of which ethylene is a member) with potassium permanganate. Similarly, the formation of hydroxides by the action of hydrogen peroxide on metals like zinc:

$$Zn+H_2O_2=Zn{<}\begin{smallmatrix}OH\\ OH\end{smallmatrix}$$

and on sulphur dioxide forming $SO_2(OH)_2$. Here the hydrogen peroxide enters into union as $2OH'$. The inference that hydrogen peroxide is accordingly constituted HO.OH is inclusive, because the hydroxides are formed by other oxidizing agents not containing hydroxyl groups.

The hydrogen of hydrogen peroxide can be indirectly replaced by the ethyl (C_2H_5) or benzoyl (C_6H_5CO) radicle, to form the corresponding peroxides—*viz.* ethyl peroxide, $(C_2H_5)_2O_2$, and benzoyl peroxide, $(C_6H_5CO)_2O_2$. It has been argued that if ethyl peroxide has the formula $(C_2H_5)_2 : O : O$, it should furnish ethyl oxide (ether), $(C_2H_5)_2O$, when exposed to the reducing action of nascent hydrogen: $(C_2H_5)_2O_2+2H \rightarrow (C_2H_5)_2O+H_2O$; and if benzoyl peroxide be constituted $(C_6H_5CO)_2 : O : O$, it should furnish benzoic anhydride, $(C_6H_5CO)_2O$, under similar conditions. As a matter of fact, A. von Baeyer and V. Villiger (1900) obtained neither ethyl oxide nor benzoic anhydride when the respective peroxides were treated with platinum and hydrogen in the cold; the actual products were respectively ethyl alcohol, C_2H_5OH, and benzoic acid, $C_6H_5.CO.OH$. Hence, it is argued that the reactions are of the type $(C_2H_5)_2O_2+2H=2C_2H_5OH$, unless a tautomeric alteration in the relations of the oxygen atoms in the molecule occurs during the reduction, and it followed that the constitution of ethyl peroxide is $C_2H_5.O.O.C_2H_5$, and of benzoyl peroxide, $C_6H_5CO.O.O.COC_6H_5$; and by analogy it is argued that hydrogen peroxide is probably constituted HO.OH, and not $H_2 : O : O$.

The view that hydrogen peroxide contains two hydroxyl groups is further supported by the fact, emphasized by M. Traube (1893), that hydrogen peroxide is formed in many reactions involving the reduction of oxygen $H.H+O : O \rightarrow HO : OH$, and not by the oxidation of water $H_2 : O+O \rightarrow H_2 : O : O$ as might be expected if

$H_2 : O : O$ represented the formula of this compound. In M. Traube's experiment, when the electrodes, during the electrolysis of acidulated water, were separated by a porous cell, no hydrogen peroxide could be detected in the electrolyte; but when air was bubbled about the cathode, the hydrogen appears to unite with molecular oxygen to form hydrogen peroxide. Consequently, he considers that hydrogen peroxide cannot be regarded as oxidized water since it is never formed as a product of oxidation, but is always formed by the reduction of molecular oxygen. He considers the peroxide to be formed by the coupling together of molecular oxygen and molecular hydrogen, and the oxygen which is given off in reactions with hydrogen peroxide is not formed from atomic oxygen, but the oxygen atoms, already paired in the hydrogen peroxide molecule, are liberated. With silver oxide, for example, the reaction is not altogether catalytic, for part at least of the silver oxide is reduced by the hydrogen of the peroxide—*vide* silver oxide.

$$Ag_2\boxed{O+H_2}O_2 \rightarrow 2Ag+H_2O+O_2 ; \text{ not } Ag_2\boxed{O+O\begin{matrix}OH\\H\end{matrix}} \rightarrow 2Ag+O_2+\begin{matrix}OH\\H\end{matrix}$$

Most of the reactions of hydrogen peroxide are similar reduction processes, while if hydrogen peroxide were built of two hydroxyl groups, it would rather act as an oxidizing agent. In all its decompositions, said M. Traube, hydrogen peroxide gives off molecular oxygen. M. Traube rather favoured the formula H.O : O.H, oxygen tervalent, but this is usually altered to H.O.O.H, oxygen bivalent, or to H.O ⋮ O.H, oxygen quadrivalent.

W. Spring (1895) considers the fact that hydrogen peroxide viewed in thick layers is rather more deeply coloured than water agrees with the view that it contains molecular oxygen, and he tries to give this rather feeble argument more weight by pointing out that ammonium iodide, NH_4I, is colourless while the tri-iodide, $NH_4I.I_2$, is green, and the pentaiodide, $NH_4I.I_4$, is violet. W. Spring also considers that the specific heat determinations of the elements H_2 and O_2 show that only part of their available free energy is used in forming hydrogen peroxide, and hence, the molecule has probably a more complex linking than is shown by the simple formula $H.H+O : O{=}HO.OH$.

J. W. Brühl (1896) determined the index of refraction and specific gravity of hydrogen peroxide purified by R. Wolffenstein's process, and found the molecular refraction R for the spectrum lines H_α and H_γ to be $R_\alpha=5{\cdot}791$ and $R_\gamma=5{\cdot}817$; hence the molecular dispersion $R_\gamma-R_\alpha=0{\cdot}136$. If corresponding constants for water and for hydrogen atom be subtracted, a value for hydroxyl OH is obtained:

	R_α	R_γ	$R_\gamma-R_\alpha$
HOH	3·69	3·71	0·09
H	1·10	1·05	0·04
HO	2·59	2·66	0·05

Doubling the value for OH to get the value for HO.OH, there follows the calculated values: $R_\alpha=5{\cdot}18$, $R_\gamma=5{\cdot}32$, and $R_\gamma-R_\alpha=0{\cdot}10$. The actual spectrometric constants are therefore larger than those calculated for the compound HO.OH, and since the additive rule here employed has been applied to a large number of compounds, the difference is explained by assuming that *the two oxygen atoms of hydrogen peroxide are joined by multiple bonds.* Again, the sum of the optical constant of an atom of oxygen, such as occurs in the molecule of water, is less than the observed constant for an equivalent of molecular oxygen, and the dispersion, $R_\gamma-R_\alpha$, of molecular oxygen is double that for the equivalent oxygen in water:

		R_α	R_γ	$R_\gamma-R_\alpha$
2O in water		2·968	3·212	0·036
Molecular oxygen	liquid	3·958	3·964	0·069
	gaseous	—	4·09	—

Again, fewer bonds are supposed to be concerned in uniting the atoms of molecular oxygen than is the case with the oxygen atoms in the molecule of hydrogen peroxide, because the optical constants calculated for hydrogen peroxide are rather less than for molecular oxygen :

	R_α	R_γ	$R_\gamma - R_\alpha$
Oxygen in water	2·968	3·212	0·036

M. Traube assumed oxygen to be tervalent in hydrogen peroxide, HO : OH, but there is no satisfactory evidence to warrant this assumption. The oxygen group of elements are bi- or quadri-valent, and there is much circumstantial evidence which warrants the assumption of quadrivalent oxygen. The multiple-bonded oxygen in hydrogen peroxide is therefore based on a quadrivalent oxygen, and the formula is written HO : OH, or HO≡OH.

J. W. Brühl [3] assumes that the oxygen in water has two latent valencies, $H\cdot\dot{O}\cdot H$, which are the cause of the tendency of water to form associated molecules. Indeed, E. Beckmann [4] found that all associated liquids are of the water type. Thus, the alcohols and the fatty acids are usually associated,[5] and J. T. Hewitt and T. F. Winmill attribute the association of phenols, R.OH, in the liquid condition to the coupling of the molecules in virtue of the residual valencies of the contained oxygen.

$$\begin{matrix}R\\H\end{matrix}\!>\!O=O\!<\!\begin{matrix}R\\H\end{matrix}$$

J. W. Brühl explains the cause of the great ionizing power of water as follows: Since hydrogen peroxide has even more unsaturated valencies than water, he inferred that hydrogen peroxide must possess a great power of ionization—three-quarters perhaps even greater than that of water. The ionizing power is not easily determined because of the great tendency of hydrogen peroxide to decomposition. Owing to the parallelism between dielectric constants and ionizing power, it also follows that the dielectric constant of hydrogen peroxide will be high. This has been demonstrated by H. T. Calvert,[6] who found the dielectric constant to be 92·8 (18°), when the value for water is 81 (18°). Again, according to P. Drude,[7] all hydroxyl compounds, with the exception of water, show an anomalous electrical absorption in that they are poor conductors of electricity and yet they absorb electromagnetic waves of short wave-length (70 cm.)—normally, substances which conduct electricity moderately well are non-absorbent. H. T. Calvert also found that hydrogen peroxide does not show this phenomenon of anomalous absorption. Hence, this compound is not to be regarded as a di-hydroxyl HO.OH, but, preferably, as a compound H.O$\vdots$O.H, "analogous with acetylene, and like acetylene it is formed endothermally, and is explosive."

2. *Evidence for* $H_2=O=O$.—A. Bach's formula $H_2=O=O$ is regarded by some as "undoubtedly representing the structure of the molecule correctly." The central quadrivalent oxygen is considered to be so heavily loaded with atoms that it readily parts with the two hydrogen atoms in the presence of oxidizing substances, or gives up the extra oxygen in contact with reducing agents. In the former case, it acts as a reducing agent, and in the latter, as an oxidizing agent. On this assumption, the reactions of ozone with hydrogen and barium peroxides are represented :

$$H_2=O=O+O=O=O \rightarrow H_2O+2O_2 ; \quad Ba=O=O+O=O=O \rightarrow BaO+2O_2$$

R. Willstätter and E. Hauenstein [8] have shown that the reduction of ethyl and benzoyl peroxides by platinum and hydrogen in the cold furnishes ethyl alcohol and benzoic acid respectively. It is therefore argued that the formula of benzoyl peroxide must be

$$\begin{matrix}C_6H_5.CO.O\\C_6H_5.CO.\dot{O}\end{matrix} \quad \text{and not} \quad \begin{matrix}C_6H_5.CO\\C_6H_5\,CO\end{matrix}\!>\!O=O$$

since the latter would give rise to benzoic anhydride, not the acid. A. Rius y Miró claims that this argument is weakened by the fact that the water formed in the reaction might hydrolyze any aldehyde formed; but the same result is obtained by reducing the peroxide in a boiling solution by means of yellow phosphorus. In addition, potassium orthophosphate is the sole product of the reduction of potassium perphosphate by potassium iodide in acetic acid solution, or by ferrous or cobalt hydroxides in alkaline solution. It is also shown that sulphuric acid cannot be oxidized to persulphuric acid by permanganic acid, plumbic salts, or nickel peroxide. The majority of oxidations due to hydrogen peroxide are really hydroxylations, but, although this is contrary to the asymmetrical formula, the case of potassium permanganate shows it does not necessarily lead to the symmetrical formula. This formula does not explain the reducing properties of hydrogen peroxide, attributed to weakly bound hydrogen atoms. A. Rius y Miró accordingly suggests the formula $\mathrm{H}<^{\mathrm{O}}_{\mathrm{O}}>\mathrm{H}$ for hydrogen peroxide, and proposes to call peroxides of the type RO_2R, *anhydrohydroperoxides*, to distinguish them from A. Baeyer's hydroperoxides.

§ 14. Peroxides and Peracids

Hydrogen peroxide has several properties in common with the acids. For example, purified hydrogen peroxide—perhydrol—reddens blue litmus before bleaching the colour; its acidity can be partly neutralized by the addition of alkaline solutions; it can be more readily extracted from its ethereal solution by alkaline lye than by water; and hydrogen peroxide displaces the acid radicle from sodium halides, silicate, borate, metaphosphate, and sulphide, and from potassium ferro- and ferri-cyanides.[1] In 1895, W. Spring pointed out that hydrogen peroxide behaves like a mono- and a di-basic acid in that it contains two hydrogen atoms which can be replaced singly or in pairs by equivalent radicles. The substitution products can be regarded as salts. The mono-substituted products are of the type ROOH, where R denotes a monad radicle—elementary or compound—and the di-substituted products are of the type ROOR, where the two R's may be the same or different. A. von Baeyer and V. Villiger[2] called the former **hydroperoxides**—*e.g.* ethyl hydroperoxide, $C_2H_5.OOH$, the latter **peroxides**—*e.g.* diethyl peroxide, $C_2H_5.OO.C_2H_5$. The peroxides can thus be regarded as salts of the acid, hydrogen peroxide, formed by the action of this compound on, say, the hydroxide of the alkalies or alkaline earths. Thus, by the action of sodium ethoxide, $C_2H_5.ONa$, on hydrogen peroxide in alcohol solution, R. Wolffenstein[3] prepared sodium hydroperoxide: $C_2H_5ONa + HOOH \rightarrow C_2H_5OH + NaOOH$, and according to electrical conductivity methods.

it is inferred that the salt is really NaOOH, and not $NaOONa.H_2O_2$. J. Tafel called the salt NaOOH, *sodyl hydroxide*. E. Schöne[4] prepared

$$\begin{matrix}H.OO \\ H.OO\end{matrix}\!>\!Ba$$

Barium hydroperoxide

$$\begin{matrix}HOO \\ HOO\end{matrix}\!>\!Ca$$

Calcium hydroperoxide

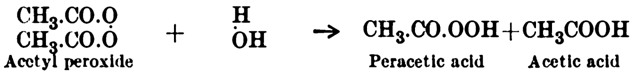
by the action of an excess of hydrogen peroxide on the hydroxides of the alkaline earths. If potassium or sodium carbonate be added to hydrogen peroxide, the corresponding alkaline peroxide is formed and carbon dioxide is evolved, *e.g.* $H_2O_2 + Na_2CO_3 \rightarrow Na_2O_2 + CO_2 + H_2O$; on the contrary, if the hydrogen peroxide be added to a solution of the carbonate oxygen is evolved: $2H_2O_2 + Na_2CO_3 \rightarrow Na_2CO_3 + 2H_2O + O_2$. The sodium carbonate in the latter case merely acts as a catalytic agent. It is not at all uncommon to find reactions progressing differently according to the way the substances are mixed together. The peroxides, in some cases, can also be precipitated from solutions of the corresponding salts by the addition of hydrogen peroxide. For instance, with lead acetate, PbA_2, lead peroxide is formed: $PbA_2 + H_2O_2 \rightarrow PbO_2 + 2HA$. An *excess* of hydrogen peroxide with lead peroxide furnished lead monoxide: $PbO_2 + H_2O_2 = PbO + H_2O + O_2$. Hydrated peroxides of the alkaline earths of the type $BaO_2.8H_2O$ are precipitated from solutions of the hydrated oxides by hydrogen peroxide; and conversely, when these peroxides are dissolved in dilute acids, the corresponding amount of hydrogen peroxide is set free. In both cases, hydrogen peroxide behaves like an acid, and the peroxides can accordingly be regarded as salts of hydrogen peroxide just as the nitrates are salts of hydrogen nitrate—to wit, nitric acid. It can be added that for similar reasons water liberates hydrogen peroxide from its assumed salts—the peroxides—and hence also water has been called an acid—water acid.

The organic radicles can also displace the hydrogen from hydrogen peroxide to form corresponding hydroperoxides and peroxides. The relations of the alcohols to the ethers and of the acids—*e.g.* acetic acid, CH_3COOH—to the acid anhydrides—*e.g.* acetic anhydride $(CH_3CO)_2O$—are analogous to the relations between the hydroperoxides and the peroxides—*e.g.*

$$CH_2.CO.OOH$$

$$\begin{matrix}CH_3.CO.O \\ | \\ CH_3.CO.O\end{matrix}$$

The action of water on the acid anhydrides—*e.g.* $(CH_3.CO)_2O + HOH \rightarrow 2CH_3.COOH$—recalls the action of water on the peroxides. For instance, with acetyl peroxide, peracetic and acetic acids are formed:



$$\begin{matrix}CH_3.CO.O \\ | \\ CH_3.CO.O\end{matrix} + \begin{matrix}H \\ | \\ OH\end{matrix} \rightarrow CH_3.CO.OOH + CH_3COOH$$

Acetyl peroxide Peracetic acid Acetic acid

with persulphuric acid, monopersulphuric acid or Caro's acid and sulphuric acid are formed:

$$\begin{matrix}HO.SO_2.O \\ | \\ HO.SO_2.O\end{matrix} + \begin{matrix}H \\ | \\ OH\end{matrix} \rightarrow SO_2\!<\!\begin{matrix}OOH \\ OH\end{matrix} + SO_2\!<\!\begin{matrix}OH \\ OH\end{matrix}$$

and with sodium peroxide, sodium hydroperoxide and hydroxide are formed:

$$\begin{matrix}NaO.O \\ | \\ Na\end{matrix} + \begin{matrix}H \\ | \\ OH\end{matrix} \rightarrow NaOOH + NaOH$$

The formation of the organic acids by the action of water on the acid chlorides is analogous with the formation of the peracids by the action of hydrogen peroxide on the acid chlorides: thus, $CH_3CO.Cl + HOOH \rightarrow CH_3CO.OOH + HCl$; or $HO.SO_2.Cl + HOOH \rightarrow HO.SO_2.OOH + HCl$. Similarly, just as the acid anhydride is formed by the action of an acid hydrate and acid chloride: $CH_3CO.OH + ClCO.CH_3 \rightarrow CH_3CO.O.CO.CH_3 + HCl$, so does hydrogen peroxide, and its acid chloride—*viz.*

hypochlorous acid, HOCl—form the corresponding acid anhydride, H.OO.OH, which, being unstable, decomposes into water and oxygen:

$$HOO\,H+Cl\,OH \rightarrow HOO.OH+HCl \rightarrow HCl+H_2O+O_2$$

D. I. Mendeléeff (1881)[5] subdivided the oxides of the type RO_2 into two classes—the superoxides and the polyoxides—depending upon the valency of the element united to the oxygen atoms: the one class was considered to be constituted on the hydrogen peroxide type, the other on the condensed water type.

Superoxides, peroxides, or true peroxides.—Those oxides in which the oxygen atom or atoms, over and above those required to form the basic oxide, are *singly linked* to the metal and to the other oxygen atoms, so as to form a chain. The valency of the metal is the *same* in the peroxide as in the basic oxide; *e.g.*

$$\begin{matrix}H-O\\ \vert \\ H-O\end{matrix}$$

Hydrogen peroxide.

$$\begin{matrix}Na-O\\ \vert \\ Na-O\end{matrix}$$

Sodium peroxide.

$$\begin{matrix}K-O-O\\ \vert \\ K-O-O\end{matrix}$$

Potassium tetroxide.

$$Ba{<}\begin{matrix}O\\ \vert \\ O\end{matrix} \text{ or } Ba{<}\begin{matrix}O\\O\end{matrix}$$

Barium peroxide.

The superoxides have also been called **peroxidates** or **peroxites** and regarded as salts of hydrogen peroxide, for they are supposed to be constituted like this compound. These oxides were Schönbein's antozonides—a term now obsolete.

Polyoxides, dioxides, or pseudo-peroxides.—Those peroxides in which the oxygen atom or atoms, over and above those required to form the basic oxide, are *doubly linked* to the metal so that the valency of the metal in the dioxide is *greater* than the valency of the metal in the basic oxide; *e.g.*

$$O{\leqslant}\begin{matrix}O\\O\end{matrix}$$

Ozone.

$$Pb{\leqslant}\begin{matrix}O\\O\end{matrix}$$

Lead dioxide.

$$Mn{\leqslant}\begin{matrix}O\\O\end{matrix}$$

Manganese dioxide.

These oxides possess feeble basic or feeble acidic properties—possibly both. They are supposed to be constituted on the double water type with a quadrivalent element taking the place of the four hydrogen atoms in two molecules of water. These oxides were Schönbein's *ozonides*—a term now applied to quite different compounds.

The peroxides which yield hydrogen peroxide when treated with water or a dilute acid are probably constituted like hydrogen peroxide. Thus, sodium peroxide with hydrochloric acid gives hydrogen peroxide; and potassium tetroxide, which gives oxygen and hydrogen peroxide, is probably constituted on the same plan. The polyoxides or dioxides are not usually attacked by dilute acids. Both types with concentrated sulphuric acid evolve oxygen. The mechanism of the reaction is probably different in the two cases. With the super- or per-oxides, hydrogen peroxide is probably formed as an intermediate product: $BaO_2+H_2SO_4=BaSO_4+H_2O_2$; followed by $2H_2O_2=2H_2O+O_2$. With manganese dioxide: $2MnO_2+2H_2SO_4=2MnSO_4+2H_2O+O_2$. Similarly with hydrochloric acid, both give chlorine, but with the peroxides hydrogen peroxide is first formed, and this reacts with the excess of acid forming chlorine: $2HCl+H_2O_2=2H_2O+Cl_2$; with the di- or poly-oxides, on the other hand, an intermediate perchloride can often be detected—with manganese dioxide, probably $MnCl_3$; and with lead dioxide, $PbCl_4$ is formed.

The differences in the behaviour of the true and false peroxides—typified by BaO_2 and PbO_2—has prompted many hypotheses. B. C. Brodie and C. F. Schönbein have assumed that the normal oxygen molecule contains a negatively and a positively charged oxygen atom, that substances undergoing oxidation have a preference for oxygen carrying one kind of charge while the oppositely charged oxygen is consumed in a secondary reaction. The positively charged oxygen was called *antozone*, and the corresponding oxides—PbO_2, $KMnO_4$, etc.—were called *ozonides*; the negatively charged oxygen atom formed *antozonides*—*e.g.* Na_2O_2, BaO_2, H_2O_2, etc. For instance, $H_2O+O=$hydrogen peroxide; and $MnO+O=$manganese dioxide. The union of antozone O^+ with ozone O^- gives ordinary oxygen, and such a reaction was supposed to occur when hydrogen peroxide (an antozonide) reacts with, say, lead peroxide (an ozonide). No direct experimental evidence can be quoted demonstrating the existence of Schönbein's antozone.

S. Tanatar[6] has suggested that the differences between the true and false peroxides are due to differences in the thermal values of the reactions which occur when the oxides are treated with acids. The formation of hydrogen peroxide from water requires 23 Cals., and if the thermal value of the reaction between the metal of the peroxide and the radicle of the acid is less than this value, no hydrogen peroxide can be produced. The strong acids—*e.g.* hydrochloric acid—give hydrogen peroxide with barium peroxide, while the weaker acids—*e.g.* phenol—give oxygen but no hydrogen peroxide. Hence, the distinction between a true or false peroxide is arbitrarily determined by the strength of the acid used in making the test. S. Tanatar further states that appreciable amounts of hydrogen peroxide are formed when nickel dioxide is treated with sulphuric acid, because (i) the solution liberates iodine from potassium iodide; and (ii) decolorizes a solution of potassium permanganate; but C. Tubandt and W. Riedel[7] could not get the confirmatory tests with chromic and titanic acids, and it is hence inferred that the liberation of iodine is due to the formation of traces of a persulphuric acid; and that the bleaching of the permanganate is not real, but rather a masking of the pink colour of the permanganate by the green colour of the nickel solution. The formation of hydrogen peroxide occurs not only when hydrocyanic acid acts on nickel peroxide, but also when nickel hydroxide is used; the peroxide is presumably formed by the autooxidation of the complex nickel cyanides which are formed. G. Pellini and D. Meneghini[8] have shown that there are possibly two nickel peroxides, one of which gives hydrogen peroxide when treated with acids, and the other does not. According to S. Tanatar, the former may really be a compound of hydrogen peroxide and nickel monoxide, and not a dioxide at all.

Attempts have been made to show that two of the best-known dioxides, PbO_2 and MnO_2, are differently constituted because lead dioxide when decomposed by sulphurous acid, H_2SO_3, furnishes lead sulphate, $PbSO_4$, while manganese dioxide furnishes manganous dithionate, MnS_2O_6. It is more probable that the action in both cases is similar, manganese dioxide forming the normal sulphite, $Mn(SO_3)_2$; and lead dioxide, the basic sulphate, $PbO.SO_3$. Both salts then undergo internal rearrangement, the former producing a dithionate, and the latter a normal sulphate.

There is a distinction between the peracids analogous to that occurring between the peroxides. The true peracids are either formed by the action of hydrogen peroxide on ordinary acids or their derivatives, or else they furnish hydrogen peroxide when hydrolyzed with dilute sulphuric acid—with concentrated sulphuric acid they behave like the peroxides and give ozonized oxygen. The prefix *per* is applied to many acids—perchloric acid, permanganic acid, etc.—to denote that they contain relatively more oxygen than the acid indicated when the prefix is deleted. These acids do not give hydrogen peroxide by hydrolysis, moreover they are not formed by the action of hydrogen peroxide. In many cases, it is not clear whether the so-called peracid is an additive compound of the acid with hydrogen peroxide of crystallization, analogous to water of crystallization, or whether it is a real peracid in which the acid radicle has united with the hydrogen peroxide.

The elements which form peracids belong to the 3rd, 4th, 5th, and 6th groups of Mendeléeff's periodic system, although O. Carrasco (1911) claims to have prepared a perzincic acid. If the claim be established, zinc in the second group will have to be included in the list of elements forming true peracids. T. S. Price[9] represents the elements forming peracids in black type as illustrated in Table IV.

TABLE IV.—ELEMENTS IN THE PERIODIC SYSTEM FORMING PERACIDS.

Group III.		Group IV.		Group V.		Group VI.	
B		**C**		**N**		O	
Al		Si		**P**		**S**	
Sc		**Ti**		**V**		**Cr**	
	Ga		Ge		As		**Se**
Y		**Zr**		**Cb**		**Mo**	
	In		**Sn**		Sb		Te
(**La**)		Ce		—		—	
—		—		—		—	
Yb		—		**Ta**		**W**	
	Tl		Pb		Bi	—	
—		Th		—		**U**	

T. S. Price also shows that, omitting the first two rows, the elements which form peracids are mainly confined to the members of the even series, and that the stability of the peracids increases with increasing atomic weight of the element in agreement with the rule that with the elements of the even series the higher the atomic weight the greater their basicity—for instance, in the 6th group, peruranic acid is the most stable peracid of the family, and can be prepared at ordinary temperatures; while permolybdic acid can be obtained only at temperatures approaching —10°. Pertungstic acid is more stable than permolybdic acid.

The peracids can be regarded as derivatives of hydrogen peroxide in which one of the hydrogen atoms is replaced by an acid radicle. Otherwise expressed, the peracids can be regarded as acids in which one or more hydroxyl groups are replaced by the monad radicle O.O.H.

Ordinary acids.		Peracids.	
Metaboric acid . . .	HO.BO	Perboric acid . . .	HOO.BO
Acetic acid . . .	$CH_3CO.OH$	Peracetic acid. . .	$CH_3.CO.OOH$

The diabasic acids form two series of peracids according as one or both the hydroxyl groups are replaced by the HOO- radicle.

$\mathrm{CO}<\begin{matrix}\mathrm{OH}\\\mathrm{OH}\end{matrix}$

Carbonic acid.

$\mathrm{CO}<\begin{matrix}\mathrm{OH}\\\mathrm{OOH}\end{matrix}$

Monopercarbonic acid.

$\mathrm{CO}<\begin{matrix}\mathrm{OOH}\\\mathrm{OOH}\end{matrix}$

Dipercarbonic acid.

Similarly with the acids of higher basicity. The peracids form **persalts**. There are theoretically two acid persalts and one normal persalt of the monoperacids, and one each of the diperacids. For example,

$\mathrm{CO}<\begin{matrix}\mathrm{OONa}\\\mathrm{ONa}\end{matrix} \quad \mathrm{CO}<\begin{matrix}\mathrm{OOH}\\\mathrm{ONa}\end{matrix} \quad \mathrm{CO}<\begin{matrix}\mathrm{OONa}\\\mathrm{OH}\end{matrix} \quad \mathrm{CO}<\begin{matrix}\mathrm{OONa}\\\mathrm{OONa}\end{matrix} \quad \mathrm{CO}<\begin{matrix}\mathrm{OONa}\\\mathrm{OOH}\end{matrix}$

Salts of the percarbonic acids.

There is also a series of acid derivatives of hydrogen peroxide in which the acid characteristics belong rather to the acid radicle itself than to the presence of the HOO-group. They are generally prepared by electrolysis, and they can be regarded as derivatives of hydrogen peroxide in which both the hydrogen atoms are replaced by acid radicles. They are rather acid peroxides than true peracids, although they are commonly called peracids. For example

Hydrogen peroxide.	Persulphuric acid.	Percarbonic acid.
$\begin{matrix}\mathrm{HO}\\\mathrm{HO}\end{matrix}$	$\begin{matrix}\mathrm{HO.SO_2.O}\\\mathrm{HO.SO_2.O}\end{matrix}$	$\begin{matrix}\mathrm{HO.CO.O}\\\mathrm{HO.CO.O}\end{matrix}$

The salts of these acid peroxides do not give the characteristic reactions of hydrogen peroxide. For instance, the persulphates do not give the blue coloration by the chromic acid and ether test; potassium permanganate in acid solution is not decolorized; iodine is not separated from potassium iodide; etc. These salts, however, may be hydrolyzed into hydroperoxides in aqueous solutions and they may then show the characteristic reactions of hydrogen peroxide. In this series of persalts, the free acids corresponding with the persulphates have alone been isolated. It will be observed that further complications are theoretically possible, for these peroxide acids may form true peracids by the replacement of one or both the hydroxyl radicles by HOO-radicles. Thus,

$$\begin{array}{ccc} \mathrm{HO.CO.\underset{\cdot}{O}} & \mathrm{HOO.CO.\underset{\cdot}{O}} & \mathrm{HOO.CO.\underset{\cdot}{O}} \\ \mathrm{HO.CO.\dot{O}} & \mathrm{HO.CO.\dot{O}} & \mathrm{HOO.CO.\dot{O}} \end{array}$$

Peracids of the acid peroxides.

CHAPTER XV

ELECTROLYSIS AND THE IONIC HYPOTHESIS

§ 1. The Products of Electrolysis

> The electricity which decomposes, and that which is evolved by the decomposition of a certain quantity of matter are (qualitatively and quantitatively) the same.—M. FARADAY.

ONE or both of the products of electrolysis may be an insoluble solid, a soluble liquid, a gas, etc. When an insoluble solid is formed it may stick to the electrode, or fall to the bottom of the electrolytic cell ; if a gas, not too soluble in the electrolyte, be formed, it can be collected in a suitable receiver. Substances are not always visible when in solution. The soluble matter can often be isolated more or less completely by surrounding the proper electrode with a porous pot which retards the diffusion and mixing of the products separated at the two electrodes. This is done, for example, in the industrial preparation of chlorine.

The electrolysis of a solution of copper sulphate furnishes the products : copper, sulphuric acid, and oxygen. This is more than was present in the copper sulphate used at the start. It is therefore assumed, as a trial hypothesis, that Cu and SO_4 ions are produced at the electrodes during the passage of the current ; that the Cu-cation carries a positive charge of electricity, and the SO_4-anion a negative charge. Consequently, the Cu-ion will be found at the negative electrode, and the SO_4-ion at the positive electrode. The ions are de-electrified at the electrodes—the Cu-ion at the cathode, and the SO_4-ion at the anode. The de-electrified copper ions are deposited as metallic copper about the cathode ; and the de-electrified SO_4-ion, at the anode, reacts at once with the solvent (water), producing sulphuric acid and oxygen: $2SO_4+2H_2O=2H_2SO_4+O_2$. When an aqueous solution of potassium nitrate is electrolyzed, potassium hydroxide and gaseous hydrogen are formed at the cathode ; and nitric acid and oxygen at the anode. It is assumed that the potassium nitrate is first decomposed into two electrified K^+ and NO_3^- ions at the electrodes ; and that the K^+-ion, when de-electrified, reacts with water at the cathode, producing potassium hydroxide and hydrogen ; and the NO_3^- ion, when de-electrified at the anode, reacts with water, giving nitric acid and oxygen: $4NO_3^-+2H_2O=4HNO_3+O_2$. Again, if a solution of copper sulphate be electrolyzed with copper electrodes, metallic copper is deposited at the cathode, and the sulphuric acid produced at the anode attacks and dissolves the copper cathode forming copper sulphate. This explains how the total concentration of a solution of copper sulphate does not alter if it be electrolyzed in a cell with a copper anode. Similar remarks apply to the electrolysis of solutions of silver nitrate with a silver anode, Fig. 1 ; of ferrous ammonium sulphate with an iron anode ; of nickel ammonium sulphate with a nickel anode ; etc.

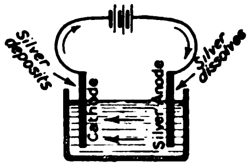

FIG. 1. — Electrolysis of Silver Nitrate.

Electroplating.—If a plate of silver be used as the anode during the electrolysis of silver nitrate, metallic silver will be dissolved by the nitric acid as fast as the acid is formed.

Thus, the concentration of the silver nitrate in the solution will remain unchanged and metallic silver will be transported from anode to cathode. This is the principle of the method of electroplating. In the case of *silver-plating* a firmer and more uniform deposit of silver is obtained by using a solution of silver cyanide in potassium cyanide as the electrolyte in place of a solution of silver nitrate. The article to be plated, say a brass spoon, is attached to a wire and dipped in the solution of silver salt, and this is made the cathode. A bar or sheet of silver is made the anode. A rather weak electric current is sent through the electrolyte. The electrolyte is decomposed, and silver (cation) is deposited on the article to be plated (cathode); the anion collecting at the anode dissolves the silver anode, and thus keeps the strength of the electrolyte unchanged. What is dissolved at the anode is deposited at the cathode. Salts of other metals—nickel, iron, gold, platinum, etc.—can be used as electrolytes in a similar manner, and accordingly articles can be nickel-plated, gold-plated, etc. The plated articles may be afterwards burnished.

Units.—We first inquire if there is any relation between the quantity of electricity passing through an electrolytic cell and the amount of decomposition. In order to fix a standard of measurement, let the quantity of electricity required to deposit 0·001118 gram of silver be called a **coulomb.** This is the so-called **unit quantity of electricity.** Hence 108 grams of silver, that is, a chemical equivalent of silver, will be deposited by 96,540 coulombs of electricity. This amount of electricity is often called a **farad.**

The so-called "hydraulic analogy" of an electric current might here be cited. The quantity of water flowing through a pipe can be expressed in gallons or cubic feet per second; in a similar way, **quantity of electricity** may be expressed in terms of coulombs per second. An electric current carrying one coulomb per second is called an **ampère.** This is the so-called **unit current of electricity.** A coulomb by the same analogy would correspond with, say, a gallon or cubic foot of water; and an ampère with a gallon or a cubic foot of water *per second*. For example, if 20 coulombs of electricity pass through a current in 20 seconds, the current is $60 \div 20 = 3$ ampères, or 3 coulombs per second. The total quantity of water delivered by a pipe is determined by the "head" or pressure of water, so that in order to pass a certain number of gallons per second through a given pipe, a certain pressure must be applied to overcome the frictional resistance of the pipe. In the same way, a certain electromotive force—electrical pressure—is required on account of the **resistance** offered by the wire to the flow of electricity. Just as water pressure is measured in pounds per square inch, or in feet "difference of level" or "head," so the unit of electrical pressure, the **volt**, is the difference of potential needed to produce a current of one ampère in a conductor whose resistance is equivalent to that of a uniform column of 14·45 grams of mercury, 106·3 cm. long. The resistance of such a column is called an **ohm.** Hence a volt is the electric pressure required to produce a current of one ampère in a conductor of one ohm resistance. The terms **voltage, electrical pressure,** and **electromotive force** are generally applied synonymously to an electric current, or, if the current be not directly under consideration, the term **difference of potential** is used. It is, of course, needless to dwell on the fact that the analogy used above in comparing an electric current with a moving fluid is merely a convenience. It is probable that electricity is not a fluid, and the analogy must not be carried much further.

§ 2. Faraday's Laws of Definite Electrolytic Action

Nature presents us with a single quantity of electricity. For each chemical bond which is ruptured within an electrolyte, a certain quantity of electricity traverses the electrolyte, which is there in all cases.—G. J. Stoney (1881).

M. Faraday (1834) [1] found that the amount of chemical work done by an electric current is directly proportional to the quantity of electricity which passes through the electrolyte. If one farad leads to the separation of 108 grams of silver, two farads will lead to the separation of 216 grams of silver, and so on. Similar results are obtained with other electrolytes. Hence, said Faraday, "**the chemical decomposing action of a current is constant for a given quantity of electricity;**" or, "the quantity of chemical decomposition is exactly proportionate to the quantity of electricity which has passed through the electrolyte;" if w denotes the number of grams of an element set free by the decomposition of a compound by the passage of a quantity of electricity C, then w is proportional to C; and consequently, "the products of decomposition . . . afford a very excellent and valuable measure of the electricity concerned in their evolution." The increase in the weight of, say, the negative electrode during the electrolysis of silver nitrate or copper sulphate owing to the deposition of metallic silver or copper respectively, is a measure of the quantity of electricity which has passed through the system. A cell specially designed for such measurements is called a **silver voltameter** or a **copper voltameter** respectively.

Provided there are no disturbing secondary actions, the amount of electro-decomposition is not affected by the strength (or intensity) of the current, the time the current is passing, the concentration of the solution, the nature of the dissolved substance, nor by the temperature. The same quantity of electricity will always liberate the same quantity of the elements stated. The accuracy of the law is said to have been established for "currents so small that a century would be required for the separation of a milligram of hydrogen," and in large electrochemical works, the law is continually being verified by the passage of millions of coulombs. In every case, the law describes the phenomena exactly. **The quantity of an element liberated by the passage of one farad of electricity is called the electrochemical equivalent of the element.**

Again, let a current be *simultaneously* passed through six cells containing respectively dilute sulphuric acid, aqueous solutions of silver nitrate, cuprous chloride and hydrochloric acid, cupric sulphate, gold chloride, and stannic chloride. The experiment is conducted by arranging the electrolytic cells as illustrated in the plan, Fig. 2. After about half an hour's electrolysis the amounts of the different elements collected at the cathode can be weighed or measured. The results will be very nearly:

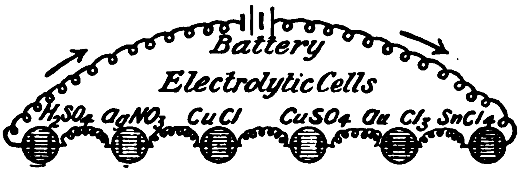

FIG. 2.—Experiment illustrating Faraday's Laws.

	Dilute H_2SO_4		$AgNO_3$	CuCl	$CuSO_4$	$AuCl_3$	$SnCl_4$
	Cathode. Hydrogen.	Anode. Oxygen.	Silver.	Copper.	Copper.	Gold.	Tin.
Amount found .	0·0266	0·2126	2·9370	1·6900	0·8440	1·7476	0·7554 gram
If H = 1 . .	1	8	108	63·5	31·8	65·7	29·8
Atomic weight .	1·01	16	107·9	63·6	63·6	197·2	119
Valency . .	1	2	1	1	2	3	4

Accordingly, chemically equivalent quantities of the different elements (that is, atomic weight ÷ valency) are liberated by the passage of the same quantity of electricity. Consequently, **the electrochemical equivalent of an element is numerically the same as the chemical equivalent.** The equivalent weights of bodies are those quantities of them which are decomposed by equal quantities of electricity. Hence, it is inferred that electricity determines the combining forces because it determines the combining weights.

At first sight, this result appears to contradict the principle of excluded perpetual motion, because, if the current from a $Zn|H_2SO_4|Pt$ battery be sent through an indefinite number of electrolytic cells containing dilute sulphuric acid, the same amount of hydrogen would be liberated in each, and sufficient hydrogen could be collected to furnish, on combustion, enough heat to evaporate the solution of zinc sulphate in the battery to dryness, to transform the zinc sulphate to metallic zinc and sulphuric acid, and so reconstruct the battery; and have some hydrogen remaining in excess. The experiment fails. The current will not traverse an indefinitely large number of cells. W. H. Wollaston[2] showed in 1801 that in dealing with electrical energy we are concerned with two different factors, and that "quantity of electricity" is only one of these factors. Faraday's law describes the influence of "quantity of electricity" upon electrolysis. It says nothing about the electrical **pressure**—the electromotive force, described, say, in volts—required to drive a given **quantity** of electricity through the system. Hence, Faraday's work may be summarized: **The same quantity of electricity passing through one or more electrolytes connected up in series, will liberate in each cell chemically equivalent amounts of the products of electrolysis, provided the electromotive force permits the necessary current to be maintained.** It might here be added that, for reasons which will be discussed later, a certain specific electrical pressure or voltage—called the **decomposition voltage**—is required to electrolyze a given solution; thus, hydrochloric acid requires about 1¼ volts, and fused sodium chloride about 4 volts.

Nomenclature.—Let each positive charge of electricity be represented by a small dot, and each negative charge by a small dash at the upper right-hand corner of the chemical symbol for an element, then, a silver ion will be written $Ag^{\cdot}$; a zinc ion by $Zn^{\cdot\cdot}$; a nitrate ion, NO_3'; and a sulphate ion by SO_4''. In the electrolysis of aqueous solutions of salts, etc., the separation of an ion at one electrode is always attended by the separation of a chemically equivalent ion or ions at the other electrode. For instance, with zinc chloride, for every $Zn^{\cdot\cdot}$ which is de-electrified at the cathode, two Cl' ions will be de-electrified at the anode. In order to designate positive ions J. Walker (1901)[3] appends *ion* to the stem with a prefix mono-, di-, tri-, . . . to indicate the number of charges carried by the ion. Thus $H^{\cdot}$ is called *hydrion*; $Na^{\cdot}$, *sodion*; $Fe^{\cdot\cdot}$, *diferrion*; $Fe^{\cdot\cdot\cdot}$, *triferrion*; etc. For negative ions, the termination of -ate becomes *-anion*; -ite, becomes *-osion*; and -ide, becomes *-idion*. Thus OH' is hydroxidion; Cl', *chloridion*; ClO_3', *chloranion*; OCl', *hypochlorosion*; SO_3'', *sulphosion*; SO_4'', *sulphanion*; etc. To this, A. Smith (1901) adds the term *ionogen* for "bodies which are capable of undergoing ionization," reserving the term *electrolyte* for the solution as a whole than for the substance dissolved.

We have just seen that the electrochemical and chemical equivalents are numerically the same, and therefore the electrochemical equivalent of an element is obtained by dividing the atomic weight by the valency. The same quantity of electricity—positive or negative—must therefore be carried by each univalent atom, and accompany it in all its movements in the electrolytic fluid. This quantity has been called the **unit charge of the ion.** At first sight this deduction appears to be rather startling, for it seems to imply either that the electric charges are divisible or that the so-called bivalent atoms are composed of two sub-atoms, the tervalent atoms, of three sub-atoms; etc. The former hypothesis is generally accepted. Accordingly, a univalent atom is supposed to carry one charge of electricity (96,540 coulombs); a bivalent atom two charges, and an n-valent atom, n charges. According to this view, valency represents the number of charges of electricity which are associated with the respective ions, **and chemically equivalent quantities of matter have the same capacity for electricity.** That is, "the chemical equivalent is the electrical unit of matter," or, as M. Faraday expressed it:

> The equivalent weights of bodies are simply those quantities which contain equal quantities of electricity, or have naturally equal electric powers; it being electricity which determines the equivalent number because it determines the combining force. Or, if we adopt the atomic theory or phraseology, then the atoms of bodies which are equivalent to each other in their ordinary chemical action have equal quantities of electricity naturally associated with them.

So close is the relation between the chemical and electrochemical equivalents that R. Luther (1905) proposed to define the combining weight of a univalent element as the quantity corresponding with 10,000 electromagnetic units, which, in turn, is very nearly 100,000 coulombs. Hence this means little more than multiplying the numbers at present in use by 3·46 per cent.

Quantity of electrolytic work done by a current.—M. Faraday has shown that the amount of chemical decomposition in a given time depends upon the amount of current employed; and that the one magnitude can be computed when the other is known. To find the relation between the chemical equivalent of an element and quantity of electricity. Let ϵ denote the chemical equivalent of a substance, then the weight w of an element liberated by constant quantity of electricity is proportional to ϵ, but, w is also proportional to the quantity of electricity C; and therefore $w=k\epsilon C$, where k is a constant sometimes called *Faraday's constant.* If suitable units be chosen, $w=\epsilon C$. Consequently, **the electrochemical equivalent of an element is the amount in grams liberated by one coulomb.** Careful measurements have shown that 0·001118 grm. of silver will be deposited by one coulomb. Since the chemical equivalent of silver is very nearly 107·88, hydrogen unity, 0·001118 grm. is 107·88 times greater than the amount of hydrogen which will be separated by a coulomb; accordingly, 0·00001036 grm. or $1{\cdot}036\times10^{-5}$ grm. *of hydrogen will be separated by the passage of one coulomb of electricity.* The electrochemical equivalent of univalent copper is $63{\cdot}5\times1{\cdot}036\times10^{-5}$; of bivalent copper, $\frac{1}{2}$ of $63{\cdot}5\times1{\cdot}036\times10^{-5}$; of ferrous iron, $\frac{1}{2}$ of $56\times1{\cdot}036\times10^{-5}$; of ferric iron, $\frac{1}{3}$ of $56\times1{\cdot}036\times10^{-5}$; and generally, if ϵ denotes the chemical equivalent of an element—that is, atomic weight $\div$valency—the electrochemical equivalent is $1{\cdot}036\times10^{-5}\epsilon$. Again, if a coulomb of electricity liberates $1{\cdot}036\times10^{-5}$ grms. of hydrogen per second, a ampères will liberate $1{\cdot}036\times10^{-5}a\epsilon$ grms. per second, and generally, *the number of grams of an element whose chemical equivalent is liberated by the passage of a ampères of electricity flowing for t seconds is* $1{\cdot}036\times10^{-5}\epsilon at$. If ϵ denotes the electrochemical equivalent of an element, such that $\epsilon=1{\cdot}036\times10^{-5}e$, the number of grams of an element whose electrochemical equivalent is ϵ liberated by the passage of a ampères flowing for t seconds is ϵat. It also follows that $1{\cdot}036\times10^{-5}A/n$ grms. of an n-valent element of atomic weight A, will be deposited per coulomb. By Avogadro's rule, a gram-molecule of a gas—of molecular weight M and N-atoms per molecule—occupies $22{\cdot}4\times10^3$ c.c. Hence $(22{\cdot}4\times1{\cdot}036\times10^{-2})/Nn$ c.c. of the gas are given off per coulomb. For a univalent gas with two atoms per molecule, $N=1$, $n=2$, and therefore 0·116 c.c. are obtained per coulomb at n.p.t., or 8·6193 coulombs are required per c.c. of gas. This corresponds with 0·4176 litre per ampère hour, or 2·3943 ampères are needed per litre of gas; or with 14·750 c. ft. are liberated per 100 amp. hours, or 67·798 amps. are needed per cubic foot of gas.

EXAMPLES.—(1) An electric current is passed simultaneously through the following solutions: Hydrochloric acid, ferrous sulphate, ferric sulphate, and silver potassium cyanide. If 5·2 litres of hydrogen at n.p.t. were evolved from the hydrochloric acid, how much metal would be deposited in the case of the iron and silver salts? Here 5·2 litres of hydrogen weigh 0·4664 grm. The chemical equivalent—that is, one gram—of hydrogen is equivalent to $\frac{1}{2}$ of $56=28$ grms. of ferrous iron; to 18·67 grms. of ferric iron; and to 108 grms. of silver. Hence, $0{\cdot}4664\times28=13$ grms. of iron will be deposited from the ferrous sulphate; 8·7 grms. from the ferric sulphate; and 50·1 grms. from the silver solution.

(2) A current of 0·04 amp. was passed through a solution of copper sulphate for $1\frac{1}{2}$ hrs. Hence, how much copper was deposited when the electrochemical equivalent of copper is 0·000329 grm.? There are 5400 seconds in $1\frac{1}{2}$ hrs., hence $0{\cdot}000329\times0{\cdot}04\times5400$ grms. of copper were deposited.

(3) A current of $2\frac{1}{2}$ amps. was obtained from a voltaic cell for $2\frac{1}{4}$ hrs. How much zinc was dissolved, given the electrochemical equivalent of zinc is 0·000337? Ansr. 6·8 grams.

(4) What are the electrochemical equivalents ϵ of hydrogen, of copper (cupric), and of zinc? Hydrogen, $1{\cdot}036\times10^{-5}\times1=0{\cdot}00001036$; copper, $\frac{1}{2}$ of $63{\cdot}5\times1{\cdot}036\times10^{-5}=0{\cdot}000329$; zinc, $\frac{1}{2}$ of $65\times1{\cdot}036\times10^{-5}=0{\cdot}000337$.

(5) In C. Höpfner's method (1900),[4] a solution of ferric and sodium chlorides is used as electrolyte and the copper passes into solution as cuprous chloride. Compare the quantity of electrical energy required to precipitate copper from Höpfner's solution, and from a solution containing copper sulphate. Here bivalent copper requires $2\times96{,}540$ coulombs for precipitating 63·57 grms., while univalent copper requires but 96,540 coulombs for precipitating the same weight of copper. Hence the precipitation of a given weight of copper from cuprous chloride requires but half the electrical energy as that required when cupric sulphate is used.

H. von Helmholtz (1881)[5] has emphasized the fact that the evidence indicates that electricity associates with the atoms of matter in multiples of one fundamental quantity, but never in fractions of it; these fractions may not be impossible, but they have not yet been found. Hence the evidence for the atomic nature of electricity is much the same as for the atomic nature of matter. The charge on a monad atom is therefore a natural unit of electricity. To illustrate the prodigious electrical capacity of the molecules, H. von Helmholtz estimates that if the opposite electricities were extracted from a milligram of water, and given to two spheres a mile apart, these two spheres would attract each other with a force of ten tons.

§ 3. The Velocity of Electrolytic Conduction

> The conduction of electricity through electrolytes is utterly indistinguishable from metallic conduction except for the action at the electrodes which is not part of true conduction at all.—J. T. SPRAGUE (1892)

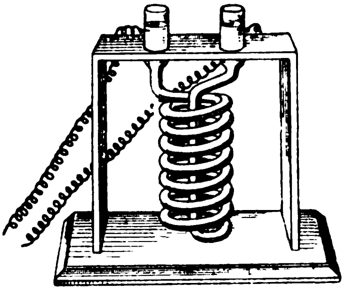

FIG. 3. — Velocity of Electrolytic Conduction.

An electric current travels through an electrolytic solution as quickly as if the same current were sent through a copper wire of the same resistance, and the products of electrolysis appear simultaneously at both electrodes, however far apart the electrodes be placed. N. M. Hopkins (1905)[1] passed a current through a tube 1500 cm. long, and through another tube 10 cm. long, and measured the time required for the current to pass by means of a chronograph sensitive to nearly 10,000 cm. per second. The tubes were filled with dilute sulphuric acid and fitted with electrodes—the anode of copper and the cathode of platinum. As soon as the current passed, bubbles of hydrogen appeared at the cathode simultaneously with the blue colour of copper sulphate at the anode. The electrolyte 1500 cm. long conducted as quickly as the electrolyte 10 cm. long. The experiment can be illustrated by the apparatus sketched in Fig. 3, which almost explains itself. The long spiral tube contains the electrolyte as in Hopkins' experiment. As soon as the circuit is closed electrolysis begins. As A. E. Dolbear puts it:

> If the two terminals of an electric circuit were on opposite sides of the Atlantic ocean, and a current were sent through the circuit, hydrogen would appear on one side and oxygen on the other . . . and in amounts defined by Faraday's laws of electrolysis.

Returning to Fig. 3, the known rates of diffusion of molecules in solutions are altogether too slow to allow the SO_4 which attacked the copper, to have come from the same H_2SO_4 molecule as the hydrogen liberated at the cathode. Further, it is supposed that the electrical energy used in electrolysis is entirely expended in overcoming the resistance of the electrolyte, and no measurable quantity of work is needed for tearing apart the components of the decomposing molecule. Hence, it follows that (i) **the molecules of an electrolyte in solution must be in a condition to conduct the electric current immediately the necessary electrical stress is applied to overcome the resistance of the liquid**; and that (ii) there must be either an exchange of partners among all the molecules of the liquid which take part in conducting the current, or else anions and cations exist in the liquid in the free state.

§ 4. The Effect of the Solvent

Those bodies only are electrolytes which are composed of a conductor and a non-conductor.—W. A. MILLER.

Does the salt alone, or the water alone conduct the current; or is the conduction of the current shared between the solvent and solute; or does neither the salt nor the water alone conduct the current, but is the current carried by a hydrate which conducts and is decomposed by the current as a whole? The more care taken in the purification of water, the less does it conduct electricity, and consequently, it is assumed that pure water is a non-conductor in spite of the fact that perfectly non-conducting water has not yet been made. Pure dry liquid hydrogen chloride, like water, appears to be a non-conductor. A mixture of water and hydrogen chloride is an electrolyte. Hence, it is inferred that **the electrolytic conductivity of a solution is a joint property of solvent and solute, and not a property of either constituent alone.** Solutions of dry hydrogen chloride in some solvents—*e.g.* dry benzene or chloroform—conduct electricity so feebly, if at all, that they are said to be non-conducting; and solutions of some substances in water conduct no better than water itself—*e.g.* solutions of sugar or alcohol in water. Hence, also, it follows: **the electrolytic conductivity of a solution depends upon some specific relation between the solvent and the solute.** The same conclusion can be deduced in the following manner: If the solute—say copper sulphate—alone conducts the current in a cell with platinum electrodes, then copper alone will be deposited at the cathode, and the SO_4 at the anode decomposes the water forming sulphuric acid and liberating oxygen; *i.e. all the free acid appears at the anode.* If the water alone conducts the current oxygen alone appears at the anode, and at the cathode, hydrogen decomposes the copper sulphate forming sulphuric acid and depositing copper; *i.e. all the free acid appears at the cathode.* If water conducts $1/x$th and the solute conducts $(1-x)/x$th of the current, then the ratio of the free acid formed at the anode, to the free acid formed at the cathode, will be as $(x-1):1$. So far as observation shows, some free acid is always formed at both electrodes, and hence the conduction of the current is probably shared by the solvent and solute. The facts observed also fit the assumption that a hydrate or hydroxylic compound exists in solution, and this conducts and is decomposed as a whole.

In a general way, aqueous solutions of acids, bases, and salts conduct electricity, and these substances are often called electrolytes, not because the salt conducts the current, but because their aqueous solutions conduct the current electrolytically. Some fused salts conduct electrolytically, *e.g.* with fused silver chloride and silver electrodes, silver is dissolved at the anode and deposited on the cathode, so that the total amount of silver chloride is maintained constant; with carbon electrodes, silver is deposited at the cathode, and chlorine evolved at the anode.

It is usually stated that an acid or alkali is added to water in order that the latter may be decomposed into its constituent elements by the electric current. The function of the acid (or, *mutatis mutandis*, of the alkali) has been a subject of some speculation. (i) It has been said that the mere presence of the acid simply makes the water a conductor and that the water alone is decomposed by the current: $2H_2O=2A_2{}^{+}+O_2{}^{-}$; it has also been said that the acid alone is decomposed by the current, and that the water is attacked by the products of the electrolysis and chemically decomposed. Symbolically, $2H_2SO_4=2H_2+2SO_4$ (electrolysis) followed by $2SO_4+2H_2O$

$=2H_2SO_4+O_2$ (chemical). As a matter of fact, it is very doubtful if pure anhydrous acid or pure water is a conductor. Hence, it is not more logical to say that the acid makes the water a conductor than that the water makes the acid a conductor. Each constituent loses its individuality when mixed together. At first sight, it seems as if **during the electrolysis of acidulated water, the mixture must be regarded as a unit which (1) conducts the current from one electrode to the other; and which (2) suffers decomposition by electrical influences at the surfaces of the electrodes.** Several working hypotheses can now be devised—*e.g.* with dilute sulphuric acid, it is plausible to assume that the electrolyte contains the complex $H_2SO_4.nH_2O$. During electrolysis, neither the water nor the acid is decomposed, but rather the complex: $2H_2SO_4.nH_2O=2nH_2^{+}+nO_2^{-}+2H_2SO_4$. The action of the current is to deprive the complex of both hydrogen and oxygen in the proportions $2H_2 : O_2$.

In a general way it may be said that (i) electrolytic conduction is accompanied by visible decomposition, or (ii) polarization phenomena (*q.v.*) may appear. (iii) An assembly of metals at a constant temperature can give no current, but if an electrolyte be introduced into the series a current can be obtained. (iv) According to the electromagnetic theory of light, if a conductor be transparent it will probably conduct electrolytically, *e.g.* fused salts, hot glass, etc.

§ 5. The Ionic Hypothesis

Let us learn to dream, then perhaps we shall find the truth.—A. Kekulé.

In framing hypotheses we must see that they agree with facts; in other respects, they may be as inconceivable (not self-contradictory) as any fairy tale.—M. M. P. Muir.

The main facts so far established by the preceding discussion of the phenomena attending electrolysis may now be summarized:

(1) Electrolytes in solution conduct electricity, and the process of electrical conduction is attended by a splitting of the molecules of the solute into anions and cations; the anions appear at the anode, and the cations at the cathode. The separation of a certain number of anions at the anode is simultaneously attended by the separation of a chemically or electrically equivalent number of cations at the cathode. During electrolysis, the anions and cations appear to be discharged electrically, because electrically neutral molecules appear as secondary products of the electrolysis.

(2) The anion which separates at the anode is not necessarily derived from the same molecule as the cation which appears at the cathode.

(3) Solvent and solute together make a conducting medium, since as a rule neither solvent nor solute alone shows any marked capacity for conducting electricity.

(4) No measurable time is needed to put an aqueous solution in a condition to conduct the current. Immediately the necessary difference of potential appears at the electrodes the process of electrolysis begins.

(5) Osmotic pressure and related phenomena show that electrolytes in dilute solution have what seems to be a molecular weight, which suggests that the ordinary chemical molecule of the electrolyte dissolved in certain solvents is dissociated into two parts.

It is generally agreed that during electrolytic conduction there is a convection of electricity by the atoms of matter, but there have been differences of opinion as to the mode of transit of the atoms through the liquid:

(1) **The molecular chain hypothesis of C. J. T. von Grotthus** was generally accepted in the first half of the nineteenth century. In his *Théorie de la décomposition des liquides par l'électricité galvanique*, he (1805)[1] assumed that the molecules of salt in solution are distributed throughout the solvent in an irregular manner without any signs of orientation, as represented diagrammatically at *A*, Fig. 4. The molecules, in the presence of a pair of oppositely charged electrodes

range themselves in "chains," like little magnets. The positively charged ions—cations—are directed towards the negatively charged cathode, and the negatively charged ions—anions—to the positively charged anode, *B*, Fig. 4. If the charges on the electrodes are great enough, the molecules in immediate contact with the electrodes will decompose, *C*, Fig. 4, and the charge on one of the ions will be neutralized by the charge on the electrodes. And the other ion will unite with the neighbouring molecule and liberate an ion with a similar charge. The free ion attacks the next molecule, and so the process is continued throughout the "chain."

To fix the idea, consider the end of the molecular chain at the cathode. There, a negatively charged ion is set free when a positively charged ion is neutralized at the cathode. This "negative" ion associates with the adjacent molecule of the chain; this molecule decomposes, forming a new molecule, liberating, at the same time, a negatively charged ion which associates with the next molecule of the chain, *D*, Fig. 4. This successive decomposition and recombination goes on throughout the chain of molecules from electrode to electrode. The new molecules so formed turn about, and are again ranged in a "chain" resembling *B*, as shown at *E*, Fig. 4. A cycle of changes of this nature is supposed to be going on all the time the current is passing through the electrolyte.

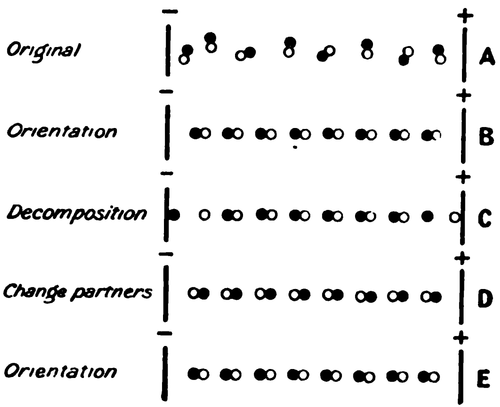

Fig. 4.—Diagrammatic Representation of C. J. T. von Grotthus' Chain Hypothesis.

C. J. T. von Grotthus' mechanical interpretation of the phenomenon is very ingenious, and it satisfactorily explained the facts known in his day, but later knowledge has shown that the hypothesis is not tenable in its original form. If the electricity be conducted by *Grotthus' chain*, no current can flow until the electromotive force driving the energy is equivalent to the energy represented by the heat of formation of the molecules undergoing decomposition *in the solution*. When a sufficient electromotive force is applied at the electrodes, the decompositions and recompositions of the molecules might proceed in the way described by Grotthus. No such critical electromotive force, however, has been found to be necessary for the passage of a current through electrolytic solutions. In H. von Helmholtz's air-free cell,[2] polarization is produced by an infinitesimal element, but no permanent leakage of electricity goes on through the cell until the applied current attains a certain voltage. The smallest electromotive force hitherto tried causes a current to flow when it is applied to copper electrodes immersed in a solution of copper sulphate. The total energy consumption is then nothing but that due to the "resistance" of the cell. Again, solutions of electrolytes, like metallic wires, conduct electricity in such a way that the rate at which electricity passes through the system is proportional to the electromotive force. This is true whatever be the magnitude of the force, and consequently, if a certain amount of electrical energy be expended in breaking up the molecules, this proportionality cannot obtain. Hence, very little electrical energy can be expended in breaking up the dissolved molecules into their respective ions, and it has therefore been urged that "the ions cannot be held together by a force of finite value." Consequently, in the homogeneous electrolyte without polarization no hypothesis which involves the tearing of the molecules asunder against the chemical binding forces can be admitted; there is no chemical cling of the atoms, but only a frictional rub. Otherwise, those electrolytes whose atoms or radicles are held together by the weakest attractions would most readily decompose electrolytically. This is by no means the case. For instance, mercuric chloride is much less stable than sodium chloride, and yet the latter is much more readily decomposed by an electric current.

G. F. Fitzgerald[3] has pointed out that the difficulty with Grotthus' hypothesis can be overcome if it be assumed that when the molecules are polarized, they draw one another apart at a rate proportional to the polarization. This at once makes the relation between electric force and decomposition a linear one, and so satisfies Ohm's law in the case of small currents. It also so far agrees with Clausius's hypothesis that it explains electrolysis and double decomposition as properties of the same kind. The molecules in a liquid will occasionally be arranged by accident in a proper polarized condition in a closed circuit for drawing one another apart; and if the circuit includes molecules of different kinds, there will result double decomposition. He added:

> The supposition that it is a particular arrangement that is required before exchanges take place, and that with this arrangement exchanges take place of their own accord, seems to explain electrolysis and double decomposition without supposing free atoms to exist within the liquid.

(2) **The electrostatic strain hypothesis of H. von Helmholtz.**—Here it is assumed[4] that each kind of matter has a specific attraction for electricity—some kinds for positive, other kinds for negative; that accordingly, work must be done to separate one atom from its electrical charge, or to remove electricity from an atom of high specific attraction and give it to another lower in the scale. Further, the chemical affinity is mainly due to the electrical attraction of oppositely charged atoms, and that when such atoms combine into a compound molecule, they do not discharge into each other, but retain their charge. During electrolysis, work is done, not in tearing the atoms asunder, but in tearing their electrical charges from them.

(3) **The ionization hypothesis of R. Clausius.**—As a trial hypothesis it may be assumed that the mere presence of the solvent leads to the fission of the molecules of the electrolyte into sub-molecules, each of which is charged with a definite amount of positive or negative electricity equivalent to 96,540 coulombs per chemical equivalent. The solution does not itself appear to be electrically charged, and hence it is assumed that equal quantities of positive and negative electricity are developed by the rupture of the molecules of the electrolyte during the process of solution. Solutions of electrolytes are supposed to normally contain a definite proportion of the sub-molecules charged with electricity. By a modification of M. Faraday's definitions the "sub-molecules" are called ions, and consequently: **ions are atoms or groups of atoms which carry a positive or negative charge of electricity, and they are formed by the dissociation of the electrolyte in the solution. Each molecule, on dissociation, furnishes two kinds of ions with equal and opposite charges of electricity.** Consonant with M. Faraday's work, it is further assumed that each monad ion carries a definite charge of electricity (96,540 coulombs); each dyad ion, two such charges; a triad ion, three such charges; etc.; but never a fraction of such a charge. To avoid confusing the phenomenon of dissociation, in which the products are not charged electrically, with the dissociation of a molecule into electrically charged ions, the term **ionization** is reserved for the latter phenomenon. The ionization of hydrochloric acid is represented in symbols: $HCl \rightleftharpoons H^{\cdot} + Cl'$; and of sodium chloride: $NaCl \rightleftharpoons Na^{\cdot} + Cl'$.

A. W. Williamson's theory of the continuous interchange of the atoms of the molecules of a compound was suggested in 1850, and it was followed in 1857 by R. Clausius' suggestion that the molecules of the solute are ionized when dissolved in the solvent, but R. Clausius appears to have assumed that *only an infinitesimally small fraction of the total number of dissolved molecules are so ionized.* As the ions are discharged at the electrodes during electrolysis, more molecules are ionized. The un-ionized molecules keep the electrolyte constantly supplied with a definite number of ions. The ions conduct the current; the "undissociated" molecules are inactive. Further, at any given temperature, there is a constant relation between the number of un-ionized molecules, and the number of ions. S. Arrhenius (1884), more bold or less cautious than R. Clausius, asserted that *a considerable fraction of the dissolved molecules are ionized, and that the number of ions increases more and more as the solution becomes more and more dilute.* W. Ostwald, J. H. van't Hoff, W. Nernst, and a large number of other workers have followed the logical consequences of Arrhenius' hypothesis in a great many directions; the results, on the whole, have been satisfactory, and the theory has thus stimulated the study of the properties of solutions in a remarkable manner. Some hold that the great cloud of subsidiary hypotheses which is needed to make the ionic theory presentable, serves also to obscure progress towards a more satisfactory view of the nature of solution. It is also maintained that the " principle of exhausting hypotheses " has not been followed, and that the favoured child—the ionic hypothesis—has grown into a tyrannical master; for instance, G. F. Fitzgerald (1896) has said that " the supposed advantage of the free ion theory is not only illusory but misleading." If this be a correct diagnosis of the ionic hypothesis we have some consolation in H. Davy's words: " The destruction of an error hardly ever takes place without the discovery of truth."

At first sight the ionic hypothesis appears so incredible and so opposed to the instinct, common sense, or prejudices of the chemist that it has been assailed by much wholesome criticism—particularly by H. E. Armstrong. For instance, it is asked:

1. *In view of the great chemical activity of metallic sodium in contact with water, is it profitable to postulate the existence of the element sodium in contact with water without chemical action?* This objection is said to " rest on a misunderstanding," because *electrically charged* ions of sodium in an aqueous solution of sodium chloride are very different from *neutral atoms* of metallic sodium. The ions of sodium carry large charges of electricity. It is urged that " chemists know practically nothing about the properties of atoms carrying large charges of electrical energy," and also that " the chemical activity of an atom of sodium charged with its 96,540 coulombs of electricity is much less than a neutral atom of sodium." In other words, the presence of the electrical charge on the sodium ion keeps the ordinary chemical activities of the atom in abeyance. This means that whenever a chemical difficulty arises in the application of the ionic hypothesis the assumption is made that " neutral atoms or atomic groups and ions are different substances," because the properties of a substance are determined as much by the energy it contains as by the kind of matter. In this way, the ions have been invested with such imaginary properties as may be needed to keep the ionic hypothesis consistent with facts.

2. *Compounds like mercuric chloride, very prone to thermal dissociation, are not readily ionized; while compounds like calcium chloride which resist thermal dissociation are readily ionized. Would not the ionic hypothesis predict the converse phenomena?* Mercuric chloride is very volatile and readily dissociates into its elements by heat; calcium chloride, on the contrary, does not readily volatilize or dissociate except at very high temperatures, yet it is said that the latter is readily ionized in solution while the former remains all but unchanged. Here again it is said that totally different phenomena are confused, and that the forces which produce ionization are quite different from those which produce thermal dissociation.

3. *Bodies carrying electrical charges of opposite sign are attracted and cling to one another; if therefore a mobile solution contains "free and independent" ions carrying enormous electrical charges of opposite sign, how can the charged ions remain more than momentarily free?* It is assumed that a certain proportion of the molecules of the solute are continually breaking down into free (charged) ions, and a certain proportion of the ions are continually recombining to form ordinary molecules, the result is, that the ratio between the number of free ions and paired ions (molecules) remains unchanged. This statement, of course, does not answer the perplexing question. Attempts have been made to refer the difficulty to the specific insulating

properties—the so-called dielectric constant—of the solvent. The action of the solvent has been compared with the function of the glass in a charged Leyden jar. This agrees with the non-conducting qualities of pure water, but experiments have shown that the relation between the insulating properties of a solvent and its ionizing properties is not an adequate and sufficient explanation of the observed facts. The two phenomena do not always vary concomitantly. A satisfactory answer to the question, therefore, has not yet been found.

4. *If an ionized salt, say, sodium chloride, is present in solution as a mixture of $Na^\cdot$ and Cl' ions, it might be thought possible to separate the two components by diffusion or by some other mechanical process.* When the molecules of certain gases—hydrogen, chlorine, etc.—exist free in a liquid, they will escape; but when, say, sodium chloride is ionized: $NaCl \rightleftharpoons Na^\cdot + Cl'$, it is said that the chlorine ions do not escape because of their electrical charge. S. Arrhenius also says that the great electrostatic attraction of the oppositely charged ions prevents any marked diffusion. W. Nernst, however, has shown that the concentration currents produced when, say, a solution of sodium chloride is carefully covered with a layer of water, leads to the conclusion that the greater mobility of the chlorine ions charges the upper layer negatively, and the lower layer positively, so that a current of electricity can be obtained by placing the two layers in electrical contact. R. C. Tolman (1911) whirled aqueous solutions of iodides—sodium iodide, potassium iodide, hydrogen iodide, etc.—in tubes in a powerful centrifugal machine, and found that the two ends of the tubes acquired charges of opposite sign. The extreme ends of the tubes acquired a negative charge presumably because of the accumulation there of the heavier positively charged iodine ions; and the opposite ends of the tubes acquired a positive charge presumably owing to the slight excess of positively charged sodium ions at that end. There is the possibility that the electrification of the tube was due to the friction against air.

5. *Salts which form solid compounds with two or more different amounts of water of crystallization have different solubilities in their different forms. Hence it is asked: Is it not more reasonable to assume that the molecules of the solute exist in solution as definite hydrates?* The ionic hypothesis answers: Only a definite fractional part of the salt is ionized, and this part is proportionally less, the more concentrated the solution. As a rule, in a saturated solution, only a small proportion of the solute is ionized. A similar observation applies to the existence of liquid crystals. This does not preclude the possibility that the un-ionized molecules and the ions are themselves hydrated.

6. *When a compound is formed from its elements with the loss of energy, the compound cannot be resolved into its elements unless energy be supplied. It is therefore pertinent to inquire: What is the source of the energy which leads to the fission of the molecule into ions carrying equal but opposite charges of electricity?* Here, again, it is necessary to reiterate that the ionic hypothesis refers not to the separation of a compound into its original constituents, but into charged ions; and it is interesting to observe that molecules of sodium chloride, etc., which appear to be very stable when dry, react with great facility when in solution. A little heat is supposed to be evolved during the ionization of many (not all) electrolytes, and the process of ionization is then presumably accompanied by an exothermal reaction which more than compensates for the energy needed for the fission of the molecule into oppositely charged ions.

There are also hypotheses which suppose ionization occurs by *collision.* G. T. Beilby (1905) considers that the ionization is essentially a mechanical operation, the result of the kinetic activity of the solute molecules, for in a dilute aqueous solution of, say, hydrogen chloride, each molecule of the solute is surrounded by and "at the mercy of" some millions of water molecules, all in a state of intense activity, and the rude mechanical jostling to which the molecule of hydrogen chloride is subjected will naturally tend to break it up into simpler portions mechanically more stable. J. Kendall[5] made a similar suggestion, but B. de Szyskowsky and J. Perrin regard this hypothesis as untenable—the latter says *la probabilité de rupture d'une molécule ne dépend pas des chocs qu'elle subit.*

W. Nernst and J. J. Thomson have found that the ionizing power of a solvent is related with its specific inductive capacity or *dielectric constant* as indicated in the chapter on "Water." W. Nernst has pointed out that water has a higher specific inductive capacity than other liquids, and that liquids like methyl alcohol, formic acid, and others, which, as solvents, give solutions having electrolytic conductivity also have high specific inductive capacities. From this it is argued that the dissociating power of a solvent, or its power of producing ions, is greater the greater its specific inductive capacity. C. B. Thwing's numbers show that the dielectric constants, K, of the hydrocarbons and non-asssociated liquids approximate to $K=2{\cdot}6D$, where D is the specific gravity. Other liquids, particularly those which contain hydroxyl groups, have higher values than correspond with this rule, and H. Crompton has shown that if i be the association factor, C. B. Thwing's data can be represented by $K=2{\cdot}6Di^3$, or $i=\sqrt[3]{(K/2{\cdot}6D)}$, where the values of i so obtained run quite parallel with the values obtained by I. Traube, but are a little higher. R. Abegg also showed that the temperature coefficient of the dielectric constant is very small for non-associated liquids—there is only a slight change between 15° and $-80°$ for toluene and ether, but with other liquids there is a larger change as the temperature is lowered, probably due to increasing density and increasing association—with ethyl and amyl alcohol, and acetone, the change is quite marked. H. Crompton therefore argues that it is almost impossible to doubt that association plays an all-important part in determining the specific inductive capacity of a liquid, and that if there is any connection between specific inductive capacity and the power of ionization, it may be looked for rather in the fact that electrolytes are solutions of approximately non-associated salts in an associated solvent than in there being any peculiar ionizing power attaching to the solvent. According to P. Dutoit and E. A. Aston, and P. Walden, the association of the solvent may in turn be referred to the unsaturated character of the molecules of that menstruum. H. Crompton added: The supposed decrease in electrolytic dissociation with rising temperature is also accounted for, and means nothing more than the decrease in the association of the solvent. What has been termed the ionic fluidity of a given solution no doubt increases continually with rising temperature, and, therefore, up to a certain point, the conductivity increases. But the association of the solvent is also continually decreasing, and in the end this effect will become the more powerful, the conductivity, therefore, never rising above a certain maximum value. This explains the maximum in the molecular conductivity with rising temperature, first noticed by S. Arrhenius.

G. Ciamician (1890) attributed ionization to the *attraction between the solvent and the positive and negative parts of the salt.* The idea is supported by the fact that those solvents which ionize readily are the very ones which unite readily with the salts as water of crystallization, alcohol of crystallization, etc. Again, not a great many salts whose ions are univalent separate with water of crystallization while those with ions of higher valency nearly always do. This is taken to mean that possibly univalent ions are less hydrated than those of higher valency. This corresponds with experiments on the speeds at which ions move through the solvent—univalent ions generally travel faster than the bivalent ions, and the latter in turn go faster than tervalent ions. However, this evidence is inconclusive, since it does not follow that because such compounds separate from a solution therefore these compounds exist in solution. J. D. van der Waals (1891) expressed a similar idea and considered that the heat of hydration of the ions furnished the energy needed for the ionization of the salt. To this, D. Konovaloff (1893) adds, "only those solvents which react chemically with the solute furnish solutions which conduct electricity," and R. Abegg (1899) expressed it, "the degree of ionization depends upon the capacity of the ions to unite with the molecules of the solvent."

In the early days of the ionic hypothesis it was assumed that the solvent acts like a passive medium preventing the re-combination of the ions ; and it came as an antithesis to the so-called hydrate theory in which the solvent was regarded as intensely active, and formed complex molecular systems with the solute. The one hypothesis assumes that simplification (ionization) precedes chemical combination, the other assumes that complication (association) precedes chemical action. The accumulation of new facts rendered it necessary for the former to borrow from the latter, so that "the hydration of ions in aqueous solutions is admitted by almost all advocates of the ionic theory." It was A. Kekulé who, in his *Ueber die Constitution und die Metamorphosen der chemischen Verbindung* (1858), emphasized that molecular coalescence is a preliminary condition for many reactions ; the complex may then undergo a reversible change ; molecular re-arrangement ; or it may dissociate into more stable components. In the reaction between ammonia and hydrogen chloride water plays an essential part, here the molecular coupling is probably dependent on unsaturated valencies of water and ammonia ; it has been suggested that the water first reacts with the ammonia :

$$H_3N{=}+{=}OH_2 \rightarrow H_3N{=}OH_2 \rightarrow NH_4OH$$

and that the acid and base then react either through their ions or molecularly :

$$\substack{H_4N\\H}\!>\!O{=}+{=}ClH \rightarrow \substack{H_4N\\H}\!>\!O\!<\!\substack{Cl\\H} \rightarrow H_4N.Cl+H.OH$$

With water and calcium oxide $CaO{=}+{=}OH_2 \rightarrow CaO{=}OH_2 \rightarrow Ca(OH)_2$. The same view was emphasized by J. H. van't Hoff in 1878, and by H. E. Armstrong in 1891. The addition compound brings together elements, previously separate, into one common sphere of activity within which it is possible for them to interact. J. Kendall and J. E. Booge now consider ionization to be preceded by a combination between solvent and solute. Any unsaturated solvent possesses the power of forming complexes with itself by association and also with any unsaturated solute. It is assumed that the attractive forces holding together the radicles of the solute are now so diminished that ionization can take place. The union of the solute with molecules of the solvent thus promotes ionization, or the dissociation of the complex into radicles of opposite charge. They add :

> The mechanism of the electronic hypothesis of J. J. Thomson, G. N. Lewis, W. A. Noyes, etc., is based on the assumption that an unsaturated molecule contains electrons not rigidly fixed but free to move under the influence of an electric field—*e.g.* the oxygen atom in a water molecule has at least two electrical doublets $H^+ \rightarrow {}^-O^- \leftarrow {}^+H$, which can move into such a position or orbit as to exert a maximum attraction on the positive part of the doublet, thus producing an unequal distribution of the electrical charges. When two such molecules come into close proximity, this inequality will be greatly accentuated, and the mutual attraction may be sufficient to enable complex molecules to be formed by association. The associated molecule possesses a larger electrostatic moment, and the constraints on the electrons are accordingly weakened. The higher the degree of association, the larger the electrostatic moment, the weaker the constraints holding the charges, and the higher the dielectric constant. Such associated molecules may exert considerable attractive forces on the molecules of a solute especially when the latter also furnish strong fields of electric force. As a result, the complex may be much less stable than the simple component molecules, and dissociation occurs.

In conformity with the hypothesis that the formation of complexes between solvent and solute is the immediate cause of ionization, J. Kendall, J. E. Booge, and J. E. Andrews found that conducting solutions invariably afford evidence of the formation of complexes—*e.g.* the formation of stable hydrates is characteristic of strong acids, and the less the strength of the acid, the less the tendency to form stable hydrates. There is no indication of hydrate formation with weak organic acids unless the acid has also the character of a phenol base. Similar remarks apply to the bases. In general, therefore, there is a uniform increase in the ionization with the acids and bases most readily hydrated.

The proposition has not yet been established with salts, although A. Werner states that the stability of an aquo-salt decreases as the strength of the acid or base increases; but R. Abegg and G. Bodländer hold that salts of weak acids and bases are most extensively hydrated. With the mercuric salts also, all the highly ionized salts yield hydrates, and all slightly ionized salts are not hydrated. If ions are formed at all they are complexes formed by association with the molecules of the solvent. The ionic theory primarily assumes that the apparent *number* of solute "molecules" is increased by ionization, and in a general sense it may be said that it makes very little difference to the applications of the ionic theory whether it be assumed that each ion is isolated as a distinct individual, or whether each ion forms a complex with the molecules of the solvent. The number of ions is the same in both cases.

The explanation of the phenomena, particularly when solutions other than water are considered, is beset with many difficulties on account of the complex relations between the solvent and solute. So much is this the case that M. le Blanc (1907) considered "it to be very fortunate for the advance of electrochemistry that such complications are generally, though not always, absent in the case of the aqueous solutions. It is due to this fact that it has been possible to deduce simple laws from the study of aqueous solutions." On the other hand, O. N. Witt (1901) has said:

> Water is a very complicated substance, and the process of solution in that liquid must be attended by very great exceptions from the simple rules which exist for other solvents, not so complicated. It has therefore been a great mistake to study aqueous solutions and then other solutions. The chapters in treatises on physical chemistry entitled "Theory of Solution" should be rightly entitled "Theory of Aqueous Solution."

Several attempts have been made to work out a consistent explanation of the fundamental facts without a theory of charged ions, but with hypotheses based upon the formation of imaginary molecular complexes by a reaction between polymerized solvent and the molecules of the solute.

These controversial matters emphasize the fact that an explanation of a phenomenon may contain part of the truth, and yet not "the whole truth, and nothing but the truth." In that case, we try the hypothesis by the test indicated in the first chapter, and ask: Is the hypothesis useful? The answer is that the ionic hypothesis has done good work, and it promises to do more. An hypothesis is not always to be discarded as a first approximation, because troublesome exceptions crop up from time to time. Newton's theory of gravitation, for instance, appeared to be afflicted with such blemishes—particularly in its early days; so was the theory of opposing reactions once considered to be unreasonable folly; and the present-day theory of light seems highly absurd when it is remembered that it is based upon the existence of an æther pervading all space, an æther which is of the highest elasticity, and denser than steel. In spite of important difficulties, we shall try how the ionic hypothesis fits in with a few important phenomena.

§ 6. The Electrolytic Conductivity of Solutions

> In electrolytic conduction, the electricity does not slip through between the molecules, it goes with them. The constituents of each molecule are free from one another, and while one set of atoms conveys positive electricity, the other set conveys negative electricity in the opposite direction, and so it is by a procession of free atoms that the current is transmitted. The atoms act as carriers. The free locomotion of charged atoms is essential for electrolysis.—O. J. LODGE (1892).

The process of electrolysis, according to the ionic hypothesis, is supposed to proceed somewhat as follows: When a salt—say, sodium chloride—is dissolved in water, (i) some of the dissolved molecules are, by hypothesis, ionized, and the ions immediately begin to recombine to form molecules. The speeds of the two reactions are supposed to behave analogously with those of opposing reactions, and a state of equilibrium is reached when the number of molecules reformed by the combination of the ions is equal to the number of molecules ionized in the same time. Still further, (ii) when the two poles of a battery—say platinum electrodes—are dipped in a solution of sodium chloride, all the chlorine ions, carrying a negative charge, are attracted to the anode or positively charged electrode, and the positively charged sodium ions are attracted to the cathode or negatively charged electrode. If a constant difference of potential be maintained between the electrodes of the battery, as each ion comes in contact with the electrode with a charge of opposite sign to its own, the charge is torn from the ion which thereby reverts to an ordinary atom of chlorine or sodium. The battery reproduces the same difference of potential as before by generating more electricity; this is again discharged at the electrodes; and so, by an alternate process of charge and discharge, electrolysis continues. (iii) The chlorine atoms, being unable to attack the water or the electrode, unite in pairs to form molecules of chlorine gas. As soon as the liquid in the vicinity of the anode is saturated with chlorine, this gas bubbles to the surface of the liquid. Similarly, the sodium ions are relieved from their charges at the cathode, and the resulting sodium atoms immediately attack the water, forming hydrogen gas and sodium hydroxide: $2Na+2H_2O=2NaOH+H_2$; the hydrogen bubbles off as a gas. (iv) The equilibrium between the un-ionized molecules and the ions is disturbed by the annihilation, so to speak, or the removal of ions at the electrodes. The difference of potential at the electrodes is maintained by the battery, and the supply of ions is kept up by the steady ionization of the salt as fast as the ions are de-electrified at the electrodes, until practically the whole of the salt in the solution has been electrolyzed. The charges drag the atoms to the electrodes, and only at the electrodes can the charges be torn from the atoms. Thus A. Smith (1890) said that "the ions do not transport the electricity of the battery, but their own." The charged ions are already present in the solution before connection is made with the battery.

Usually, the electrical conductivity of a solution is measured indirectly. The resistance which the solution offers to the passage of a current is directly measured. It is more convenient to take the reciprocal of the resistance and call it the conductivity of the solution. The **specific resistance** is first determined, that is, the resistance in ohms which is equivalent to the resistance of a cubical mass of the solution whose length of side is 1 cm., Fig. 5. The reciprocal of this quantity in *reciprocal ohms*, is the specific conductivity. Hence the **specific conductivity**, κ, represents the current in ampères which is produced in a cube of one centimetre side when a potential difference of one volt is applied to the opposite faces of the cube. From this, the so-called equivalent conductivity—symbolized λ—is calculated. **The equivalent conductivity of a substance represents the conducting power of one gram-equivalent of the substance dissolved in the solvent, and placed in a cell whose opposite walls, one centimetre apart, form the electrodes.** Otherwise expressed, the equivalent conductivity represents the conducting power of a layer of the solution 1 cm. thick, and containing one gram-equivalent of the substance in solution; or, **the quantity of electricity which, under a potential difference of one volt, passes per second between electrodes of indefinite extent, and one centimetre apart, between which is placed that quantity of solution which contains one equivalent weight of the ionizing substance.** If the conductivity be referred to a gram-molecule, and not a gram-equivalent, it is termed the **molecular conductivity** of the solution—symbolized μ.

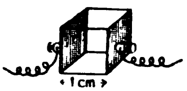

FIG. 5.

C. J. Reed[1] has pointed out the need for emphasizing the fact that electrical conductivity is a property of matter like transparency, diathermacy, magnetic permeability, and heat conductivity. The electrical conductivity of different substances is measured or compared by employing a unit in which there is a definite section across which the flux is measured, and a definite length in the direction of the flux. Units of this kind are defined by certain relations of form, in which the ratio of length to cross-section is a fixed ratio. He applies the terms *conductance* and *resistance* to bodies of definite form, length, and cross-section, while the terms *conductivity* and *resistivity* refer to properties of matter independent of shape, or form, or quantity. Conductivity is therefore specific conductance; and resistivity is specific resistance. The two ideas, however, are commonly merged in the one term conductivity or resistivity as the case might be.

When an electric current is passed through a cell composed of two metallic electrodes and an electrolyte, the total opposition to the passage of the current is made up of the resistance of the cell and the back electromotive force at the electrodes, which latter is the sum of the over-voltages at the two electrodes. The resistance of the cell is made up of the resistance of the electrolyte and the transfer resistance from electrode to electrolyte. The transfer resistance has been particularly studied by E. Newbery, etc.[2] The conditions which favour high transfer resistances are (i) low current density; (ii) low temperature; (iii) polished electrode surfaces; and (iv) high over-voltages.

§ 7. The Number of Ions in a Solution

The greater the number of ions in a liquid the better is the liquid likely to conduct electricity.—O. J. LODGE (1892).

If water be progressively added to an aqueous solution of hydrogen chloride. containing, say, one gram-equivalent (36·5 grams) per litre, at 18°, the equivalent conductivity of the solution gradually increases as illustrated by the following numbers, when v denotes the number of litres of solution containing one gram-molecule of the solute, and λ the corresponding equivalent conductivity :

$v=$	2	8	16	32	128	512	1024
$\lambda=$	305·4	328·5	331·5	342·3	349·1	349·3	349·3 units

These numbers show that the electrical conductivity of the solution increases until a certain limit is reached. Subsequent additions of water have no further influence on the equivalent conductivity of the solution. This is further emphasized by the curve, Fig. 6, which represents the rapid rise in the equivalent conductivity of sodium chloride solutions with decreasing concentration ; the conductivity reaches a maximum very quickly, when the further additions of water have no further influence on the result. Hence **the equivalent conductivity of an electrolytic solution increases with dilution, reaching a maximum value approximately corresponding with infinite dilution.** This fact is called **F. Kohlrausch's first law.** When the dilution has reached the limit beyond which no further increase in the equivalent conductivity can be observed, it is supposed that the salt is all ionized, and no more ions can be supplied by the solute, however much more solvent be added. All the ions which can be obtained from the solute take part in conducting the electric current at infinite dilution.

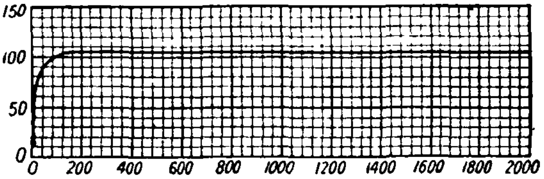

FIG. 6.—Effect of Concentration on the Equivalent Conductivity of Aqueous Solutions of Sodium Chloride.

The determination of the electrical conductivity of a solution.—Let R denote the resistance of the solution expressed in ohms. The cell containing the solution—the *conductivity cell*—is arranged as illustrated in the sketch and plan, Fig. 7, with a known resistance R (ohms) in the box of resistance coils ; a " metre " wire of known resistance ; a telephone, T ; a battery, B ; an electrolytic cell of resistance, S ; a key, K, for starting the current from the battery ; and an induction coil, N, which furnishes a rapidly alternating high potential current. It may be asked : How can there be anode and cathode when working with an alternating current ? If the impulse in one direction of the alternating current cannot bridge the gap between

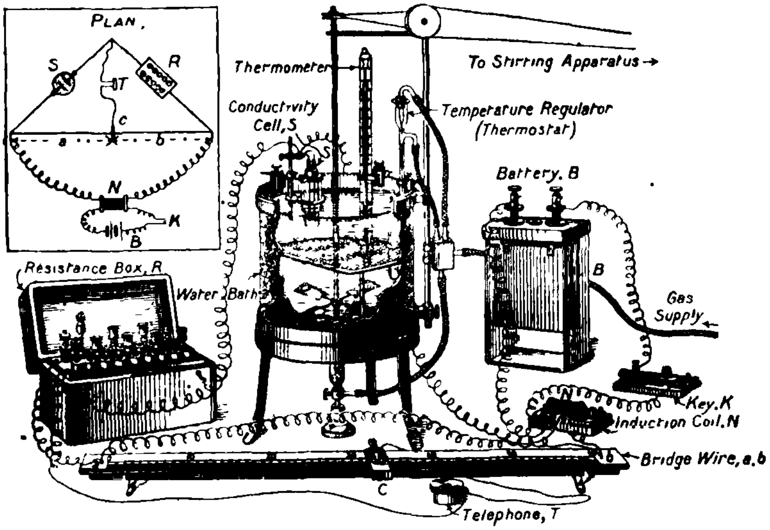

FIG. 7.—The Determination of the Electrical Conductivity of Solutions.

the electrodes, and the impulse in the other direction can, the general effect is that of an intermittent current in one direction. If the sliding contact of the bridge, C, be moved until the telephone is "silenced"—that is, makes least noise—the resistances on both sides of the system are in equilibrium. The readings are most accurate when the resistance R is so adjusted that the contact C is near the middle of the bridge. From the principle of Wheatstone's bridge—discussed in text-books on electricity—it follows that $S : R = a : b$, where a is the resistance of the bridge wire on the same side as the resistance R, and b the resistance of the wire on the other side. If the wire be 1000 mm., that is, one metre long, $b = 1000 - a$. Consequently,

$$\text{Observed conductivity} = \frac{1}{S} = \frac{b}{Ra} \text{ rec. ohms} \quad . \quad . \quad . \quad (1)$$

The specific conductivity—the reciprocal of the specific resistance—must be proportional to the observed conductivity, or, the specific conductivity is k times the observed conductivity, where k is the constant of proportion. Consequently,

$$\text{Specific conductivity} = \frac{k}{R} \cdot \frac{1000 - a}{a} \text{ rec. ohms} \quad . \quad . \quad . \quad (2)$$

The observed conductivity depends upon the *capacity of the cell* employed, and this, in turn, depends upon the *surface area* and the *distance apart* of the electrodes. If these two magnitudes are known, it is possible to compute the specific conductivity of the solution from the observed conductivity. It is simpler, however, to determine the **constant of the cell** employed, by using a solution of known conductivity. All the factors, except k, are then measured, and k is calculated from (2). With the same cell, the conductivity of the given solution can be determined and the specific conductivity computed by (2).

In illustration, the specific conductivity of a $\frac{1}{10}N$-solution of potassium chloride at 18° is 0·0112. With a resistance of 10 ohms, the telephone was silenced when $a = 535$ mm. Hence, from (2), $0{\cdot}0112 = (k/10)(1000 - 535)/535$; or $k = 0{\cdot}1289$. Hence, for this particular cell, the specific conductivity $= 0{\cdot}1289(1000 - a)/Ra$ rec. ohms; with a $\frac{1}{10}N$-solution of potassium chloride for which $a = 490$, when $R = 12$, the specific conductivity $= 0{\cdot}1289(1000 - 490)/12 \times 490 = 0{\cdot}011199$ rec. ohms. If v denotes the number of cubic centimetres containing one gram-equivalent of the compound under investigation, the quotient obtained by dividing the specific conductivity by v will represent the specific conductivity of the $\frac{1}{10}N$-potassium chloride at the dilution v, hence, since a $\frac{1}{10}N$-solution of potassium chloride has one-tenth of a molecular weight of the salt expressed in grams per litre, one gram-molecule will be present in 10 litres, or $v = 10{,}000$ c.c., and, since κ denotes the specific conductivity, the equivalent conductivity κ/v will be $0{\cdot}011199/v$, or 111·99.

During the measurements, the conductivity cell must be kept at a constant temperature since the conductivity varies with changes of temperature. Hence, the need for the water-bath, stirrer, and thermostat (temperature regulator) shown in Fig. 6. If the conductivity of the solution be large, a form of cell is employed with electrodes further apart than is the case with the cell shown in the diagram for solutions of feeble conductivity. Details are discussed in any laboratory handbook.[1] It is becoming increasingly clear from the work of E. Newbery, S. F. Acree, etc., that this method of measuring conductivity can be made much more sensitive and accurate by directing attention on the nature of the electrodes, and the frequency of the alternating current.

It is now assumed that **the number of ions which take part in conducting the electric current at any particular concentration of the solution is proportional to the equivalent conductivity, λ, of the solution.** If the number of ions in a given solution be doubled, the conductivity will be doubled. Consequently, if α represents the fraction of a gram-equivalent which is dissociated into ions when the solution occupies v litres, we have, at dilution v, the conductivity $\lambda_v = k\alpha$, where k is the constant of proportion. At infinite dilution, the whole gram-equivalent is supposed to be ionized, and consequently, $\alpha = 1$, and therefore the conductivity, λ_∞, at infinite dilution, is $\lambda_\infty = k$. Substitute this value of k in the preceding equation, and we get

$$\alpha = \frac{\lambda_v}{\lambda_\infty}$$

which, by hypothesis, means that **the fractional number of molecules ionized in a solution is numerically equal to the equivalent conductivity of the solution divided by the equivalent conductivity of the solution at infinite dilution**; or,

$$\text{Degree of ionization, } \alpha = \frac{\text{Number of molecules ionized}}{\text{Total number of molecules}} = \frac{\lambda_v}{\lambda_\infty}$$

This formula enables the electrical conductivity of a salt to be expressed in terms of the degree of ionization of the salt in solution. Thus, the equivalent conductivity of a solution of hydrochloric acid is 305·4, and the same acid at infinite dilution has the equivalent conductivity 349·3. Hence, the degree of ionization is $305\cdot4 \div 349\cdot3 = 0\cdot874$ per gram-equivalent, or 87·4 per cent. ionization. This means that 12·6 per cent. of the molecules of the solution are present as un-ionized neutral molecules, HCl; and 87·4 per cent. of the molecules are present in the ionic form $\text{H}^{\cdot}+\text{Cl}'$. Or,

$$\underbrace{\text{HCl}}_{12\cdot6\text{ per cent.}} \rightleftharpoons \underbrace{\text{H}^{\cdot}+\text{Cl}'}_{87\cdot4\text{ per cent.}}$$

The **percentage ionization** must not be confused with the **absolute concentration of the ions.** The former may be the greater in dilute solutions, and the latter greater in concentrated solutions. The ionic hypothesis thus assumes that an aqueous solution of hydrochloric acid contains three distinct kinds of "solute molecules," electrically charged molecules (hydrogen and chlorine ions), and neutral hydrogen chloride molecules.

Table I shows the degree of ionization of normal solutions (unless otherwise stated) of a few typical acids, bases, and salts selected merely for illustrative purposes.

TABLE I.—DEGREE OF IONIZATION OF SOME TYPICAL ACIDS, BASES, AND SALTS.

Acids.		Bases.		Salts.	
Acid.	Fraction ionized.	Base.	Fraction ionized.	Salt.	Fraction ionized.
Nitric acid (62%) .	0·096	Potassium hydroxide	0·77	Potassium chloride	0·74
Nitric acid (dil.) .	0·820	Sodium hydroxide .	0·73	Ammonium chloride . . .	0·75
Sulphuric acid (dil.).	0·510	Lithium hydroxide.	0·63	Potassium nitrate	0·64
Carbonic acid ($\frac{1}{10}N$).	0·002	Ammonium hydroxide	0·01	Zinc sulphate .	0·24
Hydrosulphuric acid ($\frac{1}{10}N$) . . .	0·001	Calcium hydroxide ($\frac{1}{64}N$) . .	0·90	Copper sulphate .	0·22
Perchloric acid ($\frac{1}{2}N$)	0·880	Barium hydroxide ($\frac{1}{64}N$) . .	0·92	Silver nitrate .	0·58
Acetic acid ($\frac{1}{10}N$) .	0·013	Methylamine .	0·12	Barium chloride .	0·57
Trichloracetic acid ($\frac{1}{10}N$) . . .	0·850	Ethylamine . .	0·13	Potassium sulphate . .	0·24

The effect of increasing the concentration of a solution is to increase the internal friction. This retards the movements of the ions and thus diminishes the conductivity more rapidly than would occur if the results were not affected by this disturbing factor. As the concentration decreases, the friction diminishes; and, with the more dilute solutions, the effects of internal friction can be neglected. The two factors—internal friction and conductivity—do not change with dilution in the same way, and, in consequence, the conductivity may increase with increasing dilution; reach a maximum; and then decrease with increasing dilution. This is the case, for instance, with sulphuric acid, where the maximum conductivity occurs when 30 per cent. of acid is present. The application of the ionic theory to *concentrated* solutions is beset with many difficulties, and consequently the theory has been mainly developed from results obtained with *dilute* solutions.

Strong and weak acids and bases.—The terms "strong" and "weak" are sometimes applied to the acids and bases, and these terms refer to the conductivity or to the degree of ionization in aqueous solution of moderate dilution. A strong acid or base has a high conductivity and accordingly a high degree of ionization at moderate dilutions; while the converse is the case with a weak acid or base. There is no real line of demarcation between the two. Acids like carbonic and hydrosulphuric acids, and bases like ammonia, are weak. Their degree of ionization is less than one per cent. If the degree of ionization exceeds 70 per cent. the acid is undoubtedly strong. Electrolytes like solutions of sodium chloride are good conductors, and some solutions with a conductivity midway between good conductors and non-conductors are sometimes called semi- or half-electrolytes. Most salts are highly ionized, even at moderate dilutions, but there are many exceptions, *e.g.* mercuric chloride, the cadmium halides, and mercuric cyanide are but slightly ionized in moderately dilute solutions.

W. Ostwald[2] noted that, as a rule, the ionization of analogous salts is the greater the further apart the anions and cations are in the electrochemical series. R. Abegg and G. Bodländer found that the tendency to form complex ions increases as the tendency of the salt to ionize decreases. The electrical conductivity of aqueous solutions increases with a rise of **temperature,** and F. Kohlrausch[3] represented his observations at 0° by the formula $K=K_0\{1+a(\theta-\theta_0)+b(\theta-\theta_0)^2\}$, where θ_0 represents the initial temperature, in the present case 18°. The constants a and b are characteristic of each solution of a given electrolyte. Thus, for nitric acid, $a=0{\cdot}0163$, $b=-0{\cdot}000016$; potassium chloride, $a=0{\cdot}0197$, $b=+0{\cdot}000047$; etc. F. Kohlrausch suggested that on a falling temperature, the conductivities of all aqueous solutions approach zero at about the same temperature, because of the decreasing fluidity or increasing viscosity of the solvent. J. Kunz found this temperature approximates to −40°. Owing to the opposite effects of viscosity and temperature on conductivity, negative coefficients might be anticipated, and S. Arrhenius found this to be the case with phosphoric acid. There is also a maximum in the curve with many salts—and the more concentrated the solution the lower the temperature at which a maximum occurs. There does not appear to be any anomaly in the conductivity as the temperature passes 4°, or even with undercooled solutions in passing through the freezing point.

The effect of **pressure** has been studied by G. Tammann, J. Fanjung, A. Bogojawlensky, etc.[4] If k represents the ionization constant; p, the pressure; R, the gas constant; T, the absolute temperature; and dv, the decrease in volume which occurs during the ionization of a gram-molecule of the salt, then, M. Planck's formula at constant temperature, $(d \log k)/dp=dv/RT$, describes the results of observation.

G. Wiedmann[5] noticed a relation between the conductivity and the **viscosity** of a solution, and O. Grotrian noted that there is a parallelism between the two variables, but not strict proportionality. According to H. von Euler, the viscosity η of a solution of a binary electrolyte is $\eta=\eta_1{}^{C(1-\alpha)}(\eta_2\eta_3)^{C\alpha}$, where α represents the degree of ionization; η_1, η_2, and η_3 respectively denote the viscosity coefficients of the un-ionized salt, the cation, and the anion; and C denotes the total concentration. If the electrolytic mobilities of the ions be plotted as abscissæ, and the viscosity coefficients as ordinates, the values for most of the salts lie on a straight line. M. G. Levi did not find that the stiffening of a solution with gelatine made an appreciable difference on the conductivity, but in very concentrated gelatine solutions, E. Wiedemann, C. Lüdeking, and B. von Tietzen-Hennig found that the conductivity is diminished; similar observations were made by C. Stephan, S. Arrhenius, and P. Massoulier with respect to solutions containing sugar or glycerol. W. von Beetz, B. von Tietzen-Hennig, and M. Oker-Blum studied the influence of suspensions of sand, gypsum, and blood corpuscles on the conductivity of salts.

J. Bosi,[6] E. H. Hall, and J. Nabl investigated the effect of the **agitation** of the solution on the conductivity, but no marked difference was observed. F. Neesen. H. Bagard, and G. Melani studied the effect of **magnetism** on the conductivity but without establishing any definite conclusion. C. H. Wind, E. van Everdingen, H. Bagard, F. Florio, and F. Chiavassa have studied the **Hall effect** with electrolytes. F. Kohlrausch, H. M. Goodurn, A. Wiener, and A. Miolate, etc.,[7] noticed that some electrolytes when diluted, mixed together, etc., show a transient change in the conductivity; this is attributed to chemical action. Light may also set up chemical reactions. According to J. Gibson, **light** always acts in such a way as to increase the conductivity, but whether the effect is reversible is not clear. The effect of **X-rays** has also been examined.[8]

§ 8. The Migration of Ions

It is impossible to get one kind of ion liberated at one electrode without having a precisely equivalent quantity of an oppositely charged ion appearing at the other electrode;

> **it is impossible to have a procession of positive atoms through a liquid without a corresponding procession of negative ones. In other words, an electric current in a liquid necessarily consists of a flow of positive electricity in one direction combined with a flow of negative electricity in the opposite direction.—O. J. Lodge (1892).**

Many early investigators—*e.g.* M. Faraday (1834),[1] J. F. Daniell and W. A. Miller (1844), etc.—noticed that changes in concentration are produced about the electrode during the electrolysis of a solution, and that although the quantities of anions and cations liberated at the electrodes during electrolysis are always strictly equivalent, nevertheless, the rates at which the concentrations of the electrolyte changes about anode and cathode are not the same. W. Hittorf studied the effect of strength of current, concentration of solution, and temperature on the phenomenon which was attributed to differences in the speeds at which the anions and cations drifted in the solution.

The changes of concentration about the electrodes are illustrated by an experiment due to A. A. Noyes and A. A. Blanchard. A U-tube contains a solution of gelatine colored with cupric chloride and covered with a layer of sodium chloride. The object of the gelatine is to prevent any movement of the liquid. When electrolyzed, the blue colour rises into the sodium chloride at the cathode side, and descends below the level of the gelatine on the anode side. With potassium dichromate instead of cupric chloride, the yellow colour rises at the anode side and descends at the cathode side. With copper dichromate, the yellow colour rises in the anode compartment and the blue in the cathode. The ionic theory interprets these experiments by assuming that in the case of cupric chloride, blue copper ions travel towards the cathode and colourless chlorine ions towards the anode; in the second experiment, that yellowish Cr_2O_7''-ions travel towards the anode and colourless potassium ions towards the cathode; and in the third experiment, blue copper ions travel towards the cathode and yellow dichromate ions towards the anode. The fact observed is that *the electrolysis of the coloured solutions occurs at the boundary surfaces between the gelatine and the supernatant solution.* M. Faraday (1833) has described experiments illustrating the phenomenon: "the surfaces of separation of liquids in contact act as electrodes to each other, and separation may there occur just as at a plate."

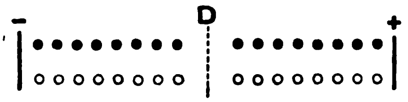

Fig. 8.

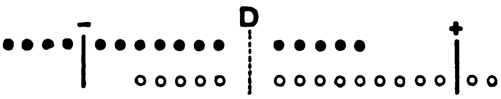

Fig. 9.

By a modification of these experiments, it is possible to measure the rates at which the concentration of the solution changes about the electrodes, or, in the language of the ionic theory, the rates at which the anions of copper, etc., drift towards the electrodes. Let the cations be represented by ● and the anions by ○, and suppose the two sets of anions to be arranged in rows as shown diagrammatically in Fig. 8, with an equal number on each side of a porous diaphragm in the electrolytic cell. There are eight molecules in each compartment, and the concentration of ion about each electrode can be represented by eight. If the cations move twice as fast as the anions, then, after a certain interval, the conditions may likewise be represented by Fig. 9, where each ion with no partner is supposed to have been discharged at the electrodes. Six cations and six anions have therefore been set free. The concentration in the cathode compartment has decreased from 8 to 6, and in the anode compartment from 8 to 4, with a loss of 2 and 4 respectively. Hence the loss in concentration about the cathode is to that about the anode, as the velocity of the anion is to that of the cation; that is, the losses in concentration about the electrodes are inversely as the speed of the correspondingly named ions. The relative velocities of the ions through the solution under a potential-gradient of 1 volt per cm. are best termed **Hittorf's transport numbers** of the ions.

If a solution of silver nitrate of known concentration be electrolyzed between silver electrodes in an apparatus similar to that illustrated in Fig. 7, the only change in the solution is a transfer of silver from the anode to the cathode, and a change in the concentration of the silver salt round the two electrodes; for the apparatus is constructed so as to reduce the mechanical convection of the dissolved salt to a minimum. The change in the concentration of the solution, after a few hours' electrolysis, can be measured by withdrawing about half the solution from the apparatus, *viâ* the stopcock, and determining the amount of silver in the solution by analysis. From the results, numbers can be obtained which are supposed to represent the speeds of migration of the anions and the cations. The following numbers, due to W. Hittorf (1853–59), serve to illustrate the principle.

W. Hittorf's experiment.—A solution of silver nitrate containing one part of silver to 49·44 parts of water was electrolyzed for nearly an hour in a cell with silver electrodes. Silver dissolved from the anode and a similar quantity deposited on the cathode. The concentration of the whole solution remained unchanged, but the concentration of the solution about the cathode decreased while that about the anode increased. In the cathode compartment, W. Hittorf found

Silver before electrolysis	0·7162 gram
Silver after electrolysis	0·5862 „
Loss	0·1300 „

The solution about the cathode thus lost 0·1300 gram of silver, and the solution about the anode must have increased by this amount owing to the action of an equivalent quantity of nitric acid on the silver electrode.

At the same time, by the simultaneous interposition of a silver voltameter in the circuit, it was found that sufficient electricity had passed through the electrolyte to deposit 0·2470 gram of silver at the cathode. If no silver ions have passed from the anode chamber, the quantity of silver in the anode chamber would have increased by 0·2470 gram owing to the transport of NO_3'-ions from the cathode chamber. The observed increase was only 0·1300 gram of silver; hence 0·2470 less 0·1300 gram; in all, 0·1170 gram of $Ag^{\cdot}$-ions were transported from the anode chamber to the cathode chamber while the cathode chamber simultaneously lost 0·1300 gram of silver due to the deposition of 0·2470 gram of silver on the cathode. Hence since *the relative speeds of the ions are proportional to the fall of the concentration about the oppositely named electrodes*, or

$$\frac{\text{Loss in cathode chamber}}{\text{Loss in anode chamber}}=\frac{0{\cdot}1300}{0{\cdot}1170}=\frac{\text{Speed of anion, }NO_3'}{\text{Speed of cation, }Ag^{\cdot}}$$

or the rate of transport of the anions is to the rate of transport of the cations as 130 : 117; or the NO_3'-ions migrate 1·1 times as fast as the $Ag^{\cdot}$-ions.

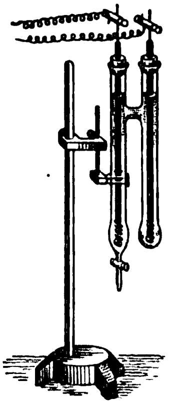

Fig. 10.—Determination of the Speed of Ionic Migration.

The mobility of the elementary ions was found by G. Bredig to vary periodically with the atomic weight; and with complex ions, W. Ostwald and G. Bredig[2] noted that the mobility decreases as the combining weight increases, and with isomeric ions the mobility is approximately the same.

§ 9. The Speeds of Moving Ions—Kohlrausch's Laws

If the anions in a solution remained stationary, the whole current would be carried by the cations; but if both ions be moved, the current will be shared between them, and the share of each will be proportional to the speed at which it moves.[1] Let $v^{\cdot}$ represent the speed of migration of the cations, and v' that of the anions. The total current carried from one electrode to the other will be proportional to the rate at which the ions separate—that is, to the joint velocity of the two ions $v^{\cdot}+v'$. Accordingly the current carried across the electrolyte is shared in such a way that the

$$\text{Anions share} = \frac{v'}{v^{\cdot}+v'}, \quad \text{Cations share} = \frac{v^{\cdot}}{v^{\cdot}+v'}$$

Hence in W. Hittorf's experiment, the relative speeds of the $Ag^{\cdot}$- and NO_3'-ions were as 0·117 : 0·130, $=v^{\cdot} : v'$, the **transport numbers** are respectively 0·130/(0·130+0·117)=0·52 and 0·117/(0·130+0·117)=0·48. Hence, if n denotes the transport number of one ion, $1-n$ will represent the transport number of the other. It might be observed that the change in the concentration of the solution about one anode is sufficient to compute the relative speeds of migration of the anions and cations under the given conditions. In W. Hittorf's experiment just cited, the solution before the passage of the current contained the equivalent of 0·7162 grm. of silver, and the anode compartment lost 0·1170 grm. of silver. The total quantity of electrical energy transported through the cell was equivalent to the 0·2470 grm. of silver deposited in the voltameter. The fraction transported by the silver ions is therefore 0·1170/0·2470=0·473. If $n^{\cdot}$ denotes the transport number of the anion, and n' that of the cation, $n^{\cdot}+n'=1$. Hence, the transport number of the NO_3'-ions is obtained by subtracting 0·473 from unity; the result 0·527 agrees with that obtained from the ratio 0·1300/0·2470=0·527. Obviously the ratio 0·473 : 0·527 is the same as 117 : 130.

EXAMPLES.—(1) F. Vogel (1903)[2] found that 100 c.c. of a solution of barium nitrate contained the equivalent of 0·4419 grm. of barium, and it weighed 100·6660 grms. This solution was electrolyzed in a suitable apparatus while a silver voltameter deposited 0·5618 grm. of silver, which is equivalent to 0·3577 grm. of barium, 187·2880 grms. of the anode solution contained the equivalent of 0·6728 grm. of barium; the concentration of the solution between the two electrodes did not change. Compute the transport numbers of anion and cation. Since 187·2880 grms. of the electrolyte before electrolysis contained the equivalent of 0·8223 grm. barium, and after electrolysis 0·6728 grm. Hence, the loss in the anode chamber was 0·1495 grm. of barium. The transport number of the cation, $Ba^{\cdot\cdot}$, is therefore 0·1495/0·3577=0·418; and of the anion, NO_2', 1−0·418=0·582.

(2) F. Warschauer (1903) found that a solution of sodium metaphosphate $NaPO_3$ contained the equivalent of 0·1775 grm. of P_2O_5 per 25 c.c. or 25·1998 grms. Before the electrolysis the anode solution contained 91·6632 grms. of liquid; hence, it contained the equivalent of 0·6384 grm. P_2O_5; 0·2792 grm. Na_2O; and 90·7456 grms. of water. After electrolysis 0·7370 grm. P_2O_5; 0·3223 grm. Na_2O; and 90·6039 grms. of water. Hence, 90·6039 grms. during the electrolysis gains 0·7370−0·6374=0·996 grm. P_2O_5, and this is equivalent to 0·1108 grm. PO_3. While the electrolysis was in progress, a solution containing 6·0035 grms. of silver nitrate per half litre deposited 0·2625 grm. of silver during the electrolysis. This amount of silver is equivalent to 0·1922 grm. of PO_3. Hence the transport number of the PO_3'-ion is 0·1108/0·1922=0·58, and that of the $Na^{\cdot}$-ion is 1−0·58=0·42.

The behaviour of electrolytes with a bivalent radicle united with two univalent radicles is a little more complex. For example, solutions of sulphuric acid may furnish two $H^{\cdot}$-ions, and one SO_4''-ion, or one $H^{\cdot}$-ion and one HSO_4'-ion. This is given as an explanation of the fact why the transport numbers for such solutions show appreciable differences when determined in dilute and in concentrated solutions. Thus, the anion of barium chloride in aqueous solution varies from 0·611 to 0·555 by progressive dilution as shown in the following scheme:

Normality of solution . . .	0·50	0·20	0·10	0·05	0·02	0·01
Transport numbers . . .	0·61	0·59	0·57	0·56	0·56	0·56

The concentration of the solution determines whether the ionization proceeds $H_2SO_4 \rightleftharpoons H^{\cdot} + HSO_4'$ or $H_2SO_4 \rightleftharpoons 2H^{\cdot} + SO_4''$. With decreasing concentration the ions become less complex, the solution yields transport numbers approaching a constant value. The variation is due to changes in the relative proportions of the anions and cations with increasing dilution: $BaCl_2 \rightleftharpoons BaCl^{\cdot} + Cl' \rightleftharpoons 2Cl' + Ba^{\cdot\cdot}$. All the molecules of the solute at infinite dilution are *ex hypothesi* ionized and take an active part in conducting the current, while the number of molecules which take an active part in conducting the current at any particular dilution is proportional to the molecular conductivity, μ, and therefore, if x represents the fraction of a gram-molecule which is ionized when the solution is diluted to v litres, $\mu = kx$, where k is the constant of proportion. At infinite dilution, the whole molecule is ionized, and consequently $x=1$; $\mu_\infty = k$; and $\mu = \mu_\infty x$. On comparing the molecular conductivities of a number of different salts at infinite dilution, F. Kohlrausch (1876) noticed a curious fact: The difference in the molecular conductivities of potassium and sodium chlorides is equal to the difference between potassium and sodium nitrates; and this in turn to the difference between sodium and potassium fluorides; etc. In illustration:

	KCl NaCl	KNO_3 $NaNO_3$	KF NaF
μ_∞	129·1 − 108·1	125·5 − 104·5	110·5 − 89·4
Difference . . .	21·0	21·0	21·1

The difference in each pair of salts with a common anion thus depends on the difference in the speeds of migration of the cations—$K^{\cdot}$ and $Na^{\cdot}$—and this is constant. Similar relations hold good for other salts containing a common cation. It is thence inferred that **the molecular conductivity at infinite dilution is the sum of two factors, one dependent upon the nature of the anion, the other on the cation** —this is **Kohlrausch's second law.** At infinite dilution, the molecular conductivity is represented by **Kohlrausch's equation :** $\mu_\infty = v^{\cdot} + v'$. Consequently, the speed of migration of any particular ion in a particular solvent is constant at infinite dilution, is dependent on its own chemical nature, and is independent of the nature of the other ion or ions which may be present. Otherwise expressed, **the speeds of migration of the different ions in a solution are independent of one another.** In illustration, the speeds of migration of the chlorine ion in 0·0001N-solutions of lithium, sodium, and potassium chlorides were respectively 65·7, 65·7, and 65·6.

W. Hittorf showed how to determine the numerical value of the ratio $v^{\cdot}/v'$, and F. Kohlrausch's equation furnishes the numerical value of $v^{\cdot} + v'$. Hence it is possible to compute the absolute velocities of the anion and cation. The results agree closely with those obtained by direct measurement.

EXAMPLE.—The molecular conductivity of a solution of silver nitrate at infinite dilution is 115, at 18°. This means that 115 coulombs of electricity are carried 1 cm. per second; but each gram ion of silver nitrate carries 96,540 coulombs (Faraday's law), hence 115 coulombs are carried $115 \div 96540 = 0{\cdot}00121$ cm. per second. This represents the velocity at which the two ions draw apart. The carriage of the electric charge is shared by both ions; the migration constants of the two ions are $Ag^{\cdot}$ 54, and NO_3' 62. The ratio $v^{\cdot}/v' = 54/62 = 0{\cdot}87$. Hence $v^{\cdot} = 0{\cdot}87v'$. From Kohlrausch's equation $0{\cdot}00121 = v^{\cdot} + v'$ or $1{\cdot}87v' = 0{\cdot}00121$, or $v' = 0{\cdot}00065$, and $v^{\cdot} = 0{\cdot}00056$ cm. per second.

F. Kohlrausch's equation was extended by W. Ostwald to represent other than infinite dilutions by introducing the term $\mu=a\mu_\infty$. Hence, when ionization is not complete, Kohlrausch's equation becomes $\mu=a(v^{\cdot}+v')$. As the solution is diluted more and more the term a becomes more and more nearly equal to unity, and finally when ionization is complete, $a=1$ and Kohlrausch's equation $\mu_\infty=v^{\cdot}+v'$ appears. The expressions assume a similar form if the equivalent conductivities be in question.

Example.—The transport numbers for the ions in a solution of sodium metaphosphate are 0·573 for PO_3', and 0·427 for $Na^{\cdot}$. The maximum equivalent conductivity of the solution is 126·2 units. What are the relative speeds of migration of the two ions ? If n be the transport number of the cation, $1-n$ will be the transport number of the anion, and $n/(1-n)=v'/v^{\cdot}$; and $\lambda=x(v^{\cdot}+v')$; by substitution therefore $v^{\cdot}a=(1-n)\lambda$, and $v'x=n\lambda$. When the equivalent or molecular conductivity is a maximum, ionization is complete, and $a=1$. Accordingly, $n=0·427$; $1-n=0·573$; $\lambda=126·2$. Hence, the relative speeds of migration of the cation $Na^{\cdot}$ is 53·9, and of the anion PO'_3, 72·3 ; or the sodium ion travels $53·9 \div 96540=0·00056$ cm. per second when the electromotive force is one volt, etc.

By measuring the rate of rise of the blue colour in A. A. Noyes and A. A. Blanchard's experiment, the velocity of copper ions can be determined under standard conditions, and in that way, with other solutions, a series of numbers have been obtained which represent the velocities of migration of the respective ions. In O. J. Lodge's experiment (1886) a current was passed through a ⊓-shaped tube containing a stiff gelatine solution of sodium chloride coloured red with phenolphthalein and a trace of sodium hydroxide. The ends of the tube dipped in beakers contained dilute sulphuric acid. The time taken to decolorize a certain measured distance was determined, and this was corrected by the time taken for the acid to diffuse in the jelly when no current was passing. In this way it was found that the hydrogen ions travelled through the jelly at the rate of 0·0026 cm. per second when a difference of potential of one volt was applied to the electrodes. H. B. Denison and B. D. Steele, and G. M. Lewis used the method of moving boundaries for measurements of the transport numbers.

The transport numbers are expressed in the same units as the equivalent and molecular conductivities, and they are proportional to the velocities of the ions. The speeds of the ions are decreased by increasing the viscosity of the solution, say, by adding non-electrolytes like cane sugar, alcohols, ether, etc. Gelatine has very little influence. The decrease in viscosity which occurs on raising the temperature is also of influence. The speeds of the ions are also augmented by using currents of greater electromotive force. Hence, the rate of motion of any given ion is determined (i) by the intensity of the electric pressure which directs or drives the ions to the electrodes; (ii) by the damping effect of the liquid on the moving ion.

It must be remembered also that the raising of the temperature or the addition of a third substance to the solution may materially modify or even mask the normal relations between solvent and solute. The conductivity of a solution may virtually vanish suddenly at the point of solidification of a cooling liquid; so that by plotting the conductivity of a molten salt cooling through a range of temperature, there will be an abrupt change in the direction of the curve at the freezing temperature, and it has been proposed to apply this principle to determine transition temperatures—solid or liquid, etc.

Many solids are poor conductors at ordinary temperatures but good conductors at temperatures above their melting points. One explanation assumes that the conductivity of fused salts is due to self-ionization, in other words, that a small portion of fused substance is ionized. Glass and porcelain are poor conductors at ordinary temperatures, but they conduct very fairly at more elevated temperatures, and this principle has been utilized in the so-called Nernst lamp.

At 18°, with a difference of potential of one volt between the electrodes, the absolute velocities of some ions are :

Anions . .	OH'	Cl'	I'	NO_3'	ClO_3'
Speeds . .	5·6	2·12	2·19	1·91	1·70 cm. per hour
Cations . .	$Cs^{\cdot}$	$Rb^{\cdot}$	$K^{\cdot}$	$Na^{\cdot}$	$Li^{\cdot}$
Speeds . .	2·32	2·32	2·05	1·26	1·11 cm. per hour

Under similar conditions, the charges carried by different ions may be equal; their speeds are different. The heaviest ions, in the alkali series of elements—that is, the ions with the greatest "atomic" weights—here appear to move fastest. This has been supposed to be due to the slower-moving ions dragging along with them a number of molecules of the solvent. This assumption seems to be justified by experiments with dilute solutions, but with concentrated solutions there is a discrepancy between results obtained by W. Hittorf's method and the method of moving boundaries, which is explained by assuming that in dilute solutions the change in the concentrations is negligibly small, whereas in a concentrated solution the difference in the concentration of the ions at each electrode must be affected by the water carried by the ions. W. Hittorf's method does not distinguish between changes of concentration about the electrodes due to the transport of ions and those due to the carriage of water by the ions.[3] In Hittorf's method it is assumed that the solvent is quite stationary during the electrolysis, and that no solvent is transferred from the one electrode to the other. If the ions are hydrated, not only the electrolyte but some of the solvent will be transferred from the one electrode to the other, unless the respective ions happen to be equally hydrated. This argument has been tested by W. Nernst, G. Buchböck, etc., by using solutions of an electrolyte containing a third substance—raffinose, mannite, sugar, etc.—not affected by the electrolysis, as a standard of reference for the concentration of the water. As a result, it was found that the numbers are not generally in agreement with Hittorf's transport numbers although they agree with those obtained by the method of moving boundaries; it was also found that during the electrolysis of hydrogen, sodium, potassium, and lithium chlorides, the ratio water : sugar decreases at the cathode and increases at the anode under conditions where no change occurs in the absence of the electrolyte. This fact can be explained either by assuming that the non-electrolytic sugar is carried from cathode to anode; or that water is carried from anode to cathode during the passage of the current. The former hypothesis assumes that the ions (or electrolyte) form a complex with the sugar, and for this there is no satisfactory evidence; the ionic hypothesis assumes that the ions are hydrated, and carry the water molecules as well as their electric charges. The molecular equivalents of water transferred from anode to cathode per farad of electricity when the electrolyte has normal concentration:

HCl	KCl	NaCl	LiCl
0·24	0·60	0·76	1·5

These numbers taken in conjunction with the transport numbers show that the degree of hydration varies with the different ions and with the concentration of the solution. The relative degrees of hydration for the different ions (chlorine assumed to be unity) are:

Cl'	$H^{\cdot}$	$K^{\cdot}$	$Na^{\cdot}$	$Li^{\cdot}$
1	0·46	2·3	3·6	7·0

the row of numbers must represent minimum values since a negative value for chlorine is impossible. Hence all the cations in the above-mentioned solutions must be hydrated, and the hydration increases markedly in passing along the series H, K, Na, Li. If the speeds of migration of the different ions be plotted on squared paper against the atomic weights of the elements, a periodic curve is obtained. H. Remy has calculated hydration numbers from the changes in volume which occurred in the anodic and cathodic solutions during electrolysis.

Evidence indicating the union of ions with the solvent has been sought in the changes which occur with boiling points and freezing points of concentrated solutions. These phenomena depend on the ratio of the number of molecules (or ions) of solute and of solvent. If union occurs, the number of molecules (or ions) is not changed, but only their size. The combination in dilute solutions can remove but a relatively small amount of solvent from the field, and the consequent effect is inappreciable. Even in concentrated solutions the deviations from the theoretical values do not show whether it is the free ions that are so combined, or whether it is not the result of something else. Measurements of the boiling and freezing points of solutions of hydrated salts in other solvents have also been made with the idea of finding if the water of crystallization remains attached to the salt. In virtually all cases the evidence points one way : the ions do unite with molecules of the solvent, and thus move more slowly than if they were not harnessed with the molecules of the solvent.

The data show that the rates at which ions move through water are surprisingly small—one centimetre per hour for the $K^{\cdot}$-ion under a pressure of one volt. And it requires a pressure equivalent to about 300,000 tons to drive a gram ion of hydrogen, $H^{\cdot}$, through water at this speed.

EXAMPLE.—By definition 10^7 dynes of energy are required to drive a coulomb of electricity one centimetre against a potential difference of one volt. A force of 10^7 dynes is equivalent to 10·18 kilograms. Hence, the force required for a gram-ion charged with 96,540 coulombs will be 96,540 × 10·18 = 983,000 kilograms ; and measurements of the absolute velocity of the hydrogen ion show that this force is required to drive these gram-ions with a velocity of 0·00325 cm. per second. Hence to drive the gram-ion with a velocity of one centimetre per second will require a force of nearly 983,000 ÷ 0·00325 = 302,000,000 kilograms. One ton is nearly equivalent to 1016·05 kilograms, and therefore 302,000,000 kilograms is nearly equivalent to 297,000 tons.

W. Hittorf's results can be deduced from the assumption that both the solvent and the solute conduct the current, for if, say, silver nitrate conducts the whole current, free acid appears only at the anode ; if the water conducts the whole current, free acid appears only at the cathode ; and if both salt and solute conduct the current, free acid appears at both electrodes, and the current can be portioned between the solvent and solute so as to make the observed facts fit the hypothesis. Hence, W. Hittorf's migration data do not prove that ions travel at unequal rates, for the observed facts can be explained by at least two plausible hypotheses.

In these experiments the *fact* observed is the changing molecular concentration of the solution about the anode and cathode during electrolysis ; the *hypothesis* is that during the passage of the current the anions and cations move in the same electrolyte with different velocities, and are yet the anions and cations given off at the respective electrodes at the same time.

§ 10. "Abnormal" Osmotic Pressures and Ionization

It is natural to assume that substances are ionized which give in aqueous solution osmotic pressures which are too great.—S. ARRHENIUS.

We are now in a position to resume our study of the abnormal osmotic pressures furnished by solutions of electrolytes. Just as the abnormally high vapour density exhibited by hydrogen fluoride was traced to polymerization : $2HF \rightleftharpoons H_2F_2$, and the abnormally low vapour density of iodine above 700° was traced to the dissociation : $I_2=2I$, so S. Arrhenius argued that salts in solution which give an abnormally high osmotic pressure are similarly dissociated. Suppose that one molecule of an electrolyte furnished m ions, and further let a denote the fraction ionized when a gram-molecule of the electrolyte is dissolved in water. The solution will then contain $(1-a)$ non-ionized molecules, and ma ions. The total number of individual molecules in the solution—that is, electrically charged molecules (ions) and neutral molecules—will be $(1-a)+ma$. As in our previous study of solutions, let n denote the total number of individual molecules formed by the ionization of a substance in a given solution. Then $n=1+ma-a$. The numerical value of n, as we have seen, can be determined from conductivity data, and from osmotic pressure and related phenomena—freezing and boiling point determinations. If the value of n so determined be divided into the value of n calculated on the assumption that no ionization occurs, the value of a can be computed ; and if a be known, the value of n can be computed.

EXAMPLES.—(1) The solution of hydrochloric acid just studied gives $a=0{\cdot}874$ and $m=2$. Hence $n=1+(m-1)a$ becomes $n=1{\cdot}874$. Hence every 100 molecules of HCl furnish the equivalent of 187·4 individual molecules. If the electrolyte has been non-ionized, n would have been unity ; and if completely ionized, n would have been 2.

(2) The boiling point of a solution of 3·400 grms. of barium chloride, $BaCl_2$, in 100 grms. of water is 100°-208°, what is the degree of ionization of the solute ? From the above expression, there will be $1+ma-a=1+3a-a=1+2a$ "molecules" in the solution, *viz.* $Ba^{\cdot\cdot}$, $2Cl'$, and hence one molecule of barium chloride furnishes the equivalent of 208/85 $=2{\cdot}447$ "molecules." Consequently, $2{\cdot}447=1+2a$, or $a=0{\cdot}723$; or 72·3 per cent. of the salt is ionized.

(3) A solution of 11·07 grms. of barium nitrate in 100 grms. of water raised the boiling point 0·466°. What proportion of the salt is ionized ? Ansr. 55·8 per cent.

(4) A solution of 0·3668 grm. of sodium chloride in 100 grms. of water freezes at −0·221°. What proportion of the salt is ionized ? Ansr. 89·2 per cent.

A comparison of the values of n calculated from osmotic pressure, freezing point, and electrical conductivity data is indicated in Table II. The numbers in the last three columns show that the values determined by independent processes are strikingly concordant; and it is therefore inferred that the abnormal osmotic pressures indicated in Table VI, Cap. X, arise from the more or less complete ionization of the electrolytes in aqueous solution.

TABLE II.—MOLECULAR WEIGHTS OF SOME ELECTROLYTES IN SOLUTION.

Salts.	Molecular concentration.	Values of n.		
		Osmotic pressure.	Freezing point.	Conductivity.
Calcium nitrate, $Ca(NO_3)_2$	0·18	2·48	2·47°	2·46
Magnesium sulphate, $MgSO_4$	0·38	1·25	1·20°	1·35
Strontium chloride, $SrCl_2$	0·18	2·69	2·52	2·51
Potassium chloride, KCl	0·14	1·81	1·86°	1·86
Lithium chloride, LiCl	0·13	1·92	1·94°	1·84
Magnesium chloride, $MgCl_2$	0·19	2·79	2·68°	2·48

Modes of Ionization.—The ionization of some of the bivalent electrolytes—H_2CO_3 ; H_2SO_4 ; $BaCl_2$; $CdCl_2$; K_2SO_4 ; $CuSO_4$; etc.—in moderately dilute solutions appears to furnish complex ions. Thus, cadmium chloride, $CdCl_2$, not only furnishes $Cd^{\cdot\cdot}+2Cl'$, but also $Cd^{\cdot\cdot}+CdCl_4''$; sulphuric acid, H_2SO_4, not only gives $2H^{\cdot}+SO_4''$, but also $H^{\cdot}+HSO_4'$; carbonic acid, H_2CO_3, gives $2H^{\cdot}+CO_3''$; and $H^{\cdot}+HCO_3'$; copper sulphate, $CuSO_4$, not only gives $Cu^{\cdot\cdot}+SO_4''$, but also $Cu_2SO_4^{\cdot\cdot}$ and $Cu(SO_4)_2''$; etc. If, however, the solutions be still further diluted, the complex ions break down into simpler ones. Hence the ionization of concentrated polybasic acids like H_2SO_4 proceeds in stages: first $H_2SO_4=H^{\cdot}+HSO_4'$; followed by $H^{\cdot}+HSO_4'=2H^{\cdot}+SO_4''$.

§ 11. Equilibrium between Ionized and Non-ionized Solute

> The evidence is so un-ambiguous and convincing that ions and some molecules combine with more or less of the solvent that it seems that it can now be accepted as a fact of science.—H. C. Jones (1913).

Reference has previously been made to the assumption that the molecules of an electrolyte, when dissolved in water, are ionized; that the ions, at the same time, recombine to form neutral molecules; and that equilibrium will ensue when the speeds of the two opposing reactions—ionization and de-ionization—are equal. Consider the ionization of ammonium hydroxide, NH_4OH, represented by $NH_4OH \rightleftharpoons NH_4^{\cdot}+OH'$. Here the process of ionization bears some analogy with the dissociation of iodine by heat: $I_2=I+I$. Let $[NH_4OH]$ denote the concentration of the ammonium hydroxide; $[NH^{\cdot}_4]$, that of the concentration of the ammonium ion; and $[OH']$, that of the hydroxide ion. Then, applying the principle of opposing reactions, the condition for equilibrium is: $[NH_4^{\cdot}]\times[OH']=K[NH_4OH]$. If this theory applies to ions, it follows that the numerical value of the equilibrium constant, K, now called the **ionization constant**, remains unchanged whatever be the concentration of the solution. This relation is sometimes called **W. Ostwald's dilution law**,[1] or Ostwald's mass law, and, for univalent electrolytes, it is also symbolized:

$$\frac{a^2C}{1-a}=K\text{; or, }\frac{C_i^2}{C_u}=K\text{; or }\frac{a^2}{(1-a)v}=K$$

where a denotes the degree of ionization; C, the total concentration; C_i, the concentration of each of the ions; C_u, the concentration of the non-ionized part; and v the number of litres of solvent containing a gram-molecule of the salt.

Example.—In a solution containing 0·125 gram-molecules of NH_4OH per litre, the equivalent conductivity shows that 0·0135 gram-molecules are ionized, and hence, 0·0135 $\times$0·125=0·0017 represents the molecular concentration of the ammonium hydroxide which is ionized. This number thus represents the concentration of the $NH_4^{\cdot}$-ions. But every $NH_4^{\cdot}$-ion is accompanied by one OH'-ion, and accordingly, 0·0017 also represents the concentration of both the $NH_4^{\cdot}$- and the OH'-ions. Hence, from Ostwald's dilution law, 0·0017 $\times$0·0017$\div$(0·125$-$0·0017)=0·000023. This last number represents the value of the ionization constant for a seminormal solution of ammonium hydroxide.

It follows from this rule that the greater the dilution v the greater will be the **percentage amount of ionization** (although, of course, the **actual concentration of the ions** must decrease). Since $a=\lambda_v/\lambda_\infty$ the value of K can be readily computed; and this has been done by W. Ostwald for a large number of organic acids, and by G. Bredig for organic bases, with results so very satisfactory that S. Arrhenius could say "in no other field has the law of mass action been applied with such good results"—the converse of this statement applies with strong electrolytes. Table III represents values for the ionization constant for solutions of ammonium hydroxide of different strength.

The constancy of the value K means that although the last-named solution of ammonium hydroxide is nearly 300 times more dilute than that named first, and the degree of ionization of the last is nearly 16 times as great as the first, the expression represented by K, deduced on the supposition than the process of ionization follows the rule for opposing reactions, is constant within the limits of experimental error.

It will be observed that two important assumptions have been tacitly made in deriving the formula: (1) that the concentration of the ions can be obtained from the conductivity ratios; and (2) that the ions and un-ionized molecules of an electrolyte follow the laws of ideal solutions. In spite of the very successful results obtained with the feebler acids and bases, for some unknown reason, the application of the dilution law to the stronger electrolytes has been a signal failure, and the so-called anomaly is regarded as the *bête noir* of S. Arrhenius' ionic hypothesis. The numerical value of K, instead of remaining constant, increases rapidly with increasing concentration. In the first place, the equivalent conductivity of a univalent substance is $\lambda=aF(v^{\cdot}+v')$, where a is the fraction of the substance ionized, and F the quantity of electricity associated with each equivalent ion; and the equivalent conductivity at zero concentration or infinite dilution is $\lambda_\infty=F(v^{\cdot}_\infty+v'_\infty)$. Hence,

TABLE III.—EFFECT OF DILUTION ON THE IONIZATION OF AQUEOUS AMMONIA.

Ammonium hydroxide. (Gram-molecules per litre.)	Proportion ionized.	Molecular concentration of $NH_4^{\cdot}$ and of OH' ions. (Gram "ions" per litre.)	Molecular concentration of non-ionized NH_4OH. (Gram-molecules per litre.)	K
1·0000	0·0047	0·0047	1·0000–0·0047	0·000023
0·1250	0·0135	0·0017	0·1250–0·0017	0·000023
0·0159	0·0376	0·0006	0·0159–0·0006	0·000023
0·0039	0·0754	0·0003	0·0039–0·0003	0·000023

$$\frac{\lambda}{\lambda_\infty}=a\frac{v^{\cdot}+v'}{v^{\cdot}_\infty+v'_\infty}$$

which shows that λ/λ_∞ is equal to a only when the mobilities of the ions are constant for the concentrations under consideration, for only then does $v^{\cdot}+v'=v^{\cdot}_\infty\pm v'_\infty$. In view of the possible electrical effects resulting from the large electric charges on the ions, this assumption is by no means certain.

Again, S. Arrhenius and W. Ostwald [2] inclined to the view that the cause of the discrepancy is due to the failure of the mass law with strong electrolytes; H. Jahn believed that imperfections in the method of measuring λ_v/λ_∞ render the ratio an imperfect measure of a; and C. A. Kraus suggested introducing a correction term for the viscosity of the medium, $\lambda_v\eta_0/\lambda_\infty\eta=a$, when η_0 and η respectively denote the viscosities of solvent and solution. E. W. Washburn proposed $\lambda\phi_\infty^m/\lambda_\infty\phi^m=a$, where ϕ represent the fluidities of the media; for solutions less than normal, $m=0{\cdot}94$, but F. G. Donnan and W. E. Garner showed that the value of m decreases with increasing concentration for $2N$- to $12N$-solutions of lithium chloride. Another set of workers—S. Arrhenius, C. A. Kraus and W. C. Bray, J. Kendall, and W. R. Bousfield, etc.[3]—have corrected the results for the effect of traces of impurity in the solvent on the conductivity measurements. A. A. Noyes and W. C. Bray, J. Walker, etc.,[4] have suggested that the deviation is to be ascribed to the abnormal behaviour of the un-ionized molecules of strong electrolytes slightly increasing the concentration of the ions. The stimulating effect of the un-ionized molecules on ionization is also assumed by B. de Szyszkowsky. P. Walden [5] suggested that the solute increases the dielectric constant of the solvent and this augments its ionizing power. H. Jahn and G. N. Lewis have suggested that there is an increase in the ionic mobility with increasing ionic concentration. J. C. Ghosh assumes with W. Sutherland that the electrolyte is completely ionized, but that part of the ions are free to move as contemplated by the kinetic theory, and part are bound so as to hold fixed positions in the solvent-like structural units in the space lattice of a crystal. Another hypothesis assumes that a Grotthus chain conductivity is superposed on the ionic conductivity, a view negatived by the work of C. A. Kraus and W. C. Bray; [6] yet another hypothesis suggests that the solvent in the solution also conducts some of the current.

The question was raised by O. J. Lodge in 1886, if pure water and pure hydrogen chloride are non-conductors, and the conductivity of hydrochloric acid is due to the ionization of the hydrogen chloride by water; presumably also the effect is not one-sided, and the water is likewise ionized by the acid.[7] J. W. McBain has pointed out that if the movement of the cation and anion add up to unity, the solvent cannot have taken a share in the conductivity, and this conclusion is not affected by the presence of various kinds of complex ions. The work of G. Poma and B. Tanzi[8] makes it appear as if the water in the presence of sodium chloride is not so much ionized as the solvent alone. W. Palmaer and K. Melander draw the opposite conclusion with respect to aqueous solutions of calcium and lithium chlorides, so also did H. S. Harned with respect to solutions of sodium bromide or the chlorides of the alkalies and alkaline earths in hydrochloric acid. A. Sachanoff found that with solvents of low dielectric constant, an increased ionization occurs when other electrolytes are added, although with water there is a decrease.

The failure has been attributed to the gradual hydration of the ions during dilution. If so, the mobility of the ions will be constant only when the hydration is complete. The conductivity, therefore, will not depend upon ionization alone, but will also depend on the degree of hydration of the ions. If the dissolved substance combines with the solvent, then, in the more concentrated solutions, part of the liquid in which the substance is dissolved will no longer function as solvent because it is in combination with the ions and the non-ionized molecules of the solute. This is virtually the **solvate theory of solution** which so much attracted H. C. Jones.[9] However, this does not affect the principles which are based upon the dilution law, for it is merely necessary to introduce an additional factor to provide for the fact that the solution is much more concentrated than it would be if all the liquid in which the substance is dissolved is doing the work of a solvent. H. C. Jones, for instance (1913), has given very good evidence for assuming that what we call a normal solution of aluminium chloride and of several other substances in water is about twice normal because about five-eighths of the water is actually combined with the dissolved substance.

Numbers of formulæ[10] have also been proposed by M. Rudolphi, L. Storch, J. H. van't Hoff, F. H. McDougall, C. A. Kraus, and W. C. Bray, etc., in place of the one based on the law of mass action. In most of these, empirical changes are made in the indices or terms are added to the simple dilution law. The results are satisfactory only when empirical correspondence with fact is desired. The present position of the theory of ionization discussed at the Faraday Society[11] (1919), made it very clear that in spite of twenty years' labour there is something fundamentally wrong in the application of the mass law to ionization, excepting in the case of weak electrolytes and of very dilute solutions of the stronger electrolytes. The general conclusion to be drawn from the work is that electrical conductivity is not an accurate measure of ionic concentration, and for strong electrolytes in concentrated solutions, λ_v/λ is not equal to a. This is confirmed by a comparison, by H. N. Lewis and G. A. Linhart, of A. A. Noyes and K. G. Falk's value of a from the ratio λ/λ_∞ and the value computed from thermochemical data for solutions with 0·01 gram-molecule of the salt per litre. The discrepancies are very pronounced :

	KCl	NaCl	KIO_3	$NaIO_3$	K_2SO_4	$BaCl_2$	$CdSO_4$	$CuSO_4$	$La(NO_3)_2$
a . .	0·925	0·925	0·872	0·872	0·687	0·716	0·338	0·290	0·571
λ/λ_∞ .	0·941	0·936	0·928	0·917	0·872	0·883	0·614	0·629	0·802

§ 12. The Solubility Law

In the case of an aqueous solution of sodium chloride, containing, say, 58·5 grams, that is, one gram-molecule per litre, we have: $NaCl=Na^{\cdot}+Cl'$, where 68 per cent. of the salt is ionized. The condition of the equilibrium, according to the dilution law, is

$$\frac{[Na^{\cdot}][Cl']}{[NaCl]}=K;\quad \frac{0\cdot68\times0\cdot68}{0\cdot32}=K;\text{ or }K=1\cdot44$$

If Cl'-ions be added they must necessarily be accompanied by an equivalent number of oppositely charged ions of, say, $K^{\cdot}$, from, say, a solution of potassium chloride; or of $Na^{\cdot}$-ions from, say, sodium hydroxide; $NaOH\rightleftharpoons Na^{\cdot}+OH'$; etc. If either $Na^{\cdot}$- or Cl'-ions be added to the solution—say, hydrogen chloride—making the concentration of the Cl'-ions 0·75 instead of 0·68—then, in order to preserve the constancy of the ratio 1·44, the concentration of the $Na^{\cdot}$-ions must be diminished. This can only occur by the union of some of the $Na^{\cdot}$- and Cl'-ions to form NaCl until the ratio K is again 1·44.

Solubility of mixtures with a common ion.—Sodium chloride is in equilibrium with its aqueous solution, when, at a given temperature, the concentration of the substance in solution has a certain definite and constant value—the solubility of the substance at the given temperature. Since the sodium chloride in solution is partly ionized, there are two equilibria to consider: first, the relation between the non-ionized and the ionized salt in solution, $NaCl \rightleftharpoons Na^{\cdot} + Cl'$ just indicated; and second, the relation between the non-ionized salt and the solid. If the solution be saturated, we have:

$$NaCl_{solid} \rightleftharpoons NaCl_{solution} \rightleftharpoons Na^{\cdot} + Cl'$$

If the concentration of the $Na^{\cdot}$ or the Cl' be augmented by the addition of hydrochloric acid, some of the $Na^{\cdot}$- and Cl'-ions will recombine to form non-ionized NaCl as indicated above. Consequently, some sodium chloride will be precipitated or the solution will be supersaturated. Hence **the solubility of a salt is usually diminished in the presence of another compound with a common ion.** If the solution of the hydrochloric acid had been isohydric with the salt solution—*i.e.* if the number of chlorine ions per cubic centimetre had been the same—no alteration in the concentration of the ions would occur, and therefore no salt would be precipitated on mixing the solutions, provided no disturbing secondary action occurs. The solubility of potassium nitrate is influenced in the same way by equivalent solutions of potassium chloride and bromide. Hence, it follows that the two latter salts are ionized to the same extent. A familiar example of this phenomenon is the precipitation of sodium chloride from its saturated solution by the action of hydrogen chloride or a concentrated aqueous solution of the acid.

The solubility of sodium chloride in the presence of increasing amounts of hydrochloric acid, decreases more rapidly than corresponds with the simple theory. The phenomenon is complicated by the chemical union of hydrochloric acid with some of the water, as is evidenced by the development of heat during the reaction. This increases the concentration of the sodium chloride solution by removing some of the effective solvent. The precipitation of sodium chloride by the addition of alcohol to a saturated solution of that salt is due to the union of the solvent with the alcohol, so that less solvent is available for the sodium chloride. The phenomenon is quite general; for example, potassium chloride in saturated solution is precipitated by hydrochloric acid, sodium chloride, or potassium sulphate; copper sulphate by copper nitrate, or sulphuric acid; barium chloride by hydrochloric acid, or sodium chloride; calcium sulphate, by sulphuric acid, potassium sulphate, or calcium nitrate. Again, nitric acid will precipitate barium nitrate from concentrated aqueous solutions; a nearly saturated solution of silver bromate will give a precipitate of silver bromate, if either silver nitrate or sodium bromate be added to the solution; sodium chlorate added to a saturated solution of potassium chlorate furnishes a precipitate of the last-named salt.

Solubility product.—It is sometimes convenient to discriminate between the total or **apparent solubility** of a salt, and the amount of the non-ionized salt present in the solution. The latter is sometimes called the **real or molecular solubility** of the salt. According to W. Nernst, if W. Ostwald's law applies to solutions, in a saturated solution the real solubility, like the apparent solubility, is regarded as constant. Hence, in the dilution law for sodium chloride: $[Na^{\cdot}][Cl'] \rightleftharpoons K[NaCl]$, indicated above, the concentration [NaCl] is invariable, K is constant, and consequently also the product of the two is constant. Therefore, for saturated solutions:

$$[Na^{\cdot}][Cl'] = \text{Constant}$$

This relation means that **in a saturated solution, the product of the "molecular" concentrations of the ions is constant.** This product is sometimes called the **solubility product** because, from what has been already stated, the product of the two ion concentrations determine the magnitude of the "real" solubility of the substance.

Rule for precipitation.—The solubility product of sodium chloride in solution is not very great, and, in consequence, if concentrated hydrochloric acid be added to a concentrated solution of sodium hydrogen sulphate, $NaHSO_4$, the solubility product of sodium chloride may be exceeded, and that salt will be precipitated. The condition of equilibrium of the mixed solutions is:

$$\begin{array}{rllll}
\mathrm{NaHSO_4} \rightleftharpoons & \left\{\begin{array}{l}\mathrm{Na^{\cdot}} \\ + \\ \mathrm{Cl'}\end{array}\right. & \begin{array}{c} + \\ \\ + \end{array} & \left\{\begin{array}{l}\mathrm{H^{\cdot}} + \mathrm{SO_4''} \\ + \\ \mathrm{H^{\cdot}}\end{array}\right. \\
\mathrm{HCl} \rightleftharpoons & & & \underbrace{\qquad\qquad} \\
 & \quad\upharpoonleft\!\downharpoonright & & \quad\upharpoonleft\!\downharpoonright \\

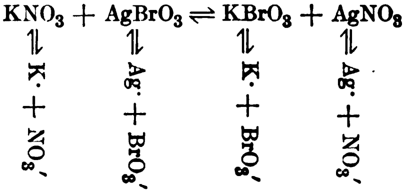
Hence, if the product of the "molecular" concentration of any pair of ions (with equal and opposite electrical charges) in a solution be greater than the solubility product for the saturated solution formed by the union of these ions, that substance will be precipitated; and conversely, if a substance be present in excess, it will be dissolved if the product of the "molecular" concentration of any pair of ions (with equal and opposite electrical charges) in a solution be *less* than the solubility product for the saturated solution formed by the union of these ions.

Apparent exceptions to the solubility law.—There are some apparent exceptions. The solubility of silver sulphate is increased, not diminished, by the addition of potassium or ammonium sulphate. Lead chloride is not precipitated from its saturated solution by lead nitrate, nor is barium chloride precipitated by barium nitrate. In both these cases a precipitate is produced by the addition of alkali chloride or hydrochloric acid. Calcium sulphate is not precipitated by sodium or ammonium sulphate, but it does separate on the addition of potassium sulphate or sulphuric acid; potassium sulphate is not precipitated from its saturated solution by sulphuric acid, but it does separate on the addition of potassium chloride or sodium sulphate. The explanation is that in each case double or complex salts are formed, which really *diminish* the number of lead or chloride ions in the case of lead chloride by forming a lead chloronitrate, $\mathrm{PbClNO_3}$. Similarly, in the other cases $\mathrm{BaClNO_3}$, $\mathrm{CaNa_2(SO_4)_2}$, $\mathrm{Ca(NH_4)_2(SO_4)_2}$, $\mathrm{KHSO_4}$, etc. In many cases the solubility of the double or complex salt so formed is less than the solubility of either constituent, and when such a solution is concentrated, the double compound separates in preference to the single components, *e.g.* potassium sulphate has a solubility of 12·5; aluminium sulphate, 8·5; and the double salt, $\mathrm{KAl(SO_4)_2.12H_2O}$, 9·5; potassium sulphate, 12·5; nickel sulphate, 6·7; and the double salt, $\mathrm{K_2Ni(SO_4)_2.6H_2O}$, 6·3; potassium carbonate, 110; sodium carbonate, 21; the double salt, $\mathrm{KNaCO_3.6H_2O}$, 13. With potassium and calcium sulphates the solubility of the latter (0·205) is less than the solubility of either potassium sulphate (12·5) or the double salt $\mathrm{CaK_2(SO_4)_2.H_2O}$—0·25. Calcium sulphate is accordingly precipitated in preference to the double salt.[1]

The solubility law developed by W. Nernst (1889) and A. A. Noyes (1890) [2] is based on assumptions which are not always valid. For example: (i) That the ionization conforms with W. Ostwald's law of mass action. As a matter of fact the ratio of the product of the concentrations of the positive and negative ions to the concentration of the un-ionized salt becomes greater as the concentration of the salt increases, otherwise expressed, the value of K in, say, $[\mathrm{M^{\cdot}}][\mathrm{Cl'}]=K[\mathrm{MCl}]$ increases with increasing concentration. (ii) It is assumed that the concentration of the un-ionized molecules of an electrolyte in solution and in equilibrium with its solid phase is always constant. S. Arrhenius, however, has shown that this is not in accord with fact, for the concentration of the un-ionized salt, *i.e.* the molecular solubility, diminishes as the total concentration of the salt in solution is increased. S. Arrhenius (1899) argued that the non-ionized part of a salt in a saturated solution is not a constant because the non-ionized part of thallous chloride, TlCl, in aqueous solution, as calculated from the electric conductivity, is 0·00179N, while if 0·8N-potassium chloride is present, the total solubility of thallous chloride is 0·00170N, or less than that of the non-ionized salt in aqueous solution—of this, 0·00170, perhaps 40 per cent., is ionized, leaving the non-ionized part of less concentration than in aqueous solute. (iii) It is assumed that the degree of ionization is independent of the presence of other electrolytes. S. Arrhenius, W. D. Harkins, M. S. Sherrill, have shown that this postulate is not in accord with fact. The solubility of calcium sulphate is increased up to a certain point by the addition of sodium chloride, and beyond that is diminished. A. E. Hill (1909) found that the solubility of silver sulphate in nitric acid behaves similarly. In both cases an increased solubility might have been anticipated owing to the formation of new compounds which would be opposed by a *small* decrease in the amount of un-ionized salt in solution, for with highly ionized salts like gypsum and silver sulphate in aqueous solution, the increased ionization is negligibly small. The diminution in the total solubility is therefore an effect of a diminution in the concentration of the ions of the solute, as distinct from chemical interaction, called by S. Arrhenius (1899) *the neutral salt effect*. According to this phenomenon, the presence of neutral salts increases the ionization of weak acids present with them in solution, either by the water acquiring a greater ionizing power, or the salt itself acting as a dissociating medium. The *Neutralsalzwirkung* has been studied by many workers. G. Poma and A. Patroni found that the ionization of cupric nitrate is augmented in aqueous solution by the presence of other nitrates—excepting those of potassium and rubidium. A. Sachanoff and P. J. Gontscharoff found the ionization of silver nitrate to be depressed by the addition of other salts—*vide* § 13. In general, observations indicate that the addition of sodium chloride to an acid solution results in an increase in hydrogen-ion concentration, whereas adding it to an alkaline solution causes an increase in concentration of the hydroxide ion.

The constancy of the solubility product is not maintained, for the work of F. K. Cameron and of A. E. Hill and J. P. Simmons has shown that the product of the concentration of the ions diminishes in value as the concentration of the electrolyte increases—*e.g.* the solubility of gypsum increases with the addition of sodium chloride up to a certain concentration beyond which it decreases; similarly, with silver sulphate and nitric acid; thallous chloride in acetic acid; with tetramethylammonium iodide in potassium hydroxide; etc. A continuous increase in solubility due to the formation of new compounds might have been anticipated; this will be opposed by a small decrease in the amount of an ionized salt as indicated by S. Arrhenius' experiments, but not sufficient to counterbalance the increase due to chemical action, since the quantity of un-ionized salt is negligibly small with such salts as silver sulphate and calcium sulphate. Hence, in order to explain the diminution in the solubility product it seems necessary to assume that the concentrations of the ions of the solute have been lessened. The solubility of mercuric chloride is increased by the addition of hydrochloric acid owing to formation of a combination of hydrochloric acid and mercuric chloride, which has a greater solubility than mercuric chloride alone. Again, a concentrated solution of cupric potassium sulphate, $K_2Cu(SO_4)_2.6H_2O$, can be separated into its components, potassium and cupric sulphates, by diffusion. A solution saturated with respect to both salts is possible in which the two salts are present in the ratio of their solubilities, but this condition is disturbed by the tendency of the more soluble salt to crystallize out. Either salt added in a soluble form will not drive the other out of its saturated solution, but there is a definite state of equilibrium when the solution is not changed by further additions. Equilibrium is the same whether one salt be added to a saturated solution of the other, or directly to the double salt. These facts strike at the foundations of the solubility product law, for the constancy of both relations was assumed in deducing that law. *The solubility product is not constant, but diminishes in value in the presence of other electrolytes.* With a decreasing value of [MR] and an increasing value for the whole proportion, it follows that the ion product $[M^\cdot]\times[R']$ might remain approximately constant if perchance the proportion grows larger to the same extent as the true solubility grows smaller. Hence, although the premises from which the solubility product law has been deduced are not the whole truth, yet it is conceivable that the law itself might be a sufficiently close approximation to be of practical assistance in the study of reactions involving precipitation, solution, etc. This alternative has been tested by J. Stieglitz (1908) with respect to the solubility of the silver salts of a number of organic acids. He finds that the solubility product must be treated as an "approximate empirical principle" without a theoretical foundation. This conclusion is confirmed by A. Findlay's experiments (1900) on the relative solubility of lead iodide and sulphate; G. Bodländer's work (1900) on the solubility of calcium carbonate in aqueous solutions of carbon dioxide; A. A. Noyes (1890–1903) on the solubility of lead iodide in solutions of potassium iodide, of lead chloride in solutions of potassium chloride, of calcium hydroxide in presence of ammonium chloride; etc.

Solubility of mixtures with no common ion.—If potassium nitrate be added to a saturated solution of silver bromate, a number of molecules of silver nitrate and potassium bromate will be formed by double decomposition, and the solution will be in equilibrium when these four salts have attained a definite concentration, and each salt is itself ionized and is in equilibrium with the corresponding ions. The condition of equilibrium is therefore complex. It may be symbolized:



$$\begin{array}{ccccccc} KNO_3 & + & AgBrO_3 & \rightleftharpoons & KBrO_3 & + & AgNO_3 \\ \upharpoonleft\!\downharpoonright & & \upharpoonleft\!\downharpoonright & & \upharpoonleft\!\downharpoonright & & \upharpoonleft\!\downharpoonright \\ K^{\cdot}+NO_3' & & Ag^{\cdot}+BrO_3' & & K^{\cdot}+BrO_3' & & Ag^{\cdot}+NO_3' \end{array}$$

The net result is that the number of ionized and non-ionized molecules of silver bromate in the solution is lessened, and the equilibrium:

$$AgBrO_{3\,\text{solid}} \rightleftharpoons AgBrO_{3\,\text{solution}}$$

is disturbed. The original relation is restored by the passage of more silver bromate into solution. Similarly, when nitric acid is added to a saturated solution of silver acetate, some silver nitrate is formed, and the equilibrium:

$$\text{Silver acetate}_{\text{solid}} \rightleftharpoons \text{Silver acetate}_{\text{solution}}$$

can only regain its former value by the passage of more silver acetate into solution. Consequently, **the solubility of a salt may be increased in the presence of a compound containing no common ion.** There are a number of complications in special cases owing to the dehydration of the solution by the added substance; the solute may form polymerized molecules in the presence of the solvent; etc. The dehydrating action is illustrated in the familiar method of preparing hydrogen chloride by dropping concentrated sulphuric acid into a concentrated hydrochloric acid. The sulphuric acid abstracts water, and thus diminishes the effective amount of the solvent, the hydrogen chloride is then evolved as a gas. The action is in part attributed to the repression of the ions of hydrogen chloride at the same time, and the consequent elimination of molecules from the water already saturated with molecules of the same kind. Similarly, an excess of sulphuric acid precipitates the di- or monohydrate of cadmium chloride almost completely; the particular hydrate formed depends on the amount of sulphuric acid added. Cadmium bromide, mercuric chloride or bromide, and copper and stannous chlorides or bromides behave similarly. The behaviour of many salts is thus not completely described by the solubility product law.

§ 13. Acids and Bases according to the Ionic Hypothesis

> The ionization hypothesis enables us to place the whole subject of acidity upon a rational basis. Without this theory, the subject would still be only so many empirically established, disconnected, and meaningless facts.—H. C. JONES (1913).

Acids.—It will be remembered that C. Gerhardt defined acids to be "salts of hydrogen," the ionic hypothesis expresses a similar idea another way: "all acids, when dissolved in water, furnish hydrogen ions." Although many substances not usually called acids when completely ionized furnish hydrogen ions—*e.g.* potassium hydrogen sulphate, $KHSO_4$, etc.—yet their acidic properties are due to the presence of $H^{\cdot}$-ions, and consequently it has been said that "there is only one acid, and that is the $H^{\cdot}$-ion," and that "the two terms acidity and hydrogen ions are co-extensive."[1] Hydrogen ions thus become the primordial acid of the older chemists. The general and characteristic properties of acids are assumed to be the general and characteristic properties of $H^{\cdot}$-ions, and thus the $H^{\cdot}$-ions are said to have a sour taste, redden blue litmus, conduct electricity in solutions containing them, behave as univalent radicles, etc. The basicity of an acid is fixed by the number of $H^{\cdot}$-ions furnished by the complete ionization of one molecule of the acid. Thus monobasic hydrochloric acid, HCl, furnishes one $H^{\cdot}$-ion, $HCl \rightleftharpoons H^{\cdot} + Cl'$; and dibasic sulphuric acid furnishes two $H^{\cdot}$-ions, $H_2SO_4 \rightleftharpoons 2H^{\cdot} + SO_4''$. Sulphuric acid also furnishes the ions $H^{\cdot}$ and HSO_4', so that it behaves also as a monobasic acid when it forms the so-called "acid sulphates."

Why is the hydrogen ion acidic?—The action of a metal, say zinc, on an acid is usually represented by the equation: $Zn + 2HCl = ZnCl_2 + H_2$; the ionic hypothesis assumes that $Zn + 2H^{\cdot} + 2Cl' \rightleftharpoons Zn^{\cdot\cdot} + 2Cl' + H_2$; and that the different atoms have different affinities—**electro-affinities**—for the electric charges as assumed by H. von Helmholtz in 1881. Since the Cl'-ions are but little affected by the change, the last equation reduces to $Zn + 2H^{\cdot} = Zn^{\cdot\cdot} + H_2$. The action is thus independent of the negative ion, for it involves little more than a transfer of the positive electric charges from the two hydrogen ions to the zinc, and generally, such typical chemical reactions can be represented as the transfer of electrical charges from hydrogen to the metal. When the solution of zinc chloride is concentrated by evaporation the ionizing solvent is removed from the system and the $Zn^{\cdot\cdot}$- and $2Cl'$-ions recombine to form zinc chloride. **The hydrogen ion is an acid because it holds its charge less tenaciously than the metals hold their charges.** If it were otherwise, says H. C. Jones, if hydrogen held its charge as firmly as the average metal, the acids would not be acids.

Why is hydrogen acidic in some compounds and not in others?—The answer furnished by the ionic hypothesis is that hydrogen separates from the former compounds as ions, but not from the latter. Hydrogen chloride in aqueous solution is an acid because it furnishes $H^{\cdot}$-ions, but it is not an acid when dissolved in dry benzene or dry chloroform because it does not then furnish $H^{\cdot}$-ions. Hence, says

H. C. Jones, **an acid is a compound which yields hydrogen ions when dissolved in an ionizing solvent.** Dry benzene and dry chloroform are not ionizing solvents. A compound becomes an acid only when it is ionized into hydrogen ions, etc. Many substances contain hydrogen, and they are not regarded as salts of hydrogen. Methane, CH_4; ammonia, NH_3; alcohol, C_2H_5OH, etc. Again, H_3PO_2 only gives one hydrogen ion per molecule, and the remaining two hydrogen atoms are not ionizable, for they form an essential part of the cation H_2PO_2'. Silicic acid is very slightly soluble in water, so that its aqueous solution has no effect on blue litmus. Silicic acid is acid because it forms a salt, sodium silicate, Na_2SiO_3, which dissolves in water and ionizes: $Na_2SiO_3 \rightleftharpoons 2Na^{\cdot} + SiO_3''$, when electrolyzed. Neither pure dry hydrogen chloride nor pure dry sulphuric acid is acidic; neither compound is ionized; nor acts on metals; nor decomposes carbonates; nor colours blue litmus.

The chemical activity of different solutions containing equivalent amounts of the different acids is referred to the concentration of the $H^{\cdot}$-ions in the solution.—The concentration of the $H^{\cdot}$-ions depends upon the degree of ionization of the different acids. Hence, the relative strengths of the acids can presumably be expressed in terms of the electrical conductivity of equivalent solutions. The speed of a reaction dependent upon an acid is thus connected with the concentration of the $H^{\cdot}$-ions. Reverting to the measurements given previously for hydrochloric, sulphuric, and acetic acids, although the solutions contained equivalent quantities of replaceable hydrogen per litre, acetic acid has but one two-hundredth the activity of hydrochloric acid.

	Hydrochloric acid.	Sulphuric acid.	Acetic acid.
Fraction ionized . .	0·78	0·51	0·004
Relative strength . .	100	70	0·5

In hydrochloric acid, a greater number of hydrogen ions are ready to react with the metal than with acetic acid, and consequently the available hydrogen in hydrochloric acid is more rapidly exhausted than with acetic acid where but few ions are in a condition to react with the metal at any moment, and consequently the reaction progresses slowly for a long time; as fast as the available ions are exhausted, new ions are formed by the ionization of the molecule of acetic acid. The total number of hydrogen ions is the same in both cases, but the number in a condition to react with the metal at any moment is very different in all three cases.

Bases.—Just as an acid has been defined to be a substance which can furnish hydrogen ions when dissolved in water, so bases, according to the ionic hypothesis, are substances which yield HO'-ions when dissolved in water. The basic properties of bases are due to the OH'-ions, and in this sense it has been said that "there is only one base, and that is the OH-ion," and that "the two terms hydroxyl ions and base are co-extensive." The general and characteristic properties of the bases are supposed to be the general and characteristic properties of the OH'-ions. Thus the OH'-ions are said to have a soapy feel, turn red litmus blue, conduct electricity in a solution containing them, etc. The acidity of a base is fixed by the number of OH'-ions it furnishes on complete ionization of a molecule of the base. Thus, the monoacid bases, like sodium hydroxide, ionize: $NaO \rightleftharpoons Na^{\cdot} + OH'$; and the diacid bases, like barium hydroxide, ionize: $Ba(OH)_2 = Ba^{\cdot\cdot} + 2OH'$. In a non-ionizing solvent, the bases do not furnish hydroxyl ions, and they do not then behave like bases. Hence, says H. C. Jones, **a base is a compound which furnishes hydroxyl ions when dissolved in an ionizing solvent.** A compound becomes a base only when it is ionized into hydroxyl ions.

The strength of a solution containing equivalent quantities of the different bases is referred to the concentration of the OH'-ions in the solution.—The strength of a base depends upon the degree of ionization, or on the concentration of the OH'-ions. The strength of a base can thus be determined from the electrical conductivity. In equivalent solutions, bases, like acids, differ very much in strength. The alkalies and alkaline hydroxides are very strong bases, for they are ionized to very nearly the same extent as hydrochloric acid in aqueous solution. Ammonia is a comparatively feeble base. The following numbers represent the relative strengths of a few bases in $\frac{1}{40}N$-solution on the assumption that the strength of the base is proportional to the electrical conductivity:

	LiOH	NaOH	KOH	NH_4OH
Relative strength . . .	100	98	98	2

Reactions between acids and salts.—When a highly dissociated acid is mixed with a salt, the two react, forming another acid and salt. The change is reversible, and the reacting system is then a further illustration of the principle of opposing reactions. For instance, the action of dilute nitric acid on potassium hypochlorite, $HNO_3+KOCl \rightleftharpoons KNO_3+HOCl$. If both products are highly ionized, there will be no perceptible change in the system, but in the illustration just cited, hypochlorous acid is but feebly ionized, and, since the $H^{\cdot}$-ions of the nitric acid, and the OCl'-ions of the potassium hypochlorite, react to form feebly ionized hypochlorous acid, the result of the reaction in dilute solutions is ionized potassium nitrate, and feebly ionized hypochlorous acid:

$$\underbrace{H^{\cdot}+NO_3'}+\underbrace{K^{\cdot}+OCl'} \rightleftharpoons \underbrace{K^{\cdot}+NO_3'}+HOCl$$

Reactions between bases and salts.—Similar remarks apply, *mutatis mutandis*, to the action of a salt on a base, and this explains how feebly ionized ammonium hydroxide is formed in relatively large quantities when highly ionized solutions of potassium hydroxide and ammonium nitrate are mixed together. The reaction proceeds almost to the end:

$$\underbrace{NH_4^{\cdot}+NO_3'}+\underbrace{K^{\cdot}+OH'} \rightleftharpoons \underbrace{K^{\cdot}+NO_3'}+NH_4OH$$

When the base is insoluble, it will be precipitated, and the reaction will proceed to an end quite apart from the degree of ionization of the reacting compounds. This is the case, for example, with ferric, aluminium, zinc, and other hydroxides:

$$\underbrace{Fe^{\cdots}+3Cl'}+\underbrace{3Na^{\cdot}+3OH'} \rightleftharpoons \underbrace{3Na^{\cdot}+3Cl'}+Fe(OH)_3$$

The determination of the basicity of acids.—W. Ostwald (1887)[2] and P. Walden (1887) noticed empirically that if n_a denotes the valency of the anion, and n_c the valency of the cation, the difference D between the equivalent conductivity of the corresponding electrolyte dilutions $v=1024$ and $v=32$ is $D=Kn_an_c$, where K is a constant which is a function of the concentration of the solution, and for the $v=1024$ and $v=32$ is nearly 10. If the sodium salts be employed, $n_c=1$; and at 25°, the basicity of the acid is approximately $\frac{1}{10}D$. For monobasic acids D is nearly 10; for dibasic acids, 20; for tribasic acids, 30; etc.; otherwise expressed, **the equivalent conductivity of aqueous solutions of the sodium salts of *n* basic acids increases by about $n \times 10$ units on diluting a solution from $\frac{1}{32}N$ to $\frac{1}{1024}N$.** This empirical relation is sometimes called **Ostwald and Walden's rule.**

The unit of conductivity is now rather smaller than that used in 1887. The constant is now more nearly 10·8 than 10, so that the empirical rule is more nearly exact if the basicity of the acid be taken as one-eleventh of the difference, D, between the equivalent conductivities of the sodium salt at dilutions $v=32$ and $v=1024$. The amended rule then reads:

$$\text{Basicity of acid} = \tfrac{1}{11}D$$

Numerous tests of the rule have been made with organic acids. Table IV shows some results with inorganic acids.

EXAMPLES.—(1) G. von Knorre (1900) showed that the equivalent conductivity of the so-called sodium trimetaphosphate with a composition corresponding with $Na_3(PO_3)_3.6H_2O$ at dilutions $v=32$, and $v=1024$, is respectively 89·5 and 122·4. Hence show that these numbers are in agreement with the inference "Nach der Ostwald-Walden'schen Regel ist demnach die Trimetaphosphorsäure als dreibasische Säure zu betrachten." Here $\frac{1}{10}(\lambda 1024-\lambda 32)=\frac{1}{11}(122{\cdot}4-89{\cdot}5)=3{\cdot}3$ nearly; and the acid is accordingly tribasic.

(2) R. Kremann and W. Decolle (1907) found that the conductivity of sodium fluoride increases on dilution from $v=32$ to $v=1024$ by 20·8 units. Explain how it might be inferred that " hydrofluoric acid is dibasic."

TABLE IV.—THE EQUIVALENT CONDUCTIVITIES OF SOME SODIUM SALTS.

Sodium salt.	Equivalent conductivities.		Differences.	$\frac{D}{11}$	Basicity of acid.
	$v=32$	$v=1024$			
Chloride, $NaCl$	113·6	126·3	12·7	1·1	1
Chlorate, $NaClO_3$	101·3	112·3	11·0	1·0	1
Perchlorate, $NaClO_4$	112·9	121·2	12·3	1·1	1
Nitrate, $NaNO_3$	108·2	120·1	11·9	1·1	1
Sulphite, $NaSO_3$	94·5	114·6	20·1	1·8	2
Tungstate, Na_2WO_4	95·9	116·4	20·5	1·8	2
Cyanoplatinate, Na_2PtCy_6	110·6	130·4	19·8	1·8	2
Orthophosphate, Na_3PO_4	97·5	114·2	26·7	2·4	3
Orthoarsenate, Na_3AsO_4	101·2	127·6	26·6	2·4	3
Trimetaphosphate, $Na_3(PO_3)$	89·4	119·4	30·0	2·8	3
Fleitmann's metaphosphate, $Na_4P_4O_{12}.4H_2O$	85·6	126·2	40·6	4·1	4

At extreme dilutions, more particularly with inorganic salts, secondary reactions—*e.g.* hydrolysis—may interfere with the conductivity determinations; in other cases, the dilution $v=1024$ does not appear great enough to ionize all the salt. There are accordingly some difficulties, but, in a great many cases, the method furnishes circumstantial evidence of the basicity of the acid in question.

§ 14. The Strengths of Acids and of Bases

I have no doubt that fixed salts choose one acid rather than another in order that they may coalesce with it in more intimate union.—JOHN MAYOW (1674).

I maintain that when several acids act upon one metallic base, the action of one acid does not overpower that of the others so as to form an insulated combination, but each of the acids has a share in the action proportionate to its capacity for saturation and to its quantity.—C. L. BERTHOLLET (1803).

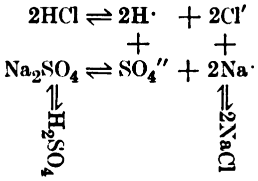
The **strength** of an acid or base refers to the extent to which the acid or base exhibits acidic or basic properties respectively. The terms *affinity*, *avidity*, and *activity* are sometimes employed synonymously with "strength," but there are objections to each of these. The term strength, too, is often used where concentration is really meant. **Concentration** refers to the "quantity in unit volume" expressed in, say, "grams per litre;" or in any other convenient form—say the number of gram-molecules per litre, etc.

The action of sulphuric acid on sodium chloride which results in the formation of hydrochloric acid, seems to prove that sulphuric acid is stronger than hydrochloric acid; again, when hydrochloric acid is added to a solution of silver sulphate, silver chloride is precipitated. The hydrochloric acid expels the sulphuric acid from its combination with silver: $Ag_2SO_4+2HCl=2AgCl+H_2SO_4$, and it seems as if hydrochloric acid is stronger than sulphuric acid. These two conclusions are contradictory, and there must therefore be a fallacy in our reasoning. We have wrongly assumed that the two acids were competing for sodium and for silver under similar conditions. This is not the case. When hydrochloric and sulphuric acids compete for the sodium, the hydrochloric acid, being volatile, escapes from the system as fast as it is formed; while the non-volatile sulphuric acid alone remains behind. Again, when sulphuric and hydrochloric acids are competing for silver, the hydrochloric acid carries the silver away from the sulphuric acid as an insoluble precipitate of silver chloride. Still further, hydrosulphuric acid is notoriously a very feeble acid, and yet it can displace relatively strong acids from combinations with the metals. Thus, it will precipitate lead sulphide from solutions of lead chloride; copper sulphide from solutions of copper sulphate, etc. Here, again, the feeble acid does its work by removing the metal from the solution as an insoluble sulphide.

To compare the relative strengths of the acids, and, *mutatis mutandis*, of the bases, it is necessary that the comparison be made under conditions where the reacting acids and the products of the reaction are in the same physical condition—say, all in solution. Thus, if an equivalent of a solution of sodium hydroxide be mixed with an equivalent of a solution of sulphuric and of hydrochloric acids, the two acids can compete for the one base under the same conditions, and hence the stronger acid will be able to unite with more sodium than the weaker acid. In 1803, C. L. Berthollet pointed out that:

> When a neutral salt is dissolved and an acid added to the solution, the free acid enters into competition with the combined acid, and they both act on the alkali base in the ratio of their respective concentrations as though no combination had existed. It cannot therefore be said that if all the conditions remain equal one acid displaces another from the base with which it has been united, but the base is shared between the two acids in the ratio of the concentrations and affinities of the respective acids.

It is found experimentally that the same result is obtained when equivalent quantities of sodium hydroxide, sulphuric acid, and hydrochloric acid are mixed together as when equivalent quantities of sodium sulphate and hydrochloric acid, or equivalent quantities of sodium chloride and sulphuric acid are mixed, provided, of course, the whole of the system has been allowed to stand long enough for equilibrium. This fact is represented by the equation: $2HCl + Na_2SO_4 \rightleftharpoons 2NaCl + H_2SO_4$, which, when translated into the language of ions, reads:



$$\begin{array}{ccccc} 2HCl & \rightleftharpoons & 2H^{\cdot} & + & 2Cl' \\ & & + & & + \\ Na_2SO_4 & \rightleftharpoons & SO_4'' & + & 2Na^{\cdot} \\ \downarrow\uparrow & & & & \downarrow\uparrow \\ H_2SO_4 & & & & 2NaCl \end{array}$$

The measurement of the relative strengths of acids and bases.—The proportions of a base shared between two acids, or of an acid between two bases, cannot be determined by the ordinary methods of chemical analysis without disturbing the equilibrium of the mixture. The distribution of an acid between two bases, or of a base between two acids, must be determined by physical processes which do not interfere with the solution.

In illustration, the heat of neutralization of sodium hydroxide by sulphuric acid is 31·38 Cals.; and by hydrochloric acid, 27·48 Cals. If, therefore, on mixing hydrochloric acid with sodium sulphate, all the sulphuric acid were displaced by the hydrochloric acid, the thermal effect resulting from the decomposition of the sodium sulphate, and the formation of the sodium chloride would be 27·48—31·38 = −3·9 Cals. After making a small allowance for secondary reactions between sodium sulphate and sulphuric acid, J. Thomsen found that the thermal value of the reaction was −2·6 Cals. Hence it follows that −2·6÷−3·9, or about two-thirds of the hydrochloric acid combines with about two-thirds of the base to form sodium chloride; and about one-third of the sulphuric acid combines with the other third of the base to form sodium sulphate.

A similar result was obtained with a mixture of sodium chloride and sulphuric acid, as with sodium sulphate and hydrochloric acid. Consequently, in the competition of sulphuric and hydrochloric acids for sodium under comparable conditions, the hydrochloric acid can hold twice as much of the base as the sulphuric acid, and consequently, hydrochloric acid is nearly twice as strong as sulphuric acid. Similar results have been obtained by measuring the specific gravity, index of refraction, absorption of light, etc. Some results obtained by three different methods are shown in Table V.

TABLE V.—RELATIVE STRENGTHS OF ACIDS.

Acid.	Thomsen's thermal process.	Ostwald's specific gravity process.	Molecular conductivity.
Hydrochloric acid	100	98	100·0
Nitric acid	100	100·00	99·6
Hydrobromic acid	89	95·00	100·0
Sulphuric acid	49	66·7	65·1
Phosphoric acid	25	—	7·3
Acetic acid	3	1·23	0·4

The relative strengths of the different acids and bases have also been determined by measuring the effects of the different acids on the speed of different reactions—*e.g.* the hydrolysis of acetamide, cane sugar, methyl acetate, etc. The actual numbers obtained by the different methods are not always quite the same, possibly because of the different conditions under which the experiments are made. If two acids are under the same physical conditions and differently influence the speed of a given reaction, the acid which induces the greater velocity is assumed to exert the greater chemical force. It has been found that in many cases the effects produced by one acid of different concentrations is roughly proportional to the electrical conductivity of its solution, which in turn is proportional to the concentration of the hydrogen ions. A. A. Noyes and A. A. Blanchard illustrate this by the following experiment:

> Mix 40 c.c. of 0·5*N*-KI, 40 c.c. of 0·5*N*-$KBrO_3$, 40 c.c. of starch solution, and make the whole up to two litres. Put 400 c.c. of this solution in each of four bottles and introduce 10 c.c. of each of the ½*N*-acids—hydrochloric, sulphuric, chloroacetic, and acetic acids—into each of the four cylinders, as quickly as possible. The bottles are immediately stoppered and shaken. The solution containing the hydrochloric acid turns deep blue almost immediately; the sulphuric acid in about half a minute; the chloroacetic acid in three or four minutes; and the acetic acid in three or four hours.

Again, the addition of an excess of foreign acid to the reaction between potassium chlorate, potassium iodide, and hydrochloric acid: $KClO_3+6HCl+6KI=7KCl+3H_2O+3I_2$, or to a mixture of bromic acid and hydriodic acid accelerates the change. The effect with different acids varies with their strength (affinity): HBr, HCl, HNO_3, H_2SO_4. This order is virtually the order as deduced from measurements of the degree of ionization of the different acids, and accordingly the catalytic effect is said to be due to the presence of hydrogen ions. Organic and other feebly ionized acids exert very little catalytic action. It was therefore postulated by W. Ostwald that the hydrolytic activity of acids is proportional to the degree of the assumed ionization.

S. Arrhenius found that the hydrolytic activity of strong acids is augmented by the addition of a neutral salt of the acid. Thus, the rate of hydrolysis of cane sugar by an aqueous solution of hydrogen chloride is considerably increased by the addition of sodium chloride or calcium chloride, although these substances decrease the degree of ionization of the acid. The effect was styled **neutral salt action** by S. Arrhenius. If the action of the acid is due to hydrogen cations, the presence of a neutral salt having the same anion should diminish the dissociation of the acid and consequently its activity, but this is not the case. Actual experiment yields results which are just the reverse of that which the theory of ions would indicate. J. W. McBain and co-workers have shown that the alleged effect can be accounted for on the assumption that the un-ionized salt is catalytically active without assuming that the solvent acquires a greater ionizing power, or that the salt acts as an ionizing medium.

Again, the molecular hydrolytic activity of strong acids is decreased by increasing dilution, whereas, if the activity were proportional to the degree of ionization, the reverse should obtain. Hence, G. Senter, H. C. S. Snethlage, S. F. Acree, etc.,[1] conclude that an electrolyte in solution may enter into chemical reactions not only by means of its ions, but also by means of its un-ionized molecules—otherwise expressed, the catalytic activity of acids is the joint effect of the hydrogen ions and of the un-ionized molecules. F. P. Worley has emphasized that instead of the rate of hydrolysis of ethereal salts and cane sugar being proportional to the concentration of the hydrogen ions, the two properties are altered in different directions by changes of concentration. For example, if n denotes the molecular proportions $H_2O : HCl$, H, the molecular hydrolytic activity, and a, the degree of ionization of hydrochloric acid,

n	30	40	50	60	80	100	200
H	385	323	290	269	243	229	201
a	0·725	0·778	0·813	0·837	0·859	0·871	0·901

Consequently, the catalytic activity of the acids is not proportional to the concentration of the hydrogen ions; and, adds F. P. Worley, "if hydrogen ions and un-ionized molecules are both chemically active, . . . in time, the extreme supporters of the ionic hypothesis may admit that both ions and un-ionized molecules may be concerned in electrolytic conductivity!"

§ 15. The Neutralization of Acids and Bases

> The importance for chemistry of the fact that hydrogen and hydroxyl ions cannot remain in the presence of one another uncombined is difficult to over-estimate. Could these ions remain separate, then an acid would not neutralize a base, and all salt formation from the process of the neutralization of acids and bases would be excluded.—H. C. JONES (1913).

The term *neutral* has been used somewhat vaguely, implying that the substance is neither acidic nor basic. The test for acidity or basicity depended upon the behaviour of the solution towards a solution of litmus. If other indicators are used, the conclusions might be different, because a substance might appear acidic towards one indicator, and neutral towards another. The ionic hypothesis, as we have seen, refers acidity to the presence of hydrogen ions, and alkalinity to the presence of OH′-ions, and the term " neutrality " refers to the case where the concentration of both ions are the same, or both ions are absent. We have seen that water is a constant product of the reaction between the solution of an acid and of a base: $HCl+KOH \rightleftharpoons KCl+H_2O$; $H_2SO_4+2NaOH \rightleftharpoons Na_2SO_4+2H_2O$, etc. When solutions of an acid and base are mixed, the hydrogen and hydroxyl ions of acid and base respectively combine to form water, because water only ionizes to an inconceivably small extent, and the two kinds of ions—$H^{\cdot}$ and OH'—cannot remain in the presence of one another uncombined. Hence when aqueous solutions of acids and bases are mixed together, OH'- and the $H^{\cdot}$-ions are removed from the solution, and the reaction is almost completed:

$$\underbrace{H^{\cdot}+Cl'}+\underbrace{K^{\cdot}+OH'} \rightleftharpoons \underbrace{K^{\cdot}+Cl'}+H_2O$$

What is here stated with respect to hydrochloric acid and potassium hydroxide applies, *mutatis mutandis*, to any strongly ionized acid and base; and consequently, the neutralization of strongly ionized acids and bases involves little more than the formation of water: $H^{\cdot}+OH' \rightleftharpoons H_2O$, because the other ions present before the acids and bases are mixed remain after the reaction is over. If, however, the water be evaporated from the solution, the ions recombine to form the salt, and the result of the reaction is then correctly symbolized: $HCl+KOH \rightleftharpoons KCl+H_2O$. This reaction probably also occurs if very concentrated solutions or solids are mixed, whereas the **neutralization of acids and bases in dilute solutions involves the formation of water, not salt molecules.**

The heat of neutralization of dilute solutions.—This view is further supported by the fact that with dilute solutions of the strong acids and bases, the thermal value of the process of neutralization—heat of neutralization—is the same. For example,

	$LiOH$	$NaOH$	KOH	$Ca(OH)_2$	$Ba(OH)_2$
Hydrochloric acid . . .	13·7	13·7	13·7	13·8	13·8 Cals.
	HCl	HBr	HI	HNO_3	HIO_3
Sodium hydroxide . . .	13·7	13·8	13·7	13·7 .	13·5 Cals.

Hence, neutralization is an isothermal process; the heats of neutralization of dilute solutions of the strong acids and bases do not depend upon the specific nature of the acid or base; and the formation of water in these reactions is accompanied by the evolution of approximately 13·7 Cals. of heat.

The law only describes the thermal effect attending the neutralization of solutions sufficiently diluted to ensure complete ionization of acid, base, and salt; it presupposes that no new electrically neutral molecules are formed. As a corollary, it follows that if two completely ionized salts are mixed, there will be no thermal change provided the salts are completely ionized before and after the mixing, and no other electrically neutral molecules are formed. The fact that **if two neutral salt solutions at the same temperature are mixed together, no change of temperature occurs,** was discovered by H. Hess in 1841, and is called **Hess' law of thermoneutrality.** For example:

BEFORE MIXING.		AFTER MIXING.	
Calcium nitrate, $Ca(NO_3)_2$ . .	451	Calcium sulphate, $CaSO_4.2H_2O$.	642
Potassium sulphate, K_2SO_4 . .	601	Potassium nitrate, KNO_3 . .	409
Thermal value . .	1052	Thermal value . .	1051

The ionic hypothesis indicates clearly the conditions which must be fulfilled before Hess' law of thermoneutrality is applicable, and it would be difficult to find such a strikingly successful explanation by any other known hypothesis.

Heat of ionization.—If the acid and base are but partially ionized, the heat of neutralization is not only determined by the heat of formation of water—13·7 Cals.—but it is also determined by the thermal value of the energy required to complete the ionization of acid and base. When a dilute solution of hydrofluoric acid is neutralized by sodium hydroxide, for example, the sodium fluoride formed during the reaction is fully ionized, whereas the hydrofluoric acid at the commencement of the process: $HF+NaOH=NaF+H_2O+16{\cdot}27$ Cals. is not fully ionized. Hence in addition to the formation of water, there is a continuous ionization of hydrofluoric acid *during* the process of neutralization, and the fact that more heat is produced has been assumed to prove that the ionization of the acid is accompanied by the evolution of heat. The heat of neutralization of hypochlorous acid, HOCl, by sodium hydroxide, NaOH, is: $HOCl+NaOH=NaOCl+H_2O+9{\cdot}8$ Cals., a number less than the normal value 13·7 Cals. The salt, NaOCl, and the base, NaOH, are completely ionized; while the acid, HOCl, is but feebly ionized. Hence, it is assumed that the ionization of HOCl is an endothermal process. Similarly, when ammonia is neutralized: $NH_4OH+HCl=NH_4Cl+H_2O+12{\cdot}1$ Cals., it is assumed that the low results are due to the absorption of heat during the ionization of ammonium hydroxide. S. Arrhenius gives the following Table VI, in his *Recherches sur la conductibilité galvanique des électrolytes* (Stockholm, 1883):

TABLE VI.—HEATS OF NEUTRALIZATION OF ACIDS AND BASES.

	HCl	HNO_3	CH_3COOH	HCOOH	$\frac{1}{2}(COOH)_2$	$\frac{1}{2}H_2SO_4$	$\frac{1}{2}H_2S$	HCy	$\frac{1}{2}H_2CO_3$
NaOH .	13·7	13·7	13·3	13·4	14·3	15·85	3·85	2·9	10·2
KOH .	13·7	12·8	13·3	13·4	14·3	15·7	3·85	3·0	10·1
NH_4OH.	12·45	12·5	12·0	11·9	12·7	14·5	3·1	1·3	5·3
$\frac{1}{2}Ca(OH)_2$	14·0	13·9	13·4	13·5	18·5	15·6	3·9	—	9·8
$\frac{1}{2}Ba(OH)_2$	13·85	13·9	13·4	13·5	16·7	18·4	—	—	11·1
$\frac{1}{2}Sr(OH)_2$	14·1	13·9	13·3	13·5	17·6	15·4	—	—	10·5

Hess' law of thermoneutrality without the ionic hypothesis.—It would not be fair to pass by this explanation without indicating how H. Crompton (1897) showed that the phenomena could have been deduced without the aid of the ionization hypothesis. It follows from the calorimetric observations of J. Thomsen and of F. Stohmann and his co-workers[1] that for non-associated organic compounds—presumably non-ionized—the replacement of hydrogen, in a compound RH, by one and the same radicle M is attended by a constant heat change which is independent of the radicle R to which the hydrogen is attached; and generally, in non-associated organic compounds if M is constant, the thermal change in the reaction $RH+M=RM+H$ is constant and independent of R; and similarly, in the reaction $ROH+M=RM+OH$, the heat change will remain constant so long as M is constant.

In the neutralization of an acid by a base, in dilute solution, where the solutes may be assumed monomolecular, the changes which occur involve the splitting of the acid $HR=H+R+Q_1$ and of the base $MOH=M+OH+Q_2$, and the combination $M+R=MR+Q_3$, and of $H+OH=H_2O+Q_4$. First, if the base be constant and the acid varied, the terms Q_2 and Q_4 will be constant. The changes $HR=H+R+Q_1$ and $M+R=MR+Q_3$ are analogous with the changes which occur in the replacement of H by M in the non-associated organic compound RH. Hence, unless inorganic compounds behave quite differently from organic compounds, the heat of neutralization of an equivalent of any non-associated acid HR by an equivalent of one and the same non-associated base MOH, is always the same, and independent of the character of the acid. H. Crompton applies a similar argument to show that the heat of neutralization of an equivalent of any non-associated base MOH by the equivalent of one and the same acid HR is always the same and independent of the character of the base. These two conclusions are then generalized: The heat of neutralization of any acid by any base is independent of the character of the acid or base, so long as these are non-associated. H. Crompton further showed that in dilute solutions, the solute assumes a non-associated state.

The heat of neutralization of an acid by a base involves the heat of replacement $MOH+H=H_2O+M$, and the heat of replacement $HR+M=MR+H$, it therefore follows that since OH is a negative radicle like R, changing the radicle does not affect the heat of replacement of H by M or of M by H. Hence the heat of the first process should exactly balance that of the second, and an acid should be neutralized by a base without any thermal change whatever. With organic compounds the heat of formation of an ethereal salt from an acid and alcohol is usually very small—sometimes positive, sometimes negative, but the results are complicated by association phenomena and the heats of association are an integral part of the thermal values of the reactions. Again, with dilute solutions of acids and bases, the acid, base, and salt are in a very attenuated condition more or less comparable with the gaseous state; but the molecules of water produced in the reaction $MOH+HR=MR+H_2O$ will immediately pass to the liquid state characteristic of the solvent. The observed heat of the reaction is therefore mainly that caused by the condensation of the molecule of water from the gaseous to the liquid state and their subsequent polymerization or association. The molecular heat of condensation of water vapour is nearly 10·8 Cals. at 0°, and this is the same order of magnitude as the 13·4 Cals. observed by J. Thomsen for the heat of neutralization in dilute solutions. J. Thomsen also found that the heat of neutralization decreases with a rise of temperature in a way comparable with the effect of a rise of temperature on the heat of vaporization. These comparisons are closer than might have been anticipated. Hence, argues H. Crompton, the assumption that salts are ionized in aqueous solution is unnecessary to explain Hess' law of thermoneutrality; and "it is not only unnecessary, but it is inadequate, for it does not bring the behaviour of electrolytes, as far as the heat changes which accompany the formation of salts in aqueous solution are concerned, into line with the behaviour of non-electrolytes."

Hydrolysis.—It will be remembered that in hydrolysis, a salt reacts with water to form the free base and free acid, or free acid and a basic salt. **Hydrolysis is thus a reversion of the process of neutralization.** Reactions like those previously discussed are probably slightly reversible, but, in addition to those examples, there are many others where the back reaction is more pronounced. Hydrocyanic acid, HCy, for instance, ionizes: $HCy \rightleftharpoons H^{\cdot}+Cy'$. With potassium cyanide, KCy, in aqueous solution, $KCy \rightleftharpoons K^{\cdot}+Cy'$. In the latter case, some of the $H^{\cdot}$-ions of the water unite with the Cy'-ions of the salt to form molecules of hydrocyanic acid, HCy. The equilibrium is disturbed, and more molecules of water ionize: $H_2O \rightleftharpoons H^{\cdot}+OH'$. The new $H^{\cdot}$-ions combine with more Cy'-ions and the process continues until the concentration of the OH'-ions becomes large enough to prevent the further ionization of the water. The solution then contains an excess of OH'-ions, and free hydrocyanic acid, as well as potassium cyanide, and K'-and Cy'-ions. The free hydrocyanic acid can be recognized by its smell; and the OH'-ions can be recognized by the alkalinity of the solution.

The ionic hypothesis in analytical chemistry.—The language of the ionic hypothesis has penetrated analytical chemistry—more particularly the qualitative analysis taught in our schools—and as a result, tests for metals and acid radicles are described as tests for the ions. Many, however, doubt if anything is really gained by describing the facts of an essentially practical art in the language of so hypothetical a doctrine. Be that as it may, since both chlorides and hydrochloric acid are supposed to furnish chlorine ions: $HCl \rightleftharpoons H^{\cdot}+Cl'$, or $NaCl \rightleftharpoons Na^{\cdot}+Cl'$, it is assumed that the test for hydrochloric acid or for a chloride is a search for chlorine ions. The silver nitrate solution used in making the test is supposed to be ionized: $AgNO_3 \rightleftharpoons Ag^{\cdot}+NO_3'$; consequently, when silver nitrate is added to sodium chloride solution, the mixed solution momentarily contains: $Ag^{\cdot}+NO_3'+Na^{\cdot}+Cl'$; but, since a small proportion of silver chloride is ionized and the salt is but very slightly soluble in water, it precipitates at once. Silver chlorate, $AgClO_3$, is soluble in water, and accordingly, when silver nitrate is mixed with a solution of, say, potassium chlorate, there is no precipitation. The solution contains four different kinds of ions but no chlorine, Cl′-ions: $AgNO_3+KClO_3 \rightleftharpoons K^{\cdot}+ClO_3'+Ag^{\cdot}+NO_3'$. Hence, silver nitrate is a test for chlorine ions, but not for chlorate ions. If potassium cyanide KCy in aqueous solution be added to a solution of silver nitrate, $AgNO_3$, a precipitate of silver cyanide, AgCy, is obtained: $Ag^{\cdot}+NO_3'+K^{\cdot}+Cy'=AgCy+K^{\cdot}+NO_3'$. If an excess of potassium cyanide be added the precipitate redissolves, and it can now be shown that the solution no longer contains $Ag^{\cdot}$-ions in appreciable quantities, since (1) sodium chloride gives no precipitation of silver chloride; (2) on electrolysis silver is deposited on the anode not on the cathode, as is the case when a solution of silver nitrate is electrolyzed; (3) a crystalline compound, $KAgCy_2$, is obtained on concentrating the solution. The solution of silver cyanide in potassium cyanide indeed ionizes thus: $KAgCy_2 \rightleftharpoons K^{\cdot}+AgCy_2'$. Here again it matters very little whether the facts be described in terms of the ionic hypothesis or in terms of basic and acidic radicles. The choice can only be decided by personal opinion since the ions in solution still remain hypothetical units.

CHAPTER XVI

ELECTRICAL ENERGY

§ 1. The Factors of Energy

> All the differences discoverable in the effects of electricity (obtained from different sources) may be owing to its being less intense but produced in much larger quantity from some sources rather than from others.—W. H. WOLLASTON (1801).
>
> The term electromotive force in electricity is equivalent to the term chemical activity or affinity just as the term quantity of electricity corresponds to the chemical notion of valency.—G. SALET (1867).

IT has been shown that every form of energy has a dual nature, for all the better-known forms of energy appear as if they were two dimensional in that they are compounded of two factors—one the capacity factor, the other the intensity factor. The latter determines whether a given change will occur. The capacity and intensity factors of heat energy are respectively entropy and temperature. The flow of heat is not determined by the quantity of heat in a given system, but rather by the difference of temperature. The heat in a furnace can do work not because it is hot, but because it is hotter than its surroundings. With electrical energy, the quantity of electricity expressed in suitable units—say coulombs—is the capacity factor, and the electromotive force expressed in suitable units—say, volts—is the intensity factor. The product of these two factors expresses the magnitude of electrical energy.

What are the factors of chemical energy ?—A. Butleroff (1861) pointed out that it is necessary to distinguish the quantity of affinity from its intensity, that is, the smaller or greater energy with which it tends to become active. If chemical energy can be resolved into two factors, the one factor must be analogous to the capacity, and the other to the intensity factor of thermal or electrical energy. J. W. Gibbs [1] calls the intensity factor of chemical energy the **chemical potential** ; G. H. Helm calls it the **chemical intensity**; and it is often called **the driving force of a reaction.** These terms are employed with the idea of evading the vagueness of the old term, **chemical affinity,** which is undoubtedly the correct designation for "chemical intensity." Now, the quantity of a substance which takes part in any chemical change is proportional to the *equivalent weight* of the substance, where the term equivalent weight refers to quantities of matter which have the same valency. Assuming then that the chemical equivalent is the capacity factor of chemical energy, we may write—

Chemical energy = Equivalent weight × Chemical affinity ; or,
Chemical energy = Equivalent weight × Chemical intensity.

Some follow G. Salet, *vide supra*, and hold that valency is the capacity factor, but that does not seem the right thing to do.

If two bodies at the same temperature be placed in contact, there will be no apparent conduction of heat from the one to the other ; but when the temperature of the one body—*i.e.* the intensity factor—is higher than that of the other, heat will pass from the hot to the cold body, so that the cold body is warmed and the hot body is cooled. So with chemical energy. We assume that **the molecules of every substance possess a specific amount of chemical energy, which has a**

definite intensity under certain specified conditions. One substance can only react with another when the intensity of the energy associated with the original mixture is greater than that of the final system. If the intensity of the energy associated with the original mixture be the same as that associated with the products of the reaction, no reaction will take place, for the system will be in stable equilibrium; if the intensity factors are not equal, the energy will not usually be in stable equilibrium. Just as the value of heat energy as a source of power depends on its temperature, so does the availability of chemical energy depend on the magnitude of its intensity factor.

W. Ostwald has drawn attention to the fact that if the chemical process be performed in a voltaic cell, the work derived from that process will be transformed into an equivalent amount of electrical energy. The quantity C of electricity generated when w grams of a compound are formed or decomposed in a cell will be $w=\epsilon C$, where ϵ denotes the electrochemical equivalent. This means that the capacity factor—quantity of electricity—is proportional to the quantity of matter decomposed, and that the capacity factor of the electrical energy is proportional to the capacity factor of the chemical energy. If the current does no work other than the chemical decomposition of the compound into its elements, and the difference of potential is E, the work done by the current will be EC. Again, if chemical affinity performs an amount of work W in building up w grams of a substance from its elements, wW units of work will be required. Accordingly, $wW=EC$. By substituting $w=\epsilon C$, and reducing the expression to its simplest terms, $\epsilon W=E$; otherwise expressed, the electromotive force of a cell E is equal to the chemical affinity per gram equivalent of the compound in question. Consequently, as G. Salet showed, the product of the quantity of electricity into electromotive force not only represents the electrical energy of a battery, but also measures the work of affinity which that energy transformation can perform. It therefore follows that the respective intensity factors of chemical and electrical energies are proportional, and since the electromotive force is proportional to the intensity factor of electrical energy, it follows that the **electromotive force is proportional to chemical affinity.** We see, then, that electromotive force and chemical affinity are manifestations of one form of energy; or, in the words of M. Faraday, " the forces called electricity and chemical affinity are one and the same." The problem is solved for conductors of electricity—electrolytes. Chemical action takes place when the electrical potential or the chemical affinity of the reacting substances is greater than that of the reacting products. We can to-day express the " affinity " between a number of reacting substances roughly in terms of difference of potential. The measurement of electrical potential of voltaic combinations under conditions where disturbing effects due to thermal changes, secondary reactions, etc., are eliminated, will represent the free energy or affinity of the reaction in question. How this may be done for non-conductors of electricity has not yet been determined.

The temperature or intensity factor of heat energy required for the decomposition of many substances—say calcium or potassium chloride—is so great that commercial methods of decomposing these substances by thermal energy are not profitable. A great many compounds thus appear to be very stable when heated at high temperatures; these can often be decomposed by electrical energy at a comparatively low voltage (intensity factor). This illustrates how the commercial production of metals like aluminium, calcium, etc., were not particularly successful until electrical methods were adopted. The prediction of C. L. Berthollet (1803) has been fulfilled :

> The electrical current has furnished chemistry with an agent whose energy may be carried to a degree, which as yet can scarcely be imagined, and which will furnish the means of producing in the formation and decomposition of chemical combinations, effects unforeseen, and superior to those which it is possible to obtain by the action of heat.

It has been suggested, too, that if a source of energy with a particularly high intensity factor were available, it would most likely be possible to decompose many of the so-called elements into still simpler substances, but this, of course, is merely a speculation.

§ 2. Electrochemical Series of the Elements

> An electrochemical series is obtained by arranging substances in accord with their electrical properties, and this series is better than any other for giving a general idea of chemistry.—J. J. BERZELIUS (1825).
>
> The metals precipitate one another after a certain order.—T. BERGMANN (1779).

Near the beginning of the fourth century, Zosimus mentioned the fact that when iron is immersed in a solution of a copper salt, the iron acquires a coating of copper; and miners have frequently noticed that their iron tools become coated with copper when brought in contact with the water percolating through certain mines. We now know that such water may hold in solution copper sulphate from the oxidation of ores containing copper sulphide associated with iron sulphide, and we have also learned that when the copper is deposited, an equivalent amount of iron passes into solution. The reaction is represented in symbols, $Fe+CuSO_4=Cu+FeSO_4$. Curiously enough, even as late as the sixteenth century Paracelsus attributed the phenomenon to the transmutation of iron into copper. The transmutation hypothesis certainly appeared a very plausible explanation of the facts. As T. Bergmann emphasized near the middle of the eighteenth century in his *De præcipitatis metallicis*:

> The man who first saw a metal corroded by a limpid menstruum, in such a manner that a body so extremely ponderous and so opaque should gradually and entirely disappear, and afterwards, upon the addition of a suitable precipitant to a liquid which appeared to be simple and homogeneous, saw the metal separate and again come into view, that man, I say, who first saw this, must have been struck with astonishment and admiration. Persons accustomed to these wonderful phenomena neglect, perhaps too much, the accurate investigation of them, though these operations are of the highest importance, and form as it were the whole of the effective part of chemistry.

Metallic magnesium will displace hydrogen from dilute acids: $Mg+H_2SO_4=MgSO_4+H_2$; or in the language of the ionic hypothesis: $Mg+2H^{\cdot}+SO_4''=Mg^{\cdot\cdot}+SO_4''+H_2$. Magnesium will also precipitate zinc from a solution of a zinc salt: $Mg+ZnSO_4=MgSO_4+Zn$; or in the terms of the ionic hypothesis: $Mg+Zn^{\cdot\cdot}+SO_4''=Mg^{\cdot\cdot}+SO_4''+Zn$. Zinc in turn will precipitate iron from iron salts; iron will precipitate copper from copper salts; copper will precipitate silver from silver salts, etc. By treating the different metals in a similar manner it has been found possible to arrange them in a series such that, under like conditions, any metal in the list will displace those which follow it, and be displaced by those which precede it.

Again, when zinc is treated with dilute acids under suitable conditions in a voltaic cell, so as to eliminate disturbing effects, the reaction produces an electric current at a certain voltage. If the zinc be replaced by some metals—aluminium, magnesium, etc.—the voltage of the cell is increased; and conversely, if the zinc be replaced by other metals—cadmium, iron, cobalt, etc.—the voltage of the cell is diminished. It is thus possible to arrange the elements in a series representing the potential difference in volts which is developed between the metals and solutions of their salts. The list of the elements so arranged is called **the electrochemical series.** A more complete list is indicated in Table I. The order of the metals in the electrochemical series not only depends on the nature of the elements themselves, but also on the chemical composition of the solution in which they are placed, the degree of concentration, and its temperature. In an acid solution, for example, the following six metals have this order: zinc, iron, lead, copper, silver, antimony; and in 12·5 per cent. potassium cyanide solution the order zinc, copper, silver, antimony, lead, iron. When silver and potassium cyanide replace zinc and sulphuric acid in the Daniell cell, a strong current is developed and copper is precipitated; copper is usually supposed to precipitate silver, but silver here precipitates copper. These variations promised to obscure the use of the electrochemical series for predicting the course of chemical reactions. Again, tin precipitates lead from its solution in acetic acid, and lead precipitates tin from its solution in nitric acid. Calcium iodide at about 740° is reduced by metallic sodium, but the reverse action occurs above 800° for sodium is displaced by calcium; hence sodium is more electropositive than calcium at low temperatures, and less so at high temperatures. Similar phenomena occur with potassium and strontium. In many cases the displacement is so complete that the reaction is employed in quantitative analysis. The further apart any two elements are in the series: (1) The greater the electromotive force of the currents generated when the two elements are used as plates in a voltaic couple; (2) The greater the amount of heat liberated when the displacement occurs, *e.g.* when the zinc precipitates silver more heat is evolved than when it precipitates tin. (3) Similar remarks apply, *mutatis mutandis*, to the speed of precipitation. (4) The greater the amount of heat or electrical energy required for the decomposition of their compounds; (5) The greater their chemical affinity for one another.

Fluorine	

A similar table would be obtained if the elements were arranged in the order of their chemical activity. Thus, (1) The earlier members on the list oxidize or rust on exposure to the air. (2) Oxides of the metals succeeding manganese are reduced to metals when heated in a stream of hydrogen, while the metals which precede manganese, under the same conditions, may be reduced to lower oxides, but not to the metallic condition. (3) The oxides of the metals ranging from mercury to osmium may be decomposed into their elements by simply heating them to a comparatively low temperature. (4) The metals preceding hydrogen on the list can give hydrogen when treated with acids, although secondary actions may simultaneously lead to the formation of some product other than hydrogen. The metals succeeding hydrogen do not usually displace hydrogen from the acids. (5) With the possible exception of tin and lead (metals close to hydrogen) the freed elements are rarely, if ever, found in nature excepting possibly in meteorites. This arises from the fact that natural waters containing carbonic and other acids in solution attack these metals; consequently, even if these elements were produced by subterranean agents—volcanic or otherwise—they must eventually succumb to attack by natural waters.

It will be noticed that the series refers only to the action of the *free elements*, and it has no direct reference to the mutual action of chemical *compounds* of the elements upon one another. The order of the elements in the electrochemical series depends to some extent upon the temperature as well as on the nature and concentration of the electrolyte. For example, zinc and copper behave in what appears to be an abnormal manner in the presence of potassium cyanide. Thus copper and iron will precipitate zinc from potassium zinc cyanide, whereas zinc will precipitate copper from copper sulphate; and iron from neutral ferrous sulphate. Again, silver will displace hydrogen from aqueous hydriodic acid; copper will precipitate nickel from sodium nickel chloride; and platinum will liberate hydrogen from aqueous solutions of potassium cyanide. R. Abegg and G. Bodländer[1] have developed H. von Helmholtz's assumption that the ions hold their charges with different degrees of tenacity. The ions—$K^{\cdot}$, $Na^{\cdot}$, NO_3', Cl', etc.—which hold their charges very tenaciously, are called **strong ions**; and ions—$Hg^{\cdot\cdot}$, $Ag^{\cdot}$, OH', Cy', etc.—which readily lose their charge, are called **weak ions**. The degree of tenacity with which the ions of an element hold their charges has been called the **electro-affinity** of the element. The electro-affinities of the elements are roughly measured as decomposition voltages. Ions with strong electro-affinity are difficult to prepare in a free state, and conversely. If an element with a strong electro-affinity comes in contact with the ion of an element with a weak electro-affinity, the charge on the latter passes over to the former. Thus zinc has a stronger electro-affinity than copper, and, in consequence, as indicated above, zinc will precipitate copper from solutions of its salts: $Zn+Cu^{\cdot\cdot}=Zn^{\cdot\cdot}+Cu$. Zinc also has a stronger electro-affinity than hydrogen, and consequently zinc dissolves in dilute acids with the evolution of hydrogen: $Zn+2H^{\cdot}=Zn^{\cdot\cdot}+H_2$. Similarly, chlorine has a stronger electro-affinity than bromine, and bromine a stronger electro-affinity than iodine. In consequence, chlorine will displace bromine from aqueous solutions of the bromides: $Cl_2+2K^{\cdot}+2Br' \rightleftharpoons 2K^{\cdot}+2Cl'+Br_2$; and bromine will displace iodine from the iodides: $Br_2+2K^{\cdot}+2I' \rightleftharpoons 2K+2Br'+I_2$.

The attempt of R. Abegg and G. Bodländer to show that certain properties and reactions of the inorganic salts are directly dependent upon the electro-affinities of the respective + and − ions. These properties are especially (1) solubility—where it is supposed that the greater the electro-affinity of the + and − ions, the greater the solubility—*e.g.* the electro-affinity of sodium ion in sodium salts is usually very great and the salts are usually very soluble in water; whereas with silver salts, the silver ion has a weak electro-affinity and the salts are sparingly soluble. If one of the ions has a high and the other a low electro-affinity the salt is usually soluble, *e.g.* silver nitrate. (2) Tendency to form complex positive or negative ions—if the neutral compound of the complex ion has low electro-affinities, the tendency to form complex salts will be great—*e.g.* in potassium ferricyanide K_3FeCy_6, the complex ion $FeCy_6'''$ is composed of single ions $3Cy'$ and the neutral component $FeCy_3$, where the electro-affinities are weak. A further examination of these hypotheses by J. Locke shows that the relations deduced by R. Abegg and G. Bodländer are not generally applicable.

§ 3. Solution Pressure—Contact Differences of Potential

> Whenever there is free energy present, or whenever there is potential energy seeking to become free when chemical affinities come into play in the *presence* of differential molecular structures or conditions, this energy takes the form of electrical potential.—J. T. SPRAGUE (1892).

If a spherical globule of mercury at the bottom of a watch glass—*a*, Fig. 1—be electrified at either the positive or negative pole of an electric machine, the globule flattens—*b*, Fig. 1—showing that the surface tension of the metal has diminished, and that changes in the surface tension of mercury accompany variations in its electrical condition. The greater the electric *charge* impressed on the metal, the smaller the surface tension. If σ denotes the surface tension; E, the potential difference between the metal and electrolyte; and ϵ, the quantity of positive electricity per unit surface of metal, G. Lippmann,[1] H. von Helmholtz, and W. Ostwald find $d\sigma/dE=\epsilon$.

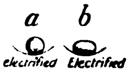

FIG. 1.—H. Herwig's Experiment.

In P. Lippmann's experiment (1873), two glass U-tubes, *A* and *B*, Fig. 2, each with one leg drawn to a capillary bore, were partially filled with mercury, and partially immersed in a beaker of dilute sulphuric acid (1 : 6) as shown diagrammatically in Fig. 2. The mercury rose to a higher level in the wider limb than in the capillary, and the finer the capillary the greater the difference of level in the two limbs—care must be taken to displace any bubbles of air in the capillary which would prevent the acid coming in contact with the mercury. Connect the mercury in the wider limbs by means of a source of electrical energy at a pressure not exceeding 0·5 volt. The meniscus of the mercury *a* through which the current enters the electrolyte—dilute sulphuric acid—will rise, and the meniscus *b*, through which the current leaves the electrolyte, will be depressed. The arrows show the direction of the current. If the meniscus in one capillary falls, the surface tension of the mercury must be increasing, and conversely, if the meniscus rises, the surface tension is diminishing. Hence, when the electrical connections were made the electrical potential of *a* was increased, and that of *b* decreased. If the potential difference between *A* and *B* were gradually increased from 0·5 volt, the meniscus at *a* would continue ascending, and that at *b* would continue descending until a potential difference of 0·93 volt is attained—after that, any further increase in the potential difference between *a* and *b* causes the mercury in *b* to rise. The explanation is that mercury in contact with dilute sulphuric acid normally acquires a potential difference of 0·93 volt, which, for convenience, is called the **contact difference of potential,** or the **electrode potential** of the mercury. Under the influence of an increasing potential difference, the positive charge is gradually augmented at *a*; and the increasing negative charge at *b* reduces the total charge on *b* by neutralizing the normal positive charge already there. When the difference of potential applied at *b* reaches 0·93 volt, the charge at *b* will be zero, and the mercury will have its maximum surface tension and *b* reaches its lowest level in the capillary. Any further increase in the difference of potential between *a* and *b* will cause *b* to be charged negatively and the mercury at *b* will begin to rise in the capillary. The mercury in both capillaries will continue rising until the difference of potential reaches 2 volts. The acid then begins to decompose.

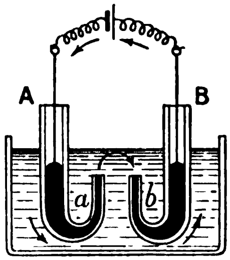

FIG. 2.—P. Lippmann's Experiment.

If the source of the electrical energy be removed and the two wires in *A* and *B* be joined, the mercury in each capillary will return to its former level. This experiment illustrates the principle of the so-called **capillary electrometer** used in various forms for measuring small differences of potential in the laboratory.

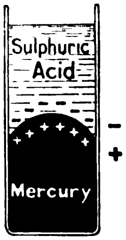

FIG. 3. — Helmholtz's Double Layer.

It is supposed that if the metal near its surface of separation from the dilute acid be positively charged—the surface of separation must act as an insulator or dielectric—and an equivalent negative charge will be induced in the acid—as represented diagrammatically in Fig. 3. The two layers of electricity of opposite sign are called **Helmholtz's double layer**—after H. von Helmholtz's investigations on this subject in 1879. Had dilute hydrochloric acid been used in place of dilute sulphuric acid, the maximum depression in the capillary *b* would have occurred with a difference of potential of 0·56 volt.

The contact difference of potential between the different metals in contact with normal solutions of their salts are indicated in Table II, due to N. T. M. Wilsmore.

A common method used in measuring contact difference of potential, or the relative e.m.f.—electromotive force—of metals in contact with different solutions, is to make a cell with two electrodes each dipping in a separate solution. (i) One electrode consists of the metal to be tested held by platinum-tipped forceps electrically connected with a galvanometer, and dipping in the required solution. (ii) The other is the so-called **normal electrode.** In Ostwald's non-polarizable normal electrode (1) mercury is electrically connected with the galvanometer by means of a glass-coated platinum wire, (2) the surface of the mercury is connected with a layer of mercurous chloride about 5 cm. thick, and (3) a solution containing a normal solution of potassium chloride. This gives an electromotive force of −0·560 volt, or a positive current tends to flow through the solution to the mercury which becomes positively electrified, while the solution itself becomes negatively electrified. When the solutions about the two electrodes are in contact, the slight e.m.f. due to the contact of the two liquids is neglected and the e.m.f. of the whole combination is the algebraic sum of the e.m.f.'s action at the two electrodes. The e.m.f. of the given metal in contact with the given solution is obtained by subtracting 0·560 volt from the observed e.m.f. of the combination. The e.m.f. of the combination is observed in terms of the deflection of a calibrated galvanometer, or by the compensation or zero method of J. C. Poggendorff described in laboratory manuals.

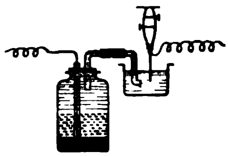

FIG. 4.

W. Nernst (1889) [2] has carried the idea of contact difference of potential still further. He assumes that if a metal rod be immersed in a liquid, it tends to dissolve. The supposed tendency of a metal to dissolve in any liquid is called the **solution pressure** of the metal. The supposed action is likened to the tendency of liquid to vaporize as indicated by the *vapour pressure* of the liquid at any given temperature. Still further, just as a liquid continues to evaporate at a free surface until the number of molecules leaving the surface of the liquid in any given time is equal to the number of molecules returning to the liquid, so W. Nernst suggests that a metal, when placed in contact with water or other liquid, tends to send charged ions into the solution and itself to assume an equivalent charge of opposite sign. A force has been invented to drive the ions into the solution, and it is called the **electrolytic solution pressure.** The force is supposed to vary with the nature of the metal, the solution, and the temperature. The solution pressure must be greatest with the metals at the cæsium end, and least with the metals at the osmium end of the electrochemical series. Conversely, the tendency of positive metal ions in solution to reprecipitate on the negative electrode must be least at the cæsium end of the series and greatest at the osmium end. The ionic hypothesis assumes that this back or **deposition pressure** represents the osmotic pressure of the ions. The ionization of the metal, so to speak, is supposed to continue until the concentration of the metallic ions in the liquid has attained a certain value when a state of equilibrium ensues. The number of ions passing into the solution is then equal to the number reprecipitated on the surface of the metal. Direct proof of the presence of iron ions in purified water, which has been in contact with the highly purified iron, is wanting. The evidence is indirect, or rather hypothetical.

When zinc is immersed in dilute hydrochloric acid, the supposed H$^{\cdot}$-ions which come in contact with the zinc plate lose their charge, and positively charged zinc ions pass into solution. If a stick of metallic zinc be dipped in a saturated solution of zinc sulphate, the solution and deposition or osmotic pressures are balanced, and no action occurs; but if a stick of metallic zinc be placed in a dilute, say normal, solution of zinc sulphate, the solution pressure is greater than the deposition or osmotic pressure, and positively charged zinc ions pass from the zinc rod into the solution. In consequence, the zinc acquires a negative charge, and the solution a positive charge, in agreement with the fact that zinc usually acquires a negative charge when immersed in a solution of its own salt. Similar remarks apply to aluminium, iron, etc. Conversely, if the solution pressure be less than the deposition or osmotic pressure of the ions, as appears to be the case with a stick of metallic copper immersed in a solution of copper sulphate, copper ions will be deposited on the metal, and the solution will acquire a negative charge while the metal acquires a positive charge. This also appears to be the case with the metals of silver, mercury, etc.

Let P denote the electrolytic solution pressure of the metal, and p the osmotic pressure of the metallic ions in the solution. It is presumed that the osmotic pressure of the metallic ions will oppose the tendency of the metallic ions to pass into solution. When the opposing forces are balanced, no action will take place—as will occur with zinc in a saturated solution of zinc sulphate.

In a normal solution of zinc sulphate, if P be *greater* than p, bivalent zinc ions will pass from the zinc rod into the solution, the solution will become positively, and the metal negatively charged. The attraction of opposite charges will cause positive ions to collect about the surface separating metal and solution, and thus form a Helmholtz's double layer. When the osmotic pressure p of the metallic ions in the solution has been augmented by the separation of ions from the metal itself until it is equal to the electrolytic solution pressure, the opposing forces will be balanced; there will be no further increase in the number of metal ions in the solution, and a definite electromotive force will be established—metal negative, solution positive. Thus zinc, aluminium, and iron are generally negative when immersed in solutions of their own salts. If the electrolytic solution pressure P be *less* than the osmotic pressure p such as occurs when copper is placed in a solution of copper sulphate, positively charged copper ions will separate from the solution and be precipitated on the metal and the rod of metal will become positively, and the solution negatively charged. An Helmholtz's double layer will be formed as the negative ions remaining in the solution collect about the surface separating solution and metal. Equilibrium will be established when $P=p$, and an electromotive force will appear at the boundary double layer in a reverse direction to that established when P was greater than p. Gold, silver, mercury, and copper are illustrations of metals usually positive when immersed in solutions of their own salts.

The electrical effect, or the contact difference of potential, produced when the different metals are immersed in a normal solution of their sulphates has been measured. B. Neumann's results are indicated in Table III. The number $+0{\cdot}524$ opposite zinc means that if metallic zinc be immersed in a normal solution of zinc sulphate, the solution will acquire a positive charge, and the metal a negative charge; and the difference of potential between the solution and the metal will be 0·524 volt. With metallic copper and a solution of copper sulphate, the solution will be charged negatively, and the copper positively, such that the difference of potential between the solution and the metal will be 0·515 volt.

TABLE III.

Metals.	Sulphate.	Chloride.	Nitrate.	Acetate.
Magnesium	+1·239	+1·231	+1·060	+1·240

Gold	—	−1·356	—	—

If a normal solution of copper sulphate be separated by a porous partition, Fig. 5, from a normal solution of zinc sulphate, and if a rod of copper immersed in the copper sulphate be connected by a wire with a rod of zinc immersed in the zinc sulphate (Fig. 5), the zinc pole on the right of the diagram acquires a negative charge *ex hypothesi* on account of the departure of positively charged ions from its surface, and the copper pole on the left acquires a positive charge on account of the departure of negatively charged copper ions from its surface. In consequence, an electrical current will flow through the connecting wire from the positively to the negatively charged pole and pass in the converse direction through the liquid. This action continues until all the zinc is dissolved or all the copper precipitated. The relative solution pressures of the two metals decide the magnitude of the resultant electromotive force of the current, and this is the difference of the two effects. The resultant electromotive force for the zinc : copper couple just described is $+0{\cdot}524 - (-0{\cdot}515) = 0{\cdot}524 + 0{\cdot}515 = 1{\cdot}039$ volts. The combination just described represents the so-called **Daniell's cell** (1836),[3] which resembled in principle the unpractical cell described by E. Becquerel in 1829. In reality, J. F. Daniell's cell contains the zinc rod with the sulphuric acid or zinc sulphate solution in a porous pot, and the copper plate with the copper sulphate solution in the surrounding jar, as illustrated by the drawing of an uncharged cell in Fig. 6. The reactions are symbolized

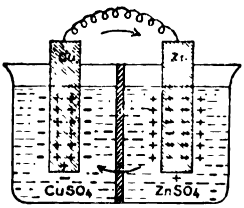

FIG. 5.—Daniell's Cell (Diagrammatic).

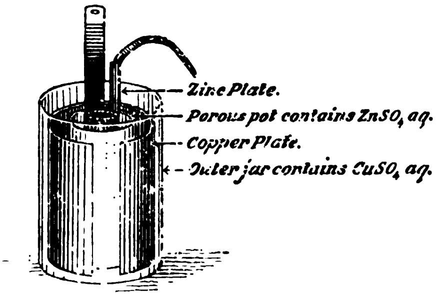

FIG. 6.—Daniell's Cell.

molecularly in the following manner: At the positive zinc plate, $Zn+H_2SO_4=ZnSO_4+H_2$. Instead of the hydrogen atoms being liberated on the negative copper plate, they are exchanged for copper in the copper sulphate solution: $H_2+CuSO_4=H_2SO_4+Cu$, and the copper is deposited on the copper plate. The net result of this round of changes is that the copper plate grows while the zinc plate lessens; and zinc sulphate increases, copper sulphate decreases. If a solution of zinc sulphate is used in Daniell's cell, the copper is exchanged for the zinc: $Zn+CuSO_4=ZnSO_4+Cu$. There are many other modifications of Daniell's cell, and numerous other types of cell with different " poles " and different solutions.

The *quantity* of electricity (coulombs) produced by Daniell's cell depends upon the amount of zinc consumed (Faraday's law); and the *rate* at which electricity is developed (ampères) depends upon the rate at which the zinc is consumed in the cell. The *difference of potential* or the electrical pressure cannot exceed 1·039 volts for the given solutions. The product of the number of coulombs into the number of volts gives the amount of electrical energy expressed in joules. If the term *ampère* be employed to represent a current equivalent to one coulomb per second, the product of the number of ampères into the number of volts gives the amount of electrical energy produced in one second by the cell, expressed in watts—a joule of electrical energy per second represents one watt.

EXAMPLES.—(1) The electrolysis of 36·5 grams of hydrochloric acid requires 96,540 coulombs of electricity at 1·31 volts. Hence the electrical energy needed for this work is $96{,}540\times1{\cdot}31=126{,}567$ units, or, defining a **joule** as the unit of electrical energy consumed by a current of one coulomb working against a resistance of one ohm (joules = volts × coulombs), the electric energy needed to decompose 36·5 grams of hydrochloric acid is 126,567 joules.

(2) A current of 100 volts and 1·5 amps. passes through a system, hence $100\times1{\cdot}5=150$ watts of energy are consumed per second.

The relation between the electromotive force and the osmotic pressure.—The qualitative sketch of Nernst's hypothesis can be described in a quantitative form. If a substance with an electrolytic solution pressure P be converted into ions with an equivalent osmotic pressure P_1, the opposing forces are balanced, and no work is done. On the other hand, if a metal with an electrolytic solution pressure P be converted into ions having an osmotic pressure p, the maximum work which can be performed during the transfer is analogous with the work performed when ions are transferred from an osmotic pressure P to an osmotic pressure p. If one gram-molecule be involved, the osmotic work will be $RT\log(P/p)$. One gram-ion carrying nC equivalents of electricity (n denotes valency) at a potential of E volts, can perform nEC units of electrical work. Assuming that the osmotic work and electrical work are equivalent, $nEC=RT\log(P/p)$, when $R=2$ cals., one volt-coulomb$=0{\cdot}24$ cal. Hence, in place of nEC we can write $nE\times96500\times0{\cdot}24=2T\log(P/p)$, and remembering that natural logarithms are converted into common logarithms by multiplying by 2·3026,

$$E=0{\cdot}000198\frac{T}{n}\log_{10}\frac{P}{p}\text{ volts}$$

This equation represents the electromotive force or potential difference developed, at the absolute temperature T, when an n-valent metal with an electrolytic solution pressure P is immersed in a solution in which the corresponding ion has an osmotic pressure p.

EXAMPLES.—(1) Let one zinc rod dip in a normal and another in a decinormal solution of zinc chloride, Fig. 7, assume that ionization is complete in both solutions. What is the resulting electromotive force of the cell? Ansr. $E=0{\cdot}0287$ volt.

(2) What is the electrolytic solution pressure of zinc in normal zinc sulphate solutions at 17° when the contact difference of potential is 0·524 volts? Here $n=2$; $E=0{\cdot}524$; p denotes the osmotic pressure of zinc ions when a gram-molecule of the salt is completely ionized in a litre of solution, $P=22{\cdot}4$ atm. Hence, $0{\cdot}524=0{\cdot}000198\times\frac{1}{2}\times290(\log P-\log22{\cdot}4)$, or $P=2{\cdot}7\times10^{19}$ atm.

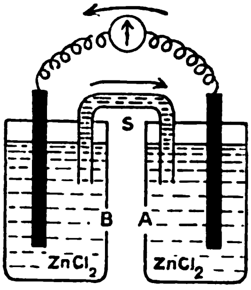
The electrolytic solution pressures cannot be measured directly, but they can be computed from the observed differences of potential as in the preceding example. The computed values for magnesium, zinc, iron, hydrogen, and silver expressed in atmospheres, are :

Magnesium.	Zinc.	Iron.	Hydrogen.	Silver.	Palladium.
10×10^{43}	$2{\cdot}7\times10^{19}$	$1{\cdot}2\times10^{4}$	$9{\cdot}9\times10^{-4}$	$2{\cdot}3\times10^{-17}$	$1{\cdot}5\times10^{-36}$

It is difficult to understand what these numbers mean. The number for zinc appears extraordinarily large; it is nearly equal to a weight of 180000,000000,000000 tons or $1{\cdot}8\times10^{17}$—the earth itself is estimated at 6000,000000,000000,000000, or 6×10^{21} tons. Nothing like these pressures have been directly observed; they are said to represent "the striving of the metal to overcome the opposing osmotic pressure of the metal ions already in solution in order that the atom of the metal may be ionized." We cannot employ the tabulated electrolytic solution pressures to calculate contact differences of potential E along with observed values of p and n in the expression $EC=RT \log (P/p)$, and compare the results with observed values of E in order to show the validity of the formula, because that would be reasoning in a circle.

Concentration cells.—Although the difference of potential of a given cell, say a Daniell's cell, is not affected by variations in the size or shape of the poles, or upon the quantity of liquid in the cells, the difference of potential is altered by changing the concentration of the solutions. In general the difference of potential between a metal and a solution of one of its salts is greater with increasing dilution. A tenth normal solution of zinc sulphate, for instance, will give a difference of potential of 0·551 volt, whereas with a normal solution a potential difference of 0·524 volt is obtained as indicated above.

If two rods of zinc be separately placed in a N-solution of zinc sulphate, the difference of potential in both "tends" to drive an electric current from the metal to the solution with a pressure of 0·524 volt.. If both rods be joined by a wire, no electric current will flow because the two equal forces are oppositely directed. On the other hand, if the zinc rods be dipped in solutions of a *different* concentration, the two contact differences of potential will be different, and an electric current will flow from the concentrated solution to the dilute solution outside the cell as indicated in Fig. 7. Here a normal solution of zinc chloride is supposed to be placed in one vessel, *A*, and a decinormal solution of zinc chloride in the other vessel, *B*. Zinc rods connected by a copper wire and galvanometer are dipped into the solutions, as illustrated in the diagram, and the two cells are connected by a syphon tube *S*. The difference of potential of the zinc in the normal solution is +0·524, and in the more dilute solution +0·551 volt. Hence an electric current tends to pass from the metal to the dilute solution with a force of +0·551 volt, and from the metal to the concentrated solution with a force of 0·524. The resultant pressure is therefore 0·551−0·524=0·027, and this represents the electromotive force of the combination. Cells in which the electromotive force is generated by the difference potential of two plates immersed in solutions of the same salt at different concentrations are called **concentration cells.** The chemical action which occurs in the two cells tends to bring the two solutions to the same concentration.



Dilute *Concentrated*

Fig. 7.—Concentration Cell.

The action is made clear by the following experiment: A layer of a concentrated solution of stannous chloride in hydrochloric acid, about 10 cm. deep, is placed at the bottom of a cylinder, and above this a layer of a dilute solution. A rod of metallic tin is fixed through a hole in the cork so that it is suspended axially in the liquid in the cylinder. The rod of tin thus represents both electrodes and connecting wire of a concentration cell. Tin is dissolved by the more dilute solution, and precipitated from the more concentrated solution. After the system has stood a couple of days, the rod of tin near the surface of the more dilute solution will be reduced in thickness. Cadmium and cadmium chloride can be used; zinc does not work so well; nickel gives negative results, probably because the surface of the metal becomes polarized; antimony and bismuth also give negative results, probably because they are not attacked by dilute hydrochloric acid.[4]

There is another interesting feature about a concentration cell. If an external electromotive force be applied so as to force an electric current to pass in a reverse direction to that which the combination normally furnishes when it is employed in a voltaic cell, the chemical actions will be reversed, and the difference in the concentration of the two solutions will be augmented. Such combinations are called **reversible cells** in contradistinction to **irreversible cells** in which the original condition cannot be restored by sending a current through the cell in a reverse direction to the current normally delivered by the cell. The $Zn|H_2SO_{4aq}|Pt$ cell is an irreversible cell; Daniell's cell, Fig. 6, and the concentration cell, Fig. 7, are reversible cells. If two metal rods are arranged so that one dips in a solution of concentration C_1 and the other rod in another solution of concentration C_2; and if the two solutions are separated by a porous partition and the rods be connected electrically, the electromotive force of the combination will be:

$$E=\frac{RT}{nE_0}\left(\log\frac{P}{p_1}-\log\frac{P}{p_2}\right);\quad \text{or } E=\frac{RT}{nE_0}\log\frac{p_1}{p_2}$$

where p_1 and p_2 respectively denote the osmotic pressures of the solutions of concentrations C_1 and C_2 respectively and P is the solution pressure of the metal. If the metal be nickel, and the solutions be nickel nitrate, $R=8{\cdot}31$ electrical units; $E_0=96{,}540$ coulombs; $n=2$; and at 18°, $T=273+18=291$; if, further, common logarithms are used, then, remembering that the osmotic pressures of dilute solutions are proportional to their concentrations,

$$E=0{\cdot}0288\log\frac{C_1}{C_2}$$

If one solution contains 0·1 gram-molecule of nickel nitrate and the other, 0·05 gram-molecule, the calculated electromotive force of the combination on the assumption that ionization is complete is $E=0{\cdot}0288\times0{\cdot}301=0{\cdot}0087$ volt; the observed value is 0·010 volt.

G. Meyer[5] showed that measurements of the e.m.f. of the combination

Concentrated amalgam | Solution of a salt of the solute metal | Dilute amalgam

enabled the molecular weight of the metal dissolved in the mercury to be computed when there is no combination between the mercury and the metal. Expressing the preceding equation in the form:

$$E=0{\cdot}002\frac{T}{n}\log\frac{C_1}{C_2}$$

divide n by the number of electrical units which go with an atom of the metal in question and the number of atoms in a molecule, and hence the molecular weight of the metal can be computed.

Mercury precipitates silver from a solution of silver nitrate, and silver precipitates mercury from a solution of mercurous nitrate. G. M. Smith (1904) has also found the following pairs of elements can be reciprocally precipitated: Zn—Cu; Ca—Cu; Fe—Hg; Fe—Ag; Hg—Ag; Hg—Pt; Hg—Au; Ag—Au. Again, potassium from a solution of potassium chloride can replace sodium from its amalgam, and conversely sodium can displace potassium from its amalgam; potassium and barium, and sodium and barium are reciprocally replaceable in spite of the fact that potassium is more electropositive than sodium, and sodium more than barium. M. Berthelot called the phenomenon an anomaly, and supposed it to be a consequence of the greater loss of energy suffered by potassium in comparison with sodium when the respective amalgams are formed. According to Nernst's theory, when one metal M_1 is immersed in the salt of another metal M_2, if M_2 is to be precipitated by M_1,

$$\frac{RT}{n_1}\log\frac{P_1}{p_1} > \frac{RT}{n_2}\log\frac{P_2}{p_2}; \text{ or } \sqrt[n_1]{\frac{P_1}{p_1}} > \sqrt[n_2]{\frac{P_2}{p_2}}$$

where the subscripts refer to the corresponding metals; P_1, P_2 are the electrolytic solution pressures; p_1, p_2 the osmotic pressures of the univalent ions; and n_1, n_2 the valencies of the metals in question. Hence the conditions which are favourable for the precipitation of M_2 are (i) a high osmotic pressure, that is, a high concentration of the ions of the second metal; and (ii) a high solution pressure, that is, a low osmotic counter pressure or low concentration of the ions of this metal. It is therefore to be anticipated that two metals might be reciprocally replaceable—all depends on the relative magnitudes of the above terms under different conditions.

There is a difference of potential at the surface of contact between two solutions. If two solutions of, say, hydrochloric acid of different concentration be in contact, the more concentrated solution will diffuse into the other; and, according to the ion theory, the hydrogen and chlorine ions can travel independently at different rates—the positively charged hydrogen ion being the faster will be in the van, the negatively charged chlorine ions will lag behind, and accordingly a difference of potential will be established. The electrostatic attractions set up by the two sets of oppositely charged ions will prevent their separating very far, but it will be sufficient to cause a layer of positively charged ions to accumulate near the surface of the more dilute solution, and a layer of negatively charged ions near the surface of the more concentrated solution. If a salt had been chosen such that the negatively charged ions moved the faster, the charges on the dilute and concentrated solution surfaces would have been reversed, for the more dilute solution must be charged by the more quickly moving ions.

Let $v^{\cdot}$ and v' respectively denote the relative velocities of the ions—assumed to be univalent. Suppose that the cation moves the faster, and that a unit charge of electricity—96,450 coulombs—is carried from the dilute to the concentrated solution. The total current, $v^{\cdot}+v'$, is shared between both ions, so that $v^{\cdot}/(v^{\cdot}+v')$ represents the cation's share, and $v'/(v^{\cdot}+v')$ the anion's share; or $v^{\cdot}/(v^{\cdot}+v')$gram-ions of the cation will have gone from the concentrated to the dilute solution, and $v'/(v^{\cdot}+v')$ gram-ions of the anion will have gone in the opposite direction. If p_1 denotes the osmotic pressure of the cations in the dilute solution it will also represent the osmotic pressure of the anion in the same solution; similarly, let p_2 denote the osmotic pressure of the anions, and of necessity, also, of the cations in the dilute solution. This means that $v^{\cdot}/(v^{\cdot}+v')$ gram-ions of the cation pass from the higher osmotic pressure p_2 to the lower osmotic pressure p_1. Hence the energy converted into electric energy by the cations, and the maximum work done upon the anions moving in the opposite direction from the higher to the lower pressure, will be respectively

$$\text{Work done by cations} = \frac{v'}{v^{\cdot}+v'}RT\log\frac{p_2}{p_1}$$

$$\text{Work done on anions} = \frac{v^{\cdot}}{v^{\cdot}+v'}RT\log\frac{p_2}{p}$$

The available electrical energy EC obtained will be the difference between these two quantities. This difference simplifies, as before, into

$$E = 0{\cdot}000198T\frac{v^{\cdot}-v'}{v^{\cdot}+v'}\log\frac{p_2}{p_1}\text{ volts}$$

More generally, (i) if the cation has a valency m and the anion a valency n; (ii) if the ratio of the concentrations of the two solutions C_1/C_2 be substituted, as before, for the ratio of the osmotic pressure p_1/p_2; and (iii) if the degree of ionization of the solution be x,

$$E=\frac{0\cdot000198\times T}{x}\cdot\frac{\frac{v^{\cdot}}{m}-\frac{v'}{n}}{v^{\cdot}+v'}\log\frac{C_2}{C_1}\text{ volts}$$

an expression which represents the contact difference of potential of two concentrations of the same solute at the absolute temperature T. This expression represents the contact difference of potential between two concentrations of an electrolyte. Obviously, if the velocities of the two ions were equal, $v^{\cdot}=v'$; and if the solutions have the same concentrations $p_1=p_2$; in either case the electromotive force would be zero.

EXAMPLE.—Calculate the electromotive force of the cell Ag|$\frac{1}{100}N$·AgNO$_3$|$\frac{1}{10}N$·AgNO$_3$|Ag at 17°, when the degree of ionization of the solution is 0·935 and the velocity of the cation is 52 and of the anion 58. There are three contacts to consider, and the electromotive force E will be the algebraic sum of the contact differences of potential of the two silver electrodes with their respective solutions, and of the two solutions with one another.

$$E=\frac{0\cdot000198T}{n}\log\frac{C_2}{C_1}+\frac{v^{\cdot}-v'}{v^{\cdot}+v'}\log\frac{C_2}{C_1}\text{ volt}$$

Here $C_2=100$, $n=m=1$, $v^{\cdot}=52$, $v'=58$, $T=290$, it follows that $E=(0\cdot000198\times290\times0\cdot935\times2\times58\times2\cdot3026)/(52+58)=0\cdot058$ volt. The observed value is 0·055 volt.

W. Nernst's method of calculating the e.m.f., E, of a concentration cell from the transport numbers $v^{\cdot}$ and v' and the ratio of the concentrations:

$$E=0\cdot0002\frac{2v'}{v^{\cdot}+v'}\cdot\frac{T}{n}\log\frac{C_2}{C_1}$$

is approximately correct for dilute solutions, but for concentrated solutions, and solutions in non-aqueous solvents of low-ionizing power, there are discrepancies attributed to incomplete ionization; and in that case, the ratio of the ionic concentrations calculated from the conductivities are substituted for the ratio of the concentrations. The prediction of the e.m.f. of a cell is dependent on the applicability of the ionic hypothesis to the solutions. Anomalies are harmonized by introducing hypotheses respecting the association of solute or solvent, or the combination of solvent and solute. H. von Helmholtz (1878) calculated the e.m.f. of a concentration cell from the vapour pressures of the two solutions, and the result is the same as that obtained by W. Nernst's method when the liquid : liquid potential difference is negligible.

L. Hermann has shown that when a current is passed from a dilute solution of a salt to one more concentrated, acid is liberated at the boundary layer, and if the current is sent in the opposite direction an alkali is set free at the same place. G. S. Walpole[6] showed that with all the neutral salts he examined, acid is always liberated when the current passes from the more dilute to the more concentrated solution, and an alkali when the current passes from the concentrated to the more dilute solution. The quantities of acid or alkali liberated bear no relation to the quantity of electricity passing through the circuit; but when the other conditions are the same, the same quantity of acid or alkali is liberated whatever neutral salt be used. G. S. Walpole calculated the effect which would be produced on the assumption that the phenomenon is due to the difference in the velocities of the hydrogen and hydroxyl ions on opposite sides of the boundary layer, and obtained numbers in agreement with the observed data.

When a substance in solution passes from a lower to a higher state of oxidation the change may be regarded as an increase in the number of electric charges on the ions in question; for instance, the oxidation of ferrous to ferric iron is represented, $Fe^{\cdot\cdot} \rightarrow Fe^{\cdot\cdot\cdot}$; and the oxidation of stannous to stannic tin, $Sn^{\cdot\cdot} \rightarrow Sn^{\cdot\cdot\cdot\cdot}$. Conversely, with the reverse changes, the reduction of stannic to stannous tin, $Sn^{\cdot\cdot\cdot\cdot} \rightarrow Sn^{\cdot\cdot}$, or of ferric to ferrous iron, $Fe^{\cdot\cdot\cdot} \rightarrow Fe^{\cdot\cdot}$. The tendency of an ion to pass from one state of oxidation to another can be expressed in terms of an electromotive force. A cell is filled with unattackable electrodes, say, with platinum electrodes immersed respectively in solutions of a ferric and a ferrous salt, and a current is passed from an accumulator in the direction of the arrow: $Pt^{+}|FeCl_2 \rightarrow FeCl_3|Pt^{-}$, the ferrous ions on the one side will be oxidized to ferric ions, and the ferric ions on the other side will be reduced to ferrous ions. If the accumulator is now removed and the circuit closed, ferric ions at one electrode will be reduced because they will give up positive charges to the one electrode, and, as a result, the other electrode will be charged positively and it will oxidize the ferrous ions in the vicinity to ferric ions. This action will continue until the ratio of the ferrous and ferric ions about the two electrodes is the same. If C_i denotes the concentration of the ferric ions and C_0 that of the ferrous ions, $K = C_i/C_0$; Nernst's equation assumes the form:

$$E = E_0 + \frac{RT}{nC} \log \frac{C_i}{C_0}$$

where E_0 is a constant representing the observed potential difference at the electrodes when the concentrations of the -ous and -ic ions are equal—say one gram-molecule per litre—so that $\log (C_i/C_0) = \log 1 =$ zero; n is the difference in the valency of the two ions—*e.g.* in the case of iron, $n=1$, and in the case of tin, $n=2$; the other symbols have their usual meaning; E is sometimes called the oxidation or reduction potential of a solution because it can be taken as a measure of its oxidizing or reducing power.

EXAMPLES.—(1) The potential difference between solutions of thallic nitrate and thallium were measured, and the mean value for E_0 for thallium solutions was 1·191 volts. What is the reduction potential $Tl^{\cdot\cdot\cdot} \rightarrow Tl^{\cdot}$ for solutions containing 0·0505 gram-molecule of thallic nitrate, $Tl(NO_3)_3$ and 0·00108 gram-molecule thallious nitrate $TlNO_3$? Here $E = E_0 + 0{\cdot}029 \log 46{\cdot}7$, or $E = -1{\cdot}233$ volts.

(2) The observed value of E_0 for solutions of uranyl and uranous sulphates is 0·615 at 27·5°, what is the electromotive force with solutions respectively containing 48·4 and 51·6 per cent. of uranyl and uranous sulphate?

Sacrificial metals.—If metallic zinc dissolving in, say, dilute sulphuric acid, be in contact with a piece of copper or platinum the rate of dissolution of the zinc is augmented. The combination Zn : Pt is called a **couple**, and it really forms a small galvanic cell with zinc, and, say, platinum electrodes connected together by metallic contact. Much of the hydrogen is evolved from the surface of the platinum. We have seen that any metal in the electrochemical series can be made one plate of a cell against a metal lower down in the series. Zinc, for instance, can be made the positive plate against a negative plate of iron, tin, lead, etc.; and iron the positive plate against a negative plate of tin, lead, etc. The further apart the elements in the series, the greater the electromotive force of the combination. *Tin-plate* is iron or steel coated with a thin layer of tin. If a little moisture be precipitated on the surface in contact with both the iron and the tin, the moisture, with its dissolved carbonic acid, dissolves the iron, and produces salts of iron; these ultimately form rust (*q.v.*). The iron is covered with a layer of tin to protect it from rust, but if there be a flaw in the protecting surface of tin so as to expose the underlying iron, rusting takes place more rapidly than if the iron had not been tinned at all. The tin remains untarnished. Zinc is also used as a protecting layer over the surface of thin iron plates—*galvanized iron.* The voltaic action developed when the protecting layer is damaged is much less than when tin is used. These facts can be illustrated by fitting up a cell like Fig. 8 with iron and tin plates, and another cell with iron and zinc plates. Water saturated with carbon dioxide is used in both cells. A feeble electric current will flow from the tin to the iron outside the cell in one case, and from the iron to the zinc in the other as illustrated graphically in the adjoining diagram. *In the iron : tin cell, iron dissolves and rusting occurs ; while in the iron : zinc cell, the zinc dissolves and no rusting occurs as long as the circuit is closed.* These results might also have been predicted from our study of Table I.

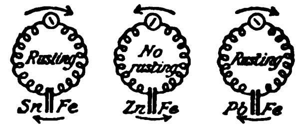


FIG. 8.

An iron : lead cell behaves like an iron : tin cell. Iron railings are often fixed in a bed of lead ; the iron corrodes first and the lead remains intact. H. Davy (1824)[7] once proposed to prevent the corrosion of the copper sheathing of ships by fixing pieces of metallic zinc here and there on the sheathing. The zinc was corroded and the copper preserved. When the zinc was all consumed, the copper ceased to poison the barnacles, and the bottom fouled as if the wood had not been sheeted with copper. In all these cases it has been fancifully said that one metal is sacrificed to ensure the safety of the other ; and all the cases quoted are examples of galvanic couples : Fe : Sn ; Zn : Fe ; Fe : Pb ; and Zn : Cu.

§ 4. The Ionic Hypothesis and Chemical Reactions

The knowledge of nature as it is—not as we imagine it to be—constitutes true science.— PARACELSUS.

There are some fervid enthusiasts who claim that " all chemical reactions are reactions between ions ; molecules as such do not react at all." This statement is not quite in harmony with known facts. The same might be said of the assumption that " chemical activity is proportional to the number of available ions." L. Kahlenberg (1902),[1] J. L. Sammis (1906), and C. B. Gates (1911) have brought forward a large number of exceptions to these statements that it appears necessary to modify the hypothesis very materially before it can be accepted as an accurate description of the facts. Some chemical reactions proceed very rapidly in solutions which are considered to be virtually non-conductors of electricity, and which, *ex hypothesi*, are almost free from ions. For instance, dry hydrogen chloride precipitates metal chlorides from benzene solutions of the oleates of copper, cobalt, and nickel ; dry hydrogen sulphide precipitates sulphides from benzene solutions of the same salts and of arsenic chloride. All this in spite of the fact that these solutions do not conduct electricity appreciably. Again, dry ammonia does not unite with dry hydrogen chloride, but union does take place if a trace of non-conducting benzene vapour be present. One metal can displace another from a non-conducting solution in a non-aqueous medium. Thus, metallic lead, zinc, tin, silver, iron, etc., will precipitate metallic copper from solutions of various salts in carbon disulphide, carbon tetrachloride, ether, alcohol, etc. Hence, L. Kahlenberg claimed that in spite of the ionic hypothesis, chemical reactions do take place in non-conducting solutions, and these reactions are similar in result and speed to those which occur in conducting aqueous solutions.

H. C. Allen and H. P. Cady and H. O. Lichtenwalter have re-examined the experimental work on this subject, and they claim that the benzene and toluene *solutions* of the salts showed some conductivity which increased when dry hydrogen chloride was introduced. The solutions of the salts also showed polarization which indicated that they possessed properties similar to those of an ordinary electrolyte. It is thus possible that these reactions may be due to ionization. although an alternative explanation is suggested in the assumption that the reactions with hydrogen chloride and the salts of the unsaturated acids take place in two stages: (1) the formation of additive products with hydrogen chloride, and (2) the decomposition of the additive products into metal chloride and organic acid.

G. Senter showed that when an electrolyte enters into chemical reactions, the non-ionized molecules as well as the ions may simultaneously take part in the change, and later, S. F. Acree and J. M. Johnson came to the same conclusion. It was also assumed in the earlier form of the ionic theory that the $H^{\cdot}$-ions are catalytically active, but this did not explain the catalytic activity of neutral salts. A. Lapworth suggests that the difficulty could be overcome by assuming that the non-ionized molecules of the acid are also catalytically active, and this hypothesis is now generally accepted as a result of the work of H. Goldschmidt, G. Bredig and W. S. Millar, H. C. S. Snethlage, S. Arrhenius, H. S. Taylor, H. M. Dawson and T. W. Crann, etc.[2]

These facts leave the uncomfortable feeling that the ionic hypothesis is rather an encumbrance on the theory of chemical reactions; and with slight modifications of phraseology, A. L. Lavoisier's indictment of the phlogiston hypothesis could be applied to the ionic theory of chemical action. The ionic hypothesis cannot ignore these observations if it is to win a permanent place among the conquests of science. As O. D. Chwolson (1910) has emphasized that there is as yet no solidly established theory of solutions which will take into account all the known phenomena, and on which reliance can be safely placed. Hence, advocates of the ionic hypothesis revert to the ordinary language of the molecular theory where the ionic hypothesis fails.

§ 5. Polarization—Back Electromotive Force

The source of chemical energy in the galvanic cell is certainly the chemical action, a correction being applied for any reversible heat which the cell absorbs from or gives up to its surroundings.—W. C. D. WHETHAM.

Just as an ordinary steam boiler is a device for transforming the chemical energy of burning coal into mechanical energy, so can the voltaic cell be regarded as an engine for converting chemical into electrical energy. In one of the simplest cases, where the cell Zn : H_2SO_4 : Pt is working, hydrogen is evolved mainly from the surface of the platinum. The chemical action is vigorous at first, but gradually diminishes in intensity, and finally nearly stops altogether. The curve, Fig. 9, shows the electromotive force of such a cell after different intervals of time when it is working with a resistance of about ten ohms in the external circuit. The rapid drop from an initial electromotive force of 1·3 volts to about half a volt in five minutes, is indicated by the rapid descent of the curve. After five minutes the electromotive force remained fairly constant at about 0·4 volt—that is, nearly 66 per cent. below the initial value. The effect is easily illustrated by connecting an electric bell with such a cell. The bell rings loudly at first, but gradually weakens, and finally stops. If the platinum plate be then removed, the surface will be found covered with a layer of bubbles of hydrogen gas, which have remained on the surface of the plate instead of passing away. If the circuit is broken, the bubbles of gas gradually dissipate from the platinum plate, and the cell then resumes its former electromotive force when the circuit is closed. This temporary reduction in the electromotive force of a cell is said to be due to the **polarization** of the cell. Polarization may be defined as the electrochemical fatigue which is caused either by a modification of one or both of the plates, or by the exhaustion of the solution about the surfaces of the electrodes during the working of the cell.

Whatever changes occur in the body of the electrolyte during electrolysis no energy is consumed in the process, but at the junctions of electrodes and electrolytes temporary or permanent changes may occur which produce the counter or negative electromotive force called polarization. If the change is transient and disappears when the current is stopped, it is *temporary polarization* in contrast with the so-called *permanent polarization* which arises from a more or less permanent alteration of the surface of the electrodes, and is utilized in the so-called *secondary batteries* or *accumulators*. All the so-called polarization phenomena are secondary effects of the change in the character of an electrochemical system produced by the progressive exhaustion of one or more of the components. As a result of polarization, the normal current furnished by a cell may appear to be weakened owing to the setting up of counter electromotive force; or to the increased resistance of a cell produced by changes in the concentration of the electrolyte or the decomposition of layers of gas on the electrodes. There are three general methods available for counteracting the ill effects of polarization; or for depolarizing a cell:

(1) *Mechanical.*—The electrolyte or liquid about the electrodes is kept agitated so that the gas layer may be brushed off, or the negative electrode may have a roughened surface so that the bubbles of gas can more easily escape from points on the surface.

In **A. Smee's cell** (1840) [1] the platinum plate is replaced by a silver plate covered with finely divided platinum. The idea is to make the hydrogen bubbles collect at the points of the roughened surface from which they escape more freely than from a plain smooth plate. The voltage drop with Smee's cell, however, is comparatively large.

(2) *Chemical.*—The negative plate is surrounded by a powerful oxidizing agent to oxidize any hydrogen which might be formed thereon. The chemical agent employed for this purpose is called a **depolarizer**—*e.g.* nitric acid, chromic acid, manganese dioxide, etc.

W. R. Grove's cell (1839) has a porous pot like Daniell's cell, but the porous pot contains a platinum plate and nitric acid; zinc and sulphuric acid are placed in the outer cell. The hydrogen produced by the action of sulphuric acid on the zinc, instead of accumulating on the platinum plate is oxidized by the nitric acid, and the latter is reduced say symbolically: $H_2+2HNO_3=2H_2O+2NO_2$. Owing to the high cost of platinum J. T. Cooper (1840) proposed to use carbon in place of platinum in Grove's cell, and this modification is generally known as **R. Bunsen's nitric acid cell** (1841).

In **R. Bunsen's dichromate cell** (1875) the zinc and carbon plates dip in a solution of sulphuric acid mixed with chromic acid or an alkali dichromate. The zinc plates are attacked by the solution when the cell is not in use, so that an arrangement is made whereby the zinc plates can be drawn out of the solution when the cell is not being worked. The object of the chromic acid is to "burn" up the hydrogen and prevent its accumulating on the negative carbon plate. The chromic acid is at the same time reduced to chromic oxide, Cr_2O_3. At the zinc plate, therefore: $Zn+H_2SO_4=ZnSO_4+H_2$, and then $3H_2+2CrO_3=Cr_2O_3+3H_2O$. The solution is acidified with sulphuric acid, and consequently the chromic acid forms chromic sulphate, $Cr_2(SO_4)_3$; potassium (or sodium) dichromate is the usual source of the chromic acid, so that chrome alum, $K_2SO_4.Cr_2(SO_4)_3.24H_2O$, usually forms, and this can be partially separated from the zinc sulphate in dark purple crystals. The end stages of the reaction are therefore symbolized: $3Zn+K_2Cr_2O_7+7H_2SO_4+Aq=Aq+3ZnSO_4+K_2SO_4+Cr_2(SO_4)_3+7H_2O$.

In **G. Leclanché's cell** (1868) a zinc rod and carbon plate are clamped between two blocks of compressed manganese dioxide and granulated carbon. This combination is dipped in a concentrated solution of ammonium chloride. When the circuit is closed the ammonium chloride attacks the zinc: $Zn+2NH_4Cl=ZnCl_2+2NH_3+H_2$. The cell does not give a constant current very long, but if left for a short time the accumulated hydrogen is "burnt" by the manganese dioxide: $H_2+2MnO_2=Mn_2O_3+H_2O$, and the cell rapidly recovers. Millions of these cells must be in use where current is required only for a few moments—electric bells, etc.—and the circuit is usually open. There are a great many modifications.

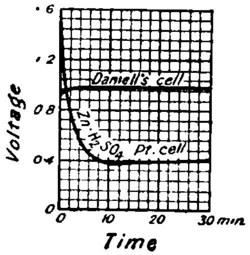

FIG. 9.—Voltage Drop of Voltaic Cells.

(3) *Electrochemical*.—The negative plate is immersed in a solution of a salt of the same metal—*e.g.* a copper plate in a solution of copper sulphate—as in Daniell's cell—is free from polarization because metallic copper is deposited upon the plate, presumably by the hydrogen which would otherwise accumulate on the copper plate. In Daniell's cell, the variation in the electromotive force of the working cell is chiefly due to changes in the concentration of the solution surrounding the battery plates. The electromotive force is therefore nearly constant. This is illustrated by the curve shown in Fig. 9, where a Daniell's cell is allowed to work for half an hour against a resistance of 10 ohms in the external circuit. A comparison of this curve with that of the $Zn|H_2SO_4|Pt$ cell emphasizes the constancy of the current delivered by the Daniell's cell. In Clarke's cell, mercury deposits and zinc dissolves; in Weston's cell, mercury deposits and cadmium dissolves.

Back electromotive force.—Again, if a current exceeding two volts be directed through an electrolytic cell containing dilute sulphuric acid, and fitted with two platinum plates and a galvanometer in circuit, bubbles of gas are disengaged at the two electrodes, oxygen at the anode, hydrogen at the cathode. The direction of the current is indicated by the deflection of the needle of the galvanometer. Now let the battery be cut out of the circuit, and the electrodes immediately joined directly with the galvanometer. The deflection of the needle shows that a feeble current passes in an *opposite* direction to that which occurred when the battery was in circuit. Here, then, when an electric current is passed through a liquid, a counter-e.m.f. is set up, relieving the stress set up by the original current. An examination of the plates of the polarized electrolytic cell shows that gaseous films are present. Obviously, therefore, after a current has passed through such a cell for a short time, the plates—originally quite similar—are no longer alike. The plates are polarized with different gases. The gases adhere to the surface and penetrate the interior of the plates. The plates then behave as if they were made of two different materials. Contact differences of potential are established. We have in fact a voltaic cell, $O_2|H_2SO_4|H_2$, which furnishes a current flowing in an opposite direction to the original current. The cell acts as a kind of "accumulator" of electrical energy until the gases absorbed by the plates are used up. This does not take long. The polarization of the plates of an electrolytic cell thus makes them behave like two different

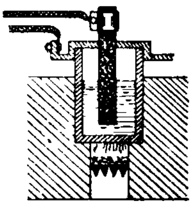

FIG. 10.

metals which exert a *back electromotive force* opposing the electromotive force of the battery. By Ohm's law, the current C (amps.), the resistance R (ohms), and the electromotive force E(volts) of a cell are related $C=E/R$; and if e denotes the back e.m.f. $C=(E-e)/R$.

A high-class steam engine will barely convert 13 per cent. of latent energy of the fuel into useful work; while a high-grade gas engine might convert up to about 35 per cent. of the available energy of the fuel into useful work. There is therefore need for a more efficient and more direct means of converting the chemical energy of the fuel into mechanical energy. Hence, one of the most important of all technical problems is to get the largest possible amount of available energy from the combustion of coal. In the ordinary zinc-platinum cell, 90 per cent. of the available energy of the zinc is converted into electrical current. Zinc is far too costly a fuel for use on a large scale, and hence chemists and physicists have sought a method of obtaining electricity directly from the combustion of carbon or coal. In the so-called *combustion cells*,[2] carbon or some other cheap fuel is transformed into electrical energy by consuming the oxygen of the air at one electrode, and some kind of fuel at the other electrode. A. C. and A. E. Becquerel (1855) tried fusing potassium nitrate in an iron crucible as one electrode and a carbon electrode dipped in the fused nitre as the other electrode. The process was far too costly, and so far, all attempts to dissolve carbon so as to convert the energy of oxidation into electric current have had no real success. In all the proposed cells yet made, including the carbon monoxide cell of W. Borchers and the coke cell of W. W. Jacques, the source of the electric current has been traced not to the primary oxidation of the carbon, but either to a secondary reaction or to a thermoelectric action similar to the development of an electric current when the junction of two dissimilar metals is in a closed circuit.

§ 6. Decomposition Voltages

> During the electrolysis of a mixture of electrolytes those substances are set free which absorb in becoming free the least intrinsic energy, or the lowest voltage.—J. T. Sprague.

Suppose a current of half a volt be sent through the electrolytic cell, containing normal sulphuric acid and fitted with platinum plates in circuit with a galvanometer. The current passes through the cell for an instant as indicated by the "throw" of the galvanometer needle, and then the quick drop to nearly zero. The hydrogen and oxygen developed on the plate sets up a back electromotive force of nearly ½ volt which very nearly stops the current. A minute steady current—**residual current**—does flow through the system, but this is only just sufficient to maintain the polarization, since if no current at all passes through, the plates would gradually depolarize owing to the dissipation of the gases from the plates. If the current be now raised to 1 volt, a similar state of things prevails. The amount of oxygen and hydrogen adhering to the plates increases; and the increased polarization raises the back electromotive force to very nearly one volt. The residual current passing through the cell is slightly larger than before. This is required to maintain the polarization. If the current is now raised to 1·7 volts, the electrodes become saturated with hydrogen and oxygen gases. Polarization reaches a maximum value, and the back electromotive force also attains its maximum value. Hence any further increase in the applied electromotive force is available for electrolysis, 1·7 volts is the minimum needed for steady electrolysis. If 2 volts are passed through the system, there is a back electromotive force of about 1·7 volts, and the "excess" or "residual" current, 0·3 volt, is the effective electromotive force available for the production of current, and the steady evolution of gases from the electrodes.

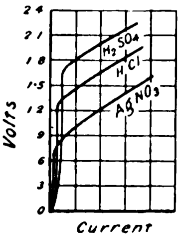

FIG. 11.—Effect of an increasing E.M.F. on some Electrolytes.

The facts here described can be exhibited very concisely by plotting the applied electromotive forces as ordinates and quantities of electricity passing through the system as abscissæ. Fig. 11 shows the results with normal solutions of sulphuric acid, hydrochloric acids, and silver nitrate. The "residual" current flowing through the cell with normal sulphuric acid rises very slowly with increasing voltages until the driving force reaches 1·67 volts. There is then a sudden change in the direction of the curve. Increasing electromotive forces now augment the quantity of electricity passing through the system, and also the amount of electrolysis. Normal hydrochloric acid gives a similar break at 1·31 volts; and silver nitrate, one at 0·70 volt.

The minimum electromotive force required to cause steady electrolysis in any solution is called the **decomposition voltage** or **discharge potential.** The decomposition voltages for a few acids, bases, and salts are shown in Table IV.

TABLE IV.—DISCHARGE POTENTIALS OF SOME ELECTROLYTES.

Salts.		Acids.		Bases.	
N-solutions.	Decomposition voltages.	*N*-solutions.	Decomposition voltages.	*N*-solutions.	Decomposition voltages.
Zinc sulphate	2·35	Sulphuric acid	1·69	Sodium hydroxide	1·69
Nickel sulphate	2·09	Hydrochloric acid	1·31	Potassium hydroxide	1·67
Lead nitrate	1·52	Nitric acid	1·69	Ammonium hydroxide	1·74
Silver nitrate	0·70	Phosphoric acid	1·70		

While the values for the metallic salts vary from metal to metal, the acids and bases have a decomposition voltage approaching 1·7 volts, and the products of the electrolysis are oxygen and hydrogen. Those acids which have a lower decomposition voltage usually give off other products on electrolysis, and attain the final value—1·7 volts—on further dilution. Thus hydrogen and chlorine are evolved when the strength of the hydrochloric acid exceeds $2N$-HCl, and the decomposition voltage of the $2N$ acid is 1·26 volts. The voltage steadily rises with increasing dilution until, with $\frac{1}{32}N$-HCl, the decomposition voltage is 1·69, and hydrogen and oxygen are the products of electrolysis. Not only do the numbers vary with concentration, within certain limits, as exemplified in the case of hydrochloric acid, but also with the nature of the electrodes. The decomposition voltage of normal sulphuric acid, for example, with polished platinum electrodes is 1·67 volts, whereas with platinum electrodes covered with platinum black, the decomposition voltage is 1·07 volts.

The contact potential between metallic zinc and a normal solution of a zinc salt, —0·493 volt, shows that when a zinc ion is deposited on a zinc electrode it conveys a positive charge to the electrode and so lessens the negative charge there present. The system is only in equilibrium when the zinc electrode is negatively charged to a potential of −0·493 volt. If, therefore, zinc is to be deposited in an electrolytic cell, this difference of potential must be counterbalanced by the current. Hence contact differences of potential may also be regarded as decomposition voltages.

The discharge potentials of a few anions and cations are indicated in Table IV, which may be compared with Tables II and III. The numbers refer to normal solutions. The prefix refers to the electrical state of the electrode in the presence of a normal solution of its ions, say, 32·5 grams of zinc per litre. Some of the numbers have not been measured directly. For instance, the number of zinc sulphate has been obtained by extrapolation, since, according to the conductivity measurements, only 23 per cent. of zinc sulphate is ionized in normal solutions.

TABLE V.—DISCHARGE POTENTIALS OF SOME ANIONS AND CATIONS.

Cations.	Charge on metal points.	Anions.	Charge in volts.
$Zn^{\cdot\cdot}$	−0·493	I'	+0·797
$Fe^{\cdot\cdot}$	−0·063	Br'	+1·270
$Ni^{\cdot\cdot}$	+0·049	O'' (in acid)	+1·396
$Sn^{\cdot\cdot}$	+0·085	Cl'	+1·694
$Pb^{\cdot\cdot}$	+0·129	OH' (in acid)	+1·96
$H^{\cdot}$	+0·277	OH' (in bases)	+1·16
$Cu^{\cdot\cdot}$	+0·606	NO_3'	+1·75
$Hg^{\cdot\cdot}$	+1·027	SO_4''	+1·9
$Ag^{\cdot\cdot}$	+1·048	HSO_4'	+2

Just as different electrical pressures (e.m.f.) are needed to produce in different solutions equivalent amounts of chemical change, so different chemical reactions in a voltaic cell generate different amounts of electrical energy, and produce currents with different electromotive forces. During electrolysis a difference of electrical pressure must be continuously supplied because the current is consumed, so to speak, by the separation of chemically equivalent quantities of matter (Faraday's law). In a voltaic cell electrical energy is produced, so to speak, from the chemical energy of the dissolving zinc. The question **whether or not a given supply of electrical energy can start electrolysis is determined by the intensity pressure, or voltage of the current.** The total supply of available electrical energy does not matter. Although a given quantity or electricity, say 96,540 coulombs, will separate chemically equivalent quantities of different electrolytes, these 96,540 coulombs must be supplied at definite pressures before electrolysis can take place. In other words, just as different compounds decompose at different temperatures, and this quite independent of the total quantity of available heat, so electrical energy at different voltages is needed for the decomposition of different electrolytes.

Current density.—If the cathode be small in comparison with the anode, the solution about the former will be very much more quickly exhausted than if a larger cathode had been used. The decomposition voltage of the substance will rise in a proportional manner. Hence, the larger the cathode the lower the "average" electromotive force needed for the decomposition of the pure metal. It is convenient to call the quantity of electricity flowing through the unit surface area, the current density at the electrode, in other words, "the number of ampères per unit surface." "Unit surface" is usually taken in the laboratory to be one square decimetre. The symbol $ND_{100}=\frac{1}{2}$ means that a current of 0·5 amp. flows for every 100 sq. cm. of electrode surface.

EXAMPLE.—What was the current density at each electrode of an electrolytic cell when 4 sq. cm. of each electrode was immersed in the electrolyte, and a current of 4·25 amperes was passed through the system for one hour? One square decimetre = 100 sq. cm. Hence, 1·0625 amps. passed per sq. cm.; or 106·25 amps. per sq. decimetre. The current density at the anode was therefore 106·25 amps., or $ND_{100} = 106\cdot25$.

Current density is one of the most important factors in electrolysis, since it determines the character and nature of the products obtained at the different electrodes. Thus, by using a large current density and a concentrated solution of sulphuric acid, hydrogen, oxygen, ozone, and free sulphur can be obtained, whereas under ordinary laboratory conditions the last substance does not appear.[1]

§ 7. Gas Cells

The term gas cell is applied to cells devised in 1839 by W. R. Grove[1] in which gases are dissolved in inert electrodes, which are then treated as if they were electrodes consisting of the gases alone—one gas may be hydrogen and the other oxygen or chlorine, or even hydrogen at a different pressure. In the first case, water is produced; in the second, hydrogen chloride; in the third, hydrogen passes from the electrode, where it is at the greater pressure to that where it is at the less. Such a cell with platinum electrodes is shown in Fig. 12. The e.m.f. of the cell is very irregular; a day or two after the preparation it approximates 1·08 volts in nearly all electrolytes, although higher voltages have been observed by F. G. Smale, T. N. M. Wilsmore, and E. Bose. Some days later the voltage falls below the value just indicated. According to theory, the potential difference between the two poles should be constant, 1·231(±0·001) volts (17°) in all electrolytes. In his review of the potential of the oxygen electrode, E. P. Schoch has pointed out that the value 1·08 volts cannot be due to the maximum e.m.f. of the gases, *i.e.* the potential with which the action of the poles is reversible. If the cell be reversed, by discharging oxygen at the poles by electrolysis, the gases are not evolved at a potential slightly greater than 1·231 volts; instead, a potential difference exceeding 1·5 volts must be applied before any current greater than those due to diffusion, convection, etc., will pass, and the evolution of gases occur.

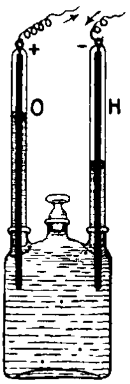

FIG. 12.—W. R. Grove's Oxygen-Hydrogen Gas Cell.

The hydrogen electrode is quite reversible in its action, and its potential is independent of the metal used in its production, and can be obtained in all kinds of electrolytes, all the observed irregularities must be due to the oxygen electrode. The work of F. Förster, E. Müller, R. Lorenz, L. Wöhler, and R. Ruer has shown that the irregularities with the oxygen electrode are due to the oxidation of the electrode.

The discharge potential of an ion is determined by the opposing potential of the electrode; thus, to discharge oxygen or hydrogen at an electrode devoid of any electrochemical activity requires but a small e.m.f., but if the respective electrodes be charged with these gases the e.m.f. required is over one volt. If the products of the electrolysis react with the electrodes, then the discharge potential is determined by the nature of the film formed at the surface of the electrode. Thus, the discharge potential of chlorine at an inert electrode, say, graphite, is quite different from its value at a silver electrode because silver chloride is formed; similarly, oxygen gas is liberated at a lower potential at platinum than at a lead electrode, because in the latter case lead dioxide is formed; R. Luther and F. J. Brisbee found the discharge-voltage of chlorine from hydrochloric acid at a polished platinum electrode is higher than is required for the discharge of chlorine from platinum electrodes, possibly because of the formation of a film of some product on the surface of the electrode; and E. P. Schoch found evidence of the formation of a hydride on the surface of iron or nickel electrodes. In cases of this kind, the main process is irreversible because the extra potential entails a loss of free energy. Hence, the term discharge potential may have two meanings, one refers to the reversible, the other to the irreversible process; it usually has the former meaning.

G. Preuner showed that with the gas cell Pt|H|H_2O|O_2|Pt, when the pressures of the gases at the electrodes are each one atmosphere, and the hydrogen electrode the partial pressure of the hydrogen in saturated water vapour are respectively reduced to p_1 and p_2, the e.m.f. E is

$$E=\frac{RT}{2}\log\frac{1}{p_1}+\frac{RT}{4}\log\frac{1}{p_2}\text{; or } E=\frac{RT}{4}\log\frac{1}{p_1^2p_2}$$

W. Nernst and H. von Wartenberg calculate at 290° K., $p_1=0{\cdot}0191\times1{\cdot}80\times10^{-27}$ atm. and $p_2=\frac{1}{2}p_1$; hence, $E=1{\cdot}2322$ volts (17°); in agreement with this value, J. N. Brönsted and G. N. Lewis respectively obtain 1·224 and 1·234 volts. The difference between these theoretical values and the observed lower value 1·15 is attributed to the observations being made on what virtually amounts to a platinum oxide, not platinum electrode. T. N. M. Wilsmore calculated $dE/dT=-0{\cdot}00121$; F. J. Smale found $-0{\cdot}00142$.

When a gradually rising e.m.f. is applied to platinized electrodes in dilute sulphuric acid or sodium hydroxide, only small currents of the order of diffusion currents pass, the potential of the anode rises rapidly until it passes 1·50 volts, when bubbles of oxygen appear; the anode potential still rises but less rapidly than before. If it were a reversible electrode, which had turned its reversible point at 1·50 volts, the current voltage curve would not have risen but continued nearly parallel to the current axis. The polarization potential also increases steadily with time so long as the current is continuous, but there is no indication of a definite maximum for a particular current density. This polarization is due to a specific surface attraction between the platinum and the gas, as H. G. Möller showed to be the case with hydrogen, because (i) the range of potential extending to nearly three volts is too great, and (ii), as F. Förster showed, the platinum is able to function at a low or high potential which would require the assumption of an arbitrary change in the absorption power of the gas. The effect is also incompatible with the difference of potential being caused by a resistance film. In this manner, E. P. Schoch argues that the potential rise requires that the active substance formed on the anode have a physical form which can change its concentration continuously. Again, if a single solid were formed, the potential would remain practically constant; and it is assumed that the material which is formed should be dissolved by the remainder of the electrode so that it exhibits an increase of potential corresponding with the increased concentration.

When the polarized oxygen electrode is left at rest, the self-discharge results in a continuous decrease in the e.m.f. until a potential difference of 1·08 volts is attained, the potential retains this value for some time—steady state—and afterwards falls to still lower values. R. Lorenz found that, unlike the platinized platinum electrode investigated by F. Förster, a polished platinum electrode exhibits a large number of abrupt changes during its discharge. The halting stages, so to speak, occur at 1·3, 1·05, 0·94, 0·74, 0·64, 0·57, 0·43, 0·27, 0·12, 0·05, and 0·008 volts. This is supposed to correspond with the formation of definite oxides, with different potentials. Generally, however, the step-by-step discharge is not shown because the drop of potential during discharge is continuous. F. Förster showed that the self-discharge of an iridium anode is quite analogous to that of the platinum anode, but the drop is rather more rapid and it falls to 0·865 volt. The behaviour of lead is rendered familiar through the accumulator; and F. Streintz studied the different potentials exhibited by the hydrated lead oxides. The nickel oxide anode in alkaline solutions has been studied by F. Förster in connection with the nickel accumulator; J. Zedner, and F. Förster and V. Herold the iron electrode; E. Müller studied the copper anode in alkali lye; and R. Lorenz has shown that oxygen gas electrodes, with the metals lead, silver, nickel, copper, iron, and zinc, exhibit potentials analogous to those shown by their oxides. The two metals usually regarded as non-oxidizable by gaseous oxygen are therefore supposed to be oxidized, and to owe their potential to the presence of oxides. In general, therefore, (1) During the discharge of "oxygen yielding" anions all metal electrodes are oxidized. (2) The potential of the electrode is that of the oxide irrespective of any (adsorbed) oxygen gas also present. (3) The oxides specifically determine the potentials with which oxygen is evolved. (4) The amount of an oxide that must be actually present to give all characteristic effects may be less than is optically perceptible. (5) Oxygen gas does not appear to be directly electromotively active.

The oxides PtO, PtO_2, PtO_3, with several hydrated forms, were prepared by L. Wöhler, and R. Lorenz determined the potentials of the different oxides used as anodes as well as the potential at which the steady state occurs during the discharge of the platinum anode.

	Oxide potential.	Potential during steady state.
$PtO_2.4H_2O$	0·93	0·94
$PtO_2.3H_2O$	0·86	—
$PtO_2.2H_2O$	0·74	0·74
$PtO_2.H_2O$	0·63	0·64
PtO_2	0·53	0·57
$PtO.2H_2O$	0·45	0·43
$PtO.H_2O$	0·34	—
PtO	0·25	0·27

The value for PtO_3 has not been measured because it decomposes so rapidly, but it is supposed to lie above 0·43, and it is therefore thought to be the oxide to which all higher potentials are due. For potentials above one volt, R. Lorenz believes the different potentials are due to a number of distinct oxides or hydrates, while F. Förster attributes them to the formation of a solution of a higher oxide in the material of the electrode.

F. Förster and E. Müller believe that the evolution of oxygen from the oxygen electrode is a secondary effect, due to the formation and decomposition of a higher oxide; if this means that oxygen is not evolved except through such action, it is not in agreement with G. Schulze's observation that the formation of oxygen also occurs while other oxides are present which are not capable of such decomposition—*e.g.* alumina, magnesia, etc.

§ 8. The Relation between Electrical and Thermal Energy

No chemical development will be satisfactory and permanent unless erected on a thoroughly physical basis.—O. J. LODGE (1885).

The total amount of electrical energy required for the liberation of chemically equivalent quantities of different electrolytes can be approximately determined by multiplying 96,540 coulombs (or one farad) of electricity by the voltage needed for electrolysis. Hence, the decomposition voltage is proportional to the energy needed for the decomposition of a gram equivalent of a given electrolyte, and the product of the quantity of electricity into its electromotive force not only representing the energy of a battery, but it also measures the chemical energy which was transmuted into electrical energy by the battery. As previously indicated, a **joule,** the unit of electrical energy, is numerically equivalent to the product of one volt into one coulomb. The amount of heat evolved when a given compound is decomposed can be measured and the minimum amount of electrical energy required to decompose a given compound must be at least equivalent to the amount of heat developed when the separate substances re-unite to form the original compound. Measurements show that a joule is equivalent to 0·24 calorie of thermal energy; and a calorie is equivalent to 4·2 joules. Hence, just as thermochemistry writes $Na+Cl=NaCl+97,900$ cals., so electrochemistry writes $Na+Cl=NaCl+411,000$ joules. As a first approximation, it may be assumed that the heat of formation of any given compound is a measure of the thermal equivalent of the electrical energy required to break up the compound by electrolysis.

From the first law of thermodynamics, the law of the equivalence of the different forms of energy, if the work W ergs done by an electric current be wholly expended in decomposing a substance, $W=JQ$, where Q cals. denotes the thermal equivalent of the electrical energy, and J is a numerical conversion factor required, to make the units of work and heat comparable. Here $J=42\times10^6$ because one calorie is nearly equivalent to 42×10^6 ergs or 4·2 joules. By definition, the work done in a circuit per unit of electricity conveyed is $W=EC$; and from the definition of electrochemical equivalent $m=eC$. Again, the heat q liberated during the formation of one gram of a compound from the radicles into which it has been decomposed by a current in $q=Q/m$ provided none of the energy remains in any form other than heat. Substituting these values of Q, m, and W in $W=JQ$, there remains $E=Jeq$, which is a symbolic form of the statement that the electromotive force required to decompose a substance into given constituents is equal to the product of the heat of formation of a gram equivalent to the substance and the number of joules per calorie; or $E=4{\cdot}2eq$ joules.

EXAMPLE.—The heat of formation of sodium chloride is 97,900 calories: what is the equivalent electrical energy needed for the electrolysis of a gram equivalent of the fused salt, and what is the decomposition voltage required? Here, 97,900 calories are equivalent to $97,900\times4{\cdot}2=411,000$ joules. But 96,540 coulombs will liberate chemically equivalent quantities of sodium and chlorine, and 411,000 joules are needed for this purpose. Consequently, since electrical energy = volts × coulombs; 411,000 = volts × 96,540; or volts = 4·3. This means that in order to liberate 23 grams of sodium and 35·5 grams of chlorine from 58·5 grams of fused sodium chloride, 411,000 joules of electrical energy must be supplied at a minimum voltage electromotive force of 4·3 volts. The minimum voltages so calculated are usually a little higher than are needed in practice. It will be observed that this arithmetic is summarized in the formula: volts = 0·043 × Cals. Where Calories are employed to represent the heat developed in the reaction of an equivalent weight of a given compound expressed in grams, the equivalent of water is half the molecular weight in grams, the equivalent of aluminium chloride is one-third the molecular weight expressed in grams.

The computation of the electromotive force of various battery cells from the heat of combination of the "elements" of the cell has been of great value in technology. It is commonly assumed that the electrical energy which a battery can supply may be calculated directly from the thermochemical data. According to the old observation of Lord Kelvin (*ante* W. Thomson),[1] the electrical energy which can be obtained from a galvanic element is equivalent to the thermal value of the chemical processes producing the current when the current is not doing any special work in the circuit—**Kelvin's rule.** In illustration, the thermal value of the reaction in a Daniell's cell is $Zn+CuSO_4=Cu+ZnSO_4+50{\cdot}11$ Cals. That is to say, every gram-atom of zinc dissolved in the reaction is attended by the evolution of 50·11 units of heat. Every gram-atom of bivalent zinc carries in the cell $2\times 96{,}540=19{,}300$ coulombs of electricity. The electromotive force developed during the action is 1·096 volts. Hence the thermal equivalent of the electrical energy developed by the dissolution of one gram-atom of zinc in Daniell's cell is $0{\cdot}24\times 1{\cdot}096\times 2\times 96{,}540=50{,}000$ cals., provided the electrical energy produced is equal to the chemical energy used up. The difference between the thermal value of the chemical processes and the thermal value of the electrical energy derived from the cell is 50·11 and $50{\cdot}00=0{\cdot}11$ Cal. The two quantities differ by about one-fourth per cent.; the difference is within the range of experimental error, and Kelvin's rule, cited above, is valid. J. P. Joule immersed a cell in a calorimeter, and its outer circuit in another, and he found that the heat energy of the cell can be made to appear in the outer circuit. Further experiments showed that some cells directly heat and others directly cool themselves.

As a matter of fact, observation shows that cells sometimes furnish more, and sometimes less energy than corresponds with the thermal data, and the difference between the thermal values of the chemical process and the electrical energy exceeds the limits of experimental error; thus, with the $Pb : Pb(NO_3)_2 : AgNO_3 : Ag$ cell the difference is -16 per cent.; with Pb : lead acetate : copper acetate : Cu the difference is nearly $+15$ per cent. The assumption that the electrical energy derived from a cell is equivalent to the heat of the reaction of the components of the cell, is one of the half truths illustrated further by Berthelot's law of maximum work. The electrical energy is equivalent to the free energy, and that alone is a measure of the maximum work obtainable from a chemical reaction.

If the cell in which the electrical energy is being produced rises in temperature, less electrical energy than is represented by Kelvin's rule will be obtained, because part of the chemical energy may also be converted into heat in working against the resistance of the cell; and a correction factor is required to allow for the energy dissipated in this way. Conversely, if a cell becomes cooler while it is working, more than the calculated quantity of electrical energy might be expected from the cell. Only when the working cell suffers no change of temperature is the electrical energy produced equal to the chemical energy expended. Similar remarks, *mutatis mutandis*, apply to the reverse action during electrolysis. In electrolyzing fused cryolite, for example, J. Hopkinson obtained but 60 per cent. of the amount of aluminium corresponding with the electrical energy expended. In addition, some energy may be expended during electrolysis in overcoming polarization, in secondary chemical reactions, etc. Suppose that the temperature changes ever so little, say dT, while the cell is working, there will be a corresponding change, dE, in the electromotive force of the cell; let q denote the amount of heat absorbed or evolved when a gram-equivalent of the electrolyte is decomposed. Let the cell be placed in a bath maintained at a constant temperature, the units of heat must be added to or given up by the cell if its temperature is kept constantly at T°. If S and T respectively denote the capacity and intensity factors of thermal energy, while C and E denote the corresponding factors of electrical energy, then $q=ST$, and $\epsilon=CE$, and when the two forms of energy are in equilibrium, $CE=ST$, and when T and E change as indicated above, $C(E+dE)=S(T+dT)$, or $CdE=S.dT$, and by substituting $q=ST$, we get

$$C.dE=Q\frac{dT}{T}, \quad \text{or} \quad q=CT\frac{dE}{dT} \quad . \; . \; . \; . \; . \; . \; . \quad (1)$$

This expression represents the change in the thermal value of the electrical energy of a cell at T° when the temperature changes dT during the working of the cell, and the electromotive force increases by dE per degree rise of temperature. The factor dE/dT is called the **temperature coefficient of a cell,** and it is usually evaluated by measuring the electromotive force of the cell at two different temperatures.

EXAMPLE.—The e.m.f. of a cell at 0° was 0·1483 volt; and at 43·3°, 0·1846 volt. Hence, the increase in the e.m.f. per degree is $(0{\cdot}1846-0{\cdot}1483)\div 43{\cdot}3=+0{\cdot}000838$ volt $=dE/dT$.

If one farad of electricity be passed through a reversible cell, and it is found necessary to apply q calories of heat in order to maintain the temperature constant, the electrical energy which would be furnished by the cell working in the opposite direction will be equivalent to the thermal value of the reaction, $Q+q$, or expressed in suitable units, electrical energy $=Q+q$. Substituting the value of q obtained in (1) above, and electrical energy $e=CE$, we get $CE=Q+CTdE/dT$, or

C = NF

$$e=Q+CT\frac{dE}{dT};\quad \text{and}\quad E=\frac{Q}{C}+T\frac{dE}{dT}$$

This is called the **Gibbs-Helmholtz equation**—after J. W. Gibbs (1878) and H. von Helmholtz (1882). The equation shows that in order to calculate the electromotive force E of a galvanic element, from Q, the thermal value of the chemical processes which occur during the working of the cell, it is necessary to know the temperature coefficient showing the variation of e.m.f. with temperature. By measuring the electromotive force E and the temperature coefficient dE/dT of a zinc-iodine combination, A. P. Laurie (1885)[2] was able to estimate the heat of combination of these two elements.

1. *If the temperature coefficient of a cell be negligibly small,* dE/dT may be taken as zero, and **Kelvin's equation** $E=Q/C$ remains. Hence, Kelvin's rule indicating the relation between the equality of the thermal and electrical energy of a cell is a limited equation which is valid only when the electromotive force of the cell does not change with variations of temperature. This is nearly the case with the Daniell's cell, and in consequence, the electromotive force calculated from the thermal value of the reactions in the cell is nearly equal to the observed value.

EXAMPLES.—(1) Assume the temperature coefficient of Daniell's cell is zero, and the heat of the reaction 50,110 cals.; then 50,110 calories equal $50{,}110\div 0{\cdot}24=209{,}900=Q$ joules; and $C=2\times 96{,}540$. Hence, $E=1{\cdot}087$ volts; the observed voltage is 1·096.

(2) According to F. Haber and S. Tolloczko (1904) the thermal value of reaction in the AgCl : CuCl cell is $\mathrm{Cu}+\mathrm{AgCl}=\mathrm{Ag}+\mathrm{CuCl}+3500$ cals., and at 200° the temperature coefficient of the cell is zero. Show that the calculated e.m.f. is accordingly 0·151 volt. (The observed value is 0·149 volt.)

2. *If the temperature coefficient of the cell* dE/dT *be negative,* the electromotive force will diminish with rising temperature, and the electrical energy derived from the cell will be less than that computed from the thermal energy. The cell will therefore become hot while it is working. This does not refer to heat due to the internal resistance of the cell. L. Clark's cell has a temperature coefficient of —0·0012345 volt per degree at about 18°.

EXAMPLES.—(1) Show that the e.m.f. of the oxyhydrogen cell is $1{\cdot}075+0{\cdot}0014\theta$ when $H_2+O=H_2O+67{,}520$ cals., and the temperature coefficient of the cell is $-0{\cdot}0014$ volt per degree.

(2) The reaction in a Clark's cell evolves 340,000 joules. Show that the temperature coefficient of the cell is $-0{\cdot}00114$ when the e.m.f. at 18° is 1·429.

(3) According to G. N. Lewis and C. A. Kraus (1910), the difference of potential of a cell with sodium and 0·206 per cent. sodium amalgam as electrodes in a solution of sodium iodide in ethylamine is 0·8456 volt at 25°, and the temperature coefficient $-0{\cdot}0000408$ volt per degree. Hence calculate the heat evolved during the solution of one equivalent of sodium in an excess of the 0·206 per cent. amalgam. Substitute in Helmholtz's equation, C is the Faraday equivalent $=96{,}540$ coulombs; $E=0{\cdot}8456$; $dE/dT=-0{\cdot}0000408$; $T=25+273$. The result furnishes $Q=82{,}850$ joules; and since one joule is equivalent to 4·186 cals., the thermal value of the process is nearly 19,800 cals.

3. *If the temperature coefficient of the cell dE/dT be positive,* the electromotive force of the cell will increase with rise of temperature and the electrical energy of the cell will be less than that computed from the thermal value of the chemical processes, and heat will be abstracted from the surrounding objects in order to maintain the temperature of the cell constant. Such a cell will become colder in action.

Examples.—(1) The slight discrepancy between the observed and calculated values of the electromotive force of Daniell's cell indicated in a preceding example is due to the small but measurable positive temperature coefficient of the cell, for $dE/dT = +0·000034$ vol. per degree at 15°. If this factor be introduced into the previous calculation for the cell working at about 15°, $T = 280°$ K., we must add $0·000034 \times 288$ to the 1·087 volts obtained in the previous computation. This furnishes 1·096 volts; the observed value is 1·092 volts.

(2) According to F. Haber and S. Tolloczko (1904), the thermal value of the reaction $Pb + 2AgCl = PbCl_2 + Ag + 24$ Cals. The temperature coefficient is +0·152 millivolt per degree at about 250°. What is the calculated e.m.f. of the lead chloride : silver chloride cell ?

The self-cooling of a working cell has been compared with the self-cooling of a freezing mixture, or of a jet of compressed gas.

§ 9. Fractional Electrolysis—G. Magnus' Rule

During the electrolysis of a number of mixed electrolytes, there is a selective power at the electrodes which is based solely on the ratio of the voltage required to free the several ions.—J. T. Sprague.

When a solution containing salts of different metals is subjected to electrolysis, there is a certain voltage at which one and only one of the metals will be deposited on the cathode—**G. Magnus' rule** (1856). If a mixed solution of nickel and copper sulphates, for example, be subjected to electrolysis, copper alone is precipitated when the applied electromotive force has reached 1·29 volts ; the nickel is not precipitated, since its decomposition voltage is 1·95 volts. On the other hand, if a mixture of nickel and iron sulphates be similarly treated, a mixture of iron and nickel will be simultaneously deposited. The decomposition voltage of these salts are too close to allow an effective separation of the two elements by electrolysis. Hydrogen is also evolved during the electrolysis of these salts. This arises from the fact that the decomposition voltage of sulphuric acid—1·67 volts—renders it also susceptible to the influence of the same current as liberated nickel and iron.

Many useful methods of analysis are based upon these principles. In metallurgy, too, electrolytic processes for refining metals—nickel, copper, lead, tin, silver, gold, etc.—have been developed. For example, in copper refining, as we shall soon see, anodes made of crude copper are dipped in a solution of copper sulphate acidified with sulphuric acid ; the cathodes are sheets of pure copper. Zinc, iron, and copper from the anode pass into solution during electrolysis. The decomposition voltage is kept below that needed for the deposition of zinc and iron. In consequence, refined copper is deposited upon the cathode. Other impurities affecting the crude copper are but slightly soluble in the electrolyte, and are deposited about the anode as a thin mud—*anode mud.*

The effect of concentration on the decomposition voltage.—The decomposition voltage of an electrolyte is greater the more dilute the solution. The concentration of any given salt about the electrode naturally decreases during the process of electrolysis. Hence also the decomposition voltage for that particular salt in the mixed electrolyte also increases. When the concentration of the copper sulphate in a mixture of copper and nickel sulphates has become so small that the decomposition voltage of the dilute solution approaches that of nickel, any further electrolysis will bring down a mixture of both metals. There is, therefore, a limit to the process of electrolytic separation, just as there is a limit to the separation of substances in ordinary analysis. The limit in the former case is determined by the decomposition voltages of the respective metals; and in the latter case, the limit is determined by the solubility of the precipitates in the given menstruum. The limiting concentration can be approximately estimated from the rule: A decrease of one-tenth in the concentration of the electrolyte raises the decomposition voltage of any given ion $0·058/n$ volt, where n is the valency of the particular ion.

As the cation is deposited about the cathode, the loss in concentration is made up by diffusion from the surrounding electrolyte. To hasten diffusion, and prevent undue attenuation of the electrolyte in the vicinity of the cathode, stirring by rotating one of the electrodes is sometimes used.
