W. Biltz and W. Stollenwerk found the heat of formation, Q, of the triammine is 8·64 Cals., and the vap. press. is given by $\log p = -Q/4{\cdot}57T + 1{\cdot}75 \log T - 0{\cdot}0028T + 3{\cdot}3$. Silver bromide dissolves readily in conc. aq. soln. of *ammonia;* according to A. Longi, for conc. between 0·08 and 0·45 mol per litre, the solubility is proportional to the conc. of the ammonia; 100 c.c. of 0·5 per cent. aqua ammonia (sp. gr. 0·998) dissolve 0·0113 grm. of silver bromide, and of 10 per cent. ammonia (sp. gr. 0·96), 0·333 grm. J. J. Pohl says that freshly precipitated silver bromide is twice as soluble as the dried salt; this is probably a question of rate of soln. J. V. Elsden noted the formation of a complex ammino-bromide. According to G. Bodländer and R. Fittig, the ammoniacal soln. contains complex ions. P. Berthier obtained a pale yellow powder by cooling a hot soln. of silver bromide in conc. aqua ammonia: when treated with water it gradually forms white silver bromide. According to R. Jarry, and A. Joannis and M. Croizier, **silver sesquiammino-bromide,** $2AgBr.3NH_3$, is obtained when the temp. of silver triammino-bromide is allowed to rise between 3·5° and 34°. Dry silver bromide in an atm. of ammonia slowly forms this same compound. G. Wiegner, and W. Peters say $AgBr.2\frac{1}{2}NH_3$ is formed. According to R. Auerbach, the addition of just enough ammonia to satisfy the reversible equation $AgBr + 2NH_3 \rightleftharpoons [Ag(NH_3)_2]Br$ does not cause either precipitation or re-soln. within five minutes. With slight but increasing excess amounts of ammonia, the coagulation speed transcends the soln. speed and then the reverse.

C. F. Rammelsberg said that silver bromide does not absorb ammonia gas, but, according to R. Jarry, he was misled by the slowness of the absorption. According to G. Bodländer, J. von Liebig obtained what was probably this compound in white crystals by allowing an ammoniacal soln. of silver bromide to stand some time. According to A. Terreil, if silver bromide sat. with gaseous ammonia is heated in a sealed tube, fusion occurs at 90°, and an explosion at 100°. The dissociation temp. of silver sesquiamminobromide is between 34° and 35°; and the dissociation press.

0°	4°	10·4°	11·2°	14°	16·6	28·6°	43·8°	53°
88	107	166	174	206	269	513	1225	1986 mm.

The ammino-bromide forms yellow crystals, which are not sensitive to light; they become turbid in ammonia-free water, and are opaque after heating to 70°. They show double refraction between crossed nicols. According to W. Biltz and W. Stollenwerk, Q for the sesquiammine, $AgBr.1\frac{1}{2}NH_3$, is 9·95 Cals., and $\log p = Q/4{\cdot}57T + 1{\cdot}75 \log T - 0{\cdot}0020\,T + 3{\cdot}3$. When the temp. of silver sesquiamminobromide lies between 34° and 51·5°, **silver ammino-bromide,** $AgBr.NH_3$, is formed. Above 51·5° it decomposes into silver bromide and ammonia. W. Biltz and W. Stollenwerk found that the heat of formation, Q, of the monammine is $Q=10{\cdot}65$, and $\log p = -Q/4{\cdot}57T + 1{\cdot}75 \log T - 0{\cdot}0015T + 3{\cdot}3$. According to G. C. Wittstein, silver bromide is soluble in hot soln. of *ammonium chloride*, sparingly soluble in soln. of *ammonium carbonate, sulphate*, or *succinate;* and very sparingly soluble in soln. of *ammonium nitrate.* H. Euler,[14] and B. Wuth have investigated the solubility of it in *ethylamine.* According to J. Neustadt, *methyl alcohol* dissolves $1{\cdot}12 \times 10^{-15}$ and *ethyl alcohol* $6{\cdot}4 \times 10^{-16}$ mol. of silver bromide per litre. F. Bezold finds it insoluble in *methyl acetate* and M. Hamers in *ethyl acetate.*

Chemical properties of silver bromide.—The remarks on the photochlorides and subchlorides apply also to the photobromides and subbromides. H. W. Vogel[15] prepared a grey precipitate which he regarded as **silver subbromide,** Ag_2Br, by the action of cuprous bromide on silver nitrate; but K. Emszt, and J. Waterhouse showed that the product is more likely to be a mixture of metal and normal bromide.

White silver bromide becomes violet in a few seconds when exposed to light. The phenomenon resembles that which occurs with silver chloride, and which has previously been discussed. The latent image with silver bromide photographic plates has also been discussed. W. Ehlers and P. P. Koch[16] found that particles of colloidal silver bromide with an average diameter of $0{\cdot}4\mu$, lose 6 per cent. of bromine when illuminated for 20 minutes by an arc lamp. B. Homolka assumed that because indoxyl or thioindoxyl developer is oxidized during the development of the exposed plate, a **silver perbromide,** $AgBr_2$ or $AgBr_3$, is present in the latent image. As W. D. Bancroft has shown, this assumption is quite unnecessary, because as the silver bromide is reduced, the developer must be oxidized, and the oxidation will be greatest in those parts where the reduction of the silver bromide is greatest. L. Bruner and E. Bekier, however, obtained indications of the formation of silver perbromide during the electrolysis by means of a silver anode, of molten bromine iodide, BrI, containing an excess of bromine.

Several observers have suggested that **silver oxybromide** is formed during the development of the latent image on a photographic plate. Thus, E. Demole[17] supposed AgBrO is formed by the action of potassium ferricyanide soln., and that this is reduced by hydroquinone. A. and L. Lumière and A. Seyewetz also supposed the oxybromide AgBr.O.AgBr to be formed by the action of an aq. soln. of benzoquinone and potassium bromide on silver bromide paper. A. Seyewetz has also prepared crystals of what he regarded as an oxybromide Ag_7Br_7O, or $Ag_2O.Ag_5Br_7$, by the action of a soln. of silver bromide in benzoquinone on finely divided silver.

Dry silver bromide, says J. S. Stas,[13] suffers no appreciable change when heated to 100°, and, according to I. Guareschi, even when heated to its m.p., no bromine is given off; according to K. Arndt and A. Gessler, decomposition begins about 900°. The molten salt is slightly ionized. G. Schulze calculates the degree of ionization at 450° to be $2{\cdot}34 \times 10^{-4}$, and **oxygen** likewise was found by M. Berthelot to have no action on hot silver bromide. A. P. H. Trivelli says that 30 per cent. **hydrogen peroxide** has no appreciable action on silver bromide alone, nor in the presence of colloidal silver. I. Guareschi found **chromic anhydride** gives off bromine and oxygen when heated with silver bromide, forming chromic oxide and silver; in some cases, chromyl bromide, CrO_2Br_2, is formed: $2AgBr + CrO_3 = 2Ag + O + CrO_2Br_2$. With conc. soln. of chromic acid some silver chromate is formed. A. Potilitzin found it to be slowly reduced when heated in **hydrogen.** A. Seyewetz reduced molten silver bromide to spongy silver by hydrogen; and A. Jouniaux has studied the equilibrium conditions of the reaction $2AgBr + H_2 \rightleftharpoons 2Ag + 2HBr$.

D. Tommasi has proved that although nascent hydrogen from **sodium amalgam** does not reduce silver bromide, the reduction readily occurs with electrolytic hydrogen, and A. J. Balard found silver bromide to be readily reduced by **zinc** and sulphuric acid. J. S. Stas showed that grey or reddish-brown metallic silver is produced with white silver bromide, and white metallic silver with the yellow bromide. H. Vogel found that **iron** or zinc acts very slowly on dry silver bromide, more rapidly if moist, and more rapidly still in the presence of dil. acids. J. Seymour found silver bromide to be reduced by **sodium hypophosphite** (L. Cramer says not) or alkaline **stannous chloride** in light or when heated, but not by acid soln. of stannous chloride; **ferrous sulphate** in sunlight is without action.

H. Moissan found that the bromine in silver bromide is displaced by *fluorine.* P. Berthier also found that when suspended in water, silver bromide is completely converted by **chlorine** into silver chloride. According to J. J. Berzelius, silver bromide is transformed by chlorine into silver chloride more slowly than is the case with silver iodide. **Iodine** vapour also, according to P. Julius, converts silver bromide completely into the iodide. P. Hautefeuille found that dry hydrogen chloride converted silver bromide at 700° into the chloride: $AgBr+HCl=AgCl+HBr$, the analogous change which takes place in soln. is supposed by M. Berthelot to involve the intermediate formation of a bromohydrate. A. Potilitzin has investigated the action of soln. of the **chlorides of the alkalies and alkaline earths** on silver bromide whereby a partial interchange of the halogens occurs, and he obtained similar results with the **alkali iodides.** A. Senier precipitated silver bromide from its ammoniacal soln. by the addition of silver chloride. Aq. **hypochlorous acid,** said A. J. Balard, converts silver bromide into a mixture of silver chloride and bromate with the simultaneous evolution of chlorine and bromine. H. Baubigny found **iodic acid** acts on an ammoniacal soln. of silver bromide, forming silver iodide, ammonium iodide, iodine, ammonia, water, and nitrogen.

According to C. Sandonnini and G. Scarpa,[19] **lithium bromide** gives a series of mixed crystals but no compound with silver bromide when mixtures of the two salts are thermally investigated. Similar results were obtained with **sodium bromide.** If silver bromide be dissolved in a hot sat. soln. of **potassium bromide,** and the soln. cooled, M. Berthelot found that crystals of **potassium silver bromide,** $3KBr.AgBr.\frac{1}{2}H_2O$, are formed, and he calculated the corresponding heat of formation. C. Sandonnini found the two salts are soluble in one another only when melted; and the f.p. curve shows a eutectic at 290° and 51 mol per cent. of silver chloride. He obtained neither a compound nor mixed crystals. He also found that the f.p. curve of mixtures of **rubidium bromide** and silver bromide exhibits a break at 265° with 55 mol per cent. of silver bromide, and at 228° with 68 mol per cent. there is a eutectic. The break corresponds with the formation of an unstable **rubidium silver bromide**—either $2RbBr.AgBr$, or $AgBr.RbBr$, which decomposes on melting.

According to A. J. Balard, boiling **nitric acid** has no influence on silver bromide. R. Auerbach found that when a silver bromide hydrosol is treated with aq. **ammonia,** coagulation and hydrolysis simultaneously occur. A. J. Balard found that boiling **sulphuric acid** decomposes silver bromide with the evolution of bromine. When fused with sodium carbonate, metallic silver and sodium bromide are formed; although at low temp. J. J. Berzelius noted that silver bromide can be melted in the presence of sodium carbonate without any appreciable change. According to L. Cramer, **formaldehyde, gallic acid,** or **tannin** in the presence of sodium carbonate; or citrate or tartrate of iron do not reduce the silver halides. M. A. Gordon calls the number of mols of silver which a mol of reducing agent or a developer separates, the *silver equivalent* of the reducing agent, *e.g.* the silver eq. of pyrogallol is 4·5.

§ 17. Silver Iodide

Silver iodide occurs in Chili, Peru, Mexico, and Spain, as the mineral *iodite*, *iodargyrite*, or *iodyrite*, in hexagonal crystals, and also massive with a colour varying from citron or sulphur-yellow to a yellowish-green or brown. When the crystals are cubic, the mineral is called *miersite*. All three haloids occur in the mineral *iodobromite* reported by A. von Lasaulx[1] in cavities in the ferruginous quartzites of Dernbach (Nassau). In the *cuproiodargyrite* of Huantajava about half the silver is replaced by copper.

The preparation of silver iodide.—Silver iodide is formed when iodine vapour is passed over heated silver, and J. H. Kastle obtained a quantitative yield by warming iodine with finely-divided silver on a water-bath. Aq. hydriodic acid acts on silver in the cold; and, as H. St. C. Deville,[2] A. Potilitzin, and H. Danneel have shown, hydrogen is evolved until the liquid is sat. with silver iodide. When the mixture is warmed, more hydrogen is evolved, and, on cooling the soln., large colourless plates separate out. These crystals are probably a hydro-iodide since, on exposure to air, they decompose, giving off hydrogen iodide. A mixture of hydrochloric and hydriodic acids forms only the iodide. According to H. St. C. Deville, aq. soln. of potassium iodide gradually convert metallic silver into the iodide, and the soln. at the same time becomes alkaline; if the soln. of potassium iodide is very conc., the silver iodide dissolves as fast as it is formed. If air be excluded, these reactions do not occur; the same remark applies to the formation of silver iodide by the action of molten potassium iodide on the metal. I. Kablukoff made silver iodide by melting together silver nitrate and potassium iodide, a reaction whose thermal value is 24·41 Cals. A. Vogel partly converted silver chloride or bromide into silver iodide by triturating a mixture of say silver chloride and powdered iodine, and subsequently washing out the excess of iodine with alcohol. P. Julius also found silver chloride or bromide is completely converted to the iodide by heating it in a stream of iodine vapour. C. W. B. Normand and A. C. Cumming made it by the action of iodine on a number of silver salts—sulphite, acetylide, cyanide, cyanate, and thiocyanate. H. St. C. Deville also converted silver chloride, bromide, or other insoluble salts into the iodide by digestion with a conc. soln. of alkali iodide; with conc. hydriodic acid and silver chloride, $AgCl+HI=AgI+HCl$. F. Field obtained fine crystals of silver iodide by boiling mercuric iodide with an excess of silver nitrate, and cooling the soln. L. Rolla places the visibility of the precipitate with potassium or sodium iodide and silver nitrate between $0·8\times10^{-8}$ and 1×10^{-8} normality, and, according to W. Böttger, a turbidity is produced when $0·34\times10^{-6}$ mol of silver iodide is present per litre. G. P. Baxter prepared pure silver iodide by precipitation from an ammoniacal soln. of silver nitrate with a soln. of ammonium iodide. The process is quite analogous to that employed for silver bromide (*q.v.*). The precipitate clots more rapidly in the ammoniacal soln. than in an acid soln. Precipitated silver iodide has a marked tendency to pass into the colloidal state when washed with water. J. S. Stas found that if the water be previously heated to 60°, and the precipitate allowed to settle at that temp., the tendency is lessened, but the precipitate is then inclined to adhere tenaciously to the walls of the precipitation vessel. G. P. Baxter recommends washing the precipitate with 1 per cent. nitric acid, when there is no tendency to pass into the colloidal state; but if the nitric acid be expelled by drying at a high temp., some silver iodide is decomposed by the acid, and the iodide acquires a dark colour.

The properties of silver iodide.—H. Hauschild,[3] and G. Tammann studied the colour of thin films of silver iodide. While the **crystals** of silver chloride and bromide belong to the cubic system, silver iodide crystallizes in the hexagonal system, forming, according to V. von Zepharovich, dihexagonal pyramids with axial ratios $a:c=1:0·8196$, although, according to F. Wallerant, these crystals belong to the cubic system, they imitate very closely the hexagonal crystals by the peculiar method of twinning. H. St. C. Deville, and H. Debray studied the crystallization of silver iodide. The **X-radiogram** has been investigated by P. Debye and P. Scherrer, A. W. Hull, and R. B. Wilsey. The lattice has the tetrahedral arrangement, with sides 6·53 A., and the distance between nearest atomic centres 2·83 A.

V. von Zepharovich noted that silver iodide changes from a yellow to an orange colour at about 138°, and O. Lehmann said that in the vicinity of this temp. this salt changes its crystalline form which passes from the hexagonal to the cubic system. G. F. Rodwell found that this change is attended by a contraction in volume, and hence it follows that the transition temp. should be depressed with increasing press. E. Mallard and H. le Chatelier examined the lowering of the transition point by raising the press. They found that at 20°, under 2500 atm. press., a variety of silver iodide with a mol. vol. 16 per cent. smaller than that of the hexagonal form, hence a denser variety must be formed with a sp. gr. approximately 6·8, and a mol. vol. 35. This denser variety is probably that which should be compared with the ordinary chloride and bromide. The subject was further investigated by G. Tammann, and P. W. Bridgman. Temp. ranging from 138° to 150° have been published for the transition point by W. Kohlrausch, G. F. Rodwell, M. Bellati and R. Romanese, W. Schwarz, etc. The best representative value is 147°. A. Steger found the transition point could be lowered from 147° to 135° by admixture with mercuric iodide. G. Tammann found with a press. of 340 kilograms per sq. cm. the transition point was lowered to 138·8°; and with 2948 kilograms, to 100·31°—curve *AB*, Fig. 15. It was also found that there are really three stable modifications: the yellow hexagonal form which is identical with the so-called amorphous precipitate, and which G. Tammann calls form I, and K. Mönkemeyer, β-AgI; the red cubic modification, form II, or α-AgI; and a third variety stable above 2940 kilograms press.—form III—whose crystalline form is unknown. The volume decreases in passing from forms I to II to III. At the **triple point**—99·4°, and 2810 kilograms per sq. cm. press.—the change of II to I is attended by a change in the sp. vol. of 0·01010 c.c. per gram; from II to III, 0·01402 c.c.; and I to III, 0·02412 c.c.; so that the high temp. forms II and III have the smaller volumes. This is not usual, although ice presents a parallel case. The values of dT/dp at the triple point are II to I, —0·01787; II to III, —0·0290; and I to III, —0·276. The equilibrium press. and temp. are indicated in Fig. 15, which represents the relation between the solid, liquid, and vapour, and is based on one by H. W. B. Roozeboom. The high temp. from II is cubic, and isomorphous with cubic silver chloride and bromide; it might, therefore, be anticipated that at low temp. silver bromide and chloride would undergo transformations, forming substances isomorphous with the low temp. form I of silver iodide. No such change has been observed. Similarly, at high press. and room temp., modifications of silver chloride and bromide analogous to form III of silver iodide might be expected; but none such has been yet observed. A. Thiel showed that the change in the potential of mixtures of silver bromide and iodide corresponds with the formation of solid soln. containing up to 30 molar per cent. of silver bromide. According to A. P. H. Trivelli and S. E. Sheppard, the mixed crystals of silver iodide and bromide are polarized between crossed nicols; and this effect is due to reflection as well as to mechanical strains in the crystals.

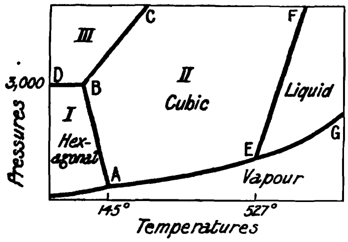

FIG. 15.—Equilibrium Diagram of Silver Iodide.

H. Stolzenberg and M. E. Huth say that hexagonal greenish-yellow silver iodide at 134° forms liquid crystals which are yellowish-red and isotropic, and which form an amorphous blood-red liquid at about 500°. C. Tubandt and E. Lorenz found no evidence of this in the change of the electrical conductivity of silver iodide with temp. The properties of the ordinary forms of silver chloride, bromide, and iodide are:

	AgCl	AgBr	AgI
Sp. gr.	5·45	6·40	5·674
Mol. vol.	25·79	29·01	24·40
Sp. compressibility × 10^6 at 20°	2·2	2·6	3·9
Heat formation . . .	39·2	23·7	13·8 Cals.
Sp. ht.	0·0911	0·0739	0·0616

The reported values for the **specific gravity** of silver iodide [4] range from C. J. B. Karsten's 5·026 to H. St. C. Deville's 5·687, at 0°; G. P. Baxter gives for the fused salt 5·674, at 25° (water 4°). A. Damour gives 5·669 (14°) for the crystallized salt, and 5·596 (14°) for the amorphous pressed variety. G. F. Rodwell says the density is a maximum at 142°. G. F. Rodwell gives the sp. gr. of the fused salt as 5·681 (0°), 5·771 (163°), and of the molten salt, 5·522 (527°). The sp. gr. of the mineral iodyrite ranges from 5·365 of J. L. Smith to 5·707 of A. Damour, P. Walden, and F. A. Henglein studied the mol. vol. During the formation of silver iodide from its elements there is an increase of nearly 15 per cent. in volume:

	Silver.	Iodine.	Silver Iodide.
Sp. gr. . . .	10·49	4·993	5·674
Mol. vol. . . .	10·28	25·73	41·38

indicating an increase of 41·38—(10·28+25·73)=5·37 c.c. Most salts show a decrease in volume during their formation. P. Walden studied the mol. vol. T. W. Richards and G. Jones' value for the **compressibility** of silver iodide at 20° between 100 and 500 megabars press. is 0·00000385 kilogram per sq. cm., 0·00000393 megabar, or 0·00000398 atm. per sq. cm. The press. required to make fused silver iodide flow through a small opening is, according to N. Kurnakoff and S. F. Schemtschuschny, 26·3 kilograms per sq. mm.

Silver iodide is an example of the very rare phenomenon of a substance contracting on a rising temp. The relation between the volume and temp. is illustrated in Fig. 16. H. Fizeau established this fact for three different varieties of this salt—precipitated, crystalline, and fused.

The other substances known to decrease in size with rise of temp. are water between 0° and 4°; liquid bismuth about 8° above its m.p. (C. Lüdeking); fused quartz below —80° (H. G. Dorsey and K. Scheel); silica between 575° and 870° (H. le Chatelier); a nickel steel (C. E. Guillaume); diamond below —42·3° (H. Fizeau); and copper oxide below —4·3° (H. Fizeau). Calcite and beryl were also shown by H. Fizeau to have a negative coeff. of expansion in the direction of their principal axes, but positive in directions vertical to the chief axes, but the cubical expansion coeff. are positive.

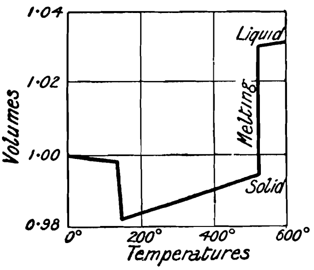

FIG. 16.—Relation between the Temperature and Volume of Silver Iodide.—(G. F. Rodwell.)

H. Fizeau found the linear **coefficient of expansion** of large crystals at 40° to be —0·000003966 along the chief axis, and +0·000000647 vertical to that axis; or the average volume contraction is 0·000002307 c.c., and for the precipitated or amorphous salt, the linear coeff. of expansion is —0·00000137 at 40°, and the cubical expansion coeff. is therefore negative, being —0·00000414. H. Fizeau, and G. F. Rodwell both showed that the coeff. of expansion of silver iodide increases rapidly with rise of temp. The average coeff., according to G. F. Rodwell, is —0·00000718 between —18° and 0°; —0·00003297, between 0° and 21°; —0·00005570, between 21° and 67°; and —0·00000335, between 70° and 150°; while the mean expansion of form II between 150° and 450° is about 0·000005. G. Jones explains the phenomenon by assuming that the change in volume which occurs when a solid is heated is due (i) to a small increase in the intramolecular free space; (ii) an increase in the volume of the molecules due to a decrease in cohesion; and (iii) a change in the volume of the atoms due to a change in the attractive force between the molecules. In the case of silver iodide, it is assumed that the attractive force increases with a rise of temp., and thereby produces an increased compression of the atoms great enough to outweigh the effects of the other two influences. The free energy F of formation of a compound is taken as an indication of the magnitude of this attractive force, and in accord with the relation $F-Q=TdF/dT$, where Q is the heat of formation in kilojoules, G. Jones finds

	F	Q	dF/dT	Coeff. Cub. expansion.
AgCl . . .	111·8	114	—0·006	+0·0000988
AgBr . . .	96·6	95	+0·005	+0·0001041
AgI	66·3	58	+0·028	—0·0000041

The marked increase in the free energy with rise of temp. is taken to support the hypothesis in question. W. Barlow and W. J. Pope explain the dimorphism by assuming the existence of alternate methods of close packing structural units which are dimensionally identical at the transition temp. They said:

> It is evident that a passage from the ideal condition in which the spheres are all equal to one in which the two kinds of spheres show a minute difference in size, instead of producing a lowering of the symmetry, may merely cause a diminution in the number of equal press., some of those which in the ideal assemblage are equal becoming a little greater

and the others a little smaller. Thus, considering a layer in which one-third of the spheres are a trifle smaller than the rest, the press. between the larger spheres would be slightly increased, and that between spheres of different sizes would be slightly diminished. And whilst an increase in size of both kinds of spheres will tend to expand the whole mass, if the increase proceeds at different rates for the two and in such a manner that the two kinds of spheres become more nearly equal, the closer approximation to equality of size will lead to a closer approximation to the closest-packed ideal assemblage, and will thus tend towards contraction of the mass as a whole. A very small increase of size of one kind of sphere and a much larger decrease of that of the other accompanying a rise of temp., can consequently lead to the observed negative coeff of cubic thermal expansion of hexagonal silver iodide if the structure more nearly approaches the ideal closest-packed arrangement of equal spheres as the temp. rises. This kind of explanation is in harmony with the observation quoted above, namely, that the coeff. of linear expansion is large and negative in the direction of the principal axis and small and positive in directions perpendicular thereto.

Silver iodide melts at a dull red heat to a yellow, red, or reddish-brown fluid whose colour is determined by the temp.; and on cooling, it freezes to a dirty yellow, translucent solid. The **melting point** given by different investigators[5] ranges from A. Steger's 526° to W. Ramsay and N. Eumorfopoulos' 556°. The best representative may be taken as 552°. According to O. Lehmann, and H. Stolzenberg and M. E. Huth, silver iodide, bromide, and chloride form anisotropic liquids or liquid crystals during their solidification. On the other hand, C. Tubandt and E. Lorenz showed that well-purified silver iodide is harder 2° below its m.p. than is yellow phosphorus at ordinary temp. If a little of another silver halide be present, ordinary silver iodide becomes much more plastic. Similar results were obtained with thallium halides and the other silver halides. Hence, these substances must be deleted from the list of substances furnishing liquid crystals. K. Mönkemeyer has studied the f p. curves of mixtures of silver iodide with silver bromide and chloride. With the bromide, there is a U-shaped curve falling to a minimum at 377° with 25 gram-mol. per cent. of silver iodide; the transformation point of silver iodide is also lowered by additions of the other halide. For instance, with about 35 gram-mol. per cent. of silver bromide it falls to 80°, and with 11 gram-mol. per cent. of silver chloride to 115°. The U-shaped curve with silver chloride and iodide has its minimum at 211° with about 57 gram-mols. per cent. of silver iodide. M. Meslans, and V. Auger prepared what they regarded as *silver fluo-iodide*, AgI.AgF, by the action of iodoform on silver fluoride, but there is nothing to show the chemical individuality of the alleged compound. The ternary system: AgI—AgBr—AgCl, has been studied by K. Mönkemeyer, and the results are indicated in Fig. 17, showing the isotectic lines.

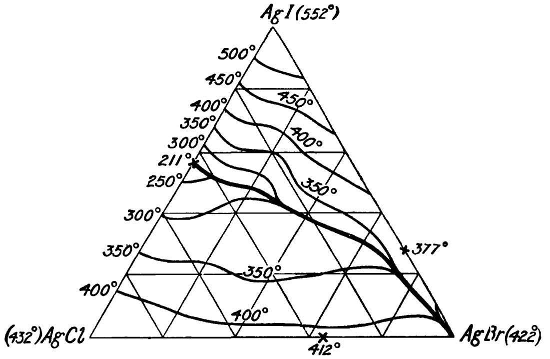

FIG. 17.—Isotectic Lines of the Ternary System, AgI—AgBr—AgCl.

A. Vogel found silver iodide to be volatile at a white heat in closed vessels, and C. Antoine has measured the **vapour pressure** of silver iodide at different temp. J. Dewar and A. Scott measured the **vapour density** and obtained values in agreement with the molecule Ag_2I_2. H. V. Regnault's value for the **specific heat** is C_p=0·0616 between 15° and 98°; M. Bellati and R. Romanese's value for the I-variety is 0·0573 (14°–142°); and for the II-variety, 0·0577 (136°–264°). F. Koref found the sp. ht. from −191·1° to −81·6° to be 0·0488; and from −77·4° to 0°, 0·0532; A. Magnus' value of the mol. heat from 17° to 507° is 6·460±0·003;

W. Nernst and F. Schwers gave 3·287 at −255·2°, and 11·355 at −156·5°; while W. Nernst's values for the mol. heat are:

	−244°	−243°	−242·4°	−197·5°	−193·2°
Mol. heat . . .	5·51	5·08	5·95	9·70	10·17

The mol. ht. of silver iodide is greater than the sum of the thermal capacities of the constituent atoms. This is unusual, but is related with the other anomalous properties of this salt.

M. Berthelot's [6] value for the **heat of formation** of silver iodide from its elements —iodide solid—is 13·8 Cals., according to J. Thomsen, or, according to M. Berthelot, $Ag+I=AgI_{cryst.}+14·3$ Cals.; $Ag+I=AgI_{amorphous}+7·7$ to 14·3 Cals. U. Fischer considers M. Berthelot's value is too small, and gives 15·169 Cals. at 15°. G. Jones and M. L. Hartmann give the **free energy** of formation of silver iodide from silver and solid iodine as 65·1 kilojoules at 0°, and 66·1 kilojoules at 25°; or 26·300 Cals., and the total energy 14·570 Cals. According to F. Gerth, the difference between U. Fischer's and G. Jones and M. L. Hartmann's results is due to the difference in the silver electrodes used in measuring the e.m.f., and to the applied corrections. F. Gerth obtained 15·158 Cals.; and H. Braune and F. Koref, and H. S. Taylor and W. T. Anderson, 15·100. J. Thomsen's value for the heat of precipitation is 26·6 Cals.

The **electrical conductivity** of silver iodide has been measured by W. Kohlrausch,[7] C. Tubandt and co-workers, K. Arndt and A. Gessler, etc. There is a marked change at the transition point: $I\text{-}AgI \rightleftharpoons II\text{-}AgI$, but not so marked a change at the m.p. Thus, the conductivities in reciprocal ohms at different temp. are:

	142·4°	145°	146·5°	150°	300°	547°	552°	554°	650°
Rec. ohms .	0·000333	<—>	7·308	1·33	1·97	2·638	melts	2·362	2·47

C. Tubandt and S. Eggert found the maximum sp. conductivity of the hexagonal form stable below 144·6° to be 0·00034; while the cubic form, at the transition point, has the greater value 1·31, rising to 2·64 near the m.p. They also investigated the electrolysis of the fused salt. The conductivity with form II and with the molten salt is thought to be electrolytic. The increase in the conductivity in the formation of the II-form is explained by the considerable contraction which silver iodide suffers during the freezing of the molten salt; this raises the molecular concentration, while the ionization and ionic mobilities remain unchanged. Within a range of about 125°, the II-form conducts better than the melted salt, and the molten salt does not reach the maximum value which the II-form reaches at about 800° when the salt begins to dissociate. This phenomenon is unique with silver iodide. C. Tubandt found that the current is carried wholly by the silver ion whose velocity, at 145°, is about $0·55 \times 10^{-3}$ cm. per sec., and at 552°, $1·1 \times 10^{-3}$. With aq. soln., the ionic velocity at 18° is nearly 0·55 cm. per sec. C. Tubandt and F. Lorenz have measured the electrical conductivities of binary mixtures of silver chloride, bromide, and iodide. According to K. Bödeker, the conductivity is raised if the salt be exposed to iodine vapour. L. Graetz has studied the effect of press. on the conductivity of silver iodide.

H. Scholl and B. A. Dima the **photoelectric effect** of this salt—*vide* silver chloride. W. Wilson found the conductivity of silver iodide to be greater when illuminated. P. Dutoit and G. von Wiesse found the potential towards $\frac{1}{10}N\text{-}AgNO_3$, at 25°, to be 0·701 volt. S. Iimori and T. Takebe have described photochemical cells with silver iodide electrodes. R. B. Archey discussed the sensitiveness of silver iodide to red light.

L. Wernicke gives for the **index of refraction** for $\lambda=431$, $\mu=2·409$; $\lambda=486$, $\mu=2·267$; and for $\lambda=656$, $\mu=2·1531$. A. Kundt's value for white light is 2·31; and A. des Cloizeaux's [8] for yellow light, 2·23. According to C. Schell, the **absorption spectrum** shows maxima at $0·4226\mu$, $0·3222\mu$, and $0·2712\mu$. J. A. Wilkinson reports a bluish-violet fluorescence. S. Meyer found the magnetic susceptibility to be $-0·29 \times 10^{-6}$ mass units at 19°.

The **solubility** of silver iodide in water is very small, and the published results are not concordant. H. Danneel[9] gives 0·00000133 grm. per litre at 13°; F. Kohlrausch and E. Dolezalek, 0·00000353 grm. per litre at 20·8°; H. M. Goodwin, 0·0000023 grm. per litre at 25°; and A. Thiel, 0·0000025 grm. per litre at 25°. A. E. Hill gives the solubility as 0·97 to $1·05 \times 10^{-8}$ mols per litre at 25°; the corresponding value for silver bromide is $6·6–8·1 \times 10^{-7}$; and for silver chloride, $1·25–1·64 \times 10^{-5}$. If ϵ_1 and ϵ_2 be respectively the electrolytic potentials of iodine (0·540 volt) and of silver (0·784 volt), C the solubility of silver iodide, and F the free energy of the formation of silver iodide, then, according to G. Bodländer, for a binary salt from univalent ions $F=\epsilon_1-\epsilon_2-2RT \log C$, and if in the first approximation the heat of formation be used in place of the free energy of formation, $Q=23100(\epsilon_1-\epsilon_2-2RT \log C)$, or $C=6 \times 10^{-8}$ mols per litre at room temp. This is in agreement with the observed values.

H. St. C. Deville[10] noted that silver iodide dissolves copiously in *hydriodic acid*, and, when the soln. is allowed to stand in air, crystals of **silver hydroiodide,** which M. Berthelot regards as $3AgI.HI.7H_2O$, are formed: $3AgI+HI_{gas}+7H_2O_{liq.}=21·6$ Cals. The mother liquid still contains some hydriodide. The crystals become yellow on exposure to air and light; when heated, they decompose, forming silver iodide; they are decomposed by water into hydriodic acid, and silver iodide is precipitated. In his memoir, *Sur les iodures doubles*, P. A. Boullay showed that silver iodide dissolves readily in soln. of *potassium or sodium iodides*, forming double salts. F. Field noticed that silver iodide is but slightly soluble in soln. of the *alkali chlorides*. The solubility of the silver halides in the alkali halides is considered to be due to the formation of complexes. This tendency to form complexes increases in passing from the chloride to the iodide, and with the electropositive character of the alkali metal. K. Hellwig gives the solubility of silver iodide in soln. of potassium iodide when the conc. are expressed in mols per litre:

KI .	0·335	0·586	1·008	1·018	1·406	1·482	1·6304	1·937
AgI .	0·000363	0·00218	0·0141	0·0148	0·0535	0·0658	0·102	0·198

According to G. Bodländer and W. Eberlein, dil. soln. hold a complex with 2Ag, possibly $K_2Ag_2I_4$, $K_3Ag_2I_5$, $K_4Ag_2I_6$, or $K_6Ag_2I_7$; and in conc. soln. of potassium iodide the complex has only one Ag—possibly K_3AgI_4. W. van Dam and A. D. Donk, in their examination of the ternary system, $AgI—KI—H_2O$, find at 0° a solid phase, KI.AgI; at 30°, 2KI.AgI; and at 50°, again 2KI.AgI, and KI.AgI, as indicated diagrammatically in Fig. 18. C. Sandonnini has examined the f.p. curves of binary mixtures of KI—AgI and of RbI—AgI, and in both cases found evidence of the formation of a compound which decomposes when fused. By cooling a warm conc. soln. of potassium iodide sat. with silver iodide, white asbestos-like crystals of the double salt **potassium argento-iodide,** KI.AgI, or $KAgI_2$, separate out; and, if the soln. is only partially sat. with silver iodide, colourless rhombic needle-like crystals of **potassium diargento-iodide,** KI.2AgI, or KAg_2I_3, have been obtained by P. A. Boullay. H. L. Wells and H. L. Wheeler find the axial ratios of 2KI.AgI to be $a:b:c=0·977:1:0·234$. J. E. Marsh and W. C. Rhymes also made the double salts, KI.3AgI and KI.AgI, by the cooling of acetone soln. of the component salts in mol. proportions. They also made KI.2AgI;

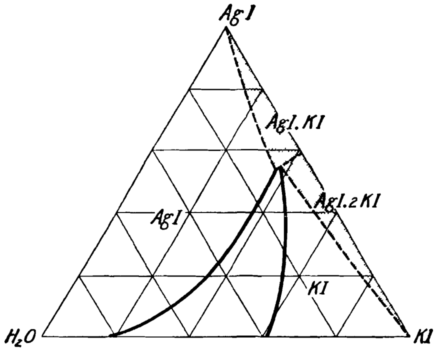

FIG. 18.—Equilibrium Curves in the Ternary System, $AgI—KI—H_2O$ at 50°

the **rubidium argento-iodides,** $RbI.3AgI$; $RbI.2AgI$, and $Rb.Ag_2I_3.2C_3H_6O$; $RbI.AgI$; $RbI.AgI.\frac{1}{2}H_2O$; $2RbI.AgI$; the **cæsium argento-iodides,** $CsI.2AgI$; $CsI.AgI$; and the **lithium argento-iodide,** $LiI.2AgI$. J. E. Marsh reported $LiI.AgI.3(C_2H_5)_2O$; but C. Sandonnini and G. Scarpa obtained only mixed crystals in their thermal study of mixtures of lithium and silver iodides. J. E. Marsh and W. C. Rhymes prepared crystals of **sodium diargento-iodide,** $NaAg_2I_3$, and of **sodium argento-iodide,** $NaAgI_2$, from acetone soln. of the component salts; and W. Krym obtained crystals of $NaI.AgI.3\cdot5H_2O$, as solid phase in soln. with the following proportions of the component salts in mols per 1000 mols of water:

$(NaI)_2$ . . .	35·63	94·25	107·25	117·96	134·40	135·83	133·81	117·11
$(AgI)_2$ . . .	8·14	47·79	57·52	51·70	46·82	46·36	43·03	11·93
	AgI		⟷	$AgI.NaI_{3\cdot5}H_2O$		⟷	NaI	

Neither N. S. Kurnakoff and P. S. Eiler, nor C. Sandonnini and G. Scarpa could detect any sign of chemical combination in the fusion curves of mixtures of potassium and silver iodides. W. Eberlein measured the e.m.f. of conc. cells of potassium silver iodide. According to A. Ditte, deliquescent crystals of **tripotassium argento-iodide,** $3KI.AgI+\frac{1}{2}H_2O$, or $K_3AgI_4+\frac{1}{2}H_2O$, are formed by evaporating the mother liquid. M. Berthelot obtained crystals of what he regarded as **hydrated tripotassium diargento-iodide,** $3KI.2AgI.H_2O$, or $K_3Ag_2I_5.H_2O$, by the evaporation of a soln. of silver in a very conc. soln. of potassium iodide in air. H. L. Wells and S. L. Penfield obtained white rhombic crystals of **dirubidium argento-iodide,** $2RbI.AgI$, or Rb_2AgI_3, with axial ratios $a:b:c=0\cdot977:1:0\cdot236$; and likewise rhombic hair-like crystals of **dicæsium argento-iodide,** $2CsI.AgI$, or Cs_2AgI_3, with axial ratios $a:b:c=0\cdot971:1:0\cdot244$ by cooling hot sat. soln. of silver iodide in conc. aq. potassium iodide. The three salts of the type M_2AgI_3 are isomorphous, and they do not conform with the now obsolete rule of I. Remsen, for they contain more halogen atoms belonging to the alkali nitrate than belonging to the silver. The tendency of the silver halides to form complexes increases in passing from chlorides to iodides, and from lithium to cæsium.

G. F. Rodwell [11] studied the sp. gr. of "alloys" of *cuprous iodide* and silver iodide; M. Bellati and R. Romanese, the thermal expansion and the sp. ht.; and G. F. Rodwell, and T. Carnelley and L. T. O'Shea, the m.p. G. T. Prior reported a mineral *miersite*, $CuI.4AgI$, sp. gr. 5·640, from Broken Hill; B. Gossner also studied the same mineral. H. Schulze's analyses of the Chilian mineral *cuproiodargyrite* agreed with the formula $CuI.AgI$.

According to J. Schnauss,[12] 100 parts of a solution of *silver nitrate*, sat. at 11°, dissolve 2·3 parts of silver iodide in the cold, and 12·3 parts when boiling. Silver iodide absorbs silver sulphate and silver nitrate. C. Stürenberg obtained crystals of what he regarded as **silver iodonitrate,** $AgI.AgNO_3$, by cooling a hot. conc. soln. of silver nitrate sat. with silver iodide; and if the soln. is not completely sat. with the iodide, there are formed needle-like crystals of **silver iododinitrate,** $AgI.2AgNO_3$, belonging to the rhombic system with axial ratios $a:b:c=0\cdot6638:1:0\cdot3123$. According to G. Scarpa, and J. Kablukoff, the f.p. curve of the two salts shows the existence of the **silver iodosesquinitrate,** $2AgI.3AgNO_3$. According to J. Preuss, soln. of *mercuric nitrate*, especially if warm, dissolve much silver iodide, and, according to H. Debray, on cooling, crystals of the salt separate unchanged. F. Field says that a soln. of *sodium thiosulphate* dissolves very little silver iodide. G. Fogh says none, but, according to E. Valenta, at 20°, 100 grms. of soln. containing 1, 5, 10, 15, and 20 of sodium thiosulphate in 100 of water dissolve respectively 0·03, 0·15, 0·30, 0·40, and 0·60 grm. of silver iodide. A. Rosenheim and S. Steinhäuser obtained crystals of $4(NH_4)_2S_2O_3.NH_4I.AgI$ by shaking silver iodide with a conc. soln. of ammonium thiosulphate. According to E. Valenta, also, 100 grms. of soln. containing 10 and 20 parts of *sodium sulphite* per 100 of water, at 25°, dissolve respectively 0·01 and 0·02 grm. of silver iodide; 100 grms. of soln. containing 5, 10, and 15 grms. of *ammonium thiocyanate* per 100 grms. of water dissolve respectively, at 20°, 0·02, 0·08, and 0·13 grm. of silver iodide; 100 grms. of a 1 : 20 soln. of *potassium cyanide,* at 25°, dissolve 8·23 grms. of silver iodide; and 100 grms. of 1 : 10 soln. of *calcium or barium thiocyanate* dissolve respectively 0·03 and 0·02 grm. of silver iodide. J. Neustadt [13] found the solubility of silver iodide in *methyl alcohol* to be $1·56\times10^{-18}$; in *ethyl alcohol,* $1·1\times10^{-19}$; and in *acetone,* about 5×10^{-24}; and F. Benzold says it is insoluble in *methyl acetate.*

According to O. Ruff and E. Geisel,[14] and E. C. Franklin and C. A. Kraus, silver iodide is soluble in *liquid ammonia.* If v represents the number of litres containing a mol of the salt, and ϕ the fluidity, and D the sp. gr. of the soln.:

$v\times10^{-3}$	0·1377	0·2956	0·5040	1·182	4·960	15·63	27·75
D	2·2275	1·4250	1·1175	0·8588	0·7215	0·6840	0·6820
ϕ	10·12	108·6	195·9	284·8	355·9	375·3	376·4

According to E. C. Franklin and C. A. Kraus, the degree of ionization of soln. of silver iodide in liquid ammonia, at —33°, is 0·18 per cent. with a dilution of 100, and 0·43 per cent. with a dilution of 1000, values which are not so high as with other binary salts. At —33° the conductivity λ in reciprocal ohms is:

$v\times10^{-3}$	0·1720	1·299	5·376	62·4	967·2	2881·0	15100·0	80000·0
λ	3·397	9·618	15·35	42·52	121·0	175·2	242·1	276·0

The solubility and fluidity of soln. of silver iodide in the substituted ammonias —*methylamine* and *ethylamine*—have been determined by F. F. Fitzgerald. The conc. soln. in these menstrua are very viscous. Silver iodide is slightly soluble in *aqua ammonia,* as shown by J. Martini, W. Wallace, H. Rose, A. Vogel, and H. Baubigny. A. Longi found 100 c.c. of 10 per cent. ammonia (sp. gr. 0·96) dissolves 0·0036 grm. of silver iodide; H. Baubigny, that 100 c.c. of ammonia of sp. gr. 0·926 dissolves 0·0167 grm. of silver iodide; and W. Wallace, that 100 c.c. of ammonia of sp. gr. 0·89 dissolves 0·04 grm. of silver iodide.

According to A. Joannis and M. Croizier,[15] when silver iodide, cooled by a freezing mixture of ice and salt, is treated with ammonia gas, **silver ammino-iodide,** $AgI.NH_3$, is formed with a dissociation temp. of 3·5° under normal press. According to A. Longi, the same compound is formed if silver iodide be digested with aq. ammonia; but on account of the low dissociation temp. this is not probable. W. Biltz and W. Stollenwerk gave $Q=8·56$ Cals. for the heat of formation of the monammine, and $\log p=-Q/4·57T+1·75\log T-0·0030T+3·3$. R. Jarry measured the dissociation press. of this compound. A. Vogel found aq. ammonia forms a compound, probably **silver hemiammino-iodide,** $2AgI.NH_3$, which is not very stable, since on washing or exposure to the air it forms yellow silver iodide. According to C. F. Rammelsberg, the hemiammino-salt is formed when unfused silver iodide is exposed to ammonia gas; heat is developed, and a white compound is formed, $2AgI.NH_3$. H. Ley and G. Wiegner found the same product was formed when silver iodide was confined with ammonia in a eudiometer; the eq. of half a mol of ammonia is rapidly absorbed. The compound slowly loses ammonia on exposure, and forms yellow silver iodide on exposure to air; the decomposition occupies about half an hour in vacuo. According to A. Joannis and M. Croizier, the dissociation temp. of this compound is 90° under ordinary press. According to F. Isambert, the dissociation press. are:

20°	34°	45°	53°	60·5°	63°	70°	76°
29	79	102	178	222	236	327	460 mm.

C. Antoine represented the vap. press in p mm., at $\theta°$, by $\log p=0·2373(14·4478+1000/t)$, when $t=\theta°+80$. W. Biltz and W. Stollenwerk gave $Q=11·59$ Cals. for the heat of formation of the hemi-ammine, $AgI.\frac{1}{2}NH_3$, and $\log p=-Q/4·57T+1·75\log T-0·0010T+3·3$. R. Jarry also measured the dissociation press. of this compound. If silver iodide sat. with ammonia is heated with aqua ammonia in a sealed tube on a water-bath, a little of the solid is dissolved and the soln. deposits on cooling white mica-like crystals of **silver diammino-iodide,** $AgI.2NH_3$, which are rapidly coloured violet in light. They lose ammonia and form yellow silver iodide. W. Biltz and W. Stollenwerk gave $Q=7\cdot05$ Cals. for the heat of formation of the diammine, and $\log p=-Q/4\cdot57T+1\cdot75 \log T-0\cdot0050T+3\cdot3$. They also prepared **silver sesquiammino-iodide,** $2AgI.3NH_3$, whose heat of formation, Q, is 7·25 Cals., and $\log p=-Q/4\cdot57T+1\cdot75 \log T-0\cdot0050T+3\cdot3$; likewise also for silver triammino-iodide, $AgI.3NH_3$, the heat of formation, $Q=6\cdot92$ Cals., and $\log p=-Q/4\cdot57T+1\cdot75 \log T-0\cdot0050T+3\cdot3$. All the ammino-iodides form mixed crystals. From the temp. of dissociation, the stability of the silver ammino-halides is in the order : AgI, AgBr, AgCl.

According to J. S. Stas,[16] pure silver iodide has a pale yellow colour ; it is not decomposed in direct sunlight unless in the presence of traces of certain impurities —*e.g.* with traces of silver salts—when the iodide darkens. The photo-iodides are discussed in connection with the action of light on silver halides. A. Guntz claims to have prepared **silver subiodide,** Ag_2I, by the action of hydrogen iodide on silver subfluoride, when much heat is developed ; H. W. Vogel also prepared a substance which he regarded as silver subiodide by the action of cuprous iodide on silver nitrate, but which K. Emszt regards as a mixture of silver and silver iodide. When heated strongly in air, A. Vogel found silver iodide is partially decomposed; it sublimes when heated in closed vessels. According to K. Arndt and A. Gessler decomposition begins when the salt is heated to about 800°. According to H. Schulze, it is not decomposed when heated in **oxygen ;** and according to A. Vogel, it is only very incompletely reduced by **hydrogen** at a white heat ; but, according to A. Jouniaux, it is not appreciably reduced by hydrogen at 700°. Electrolytic hydrogen, says H. Vogel, reduces silver iodide. H. Danneel found that the equilibrium conditions in the reaction $2Ag+2HI=2AgI+H_2$ are such that if the hydrogen is at atm. press. and the temp. 13°, the conc. of the hydrogen iodide is 0·043 normal. In order that silver iodide may be completely reduced by hydrogen in aq. soln., $2AgI+H_2=2HI+2Ag$, it is therefore necessary that the dissolved hydrogen have a greater conc. than 0·043 normal. According to H. Rose, silver iodide is completely reduced by **iron** in the presence of water, or dil. acids, but with zinc the reduction is incomplete. A. Naquet found that **antimony** and **bismuth** do not reduce silver iodide suspended in boiling water ; nor, according to D. Tommasi, does **sodium amalgam,** even in acidified soln. J. Seymour obtained no signs of reduction by **ferrous sulphate** in light ; E. Rupp and F. Lehmann also say that **formaldehyde** does not attack silver iodide suspended in alkaline soln.

According to J. J. Berzelius,[17] silver iodide absorbs **chlorine** at ordinary temp., but iodine is liberated only when the silver iodide is warmed. P. Julius converted it completely into silver bromide by passing over the molten iodide a stream of air laden with **bromine** vapour. Dry **hydrogen chloride** forms silver chloride and hydrogen iodide at about 700°. M. Berthelot has studied the action of hydrogen chloride and **hydrogen bromide** on silver iodide. According to F. W. Schmidt, when silver nitrate is added to an alcoholic soln. of potassium tri-iodide, the resulting dark brown precipitate is **silver tri-iodide,** AgI_3. The same compound is formed when the white precipitate formed by the addition of iodine to ammoniacal silver nitrate is treated with an alcoholic soln. of iodine. It is stable only in the moist condition. J. S. Johnson obtained black deliquescent crystals of $4KI_3.AgI.5H_2O$, or $K_4AgI_{13}.5H_2O$, by evaporating a soln. of potassium and silver iodides and iodine in these proportions. According to W. D Bancroft, silver iodide strongly adsorbs iodine, for M. C. Lea showed that freshly precipitated and still moist silver iodide quickly decolorizes the pale sherry-wine colour of an alcoholic soln. of iodine. F. E. E. Germann and R. N. Traxler showed that if the adsorbed silver nitrate be removed from the iodide no adsorption occurs above the limit 0·02 millimol per gram of silver iodide. The phenomenon observed by M. C. Lea was probably due to a chemical reaction between the adsorbed silver nitrate and iodine.

According to R. Brandes, dil. **nitric acid** or **phosphoric acid** has no action on silver iodide; but, according to A. Naquet hot conc. nitric acid converts it into silver nitrate; and, according to A. Ladenburg, **sulphuric acid** at 180° forms silver sulphate. H. Davy found that when silver iodide was "acted upon by fused hydrate of potassa, it was rapidly decomposed, and a solid substance having all the characters of oxide was formed. The matter soluble in water separated by a filter and acted upon by sulphuric acid, afforded the peculiar substance—iodine"; but, according to A. Vogel, the decomposition is incomplete, while boiling aq. soln. of **potassium hydroxide** turn silver iodide grey without appreciable decomposition; A. Naquet says alkali lye colours silver iodide brown, and that with boiling alkali lye the decomposition is incomplete; the **alkali carbonates** slightly discolour silver iodide, while the carbonates and oxides of the alkaline earths and magnesium are without action.

§ 18. Silver Sulphide

Silver sulphide occurs in nature in two forms—the common ore *argentite* which crystallizes in the cubic system, and the rare mineral *acanthite* which crystallizes in the rhombic system. The cubic variety of silver sulphide was described by G. Agricola[1] (1529) as *Glaserz;* by J. G. Wallerius (1750) as *Silberglas;* by J. B. L. Romé de l'Isle (1783) as *minera argenti vitrea;* by K. C. Leonhard (1821) as *Silberglanz* or *silver glance;* by F. S. Beudant (1832) as *argyrose* from ἄργυρος, silver; and by W. Haidinger (1845) as *argentite.* L. Erker (1598) showed that the mineral contained five-sixths of its weight of silver; J. F. Henkel (1725), that it contained sulphur; and B. G. Sage (1776) found that a sample he analyzed contained 16 per cent. of sulphur and 84 per cent. of silver. M. H. Klaproth obtained a similar result.

Silver sulphide is easily prepared, for silver has a strong affinity for sulphur, as was shown by A. Orlowsky, and by J. W. Langley. A. Colson found that silver is blackened when heated with sulphur to 100° in an evacuated tube. J. Margottet,[2] and J. B. A. Dumas prepared small crystals of the sulphide by passing the vapour of sulphur over silver at a low red heat. Silver sulphide was prepared by J. S. Stas by heating silver in the vapour of sulphur, and expelling the excess by heating the product in a stream of nitrogen or carbon dioxide free from oxygen or hydrogen chloride. F. Rössler crystallized silver sulphide from a soln. of sulphur in molten silver. H. Pélabon studied the fusion curve of mixtures of sulphur and silver, or of silver sulphide and silver. P. Berthier stated that silver sulphide and metallic silver *s'unissent par fusion en toutes proportions*, but J. Percy showed that this statement is wrong, for while 83·63 per cent. of silver, and 16·37 per cent. of silver sulphide can be melted so as to furnish a "homogeneous metallic product," other proportions gave a product with two distinct layers—the lower layer is a soln. of silver sulphide in silver, and the upper layer a soln. of silver in silver sulphide. K. Friedrich and A. Leroux, and F. M. Jäger and H. S. van Klooster have studied a portion of the equilibrium diagram, which is not unlike that obtained with copper and cuprous sulphide, as illustrated in Fig. 19. By adding silver sulphide to silver, the m.p. is progressively lowered to 906° with about 3 per cent. of silver sulphide; the m.p. then remains stationary with further additions of sulphur, until, with 12 per cent. of silver sulphide, the m.p. falls and continues falling to a eutectic at 806°, with 23 at. per cent. of sulphur; with between 7 and 29 at. per cent. of sulphur, the liquid separates into two layers. According to G. G. Urazoff, molten silver sulphide dissolves up to 0·65 per cent. of silver; if any more passes into soln. the fluid separates into two layers—the upper layer freezes at about 800°, and the lower one at 900°. The cooling solid has a transition point at about 175°, corresponding with passage from rhombohedral to cubic silver sulphide. There are also other transition points—*vide infra*, cuprous silver sulphide—corresponding with *stromeyerite* and *jalpaite*. C. C. Bisset studied the binary system: silver and silver sulphide.

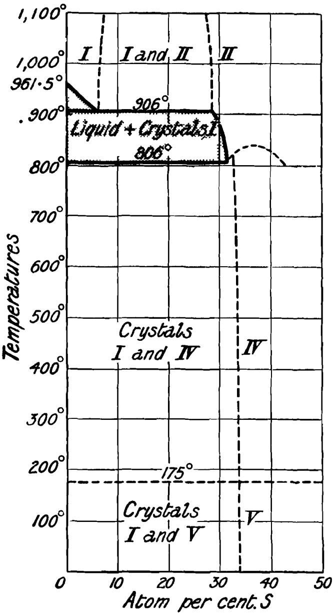

Fig. 19.—Equilibrium Curve of Binary Mixtures of Sulphur and Silver.

H. Vogel, A. C. Becquerel, and C. Geitner prepared amorphous silver sulphide by the joint action of silver, sulphur, and water in a sealed tube at 200°; but E. Obach found that sulphur dissolved in carbon disulphide has no action on silver; but A. Colson found that silver is blackened when heated with a soln. of sulphur in benzene. J. B. Senderens found that silver oxide is slowly attacked by sulphur and water at ordinary temp.; the action occupies some hours at 90°; but is faster at 100°; and he represented the reaction: $4Ag_2O+4S=3Ag_2S+Ag_2SO_4$; followed by: $3Ag_2SO_4+4S+4H_2O=3Ag_2S+4H_2SO_4$. When the mixture is heated in a sealed tube, silver sulphide and sulphate are formed. M. Raffo and A. Pieroni found colloidal sulphur acts in a similar way. E. Filhol and J. B. Senderens converted a soln. of silver sulphate into silver sulphide and sulphuric acid by boiling it with finely divided sulphur; similar results were obtained with silver nitrate, oxalate, acetate, and carbonate. G. Vortmann and C. Padberg found insoluble silver chloride, bromide, and iodide are either unaffected or only slightly blackened by boiling with sulphur and water. E. Weinschenk obtained crystals of silver sulphide by heating silver acetate with hydrogen sulphide under press., or by heating the same salt with a soln. of ammonium thiocyanate in a sealed tube at 180°—the active agent here is hydrogen sulphide formed by the decomposition of the thiocyanate. W. Spring claimed to have made silver sulphide by the union of a mixture of the two finely divided elements merely by compression under 6500 atm., but W. Hallock. and J. Johnson and L. H. Adams have shown that this statement wants modifying—*vide* **1.** 18, 23.

J. M. Caball found that hydrogen sulphide, thoroughly dried, does not attack silver at ordinary temp., but under ordinary atm. conditions, the small amount of hydrogen sulphide sometimes present was found by J. L. Proust to blacken the surface of silver; and by heating silver in a stream of hydrogen sulphide J. S. Stas prepared silver sulphide. E. Obach also found that a soln. of hydrogen sulphide in carbon disulphide attacks silver if air be simultaneously present, but not if air be excluded. Silver sulphide is precipitated as a black powder when silver oxide, or an aq. soln. of a silver salt, is treated with hydrogen sulphide or a soluble alkaline sulphide. H. St. C. Deville and L. Troost made crystals of argentite by passing hydrogen sulphide over silver *chauffé au rouge*, and J. Durocher prepared crystals of silver sulphide by the action of hydrogen sulphide on silver chloride at a high temp. V. Kohlschütter and E. Eydmann found that with a neutral soln. of silver nitrate, the precipitate always contains free sulphur which cannot be removed with carbon disulphide; while F. M. Jäger and H. S. van Klooster could extract traces with toluene. L. Bruner and J. Zawadsky studied the equilibrium conditions of the reaction. I. Block and F. Höhn found that hydrogen persulphide, dropped on silver oxide, reacts with explosive violence, and inflames; when the combustion has ceased, greyish-black crystals of silver sulphide remain.

O. von der Pfordten claimed to have made **silver subsulphide**, Ag_4S, by the action of freshly-prepared ammonium hydrosulphide on silver suboxide; and A. Guntz, by the action of hydrogen sulphide on silver subfluoride. The product is black and amorphous; it is readily soluble in nitric acid and in conc. sulphuric acid without the separation of sulphur. It decomposes: $Ag_4S = Ag_2S + 2Ag$ on standing under water, or when it is dried.

E. Priwoznik obtained silver sulphide by melting silver with potassium pentasulphide and extracting the mass with water. A yellow soln. of ammonium sulphide slowly attacks silver, and in six weeks, a crystalline crust of the sulphide is formed on the metal. V. Stanek obtained crystals of silver sulphide by heating colourless ammonium sulphide with silver in a tube at 150°–200°. K. Preis and B. Raymann found a soln. of sodium thioarsenite, Na_3AsS_3, reacts with silver nitrate, forming silver sulphide and arsenious acid. A. Beutell, and G. Strüver found that hauerite, pyrite, marcasite, and pyrrhotite act on silver, forming silver sulphide, while cobaltite and arsenical pyrites have no action.

C. Geitner obtained crystals of silver sulphide by heating the metal with sulphurous acid in a sealed tube at 200°; and he found that when silver sulphite is heated with water under similar conditions, a mixture of crystalline silver sulphide and crystalline silver is formed. When silver is heated with dry sulphur dioxide, J. Uhl found that silver sulphide and sulphate are formed. C. Geitner obtained microscopic crystals of silver sulphide by heating a mixture of silver nitrate and sulphurous acid in a sealed tube. According to W. Vaubel, silver oxide reacts quantitatively with sodium thiosulphate: $Ag_2O + Na_2S_2O_3 = Ag_2S + Na_2SO_4$; and, according to J. Fogh, and J. Girard, silver nitrate gives a precipitate of silver sulphide: $2AgNO_3 + Na_2S_2O_3 + H_2O = 2NaNO_3 + Ag_2S + H_2SO_4$, and if the thiosulphate be in great excess, the precipitate redissolves.

The physical properties of silver sulphide.—C. Paal and F. Voss[3] prepared **colloidal silver sulphide** by treating silver lysalbinate with a dil. soln. of ammonium sulphide, and dialyzing the soln. to remove the compound last named. A. Lottermoser mixed $\frac{1}{40}N$-$AgNO_3$ with an excess of $\frac{1}{40}N$-Na_2S. J. Lefort and P. Thibault used a mixture of gum arabic and silver nitrate, and E. Stiasny used casein, albumin, dextrine, gelatine, or glue in place of gum arabic. A. Pieroni treated a dil. soln. of silver nitrate in pyridine with hydrogen sulphide. S. Odén mixed dil. soln. of silver nitrate and of sulphur hydrosol. H. Freundlich and A. Nathanson made silver sulphide sol by mixing sulphur sol with silver sol; and F. V. von Hahn, by bubbled hydrogen sulphide through $0{\cdot}002N$-$AgNO_3$. The so-called *silver hydrosulphide* of S. E. Linder and H. Picton is probably the colloidal sulphide. F. V. von Hahn found that silver hydrosols pass through a range of colours from yellow to green on adding increasing amounts of potassium chloride; the precipitate is invariably brown.

Argentite has a dark leaden-grey colour, and it occurs in **crystals** which are rude uneven cubes, or octahedra, but more usually it is scaly, earthy, or dendritic. H. Rose's analyses[4] of fahlerz showed that silver and cuprous sulphides are closely related, and G. Rose emphasized the relationship by showing that cuprous sulphide, though rhombic in copper glance, does occur in a cubic form like argentite; and he added that "the isodimorphism of these two sulphides is almost established by the occurrence of a rhombic stromeyerite (Cu, Ag)$_2$S, at Rudelstadt (Silesia); but the demonstration will not be completed until rhombic crystals of silver sulphide have been discovered." In 1855, C. A. Kenngott was lucky enough to find the missing rhombic form of silver sulphide near Joachimsthal; and he called the new mineral *acanthite* from ἄκανθα, a thorn, in reference to the appearance of its acicular crystals—H. Dauber found the axial ratios to be $a:b:c=0\cdot6886:1:0\cdot9944$. There is also the rhombic form of silver sulphide *daleminzite*, so named by A. Breithaupt after Dalminzien, the ancient name for Freiberg. The angle of the rhombic prism of daleminzite is 116°, and with acanthite, 110° 54′. The former is the variety isomorphous with cuprous sulphide.

The **specific gravity** of artificially prepared silver sulphide was found by C. J. B. Karsten to be 6·8501; H. Dauber found 7·269 and 7·317 for argentite; and for acanthite, 7·164 to 7·326; while C. A. Kenngott found 7·31 to 7·36; and A. Breithaupt gave 7·02 for daleminzite. The **hardness** is about 2. In illustration of the **malleability** of silver sulphide, J. J. Berzelius related that Augustus, King of Poland, caused pieces of native silver sulphide from the Saxony mines to be struck into medals. M. Bellati and S. Lussana found the **specific heat** between 75° and 220° to be 0·0891; and at 100°, 0·0786; A. Sella gave 0·0746; while W. A. Tilden found the sp. ht. between —182° and 15° to be 0·0568; between 15° and 100°, 0·0737; and between 15° and 324°, 0·0903. E. Madelung and R. Fuchs gave $3\cdot00\times10^{12}$ dynes per sq. cm. for the **compressibility** of argentite. H. Pélabon gave 825° for the **melting point** of silver sulphide; F. M. Jäger and H. S. van Klooster gave 842°; W. Truthe, 834°; G. G. Urazoff, 842°; C. Sandonnini, 836°; and the latter found the f.p. to be not much higher than 812°. The fusion curve is shown in Fig. 19. F. M. Jäger says that silver sulphide dissociated perceptibly at 950°. O. Mügge found an appreciable softening occurs when the silver sulphide is heated to 200°. K. Friedrich, and W. Truthe found the **transition point** from the rhombic to the cubic form is 175°, C. Sandonnini gave 178°; F. M. Jäger and H. S. van Klooster, 179°. According to G. G. Urazoff, solid silver sulphide shows transition points at 576°, 175°, and 110°. The first modification forms solid soln. with up to 0·5 per cent. of silver, and this product breaks down, as the temp. is lowered, and passes through the other critical points. There is also a discontinuity in the electrical resistance at the transition point. P. W. Bridgman found that the transformation is accompanied by a very small change in vol.—less than 0·0002 c.c. per grm.

V. Kohlschütter and E. Eydmann say that silver sulphide does not sublime between 350° and 400°, but in sulphur vapour or in hydrogen sulphide the product rapidly re-crystallizes—*vide* moss silver.

The **heat of formation** of silver sulphide from the solid elements is $2Ag+S=Ag_2S+3\cdot0$ Cals. according to M. Berthelot, and 5·34 Cals. according to J. Thomsen.[5] The former also gives $2Ag_{solid}+H_2S_{gas}=Ag_2S+H_{2gas}-1\cdot6$ Cals.; and $Ag_2O+H_2S_{soln.}=Ag_2S+H_2O_{liq.}+27\cdot9$ Cals. J. Thomsen found for $2AgNO_{3aq.}+H_2S_{aq.}=47\cdot63$ Cals., and P. A. Favre and J. T. Silbermann, 57·52 Cals. W. A. Felsing calculated the **free energy** decrease at the transition temp. 448° K. to be —630 cals.

A. de Gramont[6] found the **spark spectrum** of argentite is characterized by the intensity of two green silver-lines, only comparable with the thallium-line, and stronger than the copper-line; there are also other silver lines present without special characteristics. There is also a group of sulphur-lines in the red, green, and blue parts of the spectrum; and diffuse and scarcely visible lines in the violet where they are mixed with iron-lines. Some zinc-lines are also visible. O. Rohde, and K. Herrmann have studied the **photoelectric effect** of silver sulphide. G. Chaperon and E. Mercadier, and H. Rigollot found that silver sulphide is sensitive to luminous or ultra-violet radiations, and it can serve as an *actinometre électrochimique*. Like selenium, it has a low electrical conductivity in the dark and a higher one in light. W. W. Coblentz and H. Kohler found a change in the electrical resistance of argentite when exposed to light, from 0·6μ in the visible spectrum to 3μ in the infra-red. G. Césaro said that argentite is a non-conductor, but others find it to be a conductor of electricity, but not so much as acanthite.

F. Beijerinck says that the decrease in the **electrical resistance** with decrease of temp. is more marked at a low temp. than at a higher temp.; at 180° the resistance is approximately a thousand times smaller than at 80°. K. Bädeker found that the passage of the current at room temp. is attended by decomposition and polarization, but not so at 220°; the sp. resistance at 200° is 0·0017 (when that of copper is 0·0000017). There is a marked jump in the conductivity near the transition point 175°. V. Kohlschütter and H. Stäger studied the electrolysis of sulphide soln. with anodes of silver sulphide. C. Tubandt found solid silver sulphide conducts electrolytically above 180°, the silver ions carry the current with an ionic velocity of 0·11 cm. per sec. F. Streintz noted the high temp. coeff. of the conductivity of silver sulphide. W. Mönch made observations on this subject. S. von Lasczynsky and S. von Gorsky found that a soln. of silver sulphide in pyridine is a non-conductor. F. Streintz studied the unipolar conductivity of silver sulphide. C. Tubandt also measured the conductivity of the crystalline solid. A. A. Noyes and E. S. Freed, and G. Trümpler studied the e.m.f. of silver sulphide cells; and the last-named measured the e.m.f. against sodium sulphide.

According to R. Lucas,[7] the **solubility** of silver sulphide in water is smaller than that of silver iodide. The solubility is so small that the estimates that have been made are not in agreement. O. Weigel estimated the constant to be $0{\cdot}552 \times 10^{-6}$ mol per litre at 18°; W. Biltz, $0{\cdot}8 \times 10^{-6}$ between 16° and 18°; and J. Knox, $2{\cdot}2 \times 10^{-17}$, at 25°, if complete ionization occurs, and $4{\cdot}3 \times 10^{-17}$ from the conc. of the silver ions in a sat. soln.

Chemical properties of silver sulphide.—Silver sulphide is permanent in a dry or moist atm. at ordinary temp. whether in light or in darkness; and J. Percy[8] showed that this applies even when the silver sulphide is finely powdered. A. Beutell found that when natural or artificial silver sulphide is heated in an evacuated tube for several days between 350° and 600°, some decomposition occurs; and a little silver is formed which seems to wander through the silver sulphide, appearing at the cooler end of the tube as filiform silver (*q.v.*). Neither silver foil nor filiform silver is attacked by sulphur vapour in vacuo at 450° for 48 hrs. Silver foil alone in vacuo at 450°–585° showed no trace of the formation of filiform silver, but silver and silver sulphide heated together at 450° furnishes filiform silver. The action of heat on silver sulphide was studied by M. Wasjuchnowa. When silver sulphide is heated in atm. air, silver and sulphur dioxide are formed. D. Larranga, F. de la Garza, A. V. Ezpeleta and J. M. Peimger, and P. Berthier state that if roasted at a low temp. some silver sulphate is formed, but J. Percy failed to confirm this at the lowest temp. at which any change occurs.

F. Krafft and L. Merz found that in vacuo in the cathode light, silver sulphide decomposes at a low temp. into silver and sulphur. V. Kohlschütter ascertained that silver sulphide is reduced by exposure to canal rays, even when hydrogen is absent. K. Friedrich and A. Leroux did not detect any appreciable action when silver sulphide is exposed to the radiations from radium bromide, but O. Mügge said that there is a slight action. K. Friedrich and A. Leroux found argentite is decomposed by exposure to sun-light or the arc-light, and the decomposition is the more marked the more intense the light. O. Mügge also found polished surfaces of natural or artificial silver sulphide become covered with a fine dust when exposed to conc. solar light; but the attack is very slight in an indifferent atm. At the high temp. of an electric furnace, A. Mourlot found that silver sulphide melts and is readily reduced, and the condensed drops of volatilized metal contain traces of sulphur. According to A. de Gramont, when argentite is exposed to electric sparks, it acquires a black coating—possibly metallic silver.

H. Rose[9] heated silver sulphide in a stream of **hydrogen** and observed that hydrogen sulphide is evolved, and that the silver separates in delicate hair-like fibres. S. Hauser gave 260°–276° for the temp. of the reaction. According to V. Kohlschütter and E. Eydmann, the evolution of hydrogen sulphide can be detected between 200° and 220°. H. Pélabon has studied the equilibrium conditions in the reaction: $H_2+Ag_2S\rightleftharpoons H_2S+2Ag$ in sealed tubes at different temp. Equilibrium is attained the more quickly the higher the temp.; at 360° about 160 hrs. is needed, and at 580° a few moments suffice. The liberated silver occurs in filiform masses only when the temp. is below 580°; the best samples were obtained by heating crystalline silver sulphide and hydrogen in a sealed tube at 440°. W. S. Felsing studied the equilibrium conditions in the reaction $Ag_2S+H_2=2Ag+H_2S$ between 750° K. and 890° K., and found the equilibrium constant $K=v_{H_2S}/v_{H_2}$ has the value 0·3588 at 749·15° K.; 0·3155 at 811·25° K.; and 0·2780 at 889·63° K. The relation of the thermal value of the reaction to the temp. about 448° K. is $3471-7\cdot20T$, or 245 cals. at 448° K., and allowing for 1195 cals. for the increased heat content at the transition temp., the thermal value of the reaction near 298° K. is $3740-5\cdot68T$, or 2047 cals. at 298° K. The change in the free energy of the reaction is —1527 cals. at 749·15° K.; —1861 cals. at 811·25° K.; and —2265 cals. at 889·63° K.; and for the decrease in free energy between 448° K. and 890° K., $-3471-7\cdot20T\log_e T+50\cdot26T$; and from 298° K. to 448° K., $-3740-5\cdot68T\log_e T+41\cdot58T$. Silver sulphide is reduced by "nascent" hydrogen from iron or zinc and a dil. acid, and P. Laur reduced the sulphide by the action of tin amalgam and a dil. soln. of sodium hydroxide. According to A. Mailfert, silver sulphide is oxidized by **ozone** to free sulphuric acid, etc.

Silver sulphide undergoes no appreciable change in **water** at ordinary temp., but P. de Clermont and J. Frommel found that when boiled with water, some silver oxide and hydrogen sulphide are formed. According to O. Weigel, a litre of water at 18° dissolves $0\cdot552\times10^{-6}$ mol of silver sulphide. H. V. Regnault found that silver sulphide is reduced to the metal when heated to redness in steam, and there is a marked evolution of hydrogen sulphide. G. Bischof found the reduction occurs at a little below the m.p. of zinc (418°), and the silver is left in hair-like threads exactly resembling capillary or filiform silver. G. Bischof claimed that some sulphuric acid is produced in the reaction, possibly: $4Ag_2S+4H_2O=4Ag_2+H_2SO_4+3H_2S$. F. A. Moesta showed that the products vary with the temp. of the reaction, and in his experiments, hydrogen sulphide, sulphur dioxide, and free sulphur escaped from the tube along with the excess of steam. Possibly the sulphur of the sulphide is simultaneously attacked by the water, simultaneously forming hydrogen sulphide and sulphur dioxide. B. Corenwinder found that the passage of sulphur vapour and steam over porous substances gave hydrogen sulphide, but he does not mention the production of sulphur dioxide. Artificial silver sulphide was found to be energetically reduced by steam at 100°, and by heating different parts of a tube of silver sulphide to different temp., it is easy to obtain silver in "tree-, moss-, and wire-like forms, and also in larger pieces." F. A. Moesta found a mixture of sodium chloride and silver sulphide is slowly converted into silver chloride by steam at 100°; and rapidly if magnesium chloride be substituted for the sodium salt. The reactions are faster at a higher temp., and also if finely powdered iron pyrites be present. In the latter case the increased activity is attributed to the facility with which the sulphur of the pyrites is converted into sulphuric acid.

According to H. Rose,[10] silver sulphide is not acted upon by **chlorine** at ordinary temp., and is attacked but slowly when heated in a stream of that gas, while C. J. B. Karsten stated that chlorine converts the sulphide into chloride at ordinary temp., and that the action takes place more quickly and completely when the sulphide is heated to redness in an atm. of the gas. L. R. von Fellenberg, and J. Percy also found that silver sulphide is changed by chloride into silver chloride, and the action is promoted by a rise of temp. Sulphur chloride is a product of the reaction. P. Jannasch proposed to decompose the argentiferous sulphides by dry air charged with **bromine** vapour. Chlorine water was also found by J. Percy to partially convert silver sulphide into chloride at ordinary temp., and in light; most of the sulphur is simultaneously oxidized to sulphuric acid. F. J. Malaguti and J. Durocher obtained a similar result in darkness. According to K. Heumann, dil. **hydrochloric acid** has no appreciable action on old or freshly precipitated silver sulphide; but the conc. acid, particularly if aided by heat, gives off hydrogen sulphide and forms silver chloride, which in part dissolves and in part forms a coating over the sulphide, protecting or impeding further action. F. T. Sonneschmid studied the combined action of aq. hydrochloric acid and mercury on the Mexican sulphide ores, and found that at ordinary temp. the silver sulphide is completely reduced and the whole of the silver amalgamates with the excess of mercury. Silver chloride is first formed, and this is reduced by the mercury. A. A. Noyes and E. S. Freed calculated the free energy of the reaction: $Ag_2S+2HI_{aq.}=2AgI+H_2S_{aq.}$, and they found 4070 cals. at 25°.

C. Schnabel found that silver sulphate is formed when silver sulphide is heated with **sulphur trioxide.** According to J. Percy, silver sulphide is said to be decomposed by conc. **sulphuric acid** with the formation of silver sulphate and free sulphur; but it is not acted on when boiled with sulphuric acid diluted with three or four times its vol. of water. According to T. Gross, when silver sulphide is brought into contact with a platinum cathode in dil. sulphuric acid, it is converted into a grey mass, the gas evolved from the cathode yields, with silver nitrate soln., a greyish-black precipitate consisting of glistening plates. A similar precipitate is obtained by treating silver nitrate with electrolyzed sulphuric acid. Both precipitates differ from silver sulphide, Ag_2S, in properties, but their compositions have not been determined. According to P. Berthier, and A. Guérout, silver sulphide is not soluble in **sulphurous acid.** A. Potilitzin found that when heated with an eq. quantity of **selenium,** between 600° and 700°, about 68 per cent. of the sulphur is displaced. According to H. Feigel, a benzene soln. of **sulphur chloride** converts silver sulphide into a mixture of silver chloride and sulphide.

J. Percy[11] has studied the formation of silver chloride from the sulphide, chiefly with the object of understanding the Mexican amalgamation process. When silver sulphide is treated with sodium chloride, air, and water at ordinary temp., no silver chloride is formed, but when silver sulphide is treated with cupric chloride, air, and water at ordinary temp., silver chloride and cupric oxychloride are formed, with the separation of free sulphur and sulphuric acid. It is assumed that the first reaction: $Ag_2S+2CuCl_2=2AgCl+2CuCl+S$, is followed by $2Ag_2S+8CuCl+3O_2+6H_2O=4AgCl+2\{CuCl_2.3Cu(OH)_2\}+2S$. J. B. J. D. Boussingault believed an aq. soln. of cupric chloride has no action on silver sulphide, but immediately sodium chloride is added decomposition begins, and it continues until all the silver is converted into chloride. C. J. B. Karsten made a similar observation, and added that an ammoniacal soln. of cupric or cuprous chloride likewise has no action on silver sulphide, but a reaction does occur if sodium chloride be present. F. J. Malaguti and J. Durocher claimed, like J. Percy, that the presence of sodium chloride is not necessary for the reaction between silver sulphide and cupric chloride. J. Percy also found that when a conc. aq. soln. of cupric chloride in excess is boiled with silver sulphide, the latter is rapidly converted into chloride; the action is not appreciably accelerated if a stream of air is passed through the boiling liquid—sulphur is liberated during the reaction, and a little sulphuric acid is formed. If a mixture of silver sulphide and cuprous chloride is boiled, while a stream of air is passed through the mixture, only a little silver chloride is formed. This is explained by the insolubility of both substances in water. When silver sulphide is exposed to the action of cupric and sodium chlorides, air, and water at ordinary temp., silver chloride is formed and sulphur is set free. C. J. B. Karsten found a soln. of cupric and sodium chlorides decomposes stephanite, red silver ore, and fahlerz in the course of a few days—the last-named mineral is attacked the most slowly—cuprous and silver chlorides are formed. If cuprous chloride be substituted for cupric chloride, the silver sulphide behaves in a similar way—the cuprous chloride is soluble in the soln. of sodium chloride. If air be excluded, not a trace of silver chloride is formed, so that oxygen plays an essential part in the conversion of silver sulphide to the chloride by cuprous chloride and a soln. of sodium chloride. F. J. Malaguti and

J. Durocher state that in air some silver is formed. If cupric sulphate is substituted for cupric chloride similar results are obtained; cupric chloride and sodium sulphate are first produced, and the former then reacts with silver sulphide as before. Silver sulphide, basic ferric sulphate, sodium chloride, and water, react at ordinary temp., and silver chloride is formed. Air is not needed for the reaction. According to F. J. Malaguti and J. Durocher, ferric sulphate alone has no action on silver sulphide; while, according to J. Guillemin, ferric sulphate has been successfully used at Tetela del Ora as a substitute for cupric sulphate in the Mexican amalgamation process. If ferrous sulphate be employed in place of the basic ferric sulphate, silver chloride is produced only when atm. air has access.

According to F. J. Malaguti and J. Durocher, pyrargyrite behaves like silver sulphide with a soln. of cupric chloride; and when air is present, "sulphuric acid and a mixed deposit of silver chloride and cupric oxychloride are formed; the antimony passes into soln. from which it can be precipitated along with the copper by a plate of zinc." Proustite is less energetically attacked than pyrargyrite. The presence of sodium chloride does not promote the formation of silver chloride as it does in the case of the simple sulphide. Sodium chloride inhibits the reaction with proustite. Argentiferous galena, cuprous chloride, air, and water, form cupric oxychloride, lead chloride, and cupric sulphate—some silver chloride was produced at the end of three months' action. Similar experiments were made with argentiferous blende, and argentiferous iron, or copper pyrites.

Silver sulphide dissolves in the **alkali sulphides**—*vide infra* for the resulting double sulphides—and J. Knox[12] found that at 25° 0·1 mol of sodium sulphide in *N*-soln. contains $6{\cdot}3\times10^{-24}$ gram-ions of silver per litre when sat. with silver sulphide. The blackening of silver by hydrogen sulphide or soluble sulphides has been studied by F. H. Hahn—*vide* silver. J. Percy found silver sulphide to be insoluble in an aq. soln. of **sodium thiosulphate.** P. N. Gredy found silver sulphide dissolves in conc. **nitric acid,** with the separation of sulphur. H. Gruener found that the proportions of silver nitrate and sulphate formed during the reaction vary widely with the conc., temp., and time. Silver sulphide is rapidly dissolved by nitric acid when the conc. exceeds 5 per cent. Very conc. nitric acid yields silver sulphate alone, while acid of lower conc. forms some nitrate in proportion to its dilution: thus, 20–21 per cent. acid yields the maximum proportion of silver nitrate—about 95 per cent.—and a more dil. acid again results in a smaller percentage of nitrate. Heating the acid or prolonging its time of action is unfavourable to the formation of nitrate. According to P. N. Gredy, silver sulphide is not soluble in aq. soln. of **ammonia** or **ammonium carbonate.** P. N. Gredy found aq. ammonia dissolves some silver sulphide, if it has been simultaneously precipitated with silver chloride; and, according to E. C. Franklin and C. A. Kraus, silver sulphide is not soluble in liquid ammonia. N. D. Costeanu did not observe any reaction with **carbon dioxide.** F. H. Hahn found that silver sulphide dissolves in **hydrocyanic acid,** and the soln. gives a black precipitate when treated with an excess of potassium sulphide, a violet coloration with nitroprusside, and, with hydrochloric acid, silver chloride is precipitated. W. Skey found silver sulphide to be soluble in aq. soln. of **potassium cyanide.** R. Lucas represented the reaction: $Ag_2S+6KCy+H_2O=KSH+KOH+2K_2AgCy_3$; but E. Kühn found that more silver is dissolved than corresponds with this equation, and C. Göpner represented the reaction: $Ag_2S+4KCy=K_2S+2KAgCy_2$. J. Percy found that five-sixths of the silver is reduced by fusing silver sulphide with potassium cyanide, the remaining silver remains in combination with the resulting alkali sulphide.

According to J. Percy,[13] silver sulphide is not affected by trituration with **iron** powder, dry, or in the presence of cold or hot water; but if hydrochloric acid be present, hydrogen sulphide and silver are liberated; similar results are obtained with **zinc.** F. J. Malaguti and J. Durocher reduced silver sulphide by iron in a soln. of alum, or of ferrous or cupric sulphate at 100°. In the last case the reaction must be complicated by the separation of copper. Iron completely reduces silver sulphide at a red heat, with the formation of iron sulphide; prolonged fusion, stirring, and an excess of iron are needed for the completion of the reaction. Iron does not separate the silver completely from the double sulphide of copper and iron. Silver sulphide is not completely reduced when heated with an excess of copper; the regulus formed contains silver, and the silver alloys with the copper. J. Percy said that silver sulphide is reduced by shaking it with precipitated **copper** in water, but F. J. Malaguti and J. Durocher say that copper has no action on silver sulphide even in water at 100° provided the sulphide is thoroughly freed from acid; they also report that silver sulphide is more easily reduced by copper than by iron, in water containing alum, or cupric or ferrous sulphate at 100°. When cuprous oxide is used in place of copper, a smaller amount of silver is reduced in the case of alum and cupric sulphate, but a larger amount in the case of ferrous sulphate. Similar experiments were made on pyrargyrite, and on proustite. Expressing the amount of silver reduced in hundredths of the amount of silver in the sulphide:

	Alum	$CuSO_4$	$FeSO_4$
Copper and argentite	83·39	83·39	28·44
Copper and pyrargyrite . . .	71·0	71·0	8·8
Cu_2O and proustite	22·0	43·0	17·8

Possibly an insoluble basic ferric sulphate was formed in the case of ferrous sulphate. Silver sulphide is not completely reduced when heated with **lead** in excess, since the regulus contains silver, and the silver which separates alloys with the excess of lead.

Silver sulphide is decomposed when triturated with **mercury** even at ordinary temp., and if the mercury be in excess, silver amalgam is formed: $Ag_2S+Hg=HgS+2Ag$. F. J. Malaguti and J. Durocher reported that mercury reduces silver sulphide, native or artificial, more rapidly than the chloride. The presence of alum or of ferrous or cupric sulphate greatly promotes the reducing action of mercury on silver sulphide. With mercury alone unity, the relative proportions of silver extracted by mercury with the aid of these salts is:

	Alum	$FeSO_4$	$CuSO_4$
Mercury and silver sulphide . . .	1·34	1·80	28·3

The action on pyrargyrite and proustite is slower than in the case of argentite. There are some native sulphides which contain a considerable proportion of silver sulphide but from which no silver, or only a small proportion of the total, can be extracted by treatment with an excess of mercury. Thus, of ten samples of galena from different localities, that from Sala (Sweden), with 0·8 per cent. of silver, yielded about 18 per cent. of its silver; that from Giromagny, with 0·05 per cent. of silver, yielded about 17 per cent. even though the former is 16 times richer in silver than the latter; none of the other eight samples yielded any silver to the mercury during 960 hrs.' contact. Hence, added F. J. Malaguti and J. Durocher:

> Il semble donc que les galènes dociles à l'amalgamation renferment l'argent sous forme de sulfure dont une partie au mois se trouve à l'état de mélange, tandis que les galènes qui ne cèdent rein au mercure renferment probablement le sulfure d'argent à l'état de combinaison.

Similar results were obtained with argentiferous blende, iron pyrites, and grey copper ore. R. Segura found the amalgamation occurs much more readily when the amount of water is just sufficient to make the mixture into a paste and is not in excess. V. Kohlschütter and E. Eydmann found mercury vapour passed in a stream of carbon dioxide over heated silver sulphide reduces it more slowly than hydrogen.

A boiling soln. of potassium hydroxide transforms silver sulphide into oxide. J. Percy found that the fusion of silver sulphide with four times its weight of **potassium hydroxide** reduced 88·7 per cent. of the silver, in about 30 mins. at dull redness; similar results were obtained by fusion with **sodium carbonate.** With a longer action and a higher temp. the yield was greater. Silver sulphide is not soluble in an aq. soln. of sodium or potassium carbonate. No reaction is observed when silver sulphide is heated with **calcium oxide.** When silver sulphide is fused with **alkali chloride** in the presence of air, part is decomposed, forming silver chloride and sodium sulphate, and part is resolved into silver and sulphur dioxide. It is possible also that the alkali chloride acts on some of the metallic silver liberated during the reaction.

Silver sulphide is not soluble in aq. soln. of potassium or sodium chloride. When a mixture of silver sulphide and **silver oxide** is heated, the compounds are mutually reduced: $Ag_2S+2Ag_2O=6Ag+SO_2$; **lead oxide** behaved similarly and an alloy of lead and silver was produced. If the lead oxide be in large excess, no sulphate was detected in the products of the reaction. Similar results were obtained with **copper oxide.** When a mixture of **silver sulphate** and sulphide is fused, the reaction is symbolized: $Ag_2S+Ag_2SO_4=4Ag+2SO_2$. J. Percy also found silver sulphide is not oxidized by heating it with **sodium sulphate ; potassium nitrate** forms potassium sulphate and all the silver separates as metal; a violent reaction occurs with **potassium chlorate,** and about one-third of the sulphide is reduced to silver: $3Ag_2S+4KClO_3=2Ag+4AgCl+2K_2SO_4+SO_2+O_2$. A boiling soln. of potassium chlorate has no action on silver sulphide. Silver sulphide dissolves in fused borax and in microcosmic salt, colouring the masses red. As previously indicated, C. J. B. Karsten found silver sulphide is not decomposed by a soln. of **cupric chloride,** but J. B. J. D. Boussingault observed that cupric sulphide and silver chloride are formed if the soln. of cupric chloride contains some sodium chloride. C. Schnabel reported that solid cupric chloride is reduced to cuprous chloride by silver sulphide. A. Levallois found that **lead chloride** decomposes silver sulphide: $Ag_2S+PbCl_2=PbS+2AgCl$. According to W. H. F. Wackenroder, silver sulphide is insoluble in a soln. of **mercuric nitrate ;** and H. C. Bolton found that it dissolves in **citric acid** containing a little potassium nitrate.

Silver sulphide is stated by E. Waterton [14] to have been used for the preparation of a black substance used in ancient times for inlaying silver and other jewels—*argenterie niellée*—in the so-called *niello* work described by Theophilus, and others.

J. J. Berzelius [15] emphasized the basic character of silver sulphide, in that it forms a number of double salts with other sulphides. P. Berthier stated that silver sulphide is soluble in fused alkali sulphides in all proportions, and it combines *par voie sèche* with most of the metal sulphides. According to A. Ditte, silver sulphide changes its colour when kept in darkness in contact with a cold sat. soln. of sodium sulphide, Na_2S; and if the liquid is warmed whereby its conc. increases, a stage is reached when a mass of red crystals suddenly appears. The crystals are rapidly filtered from the mother liquid, and dried on porous tiles. Their composition is then **silver sodium sulphide,** $Na_2S.3Ag_2S.2H_2O$. The crystals are immediately decomposed by water, or by a sat. soln. of sodium sulphide, with the formation of black silver sulphide. A. Ditte also prepared **potassium silver sulphide,** $K_2S.4Ag_2S.H_2O$, in a similar way. A. C. Becquerel prepared crystals of a potassium silver sulphide of unknown composition by the galvanic decomposition of silver nitrate and potassium sulphide.

According to G. Rose, dark steel-grey rhombic crystals of *stromeyerite* with axial ratios $a : b : c=0{\cdot}5822 : 1 : 0{\cdot}9668$ occur in nature. According to the analyses of F. Stromeyer, T. Sander, W. J. Taylor, and I. Domeyko, their composition corresponds with **cupric silver sulphide,** $(Cu, Ag_2)S$, up to half of the copper in chalcosine being replaced by silver. Their sp. gr. is 6·2–6·3; and hardness 2–3. Another variety of this salt occurs in cubical crystals of *jalpaite*, $(Cu, Ag_2)S$, with a sp. gr. 6·88–6·89, and hardness less than 3. They were analyzed by A. Breithaupt, and E. Bertrand. K. Friedrich's thermal analyses of mixtures of cuprous and silver sulphides do not show the existence of any compounds. The fusion curve is of the U-form, falling from the m.p. of cuprous sulphide at 1121°, to a minimum at 677°, rising again to 835°, the m.p. of silver sulphide.

Silver disulphide, Ag_2S_2.—The rise in the f.p. of mixtures of silver sulphide with increasing proportions of sulphur, points to the existence of higher sulphides. A. Hantzsch[16] prepared silver disulphide by adding a soln. of sulphur in carbon disulphide to a soln. of silver nitrate in benzonitrile; the precipitate, after remaining for 24 hrs. in a closed flask, is washed with benzonitrile and carbon disulphide, and then with alcohol and ether, and quickly dried on a porous plate. It is a brown amorphous powder which oxidizes very rapidly when damp, yields a soln. of silver sulphate when shaken with water, and does not lose sulphur when extracted with carbon disulphide; it melts to a red liquid when heated, and then gives off sulphur and sulphurous anhydride, leaving a residue of metallic silver. When treated with dil. hydrochloric acid, it yields sulphur, hydrogen sulphide, and silver chloride, whilst nitric acid dissolves it with liberation of sulphur. Silver disulphide can only be prepared from a soln. of benzonitrile; when other solvents are used, silver sulphide is obtained.

§ 19. Silver Sulphate

The action of sulphuric acid on silver resulting in the formation of silver sulphate has already been discussed. P. Brahmin preferred dissolving silver foil in sulphuric acid containing a few drops of conc. nitric acid. J. S. Stas [1] prepared normal silver sulphate by treating finely divided reduced silver with conc. sulphuric acid, and subsequently expelling the sulphur dioxide by boiling. The salt was washed with water, and heated on a platinum dish to the b.p. of sulphuric acid. It can also be made by evaporating to dryness a soln. of silver nitrate with sulphuric acid; by dissolving silver carbonate in dil. sulphuric acid; or by adding sodium sulphate or sulphuric acid to an aq. soln. of silver nitrate, when silver sulphate is precipitated as a white crystalline powder. A. E. Hill and J. P. Simmons prepared the salt in this way, and dried the washed crystals at 100°; and the preparation of the salt of a high degree of purity is discussed by T. W. Richards and G. Jones. E. Mitscherlich found the finest crystals are obtained from a soln. of the salt in nitric acid, and C. Schultz obtained a mass of plates by cooling the soln. of the salt in sulphuric acid of sp. gr. less than 1·5.

According to E. Mitscherlich, and C. F. Rammelsberg, the prismatic **crystals** belong to the rhombic system and have axial ratios $a:b:c=0·5712:1:1·2380$; and, according to J. W. Retgers, the rhombic pyramids are isomorphous with sodium sulphate and with sodium and silver selenates. The reported numbers for the **specific gravity** of the salt are: L. Playfair and J. P. Joule, 5·322 at 3·9°; C. J. B. Karsten, 5·341; E. Filhol, 5·410; O. Pettersson, 5·49 and 5·54 at 11°; H. G. F. Schröder, 5·425; and T. W. Richards and G. Jones, 5·45 at 29·2°. The last two determinations were made on the salt which had been fused. According to W. D. Harkins, the sp. gr. of a sat. soln. of the salt at 25° is 1·0052; W. D. Harkins has measured the sp. gr. of mixed soln. of silver sulphate with nitric acid, the nitrates of potassium, magnesium, and silver, and the sulphates of potassium and magnesium. B. L. Vanzetti found that if a layer of water be poured over a conc. aq. soln., sulphuric acid diffuses partially into the water.

According to J. S. Stas, silver sulphate decrepitates at about 300°, and when it melts at a dull red heat, there is scarcely any loss in weight, and it forms a pale yellow liquid, which solidifies to a white crystalline mass. If the molten sulphate contains a trace of the sulphide, it melts to a dark orange-coloured liquid, and solidifies to a brownish-black crystalline mass. According to T. W. Richards and G. Jones, the fused salt acquires a darker colour as soon as it has slightly decomposed—even when the loss is but 0·0015 per cent. According to T. Carnelley, its **melting point** is 654°±2°; W. Ramsay and N. Eumorfopoulos gave 676°; A. Potilitzin, 654°; H. O. Hofman and W. Wanjukow, 656°; R. Nacken, 651°; and K. Friedrich, 660°. J. L. Gay Lussac, and R. H. Bradford found that at a higher temp. the salt decomposes giving off sulphur dioxide and oxygen, and leaving behind the metal; H. O. Hofman and W. Wanjukow say that the dissociation begins at 752°, and is rapid at 917°; while K. Friedrich said that it decomposes into silver at 1085°. According to K. Friedrich, there is a **transformation point** at 410°; H. O. Hofman and W. Wanjukow give 417°; and R. Nacken gives 412°. According to the latter, α-silver sulphate is stable between 651° and 412°, and β-silver sulphate is the form stable below 412°. The **heat of formation,** according to J. Thomsen, is $(2Ag, S, 4O)=167·28$ Cals.; $(2Ag, 2O, SO_2)=92·2$ Cals.; $(Ag_2O, SO_3)=58·14$ Cals.; and for $(Ag_2O, SO_{3aq.})=14·49$ Cals. J. Thomsen's value for the **heat of solution** is −4·48 Cals., and M. Berthelot's, −4·40 Cals. The latter also gives for the heat of neutralization: $Ag_2O+H_2SO_{4aq.}=Ag_2SO_{4aq.}+H_2O+14·4$ Cals.

Silver sulphate is not changed by exposure to sunlight. W. N. Hartley[2] found the **absorption spectrum** of a layer of a $\frac{1}{40}N$-soln., 200 mm. thick, is continuous up to $\lambda^{-1}=4008$, and the transmitted rays extend beyond those of silver nitrate of the same conc., so that the specific absorption exerted by the silver does not limit the extent of the rays of the spectrum absorbed or transmitted by the nitrate soln.

The **electrical conductivity** λ of aq. soln. of silver sulphate has been measured by A. A. Noyes and K. G. Falk,[3] S. J. Bates, G. Jäger, E. Bouty, W. D. Harkins and F. L. Hunt, etc. In the following data, by F. L. Hunt, the conc. C are expressed in millimols per litre:

	0	1	2	4	5	10	20	40
λ at 18° .	112·5	116·3	113·6	109·85	108·4	102·9	96·1	88·0
λ at 25° .	143·4	135·7	132·6	128·0	126·3	119·9	111·7	102·2

The corresponding **percentage ionization,** α calculated from λ/λ_∞ are:

α at 18° . .	100	95·0	92·7	89·5	88·5	84·0	78·4	71·8
α at 25° . .	100	94·7	92·5	89·3	88·1	83·6	77·9	71·3

W. D. Harkins has also measured the conductivity of soln. of silver sulphate with potassium nitrate, magnesium nitrate, silver nitrate, potassium sulphate, or magnesium sulphate. J. Kendall and co-workers measured the conductivity of silver sulphate in anhydrous sulphuric acid. W. Hittorf's value for the **transport number** of the anions in $0·05N$-soln. at 17° is 0·554. A. Chassy has also measured values for this constant. F. Streintz measured the electromotive force of cells with aq. soln. of silver and cupric sulphates; and J. Miesler of conc. cells. For the formation of **silver peroxysulphate** during the electrolysis of a soln. of silver sulphate, *vide* peroxynitrate.

The **solubility** of silver sulphate in water is small; according to K. Drucker,[4] 100 parts of water at 25° dissolve 0·80 part of the salt; and, according to J. J. Berzelius, 100 parts of water at 100° dissolve 1·14 parts of the salt, which is deposited from the cooling soln. in small acicular crystals. The solubility of silver sulphate in water has been measured by C. F. Wenzel, P. Kremers, V. Rothmund, G. F. Rodwell, J. M. Eder, etc. At 17°, H. Euler found 0·770 grm. of silver sulphate was dissolved per 100 c.c.; at 18°, C. R. A. Wright and C. Thompson, 0·728 grm.; at 25°, K. Drucker found 0·801 grm. per 100 c.c., or 0·0257 mol per litre; C. M. Swan, 0·02699 mol per litre; and at 100°, C. F. Wenzel found 1·460 grms.

per 100 c.c. The composite results for the number of grams of salt in 100 grms. of soln. are:

	0°	10°	20°	30°	40°	60°	80°	100°
Ag_2SO_4 . .	0·57	0·69	0·79	0·88	0·97	1·14	1·28	1·39

A sat. soln. at 25° was found by W. D. Harkins to contain 0·02676 mol per litre; this is about 4 per cent. greater than K. Drucker's 0·0257 mol per litre. Expressing conc. in grams per litre, K. Drucker found at 25°, with soln. of sulphuric acid:

H_2SO_4	0·98	1·96	4·90	9·81
Ag_2SO_4. . . .	8·11	8·23	8·45	8·58

The solubility still further increases by increasing the conc. of the acid. F. Bergius made some inaccurate observations on the solubility of silver sulphate in anhydrous acid. Sulphuric acid of sp. gr. 1·25 is a convenient solvent for silver sulphate. By cooling a soln. of the normal sulphate in dil. sulphuric acid, yellowish rhombic octahedra of a double salt, $Ag_2SO_4.H_2SO_4$, are obtained. According to C. Schultz, and J. W. Retgers, **silver hydrosulphate,** $AgHSO_4$, or $Ag_2SO_4.H_2SO_4$, crystallizes in pale yellowish prisms from a soln. of the normal sulphate in three times its weight of sulphuric acid. J. Kendall and A. W. Davidson say the colour is white, and that there are two forms: the α-salt occurs in thick prisms stable below 66°, and the β-salt occurs in fine needles stable above 66°. The m.p. by extrapolation is 125°, but the salt probably forms normal sulphate at 122·5°. C. Schultz showed that if a soln. of this salt be treated with 8–10 parts of sulphuric acid of sp. gr. 1·6 to 1·7, prismatic crystals of $Ag_2SO_4.3H_2SO_4.2H_2O$, or $AgHSO_4.H_2SO_4.H_2O$, are formed, and the same salt is obtained by dissolving the normal sulphate in from 6–10 parts of sulphuric acid, and allowing the soln. to become diluted by leaving it exposed to moist air. This salt begins to melt at 100°, it is quite liquid at 150°, and it solidifies on cooling into a foliated crystalline mass which gradually changes into small flat crystals. If the normal sulphate be dissolved in from 4–9 parts of sulphuric acid, sp. gr. 1·75, with the aid of heat, foliated plates are formed; they have the composition $2Ag_2SO_4.3H_2SO_4.2H_2O$, or $4AgHSO_4.H_2SO_4.2H_2O$. J. Kendall and A. W. Davidson found that with anhydrous sulphuric acid the solid phase is H_2SO_4 between 10·4° and 2·4° with soln. containing up to 3·67 per cent. of silver sulphate; $Ag_2SO_4.2H_2SO_4$ between −1·5° and 37·6° with between 5·59 and 12·38 per cent. of silver sulphate in soln.; $Ag_2SO_4.H_2SO_4$ between 40·2° and 122·8° and 11·66 to 47·17 per cent. of silver sulphate in soln.; and Ag_2SO_4 between 138·9° and 197·3° with between 47·17 and 48·69 per cent. of silver sulphate in soln. The transition between $H_4Ag_2(SO_4)_3$, or $Ag_2SO_4.2H_2SO_4$ and α-$Ag_2SO_4.H_2SO_4$, is 36°, and for β-$Ag_2SO_4.H_2SO_4$, 39°.

K. Drucker also found that the solubility of silver sulphate is gradually lowered by the addition of increasing proportions of *potassium sulphate*. Expressing solubilities in grams per litre, at 25°:

K_2SO_4	1·74	3·49	8·72	17·44
Ag_2SO_4 . . .	7·67	7·36	7·30	7·24

M. Barre also found the solubility of silver sulphate to increase regularly with the conc. of the soln. of potassium sulphate. W. D. Harkins, but not J. M. Eder, obtained a similar result with potassium sulphate. The presence of *potassium hydrosulphate* decreases the solubility of silver sulphate less than the addition of potassium sulphate. W. D. Harkins explains the effect of potassium sulphate in slightly decreasing the solubility, and of sulphuric acid in increasing the solubility of silver sulphate by assuming that the proportion of the intermediate ion HSO_4' present in the acid soln. is much larger than the proportion of the KSO_4'-ion present in the potassium sulphate soln. A. G. Betts has measured the solubility of silver sulphate in sulphuric acid of different conc. between 2° and 90°. J. M. Eder found the solubility of silver sulphate is augmented with increasing proportions of *sodium sulphate*, and of *ammonium sulphate*. M. Barre obtained similar results. W. D. Harkins measured the effects of *potassium nitrate*, and *magnesium nitrate* on the solubility of silver sulphate, and he also found that the solubility is depressed with increasing proportions of *silver nitrate* or *magnesium sulphate;* the effect is less with the latter than with potassium sulphate. H. Euler found a litre of aq. soln. at 17° in contact with both silver sulphate and *silver acetate* contains 3·95 grms. of silver sulphate and 8·30 grms. of silver acetate—the sp. gr. of the soln. is 1·0094. L. Schnaubert, J. W. Retgers, and W. D. Harkins found that the solubility is increased by increasing proportions of *nitric acid* in the soln.

E. C. Franklin and his co-workers found silver sulphate to be insoluble in liquid *ammonia*, and in liquid *methylamine*. According to V. Rothmund, a litre of water at 25° dissolves 0·0267 grm. of silver sulphate, and a litre of a $\frac{1}{2}N$-soln. of *methyl alcohol* dissolves 0·0249 grm.; *ethyl alcohol*, 0·0228 grm.; *propyl alcohol*, 0·0218 grm.; *tertiary amyl alcohol*, 0·0204 grm.; *acetone*, 0·0220 grm.; *ether*, 0·0206 grm.; *formaldehyde*, 0·0227 grm.; *glycol*, 0·0259 grm.; *glycerol*, 0·0263 grm.; *mannite*, 0·0297 grm.; *grape sugar*, 0·0283 grm.; *cane sugar*, 0·0270 grm.; *urea*, 0·0303 grm.; *dimethylpyrone*, 0·0216 grm.; *urethane*, 0·0227 grm.; *formamide*, 0·0270 grm.; *acetamide*, 0·0253 grm.; *acetonitrile*, 0·0525 grm.; *glycocol*, 0·0433 grm.; *acetic acid*, 0·0252 grm.; *phenol*, 0·0379 grm.; *chloral*, 0·0233 grm.; *methylal*, 0·0205 grm.; and *methyl acetate*, 0·0212 grm. F. Bezold found it to be insoluble in methyl acetate.

J. S. Stas[5] reduced silver sulphate by heating it to a low temp. in a stream of **hydrogen** when the products are silver and sulphuric acid; at a higher temp., the first products are silver sulphide and water, and then silver and hydrogen sulphide. T. W. Richard and G. Jones obtained indications that J. S. Stas did not wholly reduce silver sulphate by hydrogen. According to A. Colson, gaseous hydrogen attacks silver sulphate at about 125°; the reaction is not reversible, because the reaction of sulphuric acid on the hydrogen sulphide changes the character of the products. N. N. Beketoff produced silver from a soln. of the sulphate by heating it under press. with hydrogen.

A. Mailfert found that with **ozone,** a black deposit of silver peroxide is produced, which is decomposed and redissolved on agitating the soln. According to J. Keutwig, **chlorine** does not act directly on silver sulphate, and only at a very high temp. above the m.p. is the salt attacked with the formation of silver chloride, sulphur dioxide, and oxygen. The heat of the reaction: $Ag_2SO_4+Cl_2=2AgCl+SO_2+O_2-37·44$ Cals. According to C. Hensgen, and A. Colson, a mol of silver sulphate absorbs 2 mols of **hydrogen chloride** at ordinary temp. with the evolution of heat, and the salt changes *complètement* into chloride; at 300° the inverse reaction observed with cupric sulphate does not occur, but the sulphuric acid is completely expelled by a current of air. The thermal data indicate that, with the salts investigated, silver sulphate changes into the chloride with the greatest evolution of heat: $Ag_2SO_4+2HCl_{gas}=2AgCl+H_2SO_{4liquid}+40·4$ Cals., or 170 kilojoules as calculated by T. W. Richards and G. Jones from J. Thomsen's observations; they found that the reaction is complete, and it was used in the determination of the at. wt. of sulphur. A. B. Prescott found that if a gram of silver sulphate be evaporated to dryness with 4·035 grms. of aq. hydrochloric acid containing 1·251 grms. of HCl, all is changed into chloride. According to C. W. B. Normand and A. C. Cumming, **bromine** at 0° forms hypobromous acid: $Ag_2SO_4+2Br_2+2H_2O=2AgBr+H_2SO_4+2HBrO$; and at a higher temp., $5Ag_2SO_4+6Br_2+6H_2O=10AgBr+5H_2SO_4+2HBrO_3$. C. Geitner found that silver sulphate is converted to the sulphide when a soln. is boiled with **sulphur.** R. Weber, and H. Schulze converted silver sulphate into the pyrosulphate by the action of **sulphur trioxide.** O. Sackur found **silver sulphide** reacts with the sulphate at 300°, giving off sulphur dioxide and separating silver. The equilibrium press. is over 10 atm. at 327°. J. Camus has studied the action of native **sulphides** and **arsenides** on silver salts.

T. Poleck and K. Thümmel prepared an amorphous red powder with a composition corresponding with **silver sulphato-sulphide,** $Ag_2SO_4.Ag_2S$, by the action of sulphur on a warm conc.

soln. of silver nitrate : $4AgNO_3+2S=4NO_2+Ag_2SO_4.Ag_2S$; or by treating silver sulphide with nitric acid of sp. gr. 1·18. The product is soluble in nitric acid, and is decomposed by water into its component salts. Cold hydrochloric acid converts it into silver chloride and sulphide. The product is stable up to 180°, but it decomposes on calcination, furnishing silver and sulphur dioxide.

E. Divers found **sulphuryl bromide** converted silver sulphate into silver bromide and sulphur trioxide ; J. Girard found that with **sodium thiosulphate** silver sulphide is formed ; J. Seymour, that a neutral soln. of silver sulphate is reduced to the metal by **ferrous sulphate.** According to L. Pissarjewsky, the heat effect obtained by mixing soln. of silver and ferrous sulphates in various solvents, varies with the conditions under which the reaction occurs ; similar variations occur in the constant of the reaction : $Ag_2SO_4+2FeSO_4 \rightleftharpoons 2Ag+Fe_2(SO_4)_3$. Hence, it is inferred that a mixture of probably two different modifications of ordinary grey silver—*allotropic silver*—is precipitated.

W. R. Hodgkinson and C. C. Trench found silver sulphate is reduced when heated in a stream of **ammonia.** H. Rose found that dry silver sulphate slowly absorbs up to 11·82 per cent. of ammonia gas with scarcely any perceptible rise of temp. The theoretical absorption for **silver diammino-sulphate,** $Ag_2(NH_3)_2SO_4$, is 10·9 per cent. When heated, the product gives off ammonia and ammonium sulphate, and it is completely soluble in water. According to C. G. and E. Mitscherlich, clear crystals of **silver tetrammino-sulphate,** $Ag_2(NH_3)_4SO_4$, are deposited when a sat. soln. of silver sulphate is poured into a warm soln. of ammonia and cooled. C. F. Rammelsberg, and E. Mitscherlich found the tetragonal crystals have the axial ratio $a : c=1 : 0·5328$. They are stable in air in darkness, and blacken in light. They are soluble in water, or aq. ammonia, and can be recrystallized unchanged. A soln. of potassium hydroxide precipitates Berthollet's fulminating silver. A. Reychler studied the lowering of the f.p. and the electrical conductivity of aq. soln. of this salt. N. W. Fischer precipitated silver from the soln. by means of indium, cadmium, lead, copper, antimony, and arsenic ; but not by tin, bismuth, iron, or mercury.

J. L. Gay Lussac completely reduced silver sulphate mixed with **charcoal** by heating it to dull redness—equal vols. of carbon and sulphur dioxides are evolved. O. Boudouard gives the equation : $Ag_2SO_4+C=CO_2+SO_2+2Ag$. K. Stammer also reduced the salt to the metal by heating it with **carbon monoxide.** According to N. W. Fischer, **copper** precipitates the whole of the silver, as a bulky, spongy, crystalline mass, when immersed in a sulphuric acid soln. of the sulphate ; **iron, zinc, tin,** and **lead** (but not antimony) also precipitate the silver. G. Goldschmidt added **cobalt** to N. W. Fischer's list—*vide supra,* the metallic reduction of silver. H. Rose found **cuprous oxide** precipitates silver from a soln. of the sulphate ; the precipitate is mixed with some basic cupric sulphate, and cupric sulphate remains in soln. C. Sandonnini and P. C. Aureggi found molten **stannous chloride** reduces silver sulphate to silver sulphide, and the metal—*vide* the metallic precipitation of silver.

R. Nacken[6] has studied the binary systems of the dimorphous lithium, sodium, and potassium sulphates with dimorphous silver sulphates. The transition and fusion temp. are indicated in the diagrams, Figs. 20 to 22. The lower sets of curves show the transition points, the upper sets represent the liquidus and solidus curves. The existence of the compounds $2Li_2SO_4.3Ag_2SO_4$ and of $K_2SO_4.3Ag_2SO_4$ has been established, and there is no sign of a complex sodium salt, Fig. 21 ; according to J. W. Retgers, sodium and silver sulphates probably form mixed crystals in all proportions. They have been studied by M. Barre. The first-named salt, **lithium silver sulphate,** $2Li_2SO_4.3Ag_2SO_4$, is capable of existence only between 572° and 420°, so that the compound breaks up as the temp. falls below 420° ; and the transition point curve shows a discontinuity at a conc. corresponding with the composition of the double salt. The region of stability of **potassium silver sulphate,** $K_2SO_4.3Ag_2SO_4$, is shown in the diagram. H. Rose reported in 1825 that when potassium and silver sulphates are fused together they freeze to a crystalline mass, but no definite compound was isolated.

§ 20. Silver Carbonate

According to N. W. Fischer, and H. Rose,[1] silver carbonate is formed when moist silver oxide is exposed to the atm.; and, according to L. Joulin, when silver oxide is suspended in an aq. soln. of sodium hydrocarbonate. J. Setterberg could not make *silver hydrocarbonate*, $AgHCO_3$, by treating silver nitrate with potassium hydrocarbonate under various conditions, and the salt in question has not been isolated. G. Wetzlar precipitated normal silver carbonate as a white powder by adding an aq. soln. of an alkali carbonate or hydrocarbonate to a soln. of silver nitrate; and E. Bohlig recommended mixing soln. of eq. amounts of silver nitrate and potassium carbonate. H. Rose observed:

> It is remarkable that silver oxide exhibits considerable affinity for carbon dioxide, and none at all for water. When a soln. of an eq. of a normal salt of silver is decomposed by a normal alkali carbonate, normal silver carbonate is obtained, without water, whether the soln. be conc. or dil., cold or hot.

J. F. Spencer and M. le Pla recommended slowly pouring a very dil. soln. of sodium hydrocarbonate, or the normal carbonate, with constant stirring, into a conc. soln. of silver nitrate. The precipitate is washed many times with water. According to V. Kohlschütter and E. Eydmann, a little decomposition occurs when the carbonate is allowed to stand under cold water for any time, and also when dried at 110°. The composition of silver carbonate is affected by conc. of the soln., the temp., and the relative proportions of the salts used in its preparation. This subject has been studied by L. Joulin. If equi-molecular parts of silver nitrate and alkali carbonate are employed at a dilution not exceeding 0·0025 molar part per litre, the precipitate is wholly normal silver carbonate; if the soln. be more dil., silver oxide will also be formed, and this the more the more dil. the soln.; with a dilution of 0·0003 molar part per litre, the oxide is wholly precipitated. If an excess of alkali carbonate be used the precipitate is a mixture of silver carbonate and oxide, with the oxide in greater proportion the greater the excess of alkali carbonate. If the silver nitrate be in excess the precipitate will be white, free from oxide, and coloured superficially violet, and it will be coloured yellow by washing. These relations were obtained at ordinary temp. At 0°, the precipitate will be free from oxide even with a large excess of sodium carbonate, and at 100° the precipitate will contain oxide, even with equi-molecular proportions of silver nitrate and alkali carbonate, and at least five eq. of silver nitrate are required for one of sodium carbonate if the precipitate is to be free from oxide. G. S. Johnson obtained crystals of the salt by passing carbon dioxide into water with silver carbonate in suspension, and allowing the soln. to stand. H. Vogel also exposed to air a mixture of an ammoniacal soln. of silver nitrate and sodium hydroxide; after some weeks, silver oxide is precipitated, and thereafter lemon-yellow needle-shaped crystals of silver carbonate are deposited. A. Lottermoser prepared **colloidal silver carbonate** by mixing $\frac{1}{40}N$-$AgNO_3$ and $\frac{1}{40}N$-Na_2CO_3, so that the latter is in excess. C. Paal and F. Voss treated a soln. of sodium carbonate with silver protalbinate or lysalbinate.

Precipitated silver carbonate is a white powder, which becomes yellow by the aggregation of its particles, an effect which is immediately produced by heat. The lemon-yellow acicular **crystals** prepared by H. Vogel were doubly refracting, and were thought to be hexagonal. C. J. B Karsten gave 6·0766 for the **specific gravity,** and P. Kremers, 6·0 at 17·5°. A. Colson gives for the **heat of formation** from its elements (2Ag, C, 3O)=120·8 Cals. M. Berthelot gives 120·4 Cals. and J. Thomsen gives 122·92 Cals.; for (2Ag, O_2, CO)=93·92 Cals.; for (2Ag, O, CO_2)=25·96 Cals.; and for (Ag_2O, CO_{2gas})=20·06 Cals.; M. Berthelot gives 18·6 Cals.; and for (Ag_2O, $CO_{2aq.}$), 13·80 Cals. J. Thomsen has also studied the heat of the reaction between silver nitrate and sodium carbonate.

According to N. W. Fischer, silver carbonate blackens when exposed to light or when heated. H. Rose found that it loses carbon dioxide at 200°, and A. Colson found that silver carbonate is less stable than lead carbonate, and it is completely decomposed at 220°, L. Joulin said 225°, and added that only a little or no carbon dioxide is taken up on cooling. V. Kohlschütter and E. Eydmann say that silver carbonate begins to give off gas between 150° and 160°, and the rate of decomposition is faster at the higher temp.; at 216° the speed of decomposition is quite rapid, and silver oxide is formed. If the decomposition occurs in vacuo, some silver is formed. A. Colson found the **dissociation pressure** to be 6 mm. at 132°; 99 mm. at 167°; 173 mm. at 167°; 173 mm. at 182° (173 mm. with the dry gas); 547 mm. at 210°; and 752 mm. at 218°; he also showed that in moist air, even at a comparatively low temp., there is a reversible reaction, $Ag_2CO_3 \rightleftharpoons Ag_2O+CO_2$—a similar result is obtained when moisture is excluded, but in that case, although there is a definite dissociation press. for a given temp., the reaction is not reversible because carbon dioxide is not taken up by the silver oxide; but he found that at a high press. the reaction is reversible. Neither moist freshly precipitated silver carbonate nor the dry salt is decomposed by cold **water,** but boiling water transforms it into silver oxide. L. Joulin obtained a port wine-red fluid by pouring two litres of boiling water on a gram of silver carbonate. H. Rose obtained basic silver carbonate, or silver oxycarbonate: $3Ag_2O.2CO_2$, or $2Ag_2CO_3.Ag_2O$, by boiling a soln. of silver nitrate with an excess of sodium carbonate; and E. Bohlig, by pouring silver nitrate into an excess of a soln. of potassium carbonate. The black precipitate dries at 100° to a dark brown mass, which, according to E. Bohlig, contains granular particles mixed with fine needle-like crystals, and is probably a mixture of the oxide and carbonate. P. Kremers said that the **solubility** is such that 100 parts of water dissolve 0·00325 part silver carbonate at 15°, A. Abegg and J. Cox found the solubility of silver carbonate in water at 25° to be about $1·2\times10^{-4}$ gram-atoms per litre, and J. F. Spencer and M. le Pla found $1·16\times10^{-4}$ mols per litre. The last-named also found that in aq. soln. the salt is almost completely—96·6 per cent.—hydrolyzed, consequently the soln. reacts alkaline to litmus and methyl orange. According to J. L. Lassaigne, 100 parts of water sat. with carbon dioxide dissolve

0·104 part of silver carbonate ; and, according to J. J. Berzelius, it is soluble in aq. *ammonia, ammonium carbonate, sodium thiosulphate,* and *potassium cyanide.* W. O. de Coninck reported that silver carbonate is somewhat soluble in an aq. soln. of *sodium nitrate ;* E. C. Franklin and C. A. Kraus, that it is insoluble in liquid *ammonia ;* insoluble in *methyl acetate ;* and M. Hamers, insoluble in *ethyl acetate.* According to A. von Baeyer and V. Villiger, **hydrogen peroxide** is decomposed by silver carbonate without the decomposition of the latter, while E. Mulder maintained some carbon dioxide is given off with the oxygen.

S. Kern added absolute alcohol to a soln. of silver carbonate in aq. ammonia, and obtained a grey powder which darkened when dried. It dissolved in aq. ammonia and, on evaporation, the soln. furnished irregular needle-like crystals, possibly **silver tetrammino-carbonate,** $Ag_2CO_3.4NH_3$, which began to lose ammonia at 80°, and lost all this gas at 100°. M. Dervin and M. Olmar obtained crystals of hydrated tetrammino-carbonate, $Ag_2CO_3.4NH_3.H_2O$, by repeatedly evaporating in air, ammoniacal soln. of silver oxide. On exposure to air the crystals lose ammonia and water; they are blackened by sunlight.

C. Wittstein found silver carbonate is slightly soluble in a cold aq. soln. of potassium carbonate, and when the soln. is warmed, a precipitate is obtained which is blackened by the organic matter of filter paper. A. de Schulten observed that when a soln. of silver nitrate is added to an excess of potassium carbonate containing some hydrocarbonate, a white precipitate is formed which changes to microscopic crystals with a composition corresponding with **potassium silver carbonate,** $AgKCO_3$. He recommended the following process :

> Dissolve 150 grms. of potassium carbonate in 150 c.c. of water, cool the soln., and agitate it with 15 grms. of potassium hydrocarbonate. When the liquid is sat. with the latter salt, filter, and mix the filtrate with a gram of silver nitrate dissolved in 25 c.c. of water. To obtain large crystals, the liquid containing the precipitate is heated with continued agitation. The precipitate dissolves, and, on cooling, deposits long transparent prisms with a brilliant lustre.

The crystals have a sp. gr. 3·769 ; they do not blacken when exposed to light except in the presence of organic matter, and when treated with water, the silver carbonate which remains retains the form of the original crystals. When heated, the compound loses carbonic anhydride, and at a higher temp. the silver oxide which is formed gives off oxygen. The crystals are microscopic, rectangular lamellæ with a terminal angle closely approaching 90°. The double refraction is almost identical with that of apatite ; the extinction of parallel polarized light is straight ; twinning plane parallel with the plane of the optical axes ; sign of elongation positive ; the maximum birefringence approximately 0·0216. The compound is decomposed by water, with removal of the potassium carbonate and formation of yellow silver carbonate. A. de Schulten also obtained a crystalline double salt, possibly **sodium silver carbonate,** by substituting sodium for the potassium salt. The product, however, was not examined further.

§ 21. Silver Nitrate

The twelfth or thirteenth-century writer, Geber, in his *De inventione ventatis*, described the preparation of silver nitrate by dissolving the metal in nitric acid, and evaporating the soln. for crystallization. Albertus Magnus, about the same period, in his *Compositum de compositis*, said the soln. blackened the skin, and that the stain was difficult to remove. In the seventeenth century, A. Sala, in his *Septem planetarum terrestrium spagyrica recensio*, called the salt *crystalli Dianæ;* N. Lemery (1675) [1] called it *vitriol de Luna;* and H. Boerhaave (1732), *vitriolum argenti*. This shows that the term *vitriol* was of more general application than it is to-day; its use is now confined to a specific group of sulphates. Silver nitrate has been called *silver-saltpetre;* and, after fusion, the mediæval alchemists also called it *lapis infernalis*, or *lunar caustic.*

As shown by Geber, silver nitrate is prepared by crystallization from a soln. of the metal in dil. nitric acid. H. Greuner [2] studied the preparation of silver nitrate from silver sulphide by digestion of that compound with dil. nitric acid. F. Laporte and P. de la Gorce found that if the soln. of silver nitrate during evaporation be not protected, it may absorb impurities from the air. Similar remarks apply during the washing and drying of the crystals. If the metal contains copper, the two metals are separated by precipitating the silver as sparingly soluble chloride, reducing the chloride as previously indicated, and then dissolving the product in nitric acid. N. J. B. G. Guibourt, R. Palm, C. J. H. Warden, etc., separated the two elements by fractional crystallization from a soln. strongly acidified with nitric acid, in which silver nitrate is far less soluble than the cupric salt. F. Nölle extracted the salt with boiling alcohol, most of the silver nitrate remained undissolved, and most of that which dissolved separated out on cooling, while the cupric nitrate remained in soln. F. Brandenburg, J. B. Trautwein, and F. W. C. Martius heated the molten mixture so that the cupric nitrate decomposed while the silver nitrate remained unchanged; the latter was then leached from the cupric oxide. M. Gräger treated a part of the mixed soln. with potassium hydroxide, and digested the washed precipitate with the remaining soln. Provided no excess of acid is present, he found that cupric oxide was precipitated and silver oxide passed into soln. Organic impurities are removed by recrystallization. In the last-named operation advantage is taken of the low solubility of the salt in soln. strongly acidified with nitric acid. T. W. Richards and G. S. Forbes, W. L. Hardin, G. P. Baxter and G. Jones, and G. D. Buckner and G. A. Hulett have prepared silver nitrate of the highest degree of purity for at. wt. determinations. G. P. Baxter and G. Jones proceeded as follows:

> Crude silver nitrate was reduced with ammonium formate, made by passing ammonia gas into redistilled formic acid. The reduced silver was washed with the purest water, until the wash-waters no longer gave a test for ammonia with Nessler's reagent, and was fused on sugar charcoal. The buttons were then scrubbed with sea-sand and thoroughly cleansed with ammonia and nitric acid. They were then dissolved in redistilled nitric acid, in a platinum dish. After the silver nitrate soln. had been evaporated on a steam bath until sat., an equal volume of redistilled nitric acid was added and the soln. was cooled. The precipitated silver nitrate was very completely drained in a centrifugal machine, provided with platinum Gooch crucibles to retain the salt. A similar recrystallization followed. The final product was preserved in Jena glass vessels under a bell-jar.

G. D. Buckner and G. A. Hulett used quartz vessels; and they melted the salt until the last trace of nitric acid was expelled. E. B. Rosa, G. W. Vinal, and A. S. McDaniel say the salt then contains but one or two parts of acid per 100,000 parts of salt.

The physical properties of silver nitrate.—Silver nitrate forms rhombic **crystals** which, according to H. J. Brooke,[3] have the axial ratios $a : b : c$=0·9430 : 1 : 1·3697. A. Scacchi, F. M. Jäger, C. F. Rammelsberg, etc., have studied the crystallography of the salt. While M. L. Frankenheim observed no change of form when the salt is heated up to its temp. of decomposition, O. Lehmann found it to exist in two modifications; the form stable below 159·4° is rhombic, and above that temp. the salt exists in rhombohedra belonging to the trigonal system. The rhombic form is the one obtained by crystallization at ordinary temp.; the trigonal was obtained by the crystallization of the molten salt. According to B. Gossner, the form stable at the higher temp. is isomorphous with trigonal sodium nitrate. It does not crystallize isomorphously with the nitrate of ammonium, potassium, rubidium, cæsium, or thallium, but, according to J. W. Retgers, it is isodimorphous with sodium nitrate since mixed soln. of the two salts furnish trigonal mixed crystals with up to 52·57 per cent. of silver nitrate, and rhombic crystals with up to 0·8 per cent. of sodium nitrate—*vide infra.*

The reported values for the **transition temperature** are 159° by J. Guinchant,[4] 159·2° to 159·8° by W. Schwarz, 159·4° by P. W. Bridgman, and 159·8° by D. J. Hissink. P. W. Bridgman measured the effect of press. on the transition temp. and found the phase diagram, Fig. 23, to be quite different in character from those of the nitrates of ammonium, potassium, rubidium, cæsium, or thallium. P. W. Bridgman was unable to trace the sudden increase of curvature with press. beyond 6000 kgrms. per sq. cm. for press. up to 12,000 kgrms. per sq. cm., at room temp. or at 200^{c}. E. Jänecke measured the transition points on the heating and cooling curves from the changes in press., and found that in the former case the transition occurred between 159·2° and 159·8°, and in the latter case about 16° lower.

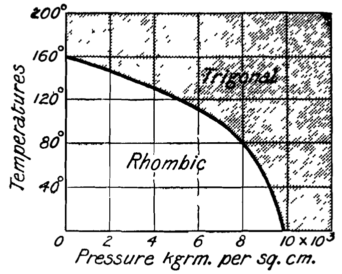

FIG. 23.—Effect of Pressure on the Transition Point of Silver Nitrate.

The **specific gravity** of silver nitrate by C. J. B. Karsten [5] is 4·3554; L. Playfair and J. P. Joule gave 4·336 (3·9°); and H. Schröder gave numbers ranging from 4·238 to 4·328. L. Poincaré gave 3·9 for the sp. gr. of the molten salt at 350°; G. Schulze also gave the same numbers for the molten salt. If molten silver nitrate be allowed to cool in a test-tube, the sudden expansion of the solid, which occurs about 160°, breaks the tube. The expansion—about 0·6 per cent.—is due to the transformation of the trigonal to the rhombic form. According to J. W. Retgers, the sp. gr. of the stable form of silver nitrate is 4·35 at 19°/4°; and for the labile trigonal form, 4·19. He also gave 39·1 for the **molecular volume** of the salt. The ratios of the **specific solution volume** of a 25-millinormal soln. of silver nitrate at 156° and 218°, were respectively 1·096 and 1·185; of a 50-millinormal soln. at 306°, 1·425; and of a 100-millinormal soln. at 156° and 218°, 1·095 and 1·182. The sp. gr. of soln. of silver nitrate has been determined by F. Kohlrausch, H. Jahn, C. Chéneveau, A. J. Rabinowitsch, and R. Wagner. The first named gives for the sp. gr. D of soln. containing upwards of 5 per cent. silver nitrate, and the second named for the soln. below 5 per cent. conc., all at 18°:

p . .	0·080	0·565	5	10	20	30	40	50	60
D . .	0·9968	1·0074	1·0422	1·0893	1·1958	1·3213	1·4773	1·6745	1·9158

F. F. Fitzgerald has measured the sp. gr. of soln. in liquid ammonia, in methylamine, in ethylamine, and in quinoline.

According to J. Wagner,[6] the specific **viscosity** of soln. of silver nitrate at 25° is :

	Water	$\frac{1}{8}N$-	$\frac{1}{4}N$-	$\frac{1}{2}N$-	N-soln.
Viscosity . .	1·0000	1·0114	1·0240	1·0491	1·1150

A. J. Rabinowitsch measured the viscosities of these soln. According to A. Scachanoff, the coeff. of viscosity of soln. with 1·403, 2·788, 4·852, and 8·460 mols per litre is 0·00990, 0·01134, 0·01451, and 0·02439 respectively. He also measured the viscosity in very conc. quinoline soln. F. F. Fitzgerald has measured the viscosity of soln. of silver nitrate in liquid ammonia, and in methylamine, ethylamine, and quinoline. G. Zemplen measured the **surface tension** of soln. of silver nitrate. According to J. Thovert, the **coefficients of diffusion** at 12° for soln. containing 0·02, 0·1, 0·9, and 3·9 mol per litre are respectively 1·035, 0·985, 0·88, and 0·535. J. C. G. de Marignac and J. D. R. Scheffer also obtained values for this constant.

E. Madelung and R. Fuchs[7] found the **compressibility** of silver nitrate to be $3·67 \times 10^{-12}$ dynes per sq. cm. P. W. Bridgman measured the compressibility of the two modifications of silver nitrate. At low press. (high temp.) the form with the larger vol. is the more compressible, but, passing along the transition curve to higher press. and lower temp., the difference becomes less and less, finally reversing its sign near the region of rapid curvature. Below 70° the modification stable at the higher temp. is the more compressible. The differences in the thermal expansions δa, the compressibilities $\delta\beta$, and the sp. hts. at constant press. δC_p in kgrm.-cm. per grm., for press., p, expressed in kgrm. per sq. cm., are :

p . . .	1	2000	4000	6000	8000	9000
$\delta\beta$ . . .	$-0·0_{6}45$	$-0·0_{6}35$	$-0·0_{6}25$	$-0·0_{6}15$	$-0·0_{7}2$	$+0·0_{7}7$
δa . . .	$-0·0_{4}55$	$-0·0_{4}37$	$-0·0_{4}22$	$-0·0_{5}6$	$+0·0_{5}5$	$+0·0_{5}5$
δC_p . . .	0·35	0·21	0·11	0·13	0·13	0·08

The change in sign of δa occurs at a lower press. than $\delta\beta$. The cause of the changes in sign is not known, " it may be a compacting together under press. of the crystal framework of the low temp. form which makes it less responsive to changes of temp. and press." Silver nitrate readily fuses without loss of weight, and it solidifies, on cooling, to a white crystalline mass which is called *lunar caustic*. In his study, *Sur la décomposition du nitrate argentique sous l'influence de la chaleur*, J. F. Persoz found that while in tranquil fusion, below 500°, bubbles of oxygen are evolved, and this is soon followed by red nitrous fumes. The product obtained by heating 15 grms. until 300 c.c. of oxygen had collected, was slightly yellow, and when extracted with boiling water gave a slight residue of silver. The crystallization of the soln. furnished long fine needles of silver nitrite, and the mother liquid contained undecomposed silver nitrate. The nitrite was formed during the heating of the salt, and not by the action of the reduced silver on the boiling soln. of the nitrate. The nitrate is stabilized by the presence of the nitrite. As indicated above, silver nitrate resists a temp. at which the cupric salt is decomposed, so that if a mixture of the two salts be heated until the effervescence due to the decomposition of the cupric nitrate has ceased, silver nitrate can be leached from the cold mass, and insoluble cupric oxide remains undissolved. Silver nitrate is also much more stable than lead nitrate ; but it can be wholly reduced to metallic silver by heating it to dull redness—nitrogen, oxygen, and nitrogen oxide gases are evolved. According to E. Divers, there is an intermediate formation of silver nitrite, and the salt begins to decompose " close to the m.p. of sulphur (444°)," for if the yellow liquid be cooled, some nitrite can be detected. The aq. soln. of silver nitrate has a neutral reaction, but if the salt has been previously fused before it is dissolved in water, H. Pellat, and A. Vogel found that the soln. reacts alkaline owing to the presence of silver oxide. According to G. Scarpa, not 2 per cent. of the salt is decomposed by heating it slowly to its m.p., and A. Colson says that it can be heated to 350° in a 2 mm. vacuum without appreciable decomposition. E. B. Rosa, G. W. Vinal, and A. S. McDaniel say that the decomposition on melting is less dependent on the temp. than on the amount of free acid present. As the last trace of acid is removed, the molten salt begins to decompose into silver oxide and colloidal silver; the presence of so little as one or two parts of acid in 100,000 parts of the solid salt hinders its decomposition. The reported **melting point** data range from J. J. Pohl's 198° to J. W. Retgers' 224°. The mean of the more recently published values is 212°.

J. Guinchant [8] found the **coefficient of thermal expansion** between 20° and 150° is 0·000077; the contraction with rise of temp. at 159° is 0·17 per cent., and the expansion on cooling is 0·22 to 0·25 per cent. This is eq. to about 0·00047 c.c. per grm. if the sp. gr. be 4·3; P. W. Bridgman found 0·00250 c.c. per grm. at one atm. press., showing that the change in vol. during the transition does not take place equally in all directions. He also found a change in vol. of 0·00330 c.c. per grm. during the transition at a press. of 9770 kgrms. per sq. cm. P. W. Bridgman's measurements of the change in the expansion of the two forms of silver nitrate are indicated above. The difference in the expansion at different press. runs parallel with the difference of compressibility. At the low press. end of the curve, the high temp. phase is the less expansible, but at the other end of the curve it becomes more expansible. H. V. Regnault [9] found the **specific heat** of silver nitrate to be 0·1435 between 15° and 99°. J. Guinchant gives 0·1411 for the rhombic form between 0° and 137°; 0·1490 for the trigonal form between 0° and 188°; and 0·187 for the liquid between 208° and 281°. The high temp. phase has the greater sp. ht. The difference in sp. ht. between the rhombic and trigonal forms of silver nitrate was found by J. Guinchant to be 0·008 cal. per grm., and P. W. Bridgman obtained a similar result at atm. press., when calculated from the values of δa and $\delta\beta$—*vide supra*. The difference decreases at higher press., but no change of sign was observed. J. Guinchant gives 17·6 to 17·9 cals. per grm. or 2·99 Cals. per mol for the **heat of fusion**; H. M. Goodwin and H. T. Kalmus gave 15·2 cals. per grm. and 2·58 Cals. per mol. P. W. Bridgman found 4·9 cals. per grm. for the heat of transition from the rhombic to the trigonal form. J. Guinchant found 3·4 cals. The former also found the latent heat of the transformation at atm. press. to be 1·422 kgrmmetres. per grm., and at 5000 and 9000 kgrms. per sq. cm. press., respectively 1·228 and 0·254 kgrmmetres. per grm. M. Berthelot [10] gives for the **heat of formation** of the salt from its elements $(Ag, 3O, N)=28\cdot7$ Cals.; J. Thomsen, 30·74 Cals.; and A. Colson, 28·7 Cals. J. Thomsen also gave $Ag_2O+2HNO_{3aq.}=2AgNO_3+H_2O$ $+10\cdot881$ Cals. M. Berthelot gives —5·7 Cals. for the **heat of solution** of silver nitrate in water between 10° and 15° for a mol of the salt in 470 to 940 mols of water. J. Thomsen found the heat of soln. at ordinary temp. to be —5·54 Cals. G. Bruni and G. Levi give —5·30 Cals. for the heat of soln. of a mol in 1000 mols. of water, or —5·70 Cals. for a mol in 1600 mols. of water.

According to W. Meyerhoffer,[11] the **vapour pressure** curve of a sat. soln. of silver nitrate has a maximum while the vap. press. at the two ends of the solubility curve—the cryohydrate and the m.p.—approximate to zero:

	121°	135°	150°	160°	167°	170°	185°	191°
Vap. press. . . .	760	800	960	1000	1015	1010	900	760 mm.

There are therefore two sat. soln. which boil at atm. press.—one at 121° and the other at 191°. If the soln. at the second b.p. is cooled, the vap. press. rises, and salt crystallizes out; in this region, the heat of soln. is positive; it then passes through zero, and at a lower temp. it is negative. W. Meyerhoffer's diagrammatic curve of the vap. press. of soln. of silver nitrate is shown in Fig. 24. *AC* is the vap. press. of ice; *BMD*, the vap. press. of a soln. sat. with the rhombic salt; *DENF*, of a soln. sat. with the trigonal salt; *GH*, that of the rhombic salt; *HF*, that of the trigonal salt; *FJ*, that of the molten salt; and *HOD*, that of the rhombic and trigonal salts, and water vapour. F. M. Raoult [12] found the difference between the vap. press.

of water vapour, and that of a soln. containing one part of silver nitrate in 100 parts of water to be 0·160×7·6 mm. According to P. Kremers, a sat. soln. of silver nitrate boils at 125°. A. Smits, and L. Kahlenberg found that soln. with w grms. of salt per 100 grms. of water had **boiling points** corresponding with:

w	0·8040	1·542	7·4949	35·08	86·43	136·36
Raising b.p.	0·044°	0·087°	0·382°	1·526°	3·143°	4·415°
Mol. raising	0·93°	0·90°	0·87°	0·739°	0·618°	0·550°

The mol. raising of the b.p. thus gradually decreases as the conc. of the soln. increases. F. M. Raoult found the difference between the **freezing point** of water and of soln. containing one part of salt in 100 parts of water to be 0·145°. W. A. Roth has measured the lowering of the f.p. of soln. containing N mols of salt per litre:

N	0·01050	0·02826	0·04046	0·05346	0·08119	0·1369
Lowering f.p.	0·0375°	0·0991°	0·1407°	0·1840°	0·2702°	0·4474°
Mol. lowering	3·57	3·51	3·48	3·385	3·33	3·265

The mol. lowering of the f.p. thus gradually decreases as the conc. of the soln. increases.

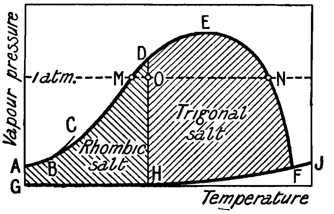

FIG. 24.—Meyerhoffer's Vapour Pressure Curves of Solutions of Silver Nitrate. (Diagrammatic.)

J. Guinchant found the cryoscopic constant to be 264; and that with soln. of the nitrates of lithium, potassium, thallium, and lead; silver sulphate; and with silver fluoride, chloride, iodide, and iodate in molten silver nitrate, the molecular lowering is about normal.

P. Werner and M. Stephani[13] found silver nitrate dissolved in benzonitrile has a **molecular weight** 176 corresponding with the formula $AgNO_3$; N. Castoro likewise found 173 for soln. in urethane; G. Schülze, L. Kahlenberg, and W. Schmujloff found the mol. wt. in pyridine soln. to be normal; while P. Walden found the salt to be polymerized in pyridine, aniline, liquid ammonia, and liquid sulphur dioxide, but the mol. wt. becomes approximately normal with increasing dilution. Silver nitrate blackens when exposed to light, but not if organic matter be rigorously excluded. The crystals of silver nitrate have a positive double refraction. The **index of refraction** μ of aq. soln. of silver nitrate was studied by E. Forster,[14] and P. Barbier and L. Roux. At 17·5°, B. Wagner gave for soln. with p per cent. of salt:

p	1	5	10	15	20	25
μ	1·33426	1·33868	1·34393	1·34882	1·35353	1·36669

K. Schaefer reports the selective **absorption spectrum** in the ultra-violet spectrum is independent of the degree of ionization; and W. N. Hartley that the specific absorption of silver does not influence that due to the nitrate-ions.

W. N. Hartley, and K. Schaefer found that soln. of silver nitrate do not conform to Beer's law since conc. soln. have a proportionately greater absorption. For layers of liquid of depth l and conc. C, the spectrum is continuous to λ_1^{-1}, and there is an absorption band between λ_1^{-1} and λ_2^{-1}:

l	10	10	50	200	200	200	200	200	200
C	N-	N-	N-	$\frac{1}{20}N$-	$\frac{1}{20}N$-	$\frac{1}{40}N$-	$\frac{1}{50}N$-	$\frac{1}{100}N$-	$\frac{1}{200}N$-
λ_1^{-1}	3004	3002	3069	3069	3067	3069	3148	3150	3504
λ_2^{-1}	—	—	3535	—	—	3579	3579	3531	3504

W. N. Hartley found that the absorption spectrum of soln. of silver nitrate, unlike that of nitric acid or potassium nitrate, is not the same for soln. containing the same quantity of nitrate in soln. of different thickness (conc. variable) for the more dil. soln. transmit rays more freely—20 to 50 times as great as soln. of normal conc.

although the same quantity of nitrate is contained in each corresponding soln. This difference is possibly due to the action of light on the soln.

According to L. Poincaré,[15] the eq. **electrical conductivity** of molten silver nitrate is 0·0537 at 300°; and the specific conductivity of the molten salt at $\theta°$ is $1·220\{1+0·00272(\theta-350)\}$. A. Leduc has studied the changes which occur in the electrolysis of a soln. of $AgNO_3$. The eq. conductivity, λ, of aq. soln. has been measured by very many observers. H. C. Jones' data for soln. with a mol. of the salt in v litres of water are:

0°	v	4	8	32	128	512	2048	4096
	λ	51·43	56·01	61·80	65·79	69·24	69·83	71·03
	α	72·4	78·8	87·0	92·6	97·4	98·3	100·00
12·5	λ	70·55	76·68	85·30	91·06	94·99	96·67	99·03
	α	71·3	77·4	86·2	92·0	95·9	97·6	100·00
	$\kappa_{0-1·25}$	1	1·65	1·88	2·02	2·06	2·15	2·24

where κ represents the **temperature coefficient** of the conductivity. H. Herwig found that increasing the *pressure* on soln. of silver nitrate did not affect the resistance; nor could E. Coehn detect any variation in the application of Faraday's law in the electrolysis of silver nitrate under press. ranging from 1 to 1500 atm. According to J. Johnston, the eq. conductivity at infinite dilution at 18° is 116·1; at 100°, 367; and at 156°, 570. According to R. Abegg and C. Immerwahr, a normal soln. of silver nitrate is 58 per cent. ionized. The **percentage degree of ionization** is represented above by α. W. A. Roth calculated a series of values for the **ionization constant** from the lowering of the f.p., and found 0·11, 0·23, and 0·32 respectively for $0·0105N$-, $0·05214N$-, and $0·1369N$-soln. J. H. van't Hoff found that the value of the ratio $\alpha=\lambda_v/\lambda_\infty$ can be represented by $\alpha^3/(1-\alpha)^2v=1·11$ at 25°. The subject has been studied by G. N. Lewis and co-workers. M. Rudolphi found the **heat of ionization** for a mol of the salt in 32 litres of water at 25° to be $-1·878$ cals., and in 512 litres of water, $-1·725$ cals. A. J. Rabinowitsch studied the anomalous ionization of soln. of silver nitrate. W. J. Mather found the **transport number** for the anions of silver nitrate to be respectively 0·538 and 0·525 for $0·025N$-soln. at 0° and 45°; M. Löb and W. Nernst gave 0·541 for $0·1N$-soln. at 0°; and W. Hittorf, for $2·3N$-soln. at 15°, 0·473. H. Jahn found 0·482 for the transport number of the cations of silver nitrate at 30°; A. A. Noyes and co-workers found for $0·02N$-soln. 0·461 at 0°; for 0·01 to $0·1N$-soln. at 18°, 0·471; for 0·01 to $0·05N$-soln. at 25°, 0·477; for 0·005 to $0·5N$-soln. at 30°, 0·481. A. Leduc studied the electrolysis of soln. of silver nitrate.

The electrical conductivities of soln. of silver nitrate in methyl and ethyl alcohols and in acetone have been studied by H. C. Jones, and he found that the ionization increases with dilution more rapidly than in water. The soln. in ethyl alcohol is positive when tested against an aq. soln., the soln. in methyl alcohol is weaker, and in acetone weaker still. A soln. in ethyl alcohol is negative towards one in methyl alcohol. The degree of ionization in alcoholic soln. is less than in aq. soln., so that it is assumed the soln. press. of silver in alcohol is less than in water, and B. Vollmer estimates that the soln. press. is 42–48 times as great in water as in alcohol. A. Roshdestwensky and W. C. McC. Lewis measured the eq. conductivity of soln. of silver nitrate in acetone, and found the transport number of the anions to be 0·58–0·60 at 90° for $0·02N$- to $0·007N$-soln., and 0·56 for soln. of less conc. C. A. Kraus and W. C. Bray, and A. Ssachanoff have studied soln. in aniline; L. Kahlenberg and O. E. Rüdorff, in amylamine; E. C. Franklin and H. D. Gibbs, F. F. Fitzgerald, and E. C. Franklin and C. A. Kraus, soln. in methylamine; G. Bodländer and W. Eberlein, soln. in methylamine and ethylamine; A. Ssachanoff, in dimethylamine; A. Ssachanoff and J. Prscheborowsky in *o*-toluidine and benzylamine; A. T. Lincoln in pyridine, piperidine, quinoline, benzonitrile, and methyl and ethyl cyanoacetates; and L. Kahlenberg, in acetonitrile and methyl thiocyanate. E. C. Franklin and co-workers measured the conductivity, the degree of ionization, and the transport numbers of soln. of silver nitrate in liquid ammonia.

F. Streintz measured the **electromotive force** of soln. of silver and cupric nitrates. The e.m.f. of conc. cells $Ag\,|\,AgNO_{3\,soln}\,|\,AgNO_{3\,soln.}\,|\,Ag$ have been measured by

J. Miesler, W. Nernst, W. Negbaur, A. C. Cumming and R. Abegg, N. Cybulsky and J. Dunin-Borkowsky, A. A. Noyes and B. F. Brann, etc. J. M. Bell and A. L. Field found that the e.m.f. of conc. cells with aq. soln. at 25° are in agreement with Nernst's formula with dil. soln. $E=\{2v^{\cdot}/(v^{\cdot}+v')\}(RT/nF)\log(C_1/C_2)$, where C_1 and C_2 refer to the conc. of silver ions; and $v^{\cdot}$ and v' to the migration ratios of $Ag^{\cdot}$ and NO_3'. With conc. soln., however, the calculated values are too great owing to the lowered velocities of the ions. E. Bichal and R. Blondlot found that the e.m.f. of the cell $Pt \mid AgNO_{3soln.} \mid Ag$ was changed about 0·5 millivolt per 100 atm. press. W. K. Lewis investigated the e.m.f. of conc. cells. J. H. Wilson studied the e.m.f. of conc. cells $Ag \mid \frac{1}{10}N\text{-}AgNO_3$ in alcohol $\mid \frac{1}{100}N\text{-}AgNO_3$ in alcohol $\mid Ag$ for methyl and ethyl alcohols. A. Roshdestwensky and W. C. McC. Lewis found the e.m.f. of conc. cells. of silver nitrate dissolved in acetone. L. R. Ferguson could not confirm F. L. Hunt's observation that only in darkness does silver separate in a cell $Pt \mid KI, AgNO_3 \mid Pt$. G. von Elissafoff studied the **electrolytic valve action** of aq. soln. and the fused salt. A. E. Oxley found soln. of silver nitrate show the **Hall effect.**

Silver nitrate is very soluble in water; the **solubility** has been determined by P. Kremers,[16] W. Middelberg, A. Étard, W. A. Tilden, W. A. Shenstone, J. Schnauss, etc. The average data for the weights of silver nitrate in grms. per 100 grms. of soln. are when the solid phase is the rhombic form:

	0°	10°	20°	30°	40°	50°	60°	80°	100°	130°
S . .	53	62	68	73·5	77	80	82·5	86·7	90·1	98·5

According to D. J. Hissink, with ice as the solid phase the solubility is 34·2 per cent. at −5·6°; and, according to W. Middelberg, the eutectic is at −7·3° with a solubility of 7·1 per cent. The solubility at the m.p. is infinite, for the salt and water then mix together in all proportions. The addition of *nitric acid* to an aq. soln. of silver nitrate lowers the solubility as noted by L. Schweigger-Seidal, C. J. H. Warden, etc. C. Schultz found that 100 grms. of conc. nitric acid dissolved 0·2 grm. of silver nitrate, and an acid $2HNO_3+3H_2O$ dissolved 3·33 grms. at 20°, and 16·6 grms. at 100°. J. I. O. Masson found that if *D* denotes the sp. gr. of the soln., *a* the number of mols of nitric acid per litre of soln., and *b* the number of mols of silver nitrate per litre of soln.—all at 30°:

D . . .	2·3921	2·2754	2·1243	1·9402	1·7052	1·4980	1·4195	1·3818	1·3976
a . . .	0·0000	0·4042	0·962	1·698	2·834	4·497	5·992	8·84	12·53
b . . .	10·31	9·36	8·08	6·54	4·526	2·590	1·698	0·843	0·347

R. Engel's empirical rule, that the introduction of an acid into a sat. soln. of a salt precipitates a chemically eq. quantity of salt, holds approximately for some acids of moderate conc., but it fails completely in other cases. J. I. O. Masson represents the results by:

$$-\frac{da}{db}=0{\cdot}40+0{\cdot}46\frac{a}{b};\ \text{or}\ \frac{a}{b}=\frac{0{\cdot}40}{1{\cdot}46}\left\{\left(\frac{B}{b}\right)^{1{\cdot}46}-1\right\}$$

where *B* is the value of *b* when *a* is zero. Silver nitrate is readily soluble in alcohol. According to C. A. L. de Bruyn, 100 parts of absolute *methyl alcohol* at 19° dissolve 3·72 parts of silver nitrate; and *ethyl alcohol,* 3·1 parts of the salt; J. M. Eder gives for the solubility *S* in grms. of the salt per 100 grms. of *p* per cent. alcohol at 15°:

Alcohol, *p* . . .	8·5	24·7	33·4	42·5	52·5	62·5	73·6
$AgNO_3$, *S* . . .	158	73·7	56·4	35·8	30·5	12·1	10·3

He also gives data at 50° and at 75°—*e.g.* the solubilities in 16·3 per cent. alcohol at 15°, 50°, and 75° are respectively 107, 214, and 340; and in 92·5 per cent. alcohol, respectively 3·8, 7·3, and 18·3. W. Kuriloff has also investigated the same subject, and F. A. H. Schreinemakers studied the ternary system: water—alcohol—silver nitrate. D. J. Hissinck studied the mutual solubility of silver nitrate and *sodium nitrate* in aq. soln. of alcohol. In addition to finding silver nitrate to be soluble in methyl and ethyl alcohols, W. G. Wilcox found it to dissolve readily in *isobutyl alcohol*

S. von Lazczynsky found 100 parts of absolute *acetone* both at 14° and at 59° dissolve 0·35 part of the salt; W. G. Wilcox also found this salt to be soluble in acetone, *chloroform*, and *carbon tetrachloride*. A. Naumann says 0·44 part at 18°. C. E. Linebarger found 100 parts of *benzene* at 35° dissolves 0·22 part of salt, and 0·44 at 40·5°. P. Werner says the salt is surprisingly soluble in *benzonitrile;* R. Scholl and W. Steinkopf find it to be soluble in *acetonitrile;* F. L. Shinn, and F. F. Fitzgerald found silver nitrate dissolves in *methylamine* and *ethylamine*, with the development of heat, forming clear colourless soln. H. D. Gibbs found that the very high solubility of the salt in this menstruum is connected with the formation of a double salt $AgNO_3.4CH_3NH_2$. F. F. Fitzgerald found that a soln. with 69·2 grms. of the salt in 100 c.c. is not sat. between −33° and 15°, and the smallest trace of moisture leads to the separation of a black precipitate. It is also soluble in *amylamine*. E. C. Franklin and C. A. Kraus, and F. M. G. Johnson and N. T. M. Wilsmore studied the solubility in *liquid ammonia*, but its solubility is not as great as might have been anticipated from its solubility in water and in ethylamine. According to E. H. Büchner, silver nitrate is insoluble in liquid carbon dioxide; F. Bezold found the salt to be insoluble in methyl acetate.

The chemical properties of silver nitrate.—J. R. Glauber[17] noted that a soln. of silver nitrate blackens in contact with organic matter. A soln. of silver nitrate gradually decomposes on exposure to light. According to F. Liebert, the reaction continues until all the organic matter has reacted, for if the soln. be then filtered through asbestos, a stable soln. is obtained which was kept for more than a year in a clear glass bottle in full daylight without change. In 1794, Mrs. Fulhame noted the reduction of silver nitrate when a piece of silk wetted with a soln. of that salt is exposed to the action of **hydrogen** gas in the dark. If, however, moisture is excluded the salt is not reduced. C. Brunner reported that he obtained a light grey precipitate by passing purified hydrogen gas through an aq. soln. of that salt for several hours; but the greater part of the salt remained unchanged after a week's exposure to the action of the gas. B. Renault, *au contraire*, maintained that the observed reduction is due to the contamination of the hydrogen with small quantities of silicane, stibine, arsine, or phosphine, although Swedish filter paper moistened with a soln. of the salt is immediately blackened. J. W. Russell, again, maintained that although no action appears when purified hydrogen is passed into a conc. soln. of the salt, after the lapse of about half an hour, metallic silver is precipitated which acts upon the liberated acid: $2AgNO_3+H_2=2Ag+2HNO_3$, forming silver nitrite; but with a very dil. soln. of the salt, metallic silver is obtained because the resulting acid is not sufficiently conc. to act on the metal. H. Pellet contradicted Russell's statement that silver nitrite is formed, and claimed that that salt cannot exist in the presence of nitric acid especially in a hot soln. H. Pellet continued that hydrogen, purified by scrubbing with soln. of sodium hydroxide and silver nitrate (1 : 33), has no action on a neutral soln. of silver nitrate at ordinary temp., a light grey precipitate is formed when hydrogen is first introduced at 80°, and after filtration no further change occurs. He also found that a cold or hot soln. of fused silver nitrate, which has an alkaline reaction owing to the presence of a little silver oxide, is attacked by hydrogen only so far as to reduce the oxide of silver in soln.; if the soln. be acidulated with nitric acid, no silver is precipitated. N. N. Beketoff found that silver is precipitated from a neutral soln. of silver nitrate only when the operation is continued for a long time; that the silver precipitated is eq. to the hydrogen absorbed, and the soln. then has an acid reaction. A. R. Leeds found a soln. of silver nitrate becomes acid and is reduced to silver and silver nitrite by the action of hydrogen scrubbed with an acid soln. of ferrous sulphate, conc. sulphuric acid, solid potassium hydroxide, and a 20-ft. column of pumice-stone and asbestos soaked with a soln. of silver nitrate. M. Paucke also says that crystals of this salt, as well as neutral and acid soln., are reduced to the metal by hydrogen gas, but that an ammoniacal soln. of the salt is not reduced. T. Poleck and K. Thümmel say that acid soln. are not reduced and that in very conc. soln., ammonia is formed.

The evidence as to the action of hydrogen at ordinary press. and temp. on a soln. of silver nitrate, is therefore somewhat discordant. J. B. Senderens found that a boiling soln. of silver nitrate is readily reduced by hydrogen, and this the more the more conc. the soln. N. N. Beketoff also found that hydrogen under press. produces a film of silver on a soln. of silver nitrate. J. Donau says that a flame of hydrogen is coloured yellow by playing on a soln. of silver nitrate.

As indicated previously, silver nitrate, prepared by crystallization from its aq. soln., has a neutral reaction, and hence there is no evidence of hydrolysis, but E. B. Rosa,[18] G. W. Vinal, and A. S. McDaniel claim that by the repeated crystallization of the salt from aq. soln., a *basic silver nitrate* is formed. Judging from the early observations of C. H. Pfaff, and A. Vogel, **water vapour** exerts a reducing action on soln. of silver nitrate. According to A. Mailfert, **ozone** with a soln. of silver nitrate gives a bluish-black flocculent precipitate of silver peroxide, and when the soln. is agitated, silver nitrate is again formed. E. Mulder found that silver nitrate accelerates the decomposition of **hydrogen peroxide,** without undergoing any change. H. Kwasnik reduced a soln. of silver nitrate to the metal by the action of **barium dioxide.** F. Wöhler[19] found that when silver is immersed in a conc. soln. of silver nitrate overlaid with water, metallic silver of dendritic form grows from a few scattered points on the surface of the metal. It is assumed that silver dissolves in the soln. of silver nitrate, and is re-deposited therefrom. According to E. Bose, a warm aq. soln. of silver nitrate dissolves metallic silver, forming **silver subnitrate ;** the metal is precipitated again when the soln. cools. K. Eisenreich also obtained a soln. of the subnitrate by the electrolysis of a soln. of silver nitrate with a silver anode.

According to H. Moissan,[20] **fluorine** does not attack cold silver nitrate, but at a dull red heat, yellow silver fluoride is formed. H. St. C. Deville found that when dried **chlorine** is passed over dried silver nitrate, between 55° and 60°, silver chloride, nitric anhydride, and oxygen gas are formed. M. Odet and M. Vignon say the reaction occurs in two phases, first the formation of nitroxyl chloride, NO_2Cl, which then reacts with silver nitrate. According to A. J. Balard and A. Naquet, when chlorine gas is passed into an aq. soln. of silver nitrate, silver chloride and hypochlorous acid are formed, whereas C. Weltzien found that with chlorine water, silver chloride and chlorate are formed. W. Dancer utilized the action of **bromine** on silver nitrate to prepare hypobromous acid. R. E. Hughes found that if moisture be excluded, **hydrogen chloride** has no action on dry silver nitrate. The action of **hydrochloric acid** and of the soluble **chlorides** on soln. of silver salts has been previously described. Similar results are obtained with **hydrobromic acid** and the soluble **bromides,** or with **hydriodic acid** and the soluble **iodides.**

According to E. C. Franklin and C. A. Kraus, slightly soluble silver chloride is precipitated by **ammonium chloride,** from a soln. of silver nitrate in liquid ammonia; very little bromide is precipitated by **ammonium bromide;** and no iodide by **ammonium iodide.** J. Preuss found that when dry silver nitrate is triturated with **iodine,** silver iodide, periodic acid, and nitric acid are formed. According to W. Pawloff and S. Schein, iodine acts on an excess of silver nitrate as symbolized by the equation : $6AgNO_3+3I_2+3H_2O=5AgI+AgIO_3+6HNO_3$; and if the iodine be in excess : $5AgNO_3+3I_2+3H_2O=5AgI+5HNO_3+HIO_3$. In alcoholic soln. C. Weltzien found iodine to react in accord with the first of these two equations.

According to J. Kablukoff,[21] if an alkali halide be dissolved in molten silver nitrate : $AgNO_3+K^{\cdot}\rightleftharpoons Ag^{\cdot}+KNO_3$. The homogeneous mass gradually separates into two layers ; the lower layer is silver halide. The m.p. of silver nitrate was depressed with increasing proportions of silver chloride from 207·2° for the pure salt down to 179·8° when 14·99 per cent. of silver chloride had been added. With mixtures of silver bromide and nitrate there is a eutectic near 163·5° with 20·2 per cent. AgBr. With mixtures of silver iodide and nitrate G. Scarpa obtained a eutectic at 80° with 55 per cent. AgI. According to J. Schnauss, P. Kremers, H. Risse, and H. Debray, silver chloride dissolves in hot soln. of silver nitrate and crystallizes out again on cooling. K. Hellwig found that 100 c.c. of a 3*N*-soln. of silver nitrate dissolves 0·08 grm. of silver chloride ; and when the soln. is diluted, the solubility sinks very rapidly. No double salt could be made from the soln. of silver chloride in the nitrate. G. Reichert claimed to have made **silver chloronitrate,** $AgCl.AgNO_3$, by dissolving the chloride in nitric acid. The colourless prismatic crystals which separated from the soln. were washed with equal parts of alcohol and ether. The crystals are only slowly blackened in light; they melt at 160° ; and are decomposed rapidly in water, slowly by commercial alcohol, and are not affected by a mixture of alcohol and ether.

The solubility of the bromide decreases rapidly as the soln. of silver nitrate is diluted. H. Risse, and K. Hellwig found that fine acicular crystals of **silver bromonitrate,** $AgBr.AgNO_3$, separate out on cooling the soln. of silver bromide in a hot conc. soln. of the silver nitrate. P. Kremers and J. Schnauss failed to make the salt by the wet process, but P. Kremers prepared the double salt by fusing eq. amounts of the component salts ; the double salt prepared by the dry process melts at 182° ; the salt obtained by the wet process melts at 172°. The crystals are decomposed by water or alcohol. Silver iodide is far more soluble than either of the other two halides in an aq. soln. of silver nitrate. K. Hellwig found at 25° :

$AgNO_3$ . .	0·20	0·40	0·70	1·215	2·54	3·75	5·9 mols per litre.
AgI. . .	0·068	0·167	0·85	3·08	16·1	33·2	85 0 grms. ,,

The results are indicated in Fig. 25 along with the three solid phases. The solubility is augmented by raising the temp. J. Schnauss found a cold soln. of silver nitrate sat. at 11°, dissolves 2·3 parts of silver iodide, and 12·3 parts when boiling. J. Preuss (1839) observed that a crystalline compound of silver iodide and nitrate is deposited from a soln. of silver iodide in a conc. soln. of silver nitrate, or from a soln. of silver iodide and oxide in nitric acid. The product is **silver iodonitrate,** $AgI.AgNO_3$, and it was prepared by C. Stürenberg by cooling a boiling conc. soln. of silver nitrate sat. with silver iodide. K. Hellwig used a similar process. The clear acicular crystals are said to belong to the cubic system, and to melt at 72° ; P. P. von Weimarn says 95°. J. Schnauss says the compound rapidly blackens in daylight. P. Kremers says it is almost insensitive to light. According to P. Kremers, the crystals dissolve in a little water without decomposition, but they are decomposed with a larger proportion of water. J. Schnauss says that silver iodide is formed when the crystals are treated with water, and C. Stürenberg added that the silver iodide is dissolved when the soln. is heated, and on cooling, crystals of **silver iododinitrate,** $AgI.2AgNO_3$, appear. According to J. Schnauss, $AgI.AgNO_3$ is not decomposed nor dissolved by hot alcohol. C. Stürenberg prepared the iododinitrate by cooling a hot conc. soln. of silver nitrate which was not completely sat. with the iodide, and by adding alcohol to a soln. of $AgI.AgNO_3$ in silver nitrate. H. Risse melted proportions of the component salts, and boiled the cold cake with water. The soln. deposited crystals of iododinitrate on slow cooling. R. Fanto prepared the salt by passing carbon dioxide charged with vapour of methyl iodide into a soln. of silver nitrate. A. Riche, C. Weltzien, and K. Hellwig also

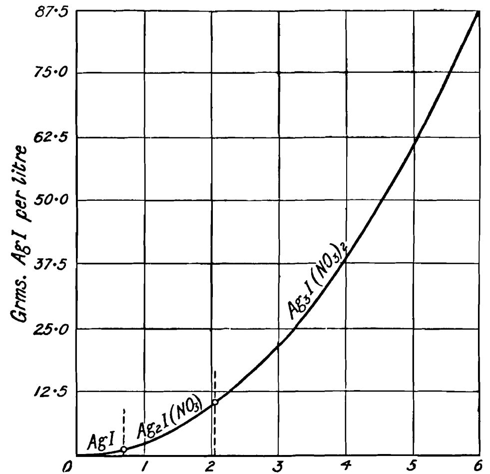

Fig. 25.—Solubility of Silver Iodide in Solutions of Silver Nitrate.

prepared the salt. It forms colourless needle-like crystals which F. M. Jäger found to be rhombic bipyramids with axial ratios $a : b : c = 0{\cdot}6638 : 1 : 0{\cdot}3123$. H. Risse says the crystals blacken rapidly in light, while R. Fanto found the blackening only occurs in moist air; in dry air, the crystals are almost insensitive to light. H. Risse found the salt melts at 105°, and exhibits under-cooling phenomena. R. Fanto gives 119° for the m.p., and F. M. Jäger, 119·1°. The crystals are decomposed with water and alcohol, but, according to H. Risse, a protective skin of silver iodide may be produced by the treatment, so that decomposition appears to be incomplete, otherwise the decomposition by water is complete. K. Hellwig found that the b.p. determinations correspond with the existence of complex salts in aq. soln.; the salt is soluble in a conc. soln. of silver nitrate with ionization; during electrolysis, the silver iodide collects about the cathode; the ionization of silver iododinitrate, $Ag_3I(NO_3)_2$, is not $Ag_3I(NO_3)_2 \rightleftharpoons Ag_3I^{\cdot\cdot} + 2NO_3{}'$; but rather $Ag_3I(NO_3)_2 \rightleftharpoons Ag_3I(NO_3)^{\cdot} + NO_3{}'$; and $Ag_3I(NO_3)^{\cdot} = Ag_3I^{\cdot\cdot} + NO_3{}'$; and $Ag_3I^{\cdot\cdot} = 2Ag^{\cdot} + AgI$; as well as $Ag_3I(NO_3)^{\cdot} = AgI + Ag^{\cdot} + AgNO_3$. The salt also dissolves sparingly in boiling water. K. Hellwig obtained evidence of still higher nitrates—*e.g. silver iodotetranitrate*, $AgI.4AgNO_3$. A. W. Hofmann, and P. Kremers also obtained products with higher proportions than $AgI : AgNO_3 = 1 : 2$, but the 1 : 2-compound may have been contaminated with silver nitrate. G. Scarpa obtained evidence of the formation of $3AgNO_3.2AgI$. K. Hellwig also prepared *silver cyanodinitrate*, $Ag_3Cy(NO_3)_2$; and *silver thiocyanatodinitrate*, $Ag_3CyS(NO_3)_2$; and C. Stürenberg triple salts of lead and silver nitrates and silver iodide.

N. W. Fischer [22] found a mixture of silver nitrate and **sulphur** detonates slightly when struck with a hammer. If a warm conc. soln. of silver nitrate be digested with sulphur, T. Poleck and K. Thümmel found that the salt is decomposed and a carmine-red amorphous powder, $Ag_2S.AgSO_4$, is formed. According to R. Fanto, the first stage in the action of **hydrogen sulphide** on a soln. of silver nitrate is the formation of **silver thionitrate,** $Ag_2S.AgNO_3$, and with the continued action of the gas, silver sulphide is formed. T. Poleck and K. Thümmel prepared silver thionitrate as a greenish-yellow precipitate by passing hydrogen sulphide into a conc. soln. of silver nitrate; and also by treating silver sulphide with fuming nitric acid. The product blackens when washed with water or alcohol, owing to its decomposition: $Ag_2S.AgNO_3 \rightarrow Ag_2S + AgNO_3$, but it is not changed by dil. nitric acid. The air-dried product loses very little in weight when heated to 180°; but when heated to redness, it gives off sulphur dioxide, etc., and leaves metallic silver. It is sensitive to light. **Galena,** copper pyrites, and the lower iron and copper **sulphides** were found by W. Skey to precipitate metallic silver; the reduction of ammoniacal soln. by cuprous sulphide occurs only when warm. R. Schneider also found that silver is precipitated by cuprous sulphide: $Cu_2S + 4AgNO_3 = 2Cu(NO_3)_2 + Ag_2S + 2Ag$. J. Myers found that when crystals of silver nitrate are in contact with a soln. of **potassium sulphide,** a crust of silver sulphide is formed and underneath this a thin film of metallic silver. According to E. C. Franklin and C. A. Kraus, **ammonium sulphide** gives a precipitate in a soln. of silver nitrate in liquid ammonia. According to H. Rose, and S. Kern, **sulphur dioxide** precipitates silver sulphite completely from an aq. soln. of silver nitrate, and while the precipitate is insoluble in aq. sulphurous acid, it is soluble in aq. ammonia or alkali sulphite. C. Geitner found that by heating silver or silver nitrate with sulphurous acid in a sealed tube at 200°, microscopic crystals of silver sulphide are formed resembling the native sulphide. According to H. Baubigny, an excess of **sodium sulphite,** at 100°, forms over 95 per cent. of sodium dithionate, $Na_2S_2O_6$, with the separation of silver; for the action of **potassium and ammonium sulphites,** see the precipitation of silver from the soln. of its salts.

Silver nitrate was found by H. Marshall to be slowly converted by **potassium persulphate** into black silver peroxide, etc.; J. Girard found **sodium thiosulphate** converts silver nitrate into the sulphide with the evolution of 23 Cals. when an eq. of each salt is dissolved in 2 litres of water at 15°. J. Fogh showed that silver thiosulphate is first formed with the development of 2·6 Cals. T. E. Thorpe found **sulphuryl chloride,** SO_2Cl_2, is without action on silver nitrate, indeed, the former can be distilled from the latter without perceptible decomposition; **thionyl chloride,** $SOCl_2$, reacts rapidly with silver nitrate forming silver chloride and nitrosulphuric chloride, $Cl.SO_2.NO_2$; and **chlorosulphonic acid,** $Cl.SO_2.OH$, acts violently, forming silver chloride and nitrosulphuric acid, $HO.SO_2.NO_2$. E. Bamberger obtained ozonized oxygen by heating **persulphuric acid** with silver nitrate.

T. Parkman found that red selenium is blackened in a soln. of silver nitrate, flakes of selenious acid are formed as well as a black powder, probably a compound of selenium and silver, Ag_2Se, from analogy with analysis on the corresponding reaction with cupric nitrate. R. D. Hall and V. Lenher have shown that the "flakes of selenious acid" were probably silver selenite. J. B. Senderens found that **selenium** reacts readily with a boiling dil. or conc. soln. of silver nitrate, forming silver selenide and selenious acid: $4AgNO_3+3Se+3H_2O=2Ag_2Se+H_2SeO_3+4HNO_3$; if the mixture be heated in a sealed tube some silver selenite, Ag_2SeO_3, is formed. N. W. Fischer observed that tellurium acts on a soln. of silver nitrate producing a black compound of tellurium and silver which does not acquire a metallic lustre under press., but he obtained no reduction with selenium. T. Parkman regarded the black powder as having the composition Ag_2Te, from analogy with analysis on the corresponding compound with copper nitrate. According to J. B. Senderens, at 100° the reaction $4AgNO_3+3Te+3H_2O=2Ag_2Te+H_2TeO_3+4HNO_3$ is faster than with the analogue selenium, and the reaction with both elements proceeds slowly but completely at ordinary temp. R. D. Hall and V. Lenher represents the reaction $4AgNO_3+3Te=2Ag_2Te+Te(NO_3)_4$.

According to E. Divers,[23] silver nitrate decomposes at a much lower temp. in an atm. of **nitric oxide** than when heated in air. The decomposition is marked at the m.p. of the salt, and at the b.p. of mercury the decomposition is slow but complete. At first, the products are silver nitrite and nitric peroxide, $AgNO_3+NO=AgNO_2+NO_2$, but very little silver is liberated, the nitrite being almost wholly preserved for a long time, through combination with the undecomposed nitrate. But when, as the nitrate becomes decomposed, the nitrite is no longer protected, it suffers decomposition, as usual, into silver and nitric peroxide; finally nothing but silver remains. Theoretically it is quite probable that nitric oxide does not, after all, act directly on silver nitrate. Assuming the first action is $2AgNO_3 \rightarrow 2AgNO_2+O_2$, and that the nitric oxide reacts with the oxygen to form nitrogen tetroxide, silver nitrate is not actually decomposed by nitric oxide, but only decomposes more rapidly in its presence in consequence of its interaction with one of the products of decomposition. E. Divers and T. Haga say that **hydroxylamine** gives a black precipitate of silver oxide when it reacts with a soln. of silver nitrate. The action of **ammonia** is treated in the next section. According to N. W. Fischer,[24] a mixture of silver nitrate and **phosphorus** detonates violently when struck with a hammer. M. Mauder also stated that a mixture of sublimed **arsenic** triturated with ten times its weight of silver nitrate takes fire immediately when shaken out on paper. The action of phosphorus, arsenic, and **antimony** have been discussed in connection with the metallic precipitation of silver.

According to H. Rose,[25] **phosphine** produces a brown precipitate in soln. of silver nitrate. D. Vitali showed that the first action results in the formation of **silver nitratophosphide,** $Ag_3P.3AgNO_3$, an unstable yellow compound studied by T. Poleck and K. Thümmel. This compound is very unstable and soon decomposes, and if the soln. of silver nitrate is dil., it is only formed momentarily: $6AgNO_3+PH_3=PAg_3.3AgNO_3+3HNO_3$. When the nitratophosphide is treated with water, or when formed in dil. soln., it gives off nitrogen tetroxide and black silver phosphide, Ag_3P, and this then decomposes into silver and phosphorous acid: $Ag_3P.3AgNO_3+3H_2O=6Ag+3HNO_3+H_3PO_3$. The nitric acid formed during the latter reaction transforms the phosphorous acid into phosphoric acid. Hence, silver, silver phosphide, and silver nitratophosphide may be produced by the action of phosphine on silver nitrate soln., the proportions depend on the conc. of the silver nitrate. Hence, T. Thomson, and G. Landgrebe could say that silver phosphide is formed by the action of phosphine on silver nitrate; P. Kulisch, a mixture of silver and silver phosphide; and H. Rose, that metallic silver is formed which, according to R. Fresenius and H. Neubauer, contains phosphorus. If purified phosphine is passed into a conc. soln. of silver nitrate, each bubble of gas is attended by inflammation; indeed, D. Vitali obtained an explosion by passing the purified gas rapidly into a conc. soln. of silver nitrate. It is therefore best to dilute the gas with carbon dioxide. E. Soubeiran observed the deposition of elemental silver when **arsine** is passed into an aq. soln. of silver nitrate. J. L. Lassaigne showed that the precipitated silver contains a little arsenic which can be removed by allowing the precipitate to stand in contact with the acidulated liquid. According to E. Reichardt, arsenious and arsenic acids, H_3AsO_3 and H_3AsO_4, are formed. J. L. Lassaigne gives the equation: $2AsH_3+12AgNO_3+3H_2O=As_2O_3+12Ag+12HNO_3$. L. Marchlewsky's objection that J. L. Lassaigne's equation cannot be right because finely-divided silver is attacked by 0·4 per cent. nitric acid—a product of the reaction—is invalid, since T. Poleck and K. Thümmel have pointed out that silver is not dissolved by nitric acid when no nitrous acid is present. According to G. Lockemann and H. Reckleben, the reaction does not always furnish end-products in accord with the equation since in acidified soln. too little silver is produced; only in alkaline soln. is the theoretical proportion obtained. The reaction has also been studied by J. A. Wanklyn, J. B. Senderens, D. Vitali, J. F. Simon, A. W. Hofmann, etc. K. Preis and B. Rayman say that in neutral soln., arsenious oxide (or silver arsenite) is produced, and in ammoniacal soln., arsenic oxide. J. L. Lassaigne stated that in a soln. of silver acetate, a bubble of arsine produces black flecks of silver, and some yellow silver arsenite which is decomposed by further contact with the gas. According to T. Poleck and K. Thümmel, the reaction is quite analogous to that which obtained with phosphine. Silver nitrate which has been fused is coloured by arsine first yellow and then black. A soln. of silver nitrate, in less than twice its weight of water, gives a citron-yellow coloration, and becomes acidic when treated with hydrogen mixed with a little arsine. The yellow liquid may be mixed with a little nitric acid, and it can be kept one or two days. Silver then separates out, arsenious and arsenic oxides are formed; the liquid becomes turbid and loses its colour. If the soln. be diluted, warmed, or treated with an excess of arsine, the changes occur more quickly. When the conc. soln., cooled below 0°, is treated with a rapid current of gas, it forms an egg-yellow crystalline mass, which rapidly blackens with the separation of silver when the temp. is allowed to rise. If the aq. soln. of silver nitrate be mixed with one-fourth its vol. of absolute alcohol yellow crystals are formed during the passage of the arsine; these crystals decompose when pressed and dried. The yellow substance obtained with conc. soln. of silver nitrate is **silver nitratoarsenide,** $Ag_3As.3AgNO_3$, which is decomposed by water into nitric acid, silver, and arsenious oxide. The first stage of the reaction is then represented: $AsH_3+6AgNO_3 =AsAg_3.3AgNO_3+3HNO_3$, and in dil. soln. the yellow nitratoarsenide is immediately decomposed: $2(Ag_3As.3AgNO_3)+3H_2O=12Ag+As_2O_3+6HNO_3$. According to Z. Pozzi, and H. Reckleben, G. Lockemann, and A. Eckardt the action is more complex than T. Poleck and K. Thümmel suppose, for besides the reaction represented by J. L. Lassaigne's equation, there occurs in neutral soln.: $AsH_3+3AgNO_3 =Ag_3As+3HNO_3$, and this the more conc. the soln. The silver arsenide so formed reacts: $Ag_3As+3AgNO_3=Ag_3As.3AgNO_3$, or else: $Ag_3As+3AgNO_3+3H_2O =6Ag+As(OH)_3+3HNO_3$—all depends on the conc. of the soln. and the duration of the action. In alkaline soln., in addition, there is the reaction: $As(OH)_3+2AgNO_3 +H_2O = 2Ag + H_3AsO_4 + 2HNO_3$; or $AsH_3 + 6AgNO_3 + 3H_2O = 6Ag + H_3AsO_3 +6HNO_3$ or $AsH_3+8AgNO_3+4H_2O=8Ag+H_3AsO_4+8HNO_3$. The reaction last symbolized is completed when the liquid is boiled. In ammoniacal soln. therefore: $AsH_3+8AgNO_3+11NH_3+4H_2O=(NH_4)_3AsO_4+8Ag+8NH_4NO_3$.

The reaction between arsine and silver nitrate has been recommended as a test by H. Hager, etc., and H. Gutzeit's test is based on the formation of the yellow nitratophosphide. This test has been studied by E. Dowzard, F. C. J. Bird, H. Strauss, A. H. Gotthelf, etc. A piece of filter paper, spotted with a soln. of silver nitrate, and exposed to arsine, gives a citron-yellow spot with a brown or black periphery which slowly broadens towards the centre until the whole spot is blackened. When the yellow spot is wetted with water, it blackens all over—0·005 mgrm. may be so detected in 15–20 mins. Stibine under similar conditions gives a grey or uncoloured spot with brownish-red or black edges. The yellow spots with phosphine or hydrogen sulphide may be distinguished, the former by oxidation with chlorine or bromine, the latter by iodine. The action of silver nitrate on arsine has also been utilized for removing the latter from gaseous mixtures. According to E. Reichardt, the absorption of arsine from a current of the gas mixed with much hydrogen, by a neutral or ammoniacal soln. of silver nitrate, is incomplete, but if the silver nitrate soln. be acidified with nitric acid—say one part of silver nitrate dissolved in 24 parts of water; mixed with an equal vol. of nitric acid of sp. gr. 1·20; and the whole diluted with 4–5 times its vol. of water—the arsine is completely absorbed.

When **stibine** is passed into a *dilute* soln. of silver nitrate, the gas is completely decomposed, and a black precipitate is formed which rapidly settles. The supernatant liquid has an acid reaction, and contains very little antimony. The reaction has been investigated by C. H. Pfaff, A. Houzeau, T. Humpert, J. W. Russell, E. Schobig, etc. The black precipitate was supposed by J. L. Lassaigne to be silver antimonide, Ag_3Sb, or a mixture of this compound with silver. T. Poleck and K. Thümmel, R. Bartels and F. Jones obtained a ratio nearer Sb : Ag=1 : 6. The reducing effect of any hydrogen accompanying the stibine has been shown by R. Bartels, and T. Poleck and K. Thümmel to be negligibly small. D. Vitali represents the reaction: $6AgNO_3+2SbH_3=2SbAg_3+6HNO_3$. J. F. Simon, and R. Bartels have shown that the product of the reaction is but slightly attacked by cold hydrochloric acid, the hot acid forms silver and antimonious chlorides; it is slowly dissolved by nitric acid; when boiled with a soln. of nickel, cobalt, or manganous chloride, antimony passes into soln. and the residue is free from nickel, cobalt, or manganese; and a boiling soln. of silver nitrate dissolves some of the antimony. F. Jones found that both silver and antimony are dissolved when the precipitate is digested with a conc. soln. of sodium chloride. A. W. Hofmann dissolved all the antimony from the precipitate by means of tartaric acid. With a *concentrated* soln. of silver nitrate, say one part of the salt to 0·7 part of water, a greenish-yellow coloration is developed and the soln. reacts acid; if the stibine is diluted with a large excess of hydrogen, the greenish-yellow colour does not appear, or it becomes grey owing to the formation of metallic silver. R. Bartels believes that the yellow compound has a similar constitution to silver monamminochloride, $Ag(NH_3)Cl$, and represents it as an addition product: $SbH_3+AgNO_3=Ag(SbH_3)NO_3$, and he says that it acts as a reducing agent on the excess of silver nitrate present in the soln.: $Ag(SbH_3)NO_3+5AgNO_3+3H_2O=H_3SbO_3+6Ag+6HNO_3$. The yellow compound cannot be isolated; and from T. Poleck and K. Thümmel's analyses, its composition agrees with that of **silver nitratoantimonide,** $SbAg_3.3AgNO_3$, and its mode of formation and properties resemble those of the corresponding products obtained with arsine and phosphine, $SbH_3+6AgNO_3=Ag_3Sb.3AgNO_3+3HNO_3$, followed by $SbAg_3.3AgNO_3+3H_2O=H_3SbO_3+6Ag+3HNO_3$.

According to A. Wurtz,[26] **hypophosphorous acid,** H_3PO_2, reduces silver nitrate soln. in the cold, without the evolution of hydrogen; and E. J. Bartlett and W. F. Rice said that if the acid be in excess, *silver hydride* is formed; C. F. Rammelsberg symbolized the reaction with barium hypophosphite: $Ba(H_2PO_2)_2+6AgNO_3+4H_2O\rightarrow 2H_3PO_4+4HNO_3+Ba(NO_3)_2+H_2+6Ag$, and he represented the action of **phosphorous acid** on silver nitrate by the equation: $2H_3PO_3+2AgNO_3+2H_2O\rightarrow 2H_3PO_4+2HNO_3+2Ag+H_2$; while H. Rose observed that dil. phosphorous acid does not at first render silver nitrate turbid, but forms first a brown then a black precipitate of *silver suboxide;* the reaction proceeds more rapidly when heated, and silver may then be deposited. According to A. Sänger, hypophosphoric acid is formed when ammonia and silver nitrate are added to a cold soln. of phosphorous acid, but the silver oxide which results from this reaction oxidizes some of the hypophosphoric acid to orthophosphoric acid. The white crystalline precipitate which is produced on the addition of silver nitrate to phosphorous acid has the composition Ag_2HPO_3, silver phosphite. U. J. J. le Verrier obtained a mixture of silver phosphate and phosphide by the action of **phosphorous suboxide** on silver nitrate. T. E. Thorpe and S. Dyson found that **thiophosphoryl chloride,** $PSCl_3$, reacts with silver nitrate in the cold: $4AgNO_3+PSCl_3 \rightarrow Ag_3PO_4+AgCl+SO_2+2NOCl+N_2O_4$. Liquid **phosphorous sulphide** with silver nitrate gives an olive-green non-metallic powder. The action of soln. of **ammonium arsenite** on ammoniacal silver nitrate was studied by H. Reckleben, G. Lockemann, and A. Eckardt; and of **sodium thioarsenate,** Na_3AsS_4, by K. Preis and B. Rayman.

H. Moissan[27] found that **boron** precipitates crystals of silver from a soln. of silver nitrate; C. Winkler, and P. Sabatier obtained a brown precipitate by the action of **boron hydride.** G. Buchner, and T. Poleck and K. Thümmel, found **silicon hydride** —SiH_4 or Si_2H_6—precipitates silver from a soln. of silver nitrate. N. W. Fischer[28] found that a mixture of **charcoal** and silver nitrate takes fire without detonation when struck with a hammer. If a piece of charcoal be allowed to stand in an aq. soln. of silver nitrate for a long time, its surface becomes studded with bright spangles of silver. J. Percy, M. Lazowsky, C. F. Chandler, said that the reduction is probably due to the hydrogen of the charcoal, for when the charcoal has been strongly heated, there is but a slight separation of the metal. M. Lazowsky added: "The parts of the charcoal on which certain metals are preferentially deposited are the extremities, whilst other metals cover equally all the surface of the reducing body; at other times the metal appears in very brilliant crystals disseminated on the periphery of the charcoal." L. F. Böck says that **coal** does not precipitate silver from boiling soln. of silver nitrate. G. Gore could detect no reaction when a mixture of **carbon monoxide** and **carbon dioxide** is passed into a soln. of silver nitrate, but **coal gas** gives a precipitate after acting about 14 days, and, according to A. Vogel and C. Reischauer, the minute crystals which are deposited behave like silver acetylide (*q.v.*).

The action of the **metals** on soln of silver nitrate has been discussed in connection with the metallic precipitation of silver; likewise also the action of cuprous, ferrous, stannous, and manganous salts; cuprous oxide and sulphide; brown silver oxide is precipitated from soln. of silver nitrate by **potassium and sodium hydroxide:** $2AgNO_3+2KOH=2KNO_3+H_2O+Ag_2O$; the precipitate is insoluble in an excess of the precipitant, but readily soluble in nitric acid and ammonia. The ammoniacal soln., on standing, deposits black fulminating silver, $Ag_2(NH_3)_2O$. According to W. Biltz and F. Zimmerman,[29] the freshly prepared **hydroxides of beryllium, aluminium, indium, zirconium, tin(ic), antimony, and bismuth** have no action on $\frac{1}{10}N$-$AgNO_3$; while **magnesium hydroxide** is coloured brownish-yellow, **zinc hydroxide,** dark brown, **cadmium hydroxide,** brownish-yellow, and **lead hydroxide,** violet-brown, owing to the absorption of silver oxide, Ag_2O. According to G. Tammann, and V. Kohlschütter and A. d'Almendra, a soln. of silver nitrate acidified with acetic acid deposits a film of silver in contact with **zinc oxide, mercuric oxide, bismuth oxide, lead oxide,** but not with acidic oxides, like **silica** or **stannic oxide.**

White silver carbonate is precipitated when **sodium carbonate** is added to a soln. of silver nitrate: $2AgNO_3+Na_2CO_3=2NaNO_3+Ag_2CO_3$; and when the mixture is boiled the silver carbonate becomes yellow owing to a slight decomposition: $Ag_2CO_3=Ag_2O+CO_2$; **ammonium carbonate** produces the same precipitate which is soluble in an excess of the precipitant. According to M. Gräger, the addition of a cream-like slip of **calcium carbonate** to an aq. soln. of silver and cupric nitrates so long as effervescence ensues, at 70°, results in the precipitation of the whole of the copper as green carbonate while the silver remains in soln. R. Griessbach studied the equilibria between silver nitrate and **sodium, barium, or lanthanum acetate.**

According to C. de Filière,[30] crystals of silver nitrate wrapped up in **paper** are gradually reduced to silver. N. W. Fischer found that **alcohol** under the influence of light slowly reduces silver nitrate; **sugar** reduces it more rapidly; **starch** and **gum** act in a similar way. A. Vogel found sugar gives a mixture of silver and silver oxide. E. Salkowsky says that cane sugar does not reduce aq. or ammoniacal soln., but it does readily if some alkali hydroxide be present. Count Rumford found that **ether** and **volatile oils** reduce silver nitrate rapidly in light, or at the boiling temp. R. Brandes and L. Reimann have studied the oxidizing action of silver nitrate on **organic compounds**; R. E. Liesegang, the action of silver nitrate on **photographic developers**; and A. Naumann, the reactions of silver nitrate in non-aq. soln.—**pyridine, acetone,** etc. Silver nitrate forms complexes with ammonia (*q.v.*), **asparagine, carbamide, urethane, leucine,** and other **ammino-derivatives** (N. Castoro); with **aldehyde** (A. Reychler); etc. According to N. Dhar, silver nitrate undergoes "practically no reduction" when boiled with **organic acids**—malic, tartaric, citric, malonic, and lactic acid—but in the presence of an oxidizing agent like potassium permanganate reduction quickly occurs.

Silver nitrate has a bitter metallic taste. Dil. soln. of the salt have an antiseptic action.[31] Under the designation, *lunar caustic*, silver nitrate has long been used as one of the best caustics where a limited action is required on any particular part, and an extensive deep action is not required—*e.g.* warts, bites, etc. A dil. aq. soln. is also used as a lotion on account of its combining an irritant stimulating effect with an astringent action. It is not used so much for internal application as was formerly the case, although it is used in checking severe diarrhœa. Long-continued use may cause blackening of the lips, inside the cheeks, gums, nostrils, eyelids, and later the skin-argyria. The coloration is thought to be due to the deposition of minute granules of metallic silver in the parts affected. Chronic silver poisoning is accompanied by many of the symptoms characteristic of lead poisoning. Acute silver poisoning is accompanied by severe vomiting and convulsions.[32]

§ 22. Silver Ammino-nitrates: Double or Complex Nitrates

Three silver ammino-nitrates have been reported with $AgNO_3 : NH_3$ as 1 : 1, 1 : 2, and 1 : 3. The existence of *silver monammino-nitrate* was reported by A. Reychler[1] in 1883 as being obtained by treating a soln. of silver nitrate with aq. ammonia until a precipitate appeared, and evaporating the filtrate on a water-bath. A. Joannis and M. Croizier also reported the formation of this salt, but W. Kuriloff showed that Reychler's salt is a solid soln. of silver nitrate and diammino-nitrate. This view was later accepted by A. Reychler. According to H. Rose, dry silver nitrate rapidly absorbs ammonia gas, at the same time the rise of temp. may suffice to fuse the salt. The analysis of the white mass so obtained corresponded approximately with that required for *silver triammino-nitrate*, $AgNO_3.3NH_3$. H. Ley and G. Wiegner, and W. Peters studied this reaction. The product is completely soluble in water. When heated to a higher temp., ammonia is given off. According to A. Joannis and M. Croizier, the salt dissociates at about 63° under normal press.; and it is very soluble in liquid ammonia below —10°.

C. G. Mitscherlich found that crystals of an ammino-salt are readily separated from an aq. soln. of silver nitrate supersaturated with ammonia; their analysis corresponded with **silver diammino-nitrate,** $Ag(NH_3)_2NO_3$. G. Wetzlar showed that the first drop of ammonia added to a soln. of silver nitrate produces no precipitate, but it renders the liquid alkaline, without imparting to it the smell of ammonia. A soln. supersaturated with ammonia gives off the excess on evaporation and deposits crystals of this salt; and he obtained the same compound by dissolving silver oxide in a soln. of ammonium nitrate, or, according to H. N. Draper, in an ammoniacal soln. of ammonia nitrate. N. Castoro obtained crystals of the salt by adding absolute alcohol to a conc. ammoniacal soln. of silver nitrate, or an amorphous precipitate by adding ether. A. Hantzsch precipitated silver diammino-nitrate by passing ammonia into a benzonitrile soln. of silver nitrate.

According to J. C. G. de Marignac, and C. F. Rammelsberg, the crystals belong to the rhombic system, and they have the axial ratios $a:b:c=0·7567:1:0·5945$. C. G. Mitscherlich noticed the crystals blacken in light. H. N. Draper said that the crystals are stable in air, while N. Castoro found them to turn brown rapidly when exposed to air, owing to the separation of silver, but if suspended in alcohol, they can be preserved some days. According to R. Kane, and H. N. Draper, the salt melts when heated, losing nitrogen, ammonia, and ammonium nitrate, and leaving behind metallic silver. J. C. G. de Marignac said the crystals do not lose in weight when heated to 100°, but A. Joannis and M. Croizier found them to dissociate irregularly at about 170°. M. Berthelot and M. Delépine found the heat of formation from a mol of silver nitrate in two litres of water and two mols of ammonia in two litres, forming $AgNO_3.2NH_3aq.$ is 12·25 Cals. G. Bruni and G. Levi gave the heat of formation $(AgNO_3, 2NH_3)=33·64$ Cals., in soln., 12·68 Cals.; and the heat of soln. per mol as —9·05 Cals. As C. G. Mitscherlich first observed, the crystals are soluble in water. A. Reychler investigated the electrical conductivity and lowering of the f.p. of ammoniacal soln. of silver nitrate—*vide* silver hydroxide. V. Kohlschütter and E. Fischmann measured the potential difference of ammoniacal soln. against aq. soln. of silver nitrate. A. A. Blanchard measured the viscosity of these soln. D. Konowaloff found the solubility of ammonia in aq. soln. of silver nitrate, and A. B. Prescott noted that approximately two mols of ammonia are required for the soln. of a mol of silver nitrate in aq. ammonia, and W. Herz studied the same reaction. W. Kuriloff reported alcohol dissolves 0·0383 mol of silver diammino-nitrate per litre.

The aq. soln. of silver diammino-nitrate was reported by G. Wetzlar to have an alkaline reaction. C. Weltzien found hydrogen peroxide reduces a conc. soln. of the salt, forming white granular silver. The complex silver diammino-nitrate dissociates to some extent in aq. soln., and accordingly it was found by N. Castoro to give a white precipitate of silver chloride with chlorides, and also Nessler's reaction. F. W. Schmidt found that a very dil. aq. soln. of iodine gives a white flocculent precipitate of silver hypoiodite, which when dried becomes yellow owing to the formation of silver iodide; an alcoholic soln. of iodine forms silver tri-iodide. According to H. Debus, the pentathionates give an intense brown coloration and silver sulphide is slowly precipitated; the trithionates and tetrathionates, dil. soln.

of ammonium sulphite, or potassium thiosulphate have no action. J. J. Berzelius found phosphorous sulphide precipitated silver sulphide. N. W. Fischer found that silver is quickly and completely reduced from the ammoniacal soln. of the nitrate by zinc, cadmium, copper, and arsenic; slowly by cobalt, mercury, and antimony; and not at all by iron, manganese, nickel, or bismuth. H. Reckleben, G. Lockemann, and A. Eckhardt found that when boiled with arsenic, silver is quantitatively precipitated; the action of arsine on ammoniacal soln. of silver nitrate has been previously discussed. Wool and silk were found by L. Cramer to be stained a deep brown by ammoniacal soln. of silver nitrate. Ethyl iodide was found by A. Reychler to react: $Ag(NH_3)_2NO_3+C_2H_5I=AgI+C_2H_5NO_3+2NH_3$, and this behaviour is said to be incompatible with the view that the diammino-nitrate is an argentoammonium nitrate. G. Bruni and G. Levi prepared **silver triammino-nitrate**, $Ag(NH_3)_3NO_3$, and found the heat of formation ($AgNO_3$, $3NH_3$)=42·94 Cals., and the mol. heat of soln., —10·44 Cals. It is assumed that only the diammines exist in soln., and that the triammines, which exhibit considerable heats of formation in the solid state, are completely decomposed in soln. into the corresponding diammines and ammonia. Measurements of the e.m.f. indicate the existence in soln. of the complex $Ag(NH_3)_2$, and of this alone.

W. J. Russell and N. S. Maskelyne[2] prepared crystals of **ammonium silver nitrate**, $NH_4NO_3.AgNO_3$, by evaporating a soln. containing eq. proportions of the component salts. A. Ditte also made the crystals in an analogous manner. J. W. Retgers says the rectangular or six-sided plates so formed are biaxial, and probably belong to the rhombic system. The crystals are very hygroscopic, and fuse at 97°. J. von Zawadsky, and F. Flawitzky have studied the f.p. curves of mixtures of the two salts. The results are shown in Fig. 26. The transition points of the four different forms of ammonium nitrate complicate the diagram. The region of stability of the double salts is represented by the portion *AB*. F. A. H. Schreinemakers and W. C. de Baat studied the ternary systems $H_2O—NH_4NO_3—AgNO_3$, and $C_2H_5OH—NH_4NO_3—AgNO_3$, as well as the quaternary system, $H_2O—C_2H_5OH—AgNO_3—NH_4NO_3$; and J. W. Retgers investigated mixed crystals of the component salts. F. A. H. Schreinemakers and W. C. de Baat's diagram is shown in Fig. 27. The region *HMZ* includes cubic ammonium nitrate; *GLSMH*, rhombohedral ammonium nitrate; *FKLG* and *ACKF* respectively, α-rhombic and β-rhombic ammonium nitrate; *CKLSRD*, the double-salt $AgNO_3.NH_4NO_3$; *PNX*, rhombohedral silver nitrate; and *BDRPN*, rhombic silver nitrate. The lines represent the corresponding two-phase system, and the points of intersection of three curves represent three-phase systems. The curve *BDCA* is a solubility curve at 30°, the other regions are diagrammatic for temp. ranging up to the m.p. of the respective salts.

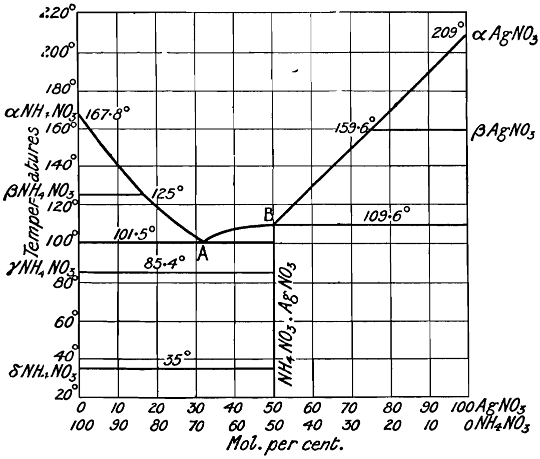

FIG. 26.—Fusion Curves of the Binary System, $AgNO_3—NH_4NO_3$ (J. von Zawadsky).

Neither A. Ditte[3] nor W. J. Russell and N. S. Maskelyne could obtain crystals of a *lithium silver nitrate* by the evaporation of mixed soln. of the component salts. The mixed crystals show isodimorphism. H. Rose evaporated a mixed soln. of sodium and silver nitrates and obtained first rhombic crystals of the latter and then rhombic crystals of the sodium salt. Mixed crystals of the two salts can be formed but no double salt, *sodium silver nitrate*. According to G. Tammann, mixed crystals of silver and sodium nitrates, prepared by slow cooling of the molten salts, give up more silver nitrate to a sat. soln. of sodium nitrate than mixed crystals prepared by slowly cooling a soln. of the two salts in aq. alcohol. W. J. Russell and N. S. Maskelyne, J. W. Retgers, A. Ditte, and E. Maumêne have also studied the subject.

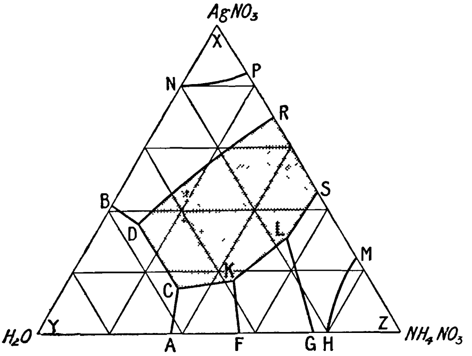

Fig. 27.—Ternary System, NH_4NO_3—$AgNO_3$—H_2O (Diagrammatic).

D. J. Hissink found the m.p. of mixtures of the two salts steadily rise from that of pure silver nitrate to that of sodium nitrate, as illustrated by the curves, Fig. 28. There are two series of mixed crystals. The series with silver nitrate predominating have a transition temp. from hexagonal (higher temp.) to rhombic (lower temp.) between 161° and 138°; the series with the sodium salt predominant are rhombohedral. Mixed crystals α and β with predominating silver nitrate and α' with sodium nitrate predominating occur as shown in the diagram. The region between the liquidus and solidus curves corresponds with Roozeboom's type IV. N. S. Kurnakoff and P. P. Eiler[4] have studied the f.p. of mixtures of the two salts. A. Benrath investigated the electrical conductivity of the mixtures.

According to H. Rose, silver and potassium nitrates crystallize together from aq. soln. in all proportions; if but a small proportion of silver nitrate is present, pure potassium nitrate separates from the soln.; if a large proportion of the silver salt is present, crystals of the form of potassium nitrate containing the silver salt are obtained. J. W. Retgers, however, did not succeed in getting mixed crystals of the two salts in all proportions—up to 0·3 per cent. of potassium nitrate from mixed crystals of the potassium nitrate type; and up to 0·5 per cent. of silver nitrate from crystals of the silver nitrate type. By evaporating soln. with an excess of silver nitrate, W. J. Russell and N. S. Maskelyne obtained crystals of the double salt, **potassium silver nitrate**, $KNO_3.AgNO_3$; if the soln. contains equi-molecular proportions of the component salts, potassium nitrate alone crystallizes out; and, according to A. Ditte, when the soln. has 3 mols of silver nitrate to one of the potassium salt, the double salt is obtained. P. Friedlander, and J. W. Retgers found the crystals of the double salt belong to the monoclinic system, with axial ratios $a : b : c = 0·8200 : 1 : 0·6963$, and $\beta = 97° 47'$. J. W. Retgers gives 3·219 for

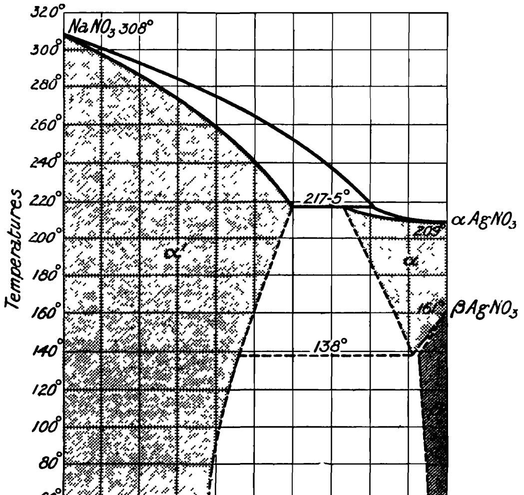

Fig. 28.—Fusion Curves of the Binary System, $NaNO_3$—$AgNO_3$ (D J. Hissink).

the sp. gr.; and at 125° for the m.p., but A. Ussoff says the double salt has not a well-defined m.p. J. G. L. Stern found silver nitrate to be but feebly ionized in soln. in molten potassium nitrate. N. S. Kurnakoff and P. P. Eiler, and A. Ussoff studied the f.p. of mixtures of the component salts; E. Mauméne the m.p.; L. Poincaré, the electrical conductivity; and L. J. Spencer, B. Gossner, and J. W. Retgers, the crystallographic relations of the mixed crystals. A. Ussoff's curves are shown in Fig. 29, where *AD* is the m.p. curve of silver nitrate with additions of increasing amounts of potassium nitrate; at *G*, α-$AgNO_3$ passes on cooling to the β-salt; *DE* is the m.p. curve of the double salt but there is no hylotropic m.p.; *E* upwards is the m.p. curve of potassium nitrate with decreasing proportions of the silver salt. *E* is a transformation point; *D* is a eutectic. F. A. H. Schreinemakers has studied the ternary systems, KNO_3—$AgNO_3$—H_2O at 30°; and KNO_3—$AgNO_3$—C_2H_5OH at 30°; as well as the quaternary system, KNO_3—$AgNO_3$—H_2O—C_2H_5OH at the same temp.

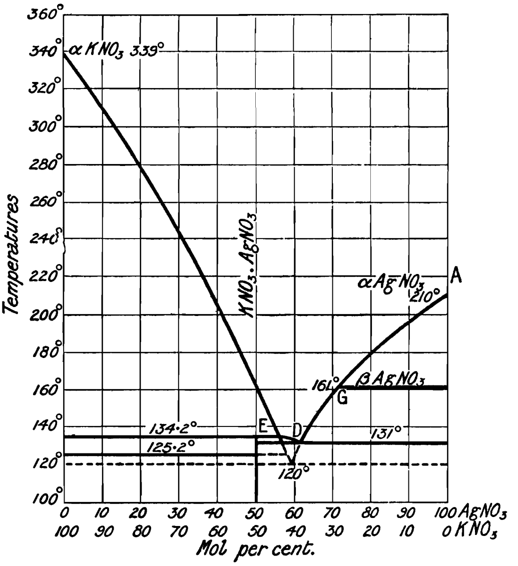

FIG. 29.—Fusion Curves of the Binary System, KNO_3—$AgNO_3$ (A. Ussoff).

A. Ditte prepared fine crystals of **rubidium silver nitrate**, $RbNO_3.AgNO_3$, and of **cæsium silver nitrate**, $CsNO_3.AgNO_3$, analogous to the corresponding potassium salt. P. Sabatier reported the formation of microscopic needles of a basic **cupric silver nitrate**, $3CuO.Ag_2O.N_2O_5.3H_2O$, or $3Cu(OH)_2.2AgNO_3$, by the action of silver oxide on a soln. of cupric nitrate, or of cupric hydroxide on a soln. of silver nitrate.

§ 23. Silver Peroxynitrate and Peroxysulphate

In 1804, J. W. Ritter [1] observed that a black crystalline deposit is formed on the anode when an aq. soln. of silver nitrate is electrolyzed between platinum electrodes. A silver cathode and platinum anode may be used. During the electrolysis, silver is deposited on the cathode and the black crystals on the anode, and there is a simultaneous formation of nitric acid. Both solid deposits are crystalline, and grow rapidly towards one another in arborescent crystals, so that the anode deposit, as F. Mahla, and M. J. Brown have observed, is a good electrical conductor.

O. Sulc recommended using a platinum dish as cathode and as anode a piece of platinum foil cut in the form of a comb and rolled up. A 15 per cent. soln. of silver nitrate was used as electrolyte, with a current of 0·06 amp. and a current density at the cathode of 0·0033 amp. per sq. cm. The electrolysis continued 3–4 hrs. when the soln. became contaminated with about 4 per cent. of free nitric acid. The electrolyte was then renewed, and the electrolysis continued. The crystalline deposit on the anode was brushed off with a glass rod, and washed with water until the runnings gave no opalescence with hydrochloric acid. The product was dried over calcium chloride.

M. J. Brown showed that the losses due to the decomposition of the black crystals breaking away from the anode is avoided if the crystals are kept in electrical contact with the anode, for the crystals are not then attacked by the nitric acid simultaneously formed; E. Mulder and J. Heringa, and E. R. Watson found that the product is the same when soln. of different conc. (5 to 15 per cent.) are electrolyzed, and when the current varies from 0·13 to 1·12 amp., and the current density varies from 0·015 to 0·14 amp. per sq. cm. V. Novak, O. Kühling, S. Tanatar, R. Böttger, and others have likewise prepared the same product. According to H. C. P. Weber, the soln. of silver nitrate being electrolyzed contains 15–25 per cent. of nitric acid, there is no deposit, but a brown soln. is formed. According to E. Wallquist, the deposit forms black octohedra united in a series of prisms and needles, and, according to C. J. D. von Grotthus, the crystals are tetrahedra. According to F. Mahla, the sp. gr. of the crystals is 5·474, and according to O. Sulc, 5·65.

The black deposit was thought to be a peroxide, Ag_2O_2, and E. Wallquist's analyses (1842) corresponded with this assumption. N. W. Fischer, however, showed that the product always contains nitric acid, and that the analogous product obtained by the electrolysis of silver sulphate also contains sulphuric acid; while the electrolysis of silver hypophosphate, or of silver acetate, does not yield the peroxidized product. N. W. Fischer's analysis (1842) corresponded with $Ag_4O_5.AgNO_3$, or with $2Ag_2O_2.AgNO_3.H_2O$; F. Mahla's (1852) with $5Ag_2O_2.2AgNO_3.H_2O$; M. Berthelot's (1881) with $4Ag_2O_3.2AgNO_3.H_2O$; W. Hampe's (1890) with $Ag_2O_3.2AgNO_3$; and O. Sulc's (1896), $3Ag_4O_5.2AgNO_3$. E. Mulder and J. Heringa's analysis

(1896) gave $3Ag_2O_2.AgNO_3$, or $2Ag_3O_4.AgNO_3$, which is eq. to Ag_7NO_{11}; S. Tanatar (1901), O. Sulc (1900), E. R. Watson (1906), M. J. Brown (1916), obtained similar results.

While these workers consider that silver nitrate is an essential constituent of the product, others like E. Wallquist believe that silver nitrate is either adsorbed or in solid soln. with silver peroxide Indeed, M. Bose made no analysis of her products because she considered it impossible to get accurate results, and added:

> When one remembers how many chemically prepared compounds can be washed free from the adhering mother liquid only with great difficulty, and how often crystals contain enclosed mother liquid, it is not surprising that the crystals, formed by electrolysis and precipitated very rapidly, should contain some of the soln. in which they grew.

She obtained only one break in the current-voltage curve for a soln. of silver nitrate or silver sulphate—in the former case 1·573 volts, and 1·53 in the latter—and considered that the two values are the same, and hence concluded that the precipitate is the same and consequently cannot contain either silver nitrate or silver sulphate. As a matter of fact, the difference between 1·573 and 1·53 volts is nothing like as large as the changes found by J. A. Wilkinson and H. W. Gillett in the decomposition voltage of soln. of silver nitrate of varying conc. and with varying amounts of nitric acid. R. Luther and F. Pokorny also determined the voltage-current curve of a silver anode in soln. of sodium hydroxide, and they obtained one break corresponding with silver oxide, Ag_2O, and another with silver peroxide, Ag_2O_2. They prepared E. Mulder's peroxynitrate and peroxysulphate, washed them with a dil. soln. of sodium hydroxide, and reduced them at constant current in N-NaOH soln. They obtained three definite potentials, 1·57, 1·41, and 1·17 volts, and they believe that these correspond respectively with Ag_2O_3, Ag_2O_2, and Ag_2O. Similar results were obtained with both the peroxynitrates and peroxysulphates, and hence the same conclusion was drawn that neither silver sulphate nor silver nitrate is an integral part of the compound, which is therefore an impure silver oxide, Ag_2O_3. B. Brauner and B. Kuzma (1907) likewise believe the compound to be silver peroxide, Ag_4O_4 or $Ag_2O.Ag_2O_3$; and G. Baborovsky and B. Kuzma (1909), Ag_3O_4.

O. Sulc's investigations on the action of heat and oxidizing properties (*vide infra*); E. R. Watson's observation that a definite crystalline product is obtained by varying the current density and conc. of the soln.; and M. J. Brown's work on the coulometer ratio of the compound to copper, show that the deposit is probably impure $(Ag_3O_4)_2AgNO_3$. In the latter case it was found that no silver peroxide or hydrated oxide can give the observed ratio of silver contents of anode deposit to copper deposited in the coulometer. The values calculated for $(Ag_3O_4)_2AgNO_3$ agree with the observed. It required ten farads to precipitate a mol of Ag_7NO_{11}. For some soln. the low values of the coulometer ratio may be explained by the possible presence of $Ag_2O_3.AgNO_3$ or $(Ag_3O_4)_2.H_2O$; or to the dissolution of the anode deposit. H. C. P. Weber suggested two probable formulæ for the oxide part of the salt—Ag_2AgO_4 analogous to red lead, and $Ag(AgO_2)_2$ analogous to magnetic oxide of iron—but transference experiments show that one-third the silver is cathodic and bivalent, and two-thirds is anodic and tervalent. This leads to the formula $Ag(AgO_2)_2$, making the oxide portion of the peroxynitrate to be the silver salt of an unstable **argentic acid,** $HAgO_2$.

According to E. Wallquist, the product decrepitates in the flame of a candle; and, according to N. W. Fischer, the product obtained with silver sulphate does not decrepitate in the flame of a candle. When the dried product is heated gently in a flask, it gives off nitrous fumes, and cold water extracts silver nitrate from the residue. According to F. Mahla, it loses oxygen at 110°, leaving a residue of silver and silver nitrate; M. Schucht says that the crystals detonate feebly at 110° with the evolution of oxygen. The speed of decomposition is moderate at 50°, but rapid between 90° and 100°. W. Hampe also records the spontaneous explosion of a sealed tube containing this product. At 150°–160°, O. Sulc found that oxygen is given off and a dark brown voluminous powder is formed; when heated to redness, reddish-brown fumes are evolved, and metallic silver remains. M. Berthelot says that the crystals are not stable at ordinary temp., but O. Sulc found them to be fairly stable in air, and to decompose only after keeping them some months. E. Mulder and J. Heringa, E. R. Watson, and O. Sulc found oxygen to be evolved in the proportion corresponding to the equation: $2Ag_7NO_{11}=2(3Ag_2O.AgNO_3)+5O_2$. They believed that three out of the five atoms of oxygen liberated per mol of Ag_7NO_{11} are different from the other two because only these three take part in the reaction with ammonia and probably oxalic acid; and it is probably these three atoms which give the substance the properties of a peroxide as evidenced by the energetic oxidizing properties. The powdered crystals are slowly decomposed when in contact with **water** at ordinary temp. with the evolution of oxygen. The change is completed in an hour when the water is boiled, and a greyish-black powder of silver peroxide, Ag_2O_2, of sp. gr. 7·44, remains: $Ag_7NO_{11}=AgNO_3+3Ag_2O_2+O_2$. According to O. Sulc, the salt is decomposed very slowly by water at ordinary temp. and silver nitrate passes into soln.; but when boiled with water for about 36 hrs. silver is deposited as a mirror on the flask.

F. Mahla observed no action when **hydrogen** is passed over the cold salt, but when heated, a feeble explosion occurs and the salt is reduced. R. Böttger also noted that **hydrogen sulphide** is inflamed by the salt; and when triturated with **antimony pentasulphide** inflammation occurs. C. J. D. von Grotthus says that the compound detonates when struck in contact with **sulphur** or **phosphorus.** According to H. Rose, and E. R. Watson, conc. **sulphuric acid** forms a greenish-black or olive-green soln. which slowly decomposes at ordinary temp., and the oxygen which is evolved smells of ozone; N. W. Fischer, E. Wallquist, and F. Mahla also noted that oxygen is evolved when the salt is treated with sulphuric acid, and likewise also with **phosphoric acid**—with syrupy phosphoric acid, H. Rose noted that the product is not dissolved at ordinary temp., but when warmed a colourless liquid is formed with the evolution of oxygen. N. W. Fischer said that the salt dissolves unchanged in **nitric acid**; and F. Mahla obtained a port-wine coloured liquid with nitric acid of a sp. gr. 1·2, and the soln. became colourless with the evolution of oxygen when warmed. With cold conc. nitric acid, E. R. Watson obtained a brown soln., which cannot be distinguished from the soln. obtained similarly with silver peroxide. It is assumed that the coloured soln. contains *silver peroxynitrate* in the case of nitric acid, and *silver peroxysulphate* in the case of sulphuric acid. The presence of salts is the cause of the coloration. These peroxy-salts gradually decompose at ordinary temp., more quickly when heated; or when diluted with water. No hydrogen peroxide has been detected during the decomposition. E. R. Watson found the rate of decomposition of the coloured nitric acid soln. is proportional to the conc. x of the coloured salt, or $dx/dt=kx$. This does not agree with the assumption that the coloured compound is $Ag(NO_3)_2$, although the formula $[Ag(NO_3)_2]_4$ satisfies the condition that the decomposition is a unimolecular reaction: $Ag_4(NO_3)_8+2H_2O=4AgNO_3+4NHO_3+O_2$; the same condition is satisfied by $Ag_2(NO_4)_2=2AgNO_3+O_2$. Attempts to isolate the peroxy-salts have not been successful. G. A. Barbieri believes the brown nitric acid soln. of silver peroxynitrate, like that of silver peroxide, contains *silver dinitrate*, $Ag(NO_3)_2$, with silver bivalent.

Silver peroxynitrate, said J. W. Ritter, is converted by **hydrochloric acid** into silver chloride with the evolution of chlorine; A. J. Balard found that with **hypochlorous acid,** silver chloride, oxygen, and a little chlorine are formed. N. W. Fischer and S. Tanatar say that a cold soln. of **sodium chloride** has no action, but a boiling soln. gives off a gas, and forms silver chloride and sodium hydroxide; the last-named also found that a soln. of **potassium iodide** forms silver iodide and potassium iodate. N. W. Fischer also found that with **ammonium chloride** soln., a gas is evolved and silver chloride is formed—partly in soln. and partly precipitated. H. Rose said that if the nitric acid soln. be poured into a dil soln. of **potassium hydroxide,** an alkali peroxide and yellowish-brown silver oxide are formed; with

sodium carbonate, sodium phosphate, or **potassium chromate,** precipitates of silver carbonate, phosphate, or chromate are respectively produced. O. Kühling found that **manganous salts** are converted into permanganates. According to C. J. D. von Grotthuss, and O. Sulc, the salt dissolves in aq. **ammonia** and is completely decomposed with the evolution of nitrogen, and the formation of silver ammino-oxide ; and, according to O. Sulc, two mols of ammonia are oxidized by three of the oxygen atoms of the peroxynitrate, Ag_7NO_{11}. H. Rose says that when the nitric acid soln. of the salt is dropped into very dil. aq. ammonia, a peroxide is first formed, and this soon passes into soln. R. Kempf has shown that silver peroxynitrate acts as an oxidizing agent on organic compounds. F. Mahla and O. Sulc found that it is completely decomposed by **oxalic acid** with the evolution of carbon dioxide ; **alcohol** is converted into aldehyde with the simultaneous deposition of a silver mirror ; **oil of cloves,** and similar compounds, are inflamed (R. Böttger), and it is decomposed by filter **paper** (E. R. Watson).

§ 24. Silver Phosphates

According to G. Wetzlar,[1] silver oxide reacts with an aq. soln. of phosphoric acid or disodium hydrophosphate, forming **normal silver orthophosphate,** Ag_3PO_4; and, according to J. J. Berzelius and E. Mitscherlich, the same salt is precipitated when diammonium, dipotassium, or disodium hydrophosphate is added to a soln. of silver nitrate, and the supernatant liquid contains free nitric acid ; but, according to T. Graham, the liquor is neutral if normal sodium orthophosphate be employed as precipitant: $Na_3PO_4+3AgNO_3=3NaNO_3+Ag_3PO_4$. In all cases also, T. Graham found that the precipitate carries down a little silver nitrate which cannot be completely removed by washing, and consequently nitrous fumes are evolved when the salt is heated. It was also remarked that sparingly soluble orthophosphates—*e.g.* the calcium or magnesium salts—are coloured yellow when moistened with a soln. of silver nitrate owing to the formation of silver phosphate. It is not feasible to purify normal silver orthophosphate by recrystallization, and the conditions of precipitation must be so chosen that a pure product is obtained at once. G. P. Baxter and G. Jones did not obtain satisfactory results with disodium ammonium phosphate or with trisodium phosphate as precipitant, but the precipitates with disódium hydrophosphate, disodium ammonium phosphate, and sodium ammonium hydrophosphate had very nearly the same composition.

A $0 \cdot 3N$-soln. of one of these salts was slowly poured into a $0 \cdot 3N$-soln. of silver nitrate; the precipitate was washed by decantation with water and allowed to stand in contact with water for 24 hrs. in order to allow all soluble matters to be leached out. The precipitate was drained in a centrifugal machine, and then dried in a current of air for several hours, first at 90° and then at 100°. All the operations were conducted in a dark room. The excess of silver in soln. prevents the conc. of the phosphate from exceeding a small value, and the soln. can neither become alkaline by hydrolysis, nor dissolve an appreciable amount of acid phosphate. The addition also prevents the formation or occlusion of acid phosphates.

F. Stromeyer found the salt contained no water, J. J. Berzelius observed about half per cent., and G. P. Baxter and G. Jones ascertained that the salt can be completely dried, without fusion, by heating it to about 400° in a current of dry air for about 7 hrs.

The reaction between disodium orthophosphate and silver nitrate is usually represented: $Na_2HPO_4+3AgNO_3=Ag_3PO_4+2NaNO_3+HNO_3$, but W. Ostwald gave $2Na_2HPO_4+3AgNO_3=Ag_3PO_4+NaH_2PO_4+3NaNO_3$ as more in accord with observations, but added that "it no doubt fails to express all that goes on." W. R. Lang and W. P. Kaufmann have shown that the reaction takes place in several distinct stages: $Na_2HPO_4+AgNO_3+HNO_3=2NaNO_3+AgH_2PO_4$; $AgH_2PO_4+AgNO_3=Ag_2HPO_4+HNO_3$; and $Ag_2HPO_4+AgNO_3=Ag_3PO_4+HNO_3$. The filtrate contains both phosphoric and nitric acids, and this is accounted for by the equation, $4Na_2HPO_4+9AgNO_3=3Ag_3PO_4+8NaNO_3+HNO_3+H_3PO_4$. The composition of the precipitate approaches that of Ag_3PO_4, but more usually is nearer $Ag_5H(PO_4)_2$, or $Ag_3PO_4+Ag_2HPO_4$. According to M. Berthelot, when disodium hydrophosphate is employed as precipitant, the normal silver phosphate is contaminated with the disilver orthophosphate, and a double silver disodium orthophosphate. The relative quantities of these three salts in the precipitate is determined by the composition of the mother liquid, and the equilibrium conditions have been studied by Y. Osaka.

A. Lottermoser[2] prepared **colloidal silver orthophosphate** by mixing $0 \cdot 05N$-$AgNO_3$ with an excess of $0 \cdot 05N$-normal sodium phosphate, or disodium hydrophosphate. C. Paal and F. Voss added silver nitrate to a soln. of disodium hydrophosphate and sodium lysalbinate or protalbinate.

Precipitated silver orthophosphate is a yellow amorphous powder which J. J. Berzelius, and A. Joly found can be recrystallized from orthophosphoric acid (38 per cent. P_2O_5). H. Dufet says the **crystals** belong to the cubic system, F. Stromeyer found the **specific gravity** to be 7·321 at 7·5°; G. P. Baxter and G. Jones, 6·37 at 25°/4°. The salt becomes reddish-brown when heated, and, according to J. J. Berzelius, it melts like silver chloride at a red heat. T. Carnelley places the **melting point** at about 849°. According to F. Stromeyer, the molten salt is coloured dark brown, and, on cooling, solidifies to a yellow mass; if the salt be kept fused for a long time, it is partly reduced, and becomes paler and more fusible, owing to the formation of the pyrophosphate. The salt blackens on exposure to light. Silver orthophosphate is sparingly soluble in water; R. Böttger found the **solubility** in water at 19·3° to be $6 \cdot 5 \times 10^{-3}$ grms. per litre. According to J. F. H. Suersen, the salt dissolves readily in an aq. *orthophosphoric acid.* A. Joly observed that the soln. of the salt in phosphoric acid with less than 80 per cent. P_2O_5, sat. at 80°, deposits pale yellow crystals of normal silver phosphate, Ag_3PO_4, on cooling, but if the soln. contains about 40 per cent. P_2O_5, colourless crystals of disilver hydrophosphate, Ag_2HPO_4, are produced. According to J. F. H. Suersen, normal silver phosphate is readily soluble in *nitric acid.* The soln. in nitric acid yields crystals of silver nitrate. J. F. H. Suersen also found silver phosphate to be readily soluble in *acetic acid,* and, according to W. Skey, crystals of the normal phosphate separate from the soln. J. F. H. Suersen also found the normal phosphate to dissolve readily in aq. *ammonia* or *ammonium carbonate;* it is less readily soluble in an aq. soln. of *ammonium nitrate* or *ammonium succinate;* and still less soluble in an aq. soln. of *ammonium sulphate.*

E. C. Franklin and C. A. Kraus ascertained that normal silver phosphate is insoluble in liquid *ammonia;* F. Bezold, that it is insoluble in *methyl acetate,* and M. Hamers, in *ethyl acetate.*

A. Colson found that **hydrogen** reduces normal silver phosphate by an irreversible reaction, and the speed of absorption is accelerated by a rise of temp. or press. J. B. Senderens observed that when boiled with **sulphur** and water, silver sulphide and phosphoric and sulphuric acids are formed. J. L. Lassaigne found that freshly prepared silver phosphate is decomposed when digested with a soln. of **sodium, calcium, or magnesium chloride,** silver chloride being produced. A soln. of **calcium or magnesium nitrate** is not decomposed.

O. Widmann found that if ammonia gas be passed over dry normal silver phosphate, until the solid has a constant weight, the eq. of three mols of ammonia are absorbed per mol of silver phosphate, and A. Reychler found between 3 and 4 mols of gas are absorbed. O. Widmann also reported that if a soln. of normal silver phosphate in aq. ammonia be conc. in a desiccator, over quicklime mixed with ammonium chloride, colourless prismatic needles of **silver tetrammino-orthophosphate,** $Ag_3PO_4.4NH_3$, are formed. O. Widmann found the crystals are rapidly coloured yellow on exposure to air, and lose all their ammonia in a desiccator over sulphuric acid. Neither A. Reychler nor A. Terreil could get a product of constant composition by this procedure. The latter reported that the soln. rapidly becomes brown, and finally deposits a brownish-black substance resembling silver fulminate.

Disilver hydrophosphate, Ag_2HPO_4.—J. J. Berzelius found that the evaporation of a soln. of normal silver phosphate in phosphoric acid at first deposits the same salt, but as the soln. is allowed to evaporate spontaneously, white feathery crystals assumed to be disilver hydrophosphate are formed. Similar results were obtained by L. Hurtzig and A. Geuther, and A. Joly—*vide supra*—who ascertained the conditions under which each salt is produced. J. J. Berzelius also obtained crystals of this salt by evaporating at a gentle heat, a mixture of silver nitrate with a large excess of orthophosphoric acid. A. Schwarzenberg did not succeed in preparing crystals of this salt by Berzelius' process, but he evaporated the soln. of silver phosphate in phosphoric acid to a syrupy consistence, and mixed it with ether, much heat was evolved, and a white crystalline powder was obtained which after washing with absolute alcohol to remove as much adherent phosphoric acid as possible, and drying at 100°, had a composition corresponding with disilver hydrophosphate. A. Joly found that the salt is not altered by washing with ether, and the excess of phosphoric acid can be washed from the crystals by that menstruum. According to H. Dufet, and O. Mügge, the colourless prismatic crystals of this salt belong to the hexagonal or trigonal system, and have the axial ratio $a:c=1:0{\cdot}7297$. They are quickly reduced by exposure to light. A. Schwarzenberg found the crystals lost no water at 100°, but at 170°, 2·87 per cent. of water was given off, and silver pyrophosphate was formed—A. Joly reported that the last-named change occurs between 110° and 150°. The crystals are blackened on exposure to light, and are immediately converted into the normal silver phosphate and free phosphoric acid by contact with water. Alcohol and ether have no action on the salt. The primary salt, *silver dihydrophosphate,* AgH_2PO_4, has not been isolated.

Normal silver pyrophosphate, $Ag_4P_2O_7$.—T. Clark [3] prepared this salt, in 1827, by precipitation when a soln. of sodium pyrophosphate is added to one of silver nitrate; the filtrate from the white precipitate is neutral. F. Stromeyer observed that if a soln. of silver nitrate be added to a mixture of sodium orthophosphate and pyrophosphate, yellow normal silver orthophosphate is first precipitated, and afterwards the white pyrophosphate; and he added that at the first instant of the precipitation, white silver pyrophosphate appears to be hydrated but soon parts with the combined water. A. Joly's and A. Schwarzenberg's production of this salt by heating disodium hydro-orthophosphate has already been indicated.

According to F. Stromeyer, the white pulverulent normal silver pyrophosphate has a sp. gr. 5·306, and it fuses below a red heat, without decomposition, forming a dark-brown liquid, which on cooling solidifies to a white mass of radiating crystals. T. Carnelley gave 585° for the m.p. F. Stromeyer added that the salt acquires a reddish tint on exposure to light. When silver pyrophosphate is boiled with a soln. of disodium hydrophosphate, it is decomposed into yellow normal silver orthophosphate, and a soln. of sodium pyrophosphate. The salt is soluble in cold dil. nitric acid, but when boiled with either nitric acid or sulphuric acid, it is converted into ordinary silver phosphate which is precipitated when the acid is neutralized with the alkalies or ammonia; it is converted by hydrochloric acid into silver chloride and free phosphoric acid. It readily dissolves in aq. ammonia, and is re-precipitated by acids; it is insoluble in acetic acid, and is not affected by boiling water. A. Schwarzenberg continued that the salt is slightly soluble in a soln. of silver nitrate, and insoluble in a soln. of the pyrophosphates.

Disilver dihydropyrophosphate, $Ag_2H_2P_2O_7$.—This salt was prepared in 1859 by L. Hurtzig and A. Geuther, by heating a soln. of normal silver pyrophosphate to 180° for 14 days. The crystals are washed free from the syrupy mother liquid first with ether, and then with alcohol. J. Cavalier heated a mixture of 40 grms. of normal silver pyrophosphate with 200 grms. of pyrophosphoric acid until the liquid was clear; it was then dissolved in half a litre of water at 0°, and precipitated by the addition of alcohol or ether.

The white crystalline powder softens at 150°; melts at 235°; and decomposes at 240°. L. Hurtzig and A. Geuther say that the salt loses 2·19 per cent. of water at 225° when it melts to a dirty green glass; and at a red heat, 1·95 per cent. more water is given off. A. Cavalier found the salt is decomposed by cold water, forming pyrophosphoric acid and normal silver pyrophosphate; it reacts with a soln. of disodium hydrophosphate to form normal silver phosphate and pyrophosphoric acid; and it reacts with alkali iodides to form silver iodide, and the alkyl esters of pyrophosphoric acid. L. Hurtzig and A. Geuther believed that they also obtained a compound of silver dihydropyrophosphate with metaphosphoric acid, *viz.*, $2Ag_2H_2P_2O_7.HPO_3$.

M. Stange reported the formation of **sodium trisilver pyrophosphate,** $NaAg_3P_2O_7$, with about 0·4 mol part of water by gradually mixing in darkness a cold sat. soln. of 20 parts of normal sodium pyrophosphate, and 50 c.c. of a 2·5 per cent. soln. of silver nitrate. The white crystals are washed, and dried on a porous tile. They are changed in light, and when heated to drive off the water, the crystals blacken, and when heated more strongly they decompose into normal silver phosphate and sodium metaphosphate.

Silver dimetaphosphate, $Ag_2P_2O_6$.—T. Fleitmann[4] added an excess of silver nitrate to a conc. soln. of alkali dimetaphosphate, and obtained a crystalline precipitate; the crystals which separate when a dil. soln. is allowed to stand for some time are similar to silver trimetaphosphate, but are much less soluble in water. F. Warschauer dropped a soln. of sodium tetrametaphosphate into a 10 per cent. soln. of silver nitrate, and J. Müller stirred sodium metaphosphate with a conc. soln. of silver nitrate at 50°. Silver dimetaphosphate is gradually formed. K. Langheld emphasized that these methods of preparation are not free from objections. The crystals melt at an incipient red heat, forming a clear glass insoluble in water, and which cannot be distinguished from the hexametaphosphate. The air-dried salt does not lose any noteworthy quantity of water when heated to redness. The salt is sparingly soluble in water. G. Tammann obtained *monohydrated silver dimetaphosphate*, $Ag_2P_2O_6.H_2O$, by adding lithium disodium metaphosphate or potassium disodium metaphosphate to a soln. of silver nitrate; the same salt was obtained by adding a soln. in hot water of freshly precipitated ammonium metaphosphate to an excess of a soln. of silver nitrate. K. Langheld, F. Oppmann, and E. Meyer dissolved 35 grms. of silver nitrate in a little water and poured the soln. into one of 20 grms. of sodium dimetaphosphate. The crystallization of the salt begins after some time. The octahedral crystals lose their water when exposed in vacuo to 150°.

Silver trimetaphosphate, $Ag_3P_3O_9$.—T. Fleitmann and W. Henneberg, and C. G. Lindböm obtained the anhydrous salt by heating disilver dihydropyrophosphate to its m.p.; and *monohydrated silver trimetaphosphate:* $Ag_3P_3O_9.H_2O$, by mixing the conc. soln. of sodium trimetaphosphate with silver nitrate. Crystallization sets in immediately, and continues some days. C. G. Lindböm recommended a great excess of sodium trimetaphosphate, and A. Weisler used 5 grms. of sodium trimetaphosphate and 15 grms. of silver nitrate. The crystals are probably monoclinic. If an excess of the sodium salt is used, the crystals are much larger than if an excess of the silver salt is used, but they are then contaminated with up to about 0·3 per cent. of soda. The crystals do not lose weight when confined over sulphuric acid. The solid does not alter very much in daylight. The hydrated salt loses about half its combined water at 100°; the product absorbs over 3 per cent. of moisture from the atm., and this is not lost by re-heating the salt to 100°. When the hydrated salt is melted, the loss of water is attended by bubbling. C. G. Lindböm found that the clear glass ultimately obtained by fusion is easily soluble in nitric acid; 100 parts of cold water dissolve 1·67 parts of the salt. C. G. Lindböm found the aq. soln. changes when warmed. The salt is easily soluble in nitric acid, and crystallizes from soln. in conc. nitric acid.

Silver hexametaphosphate, $Ag_6P_6O_{18}$.—J. J. Berzelius made this salt by mixing silver nitrate with an aq. soln. of freshly ignited phosphoric acid in ice-cold water. The salt separates out in white gelatinous flakes. T. Graham obtained it by adding silver nitrate to a soln. of sodium hexametaphosphate—the filtrate was noticed by H. Rose to have an acid reaction. According to H. Lüdert, it is best made by pouring a soln. of the sodium salt slowly and with constant stirring into a soln. of silver nitrate containing four times the calculated quantity of that salt. The mixture is rapidly washed with a small quantity of cold water, and dried on a porous tile. G. Tammann used a similar process. T. Fleitmann melted silver oxide with an excess of phosphoric acid so as to form a clear glass, and found shining crystalline scales of this same salt separate as the mixture cools.

The white powder prepared by J. J. Berzelius became soft and viscid at 100°; and at a rather higher temp., it fused to a transparent colourless liquid which on cooling formed a crystalline mass which shattered to fragments; cold water extracted part of the acid, and boiling water resolved it into an acid soln. and silver tetraphosphate, $6Ag_2O.4P_2O_5$ or $Ag_6P_4O_{13}$. T. Graham's product dissolved in aq. ammonia, in nitric acid, and in a large excess of a soln. of the sodium salt. When boiled with water it fuses to a grey viscid mass capable of being drawn out into threads. T. Fleitmann's crystals are insoluble in water, and when treated with sodium sulphide, they yield ordinary deliquescent sodium hexametaphosphate.

G. Tammann prepared crystals of **sodium pentasilver hexametaphosphate,** $NaAg_5(PO_3)_6$, and **disodium tetrasilver hexametaphosphate,** $Na_2Ag_4(PO_3)_6$, by the action of silver nitrate on sodium hexametaphosphate. He also obtained **dipotassium tetrasilver hexametaphosphate,** $K_2Ag_4(PO_3)_6$, in a similar manner. G. Tammann believed that he could prepare **silver decametaphosphate,** $Ag_{10}P_{10}O_{30}.8H_2O$, by the action of silver nitrate on T. Fleitmann's sparingly soluble sodium dimetaphosphate.

According to J. J. Berzelius, if freshly precipitated and moist silver hexametaphosphate is introduced into cold water which is gradually raised to the b.p., the salt melts into a grey viscid mass capable of being drawn out into threads. The hot water when poured out and evaporated, gives silver hexametaphosphate, and the solid can be washed with cold water. Some silver hexametaphosphate in the interior of the mass remains undecomposed. T. Fleitmann and W. Henneberg consider this salt to be **silver tetraphosphate,** $6Ag_2O.4P_2O_5$, or $Ag_6P_4O_{13}$, or *silver* *pyrometaphosphate*, $Ag_4P_2O_7.Ag_2P_3O_6$, identical with that made by the action of silver nitrate on the sodium salt; if the latter be in excess, the precipitate will be contaminated therewith. The salt rapidly prepared and dried at 100° contains very little water. The salt is decomposed by the prolonged action of boiling water, and phosphoric is set free. Hence H. Uelsmann's analysis of the salt is rather high in silver oxide, owing to his preparations having been partially decomposed by washing. T. Fleitmann prepared what he regarded as **silver decaphosphate,** $6Ag_2O.5P_2O_5$, or $Ag_{12}P_{10}O_{31}$, by the action of silver nitrate on the corresponding sodium salt. The product is soluble in an excess of the last-named salt.

In normal silver metaphosphate, the ratio $Ag_2O : P_2O_5$ is 1 : 1. A. V. Kroll has reported a series of what he calls **silver ultraphosphates** with the ratio $Ag_2O : P_2O_5 = 1 : 2$ and 1 : 3. **Silver triphosphate,** $Ag_2O.3P_2O_5$, was obtained by the action of phosphorus pentoxide on silver at a high temp. when a yellow glass is formed which dissolves in water to a ruby-red soln., containing colloidal silver. If the glass is somewhat overheated, a silver ruby glass is obtained. This has not yet been found to occur with silicates or phosphates. The fused product is almost colourless, but yields the red colloidal soln. with water. The aq. soln. contains an acid silver metaphosphate. It yields a brown precipitate with sodium orthophosphate.

Hydrated **silver diphosphate,** $Ag_2O.2P_2O_5.H_2O$, was obtained by the action of an excess of metaphosphoric acid on $Ag_2O.3P_2O_5$.

CHAPTER XXIII

GOLD

§ 1. The Occurrences and Distribution of Gold

> Gold occurs in the bowels of the earth native, possessing a complete metallic form although in general the small particles of it are so interspersed with various matrices that they are entirely invisible.—T. BERGMAN (1780).

GOLD is rather widely distributed in nature, generally in quantities too small to be profitably extracted. Deep sea water from the Atlantic Ocean has 0·015 to 0·267 part of gold per million of liquid; water from the Christiania Fjord, Norway, 0·005 to 0·006; from the coast of New South Wales, 0·032 to 0·065; and from the coast of New Zealand, 0·005 part of metal per million parts of liquid.[1] According to L. Wagoner, granites from California and Nevada had about 0·37 part of gold per million; sandstone, 0·03; and limestones, 0·007 part per million. Gold also occurs in small quantities in clays, coal, rock salt, pyrites, and in almost all silver, copper, bismuth, lead, tellurium, zinc, and antimony ores.[2] Gravels which need not be crushed can sometimes be profitably treated for gold—alluvial gold—if but 2 to 3 grains per ton be present, that is, about one part of gold per million parts of worthless material. The mean of the returns for the Rand is something less than half an ounce of gold per ton of material treated. The gold and silver in copper and lead ores can usually be profitably extracted, indeed, a comparatively large proportion of the world's output of gold is obtained as a kind of by-product from lead and copper ores.

Gold is found native in irregular masses, sometimes of microscopic size, in crystals, in veins of quartz or quartzite in rocks—**reef gold**—in metalliferous veins along with metal sulphides—chiefly iron pyrites; and in alluvial gravels and sands as **alluvial or placer gold.** The alluvial drifts represent the *débris* from the weathering of auriferous rocks which has been washed into river beds, etc. Large nuggets are occasionally found—one in California weighed over 190 lbs., and one in Victoria, 183 lbs. The presence of large well-formed crystals of gold with unworn edges, sometimes found in alluvial drifts, is quoted in support of the hypothesis that gold can grow *in situ* in these deposits—presumably carried in soln. by percolating waters. As N. Lemery[3] expressed it in 1675: "Seeing that gold as well as silver is drawn from mines surrounded with waters, it is very probable that these waters bring along with them some saline principles that congeal and mix with earths of a particular composition." The largest and most perfect crystals have been found in alluvial deposits; and the finest specimens hitherto recorded are from the gravels of Victoria. *Filiform gold,* gold filaments or *wire gold,* and other dendritic forms represent incipient stages of crystallization. The gold disseminated in quartz rocks is also supposed to have been introduced by percolating soln. along with silica, for gold is soluble in alkali silicate soln.;[4] in alkali sulphides,[5] and possibly also in alkali tellurides.[6] J. R. Don showed that in the rocks in the neighbourhood of Ballarat, the gold occurs in the vicinity of pyrites; where the sulphide is abundant, gold is abundant, and where a small quantity of pyrites is present, there is a paucity of gold.[7] Gold is also soluble in ferric chloride soln. and in waters containing free chlorine.[8]

There is rather an extensive literature on the geographical distribution of gold.[9] Fig. 1 gives a general idea of the leading gold fields.

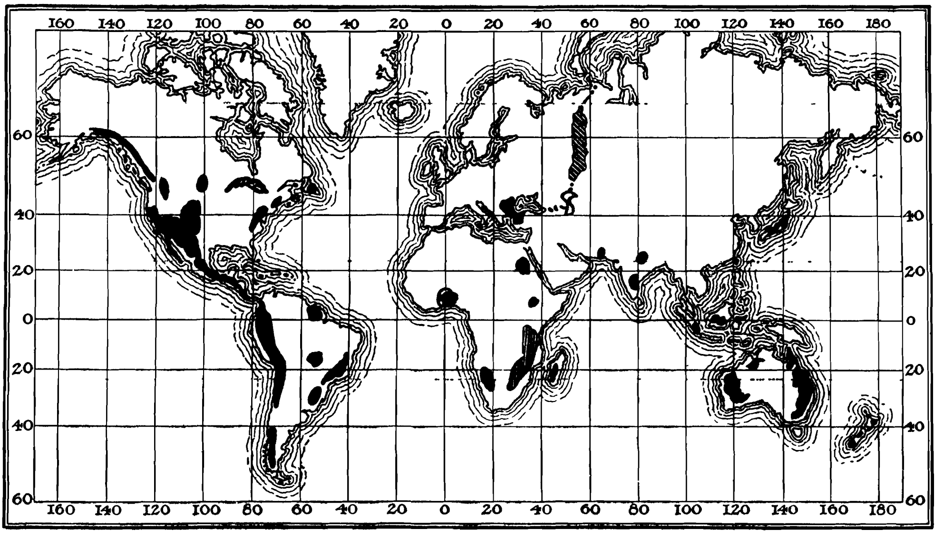

Fig. 1.—The General Distribution of the Auriferous Provinces.

In **Europe**, the principal gold mines are along the inner arc of the Carpathian Mountains in Hungary, and Transylvania. Gold mining at Schemnitz has been traced back to the pre-Christian era. The gold at Bosnia was also mined by the Romans. Most of the gold extracted in Germany is derived from metallic ores—galena, pyrites, zinc blende, etc. Gold has been obtained in Bavaria, Thuringia, and Silesia. Most of the Rhine workable gold was exhausted long ago. Gold has been worked in the British Isles on a small scale from the time of the Romans, and probably earlier, since gold ornaments were worn by the ancient Britons. Small quantities were once obtained in Cornwall, Devon, North Wales, Lanarkshire (Lead hills), Sutherland, Perthshire, and Wicklow in Ireland. The Phœnicians and the Romans obtained gold from Spain, but the supply seems now to be almost exhausted. In Pliny's time, the gold mines of Austria were considered to be the richest in the world. In France, the streams in the departments of Ariège, Garonne, Tarn, Hérault, Ardennes, and Meurthe-et-Moselle have gold-bearing sands, but they are not of much importance. Pliny mentions the gold mines of Northern Piedmont in Italy, and these mines are also mentioned by Strabo. Most of the tributaries of the Po have auriferous sands, and there are also auriferous veins on the Western Alps. Norway, Sweden, Finland, the Ural Mountains of Russia, and the streams of the Caucasus—the land of the golden fleece of the Argonaut expedition—have some auriferous deposits. **In Asia** gold is obtained from Siberia—east and west. There are gold fields in Borneo, Sumatra, and several of the East Indian Islands ; in New Guinea, the Philippines, and the Malay peninsula. Gold is also obtained from China, Corea, Japan, Colar (Mysore), and the presidencies of Madras and Bombay. Gold is widely distributed in **Africa**—Egypt, Soudan, Abyssinia, the Gold Coast, Madagascar, and Rhodesia. The discovery of the auriferous conglomerates in the De Kaap district of the Transvaal in 1884, has converted that district into one of the most important of the gold-producing countries. The United States, **America**, is one of the world's largest producers of gold. Marshall's discovery of gold at Coloma (Cal.) on January 19, 1848, started the rush of gold-seekers to the Pacific coast of America, and numerous deposits were discovered in various American States shortly afterwards. Quartz mining commenced in the States about 1850. The most important gold fields are in Colorado, California, Alaska, South Dakota, Montana, Arizona, Utah, Nevada, Idaho, Oregon, Washington, New Mexico, and some of the smaller amounts from a number of other States. The more important Canadian gold fields are in Klondyke (Yukon), British Columbia, Nova Scotia, and Ontario. Gold is also found in Mexico, various smaller States of Central America, Brazil, Chili, Peru, Bolivia, etc. Gold is found in all the colonies of **Australasia**. Kalgoorlie (Western Australia) is perhaps the most prolific, and there are mines at Kimberley, Pilbarra, Murchison, Coolgardie, etc., in Western Australia ; at Teetulpa, Mount Pleasant, etc., in South Australia ; Mount Morgan, Charters Towers, Gympie, Croyden, etc., in Queensland ; Clarence, Richmond, Bathurst, Albert, Mudgee, etc., in New South Wales ; Bendigo, Ballarat, Castlemaine, Maryborough, Ararat, Gippsland, etc., in Victoria; Beaconsfield, Waterhouse, etc., in Tasmania; Otaga, Westland, Nelson, and Auckland, in New Zealand. Count Strzelecki [10] is said to have discovered gold in New South Wales in 1839, but the discovery was kept secret in deference to the wishes of the Governor of the then penal colony. It is possible that a surveyor named O'Brien discovered the metal sixteen years earlier, but there are doubts as to whether or not O'Brien's samples were mica or pyrites, and not gold. The gold was rediscovered in the colony by W. Clark in 1841, and the value of the deposits was not realized until again discovered by E. H. Hargreaves in 1851. The Thames gold field in Auckland was discovered in 1867.

The world's production of gold [11] in troy ozs. has been estimated as:

1493–1520	1601–1620	1710–1720	1801–1810	1876-1886	1896–1906
186,470	263,918	422,163	560,572	5,364,685	5,135,673

The values for 1918 were:

	Troy ozs.		Troy ozs.
Austria-Hungary	8,700	Brazil	135,400
France	129	Colombia	235,440
Italy	1,100	Ecuador	38,700
Russian countries	830,000	Peru	57,645
Sweden	482	Uruguay	484
Belgian Congo	123,649	Venezuela	22,890
French W. Africa	2,000	Dutch Guiana	15,590
Madagascar	22,000	French Guiana	45,781
Portuguese E. Africa	5,592	China	174,000
Central America	164,500	Japan	431,806
Mexico	813,799	Dutch East Indies	95,518
United States and Colonies	3,320,784	Australasia	10,000,000
Argentina	194	South Africa	1,053,200
Chile	38,449		

On the whole, the world's output is still increasing, although only a small advance has been made in recent years. The expansion is attributed to the increased attention to the gold-mining industry. The output of the principal gold-producing countries in 1920 were: South Africa, about 47 per cent. of the world's supply; the United States, 16·5 per cent.; Australasia, 8 per cent.; and Russia, 2 per cent. The price of gold is roughly inversely equivalent to the measure of the adverse exchange against that country; and the price of gold fluctuates accordingly. Some European countries accumulated large debts in the United States while the severest stages of the Great War were being fought, and large stocks of gold were accordingly transferred to the United States from those countries. As a result it is estimated that the United States holds about 35 per cent. of the world's total. A curious feature occurred in 1920 when the Soviet Government of Russia made earnest but largely ineffectual attempts to dispose of the so-called *Soviet gold* which had formerly figured in the reserves of the Russian State. "Accustomed as the London market has always been to deal in gold by the ounce, the offer of gold in terms of a dozen tons at a time was regarded as a quaint innovation."

Native gold nearly always contains silver. Gold from Schnabrowsky has 0·16 per cent. of silver, and a sample from Siranowsk, 38·38 per cent.,[12] and there are numerous intermediate proportions in samples from different parts of the world. According to H. van Furman, a sample from Cripple Creek (Colorado) contained 99·9 per cent. of gold, and represents the purest native gold which has been found. Gold from the Californian placer deposits assayed 88·4 per cent. of gold; Australian gold averages 95·0 per cent.; Japanese placer gold, 62·0 to 90·4 per cent.; and Japanese vein gold, 56·6 to 92·6 per cent. gold. Native gold also contains a little copper, and occasionally iron. Palladium has been found in Brazilian gold; rhodium in Mexican gold; and bismuth in Victorian gold. Although some of the native binary alloys of gold with other metals have been stated as if they were real chemical compounds, their chemical individuality is not accepted on the results of chemical analysis alone. Pliny's **electrum,** named from ἤλεκτρον, which in Homer's time was the term used for amber, was a native alloy of gold and silver of the same yellow colour as amber, and which contained one-fifth of its weight of silver—*ubicunque quinta argenti portio est, electrum vocatur.* The term is now sometimes used for the alloys with other proportions of silver and which range in colour from white to pale yellow. The sp. gr. ranges from 12·5 to 15·5 according to the proportion of silver. Mol. proportions of the two elements are sometimes present, and J. B. J. D. Boussingault[13] thought these proportions corresponded with 2, 3, 5, 6, 8, and 12 gram-atoms of gold per gram-atom of silver, but G. Rose said that *eine Verbindung von Gold und Silber nach bestimmten Proportionen gar nicht zu denken sei,* otherwise expressed, there is nothing to justify the assumption that a chemical compound is formed. The two elements form a series of isomorphous mixtures.

An alloy of bismuth and gold containing from 34 to 35·5 per cent. of bismuth was discovered by G. H. F. Uhlrich,[14] and called **maldonite** from Maldon (Victoria), where it was found. C. U. Shepard also reported what he called **bismuthaurite,** in some palladium grains of North Carolina; the sp. gr. is stated to be 12·44 to 12·90. Some consider that a mistake has been made and that the alleged bismuthaurite is an artificial product. Similar remarks apply to the **rhodite** of M. Adam,[15] which is supposed to be a rhodium-gold alloy described by A. del Rio in 1825 as *un alliage d'or* obtained from the mint at Apartado (Mexico). A native alloy of palladium and gold containing 5 to 10 per cent. of the latter metal has been named **propezite.** There is nothing to show that a compound Au_6Pd is formed as was once supposed, for the two metals form a continuous series of mixed crystals. A sample of the mineral from Taguaril (Brazil) had 8·21 per cent. of palladium. Specimens have been obtained from Minas Geraes province (Brazil) and in the Caucasus near Batoum.[16] **Gold amalgam** is an alloy of gold with varying amounts of mercury; a sample from Mariposa (California) contained 61 per cent. of mercury, and one from Columbia, 57·4 per cent.[17] Some amalgams are of secondary origin, and are thought to be derived from the mercury lost by the old miners. The so-called gold tellurides form a group of minerals the first specimen of which—from Zalathna (Transylvania)—was described by M. H. Klaproth[18] in 1802, and many varieties from other localities have been described. The tellurium deposits at Cripple Creek (Colorado), and at Kalgoorlie (Western Australia) are the most important from an economic point of view. The telluride ores seem to have been deposited from aq. soln. in zones or belts. The mineral **calaverite** from Calaveras County (Cal.) was described by F. A. Genth[19] in 1868; and large deposits occur at Cripple Creek and Kalgoorlie. Analysts have reported from 57·3 to 60·3 per cent. of tellurium, 33·9 to 42·0 per cent. of gold, and up to 5 per cent. of silver, with smaller amounts of copper, zinc, iron, nickel, lead, sulphur, and selenium. Calaverite is supposed to be a compound with the formula $AuTe_2$, and the supposition is probably correct. Calaverite has a pale bronze colour. A related telluride with silver as well as gold contains from 59·7 to 62·0 per cent. of tellurium, 26·1 to 28·6 per cent. of gold, and 9·7 to 13·9 per cent. of silver, with smaller quantities of copper, lead, iron, nickel, antimony, selenium, and sulphur. This mineral has been represented by the formula $AuTe_2.AgTe_2$, or $AuAgTe_4$, and called **sylvanite,** or *graphic tellurium,*[20] because the crystals are sometimes arranged in a manner which recalls written characters. Sylvanite occurs in monoclinic crystals varying from a steel-grey to a silver-white or brass-yellow. Another variety called **müllerine** has crystals varying from a brass-yellow to white in colour, and it contains larger proportions of antimony and lead than sylvanite proper.[21] **Krennerite** is similar to sylvanite,[22] but crystallizes in the rhombic system. When massive, the two forms are said to be indistinguishable. Another telluride of silver and gold, called **petzite,** does not occur in crystals. Its colour is steel or iron-grey. Its composition corresponds approximately with Ag_3AuTe_3. A silver telluride called **hessite,** Ag_2Te, crystallizes in the cubic system, and it may contain up to 25·5 per cent. of gold. **Kalgoorlite** and **coolgardite** are different names for a variety found at Kalgoorlie. The mineral is almost black in colour, and it may contain 4 to 10 per cent. of mercury. It has been regarded as a mixture of coloradoite (mercury telluride, HgTe) and petzite—may be with calaverite and sylvanite as well.[23] **Nagyagite** is a telluride of lead and gold with more or less sulphides. Samples have been reported with from 17·5 to 30·5 per cent. of tellurium, 8·0 to 12·3 per cent. of sulphur, 3·8 to 7·5 per cent. of antimony, 50·3 to 60·3 per cent. of lead, and 5·9 to 9·6 per cent. of gold with smaller quantities of silver, copper, selenium, and iron. It crystallizes in the rhombic system. It has been called *foliated tellurium* because it also occurs foliated like graphite. The so-called **nobilite** and **Phyllinglanz** are varieties. There are no definite gold sulphide, selenide, chloride, or silicate minerals, although many gold minerals contain sulphur, selenium, and chlorine.

§ 2. The Mining and Extraction of Gold—Amalgamation Process

The amount of gold in a ton of ore is usually so small that even if the ore be conc. by washing, there is a loss of the finer particles of gold, and it is generally quite impracticable to smelt the ore so as to collect the precious metal in lead or copper, and afterwards remove the base metal by cupellation or some other process. The cost in fuel and fluxes is usually too great.[1] When gold occurs scattered as grains or nuggets in alluvial sand or gravel, hand picking, dry-blowing, winnowing, or simple sifting may suffice to separate much of the precious metal. The melting of the collected fragments together is a comparatively simple operation. The sand may also be washed over smooth sloping rocks by running water, when the particles of gold have a tendency to sink to the bottom of the stream owing to their high density. The rock carvings of Upper Egypt give several pictorial representations of the art of washing auriferous sands by stirring them up with water in hollow stone basins, followed by the melting of the gold in simple furnaces heated by mouth blowpipes, as shown in Fig. 4, Cap. I. The oldest of these carvings dates back about 2500 B.C.[2] In his *Geographia* (**3.** 2), written near the beginning of the Christian era, the old historian Strabo says that the ancients washed gold from the hills by torrents of water, and the gold was caught and entangled in the hair on the skins of animals spread on the rocks over which the water flowed. In some of the primitive mines even to-day, a similar plan is employed, although woollen blankets or pieces of plush are generally preferred. The legend of the quest of the golden fleece, by the Argonauts under Jason, is considered to describe a piratical expedition to Armenia to steal the gold obtained by the natives from streams of water by the aid of sheepskins.

The so-called **placer deposits** comprise sands, gravels, and earthy beds containing gold. The shallow or recent deposits are usually near river-beds, and have not been covered by much *débris*, while the deep-seated or ancient placer beds were formed by rivers which have since been deflected into other channels by more or less extensive changes in the physical geography of the district, and they are usually covered by more or less compact *débris*. In **panning** or **pan washing,** the auriferous sand or gravel is agitated with water in pans, troughs, or *cradles* of various forms, and the rocky matters are floated off, while the free particles of gold remain on the bottoms of the cradle or pan as gold-dust. The primitive methods of extracting gold by individual workers, more or less on the principle of hit or miss, are successful in dealing with comparatively rich beds, and with them, gold-mining is more or less a gambler's lottery. To-day, with large companies, gold-mining is a carefully organized industry with approximately the same output from day to day.

In the simplest form of **placer mining,** the sand or gravel is shovelled into a *sluice*, Fig. 2, that is, in long a flume or trough with transverse cleets, riffles, or obstructions along the bottom, and through which a stream of water flows. The water sweeps along the sand, and the heavier gold collects in the crevices on the bottoms of the sluice.[3] Dredging is also used to convey auriferous sands, etc., on river bottoms into the sluices. In **hydraulic mining,** water under high press. is directed against the earth containing the gold. The water is conveyed from a reservoir in the hills across the country, by means of flumes or aqueducts, to a large wooden tank near the placer deposit. The tank is provided with valves and thick iron pipes which lead to a cast-iron chamber, with valved apertures at the sides to which a number of flexible hose-pipes can be attached by means of union joints. The opposite end of a hose-pipe terminates in a bronze nozzle which enables a powerful jet of water to be directed against the bank of auriferous earth and gravel. As a result the bank is rapidly disintegrated and washed into sluices. Some idea of the method will be obtained from the sketch, Fig. 3. The head of water is sometimes up to 500 ft., and the nozzles are sometimes up to 11 ins. in diameter. The sluices with both placer or hydraulic mining may have wooden or stone riffles or obstructions of various kinds charged with mercury which amalgamates with the gold. Blankets or pieces of plush may be spread in the sluices to catch the lighter spangles of the precious metal. When a *clean-up* is desired, the riffles are taken out, and clean water is run along the sluices. The mercury amalgam is washed down to some convenient spot, and ladled into bags of canvas or leather. The amalgam in the bags is squeezed so that the excess of mercury, as Pliny expressed it about 77 A.D.—*per quas sudoris vice defluit*—exudes through the bags as a kind of perspiration. The pasty amalgam containing about one-third of its weight of gold is heated in suitable retorts. The mercury distils over, and the gold remains behind. This is then fused and cast into ingots to be subsequently refined.[4]

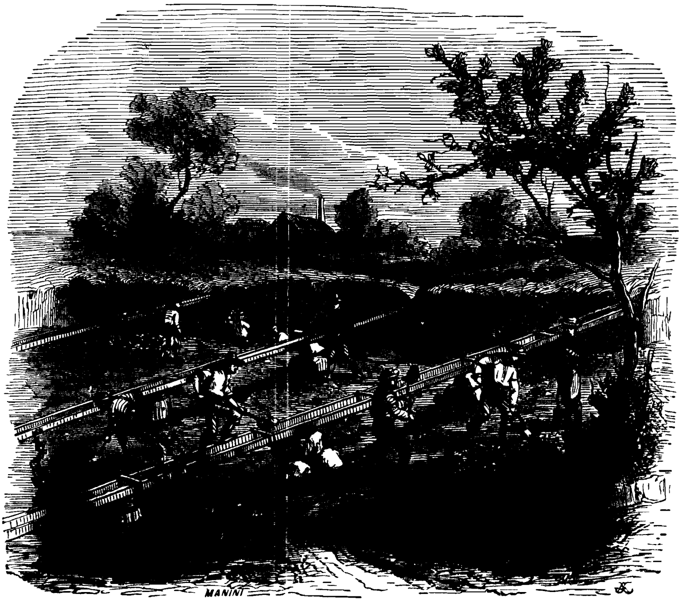

FIG. 2.—Simple Form of Placer Mining.

It will be observed that the process of separating the gold from sands is dependent upon two principles—(i) the greater density of the precious metal; and (ii) the attraction which mercury has for gold, which, as Pliny said about 77 A.D., enables the mercury to attract the gold to itself, and to reject the associated impurities. The gold is miscible with mercury in all proportions, and the small particles of the liquid amalgam in the sluices coalesce into larger globules which collect in the inequalities in the bottom of the sluices.

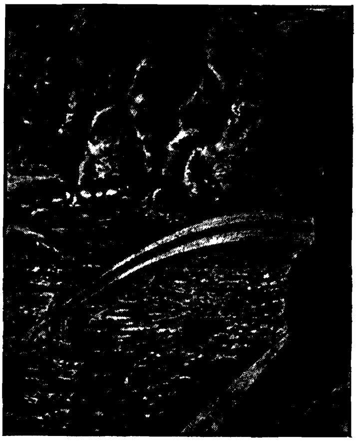

FIG. 3.—The Hydraulic Mining of Placer Gold.

When the richest of the placer deposits have been worked out in a country, attention is naturally directed to the extraction of gold from quartz rocks. In **vein or reef mining,** the auriferous quartz is mined by blasting. Holes are bored in the *face* of quartz up to the depth of four feet, into which sticks of gelignite or other explosives are placed and fired. The quartz is thus loosened and conveyed to the batteries where the conveyor trucks are tipped into a series of *crushers*, the quartz is broken into fragments about the size of a hen's egg. An endless belt carries the quartz which drops from the crushers to the stamps. Each stamp is a block of steel weighing say 1200 lbs., worked up and down by two-toothed cogs. About 300 stamps will pulverize 500 tons of quartz per day. The powder from the *stamper mill* is screened through a 40-mesh sieve; agitated with water; and elevated to a series of conduits, where it is conveyed to the so-called *tube or ball mills*—that is, in revolving cylinders lined with quartz, and containing lumps of quartz, flint pebbles, or steel balls—where it is ground still finer. The powder is floated with water as *pulp* in a thin stream, about a quarter of an inch deep, over slightly inclined plates amalgamated with mercury, and kept in a gentle pulsating motion—*amalgam tables.* The fine particles of gold amalgamate with the mercury. After some time, the plates are scraped, the excess of mercury squeezed from the scrapings, and the gold is separated from the mercury by distillation, as indicated above. Instead of the amalgam table, a *pulsator table* about 10×4 ft. is covered with linoleum, and rills, or narrow strips of wood, are tacked length-wise. The table is set on rollers arranged so that it can be set at any angle, and given a gentle sea-saw motion. The supply pipe sends a stream of water and pulp over the top of the table, and the heavy gold is caught by the rills. The pulp with which a little lime is mixed to facilitate the sedimentation of the gold—is washed over the upper edge of the table. The "muddy" water still containing recoverable gold is run along conduits or *flumes* to the settling tanks. The "free gold" from the rills is conveyed to the concentrate tube mills and ground still finer, whence it is transported to the cyanide tanks. The auriferous mud from the roller tables, after settling, is freed from the excess of water and also conveyed to the cyanide tanks.

Diodorus (*vide supra*) described the Egyptian process for mining quartz for gold. The rock was crushed to a coarse powder, and finely ground in hand mills. The further treatment of the ore resembled the process employed for washing auriferous sand. It is thought that P. Grommesterrer[5] first used the stamp mill in 1519, and in his *De re metallica* (Basel, 1556), G. Agricola described the treatment of auriferous quartz in Germany, and it is virtually the very process which is employed in Transylvania and Tyrol at the present day. A considerable number of improvements in the mechanical preparation of auriferous quartz have been introduced since Agricola's time. The amalgamated copper plates were used in California in 1856, although the actual date of their introduction is unknown.[6] The process was probably suggested as a result of experience derived from the working of the Cazo process for the extraction of the precious metals. It was noticed, even as early as 1786,[7] that the thickness of the layer of amalgam on the inside of the copper kettle daily increases by slow and gradual apposition, and ultimately becomes so thick that the crust often falls off by its own weight.

J. A. Edman counted over 300 particles of gold, varying from $\frac{1}{1000}$th to $\frac{1}{12000}$th of an inch in size, by the examination of a piece of auriferous quartz $\frac{1}{50}$th of an inch in size, and magnified about 50 diameters. A still greater number of particles of gold were counted under a higher magnification. The gold in this extremely fine state of subdivision is apt to float away with the tailings and escape the amalgamated copper plates, particularly when the gold is intimately associated with metal sulphides which prevent the particles amalgamating with the mercury; the mercury is also apt to *flour* or *sicken* by contact with the sulphides of arsenic, antimony, copper, zinc, lead, and bismuth, and it then fails to adhere to the amalgamation plates. Indeed, many ores are not worked by the amalgamation process because so little gold is recovered from the ores, and this even with comparatively rich ores. Ores which yield up their gold to the amalgamation process are called *free milling ores;* and those in which gold does not amalgamate with the mercury are called *refractory ores.* Even with free milling ores, the tailings from the amalgamation process usually contain one-third, often one-half, their total gold content. Tailings from the amalgamation process, and refractory ores, can usually be profitably treated by the chlorination or cyanide process.

§ 3. The Chlorination and Cyanide Processes for the Extraction of Gold

Chlorine, or rather chlorine water slowly, attacks gold, and in 1848, J. Percy[1] attempted to apply this agent for the extraction of gold from its ores, and simultaneously, C. F. Plattner proposed the method for treating the residues obtained after the ore at Reichenstein had been treated for arsenic. A. Duflos investigated Plattner's proposal, and he obtained the same experimental results by allowing chlorine water to percolate through the ore in a stationary vat, and by the agitation of the ore with chlorine water in a barrel. V. von Lange followed up the work and found that better results could be obtained by acting on the moist ore with chlorine gas than by leaching it with chlorine water. Chlorine has a vigorous action on sulphides, and to avoid the great waste of gas which would be involved by the presence of sulphides in the ore, the ore is first roasted.

The chlorination process is applied on a large scale in one of three different ways: (1) The moist ore is treated with chlorine gas in closed vats for a couple of days. The actual solvent is a sat. soln. of chlorine water. The soluble salts are washed away from the ore by water, the tailings are rejected, and the gold is precipitated from soln. by ferrous sulphide, hydrogen sulphide, or other suitable agent. The particles of precious metal are allowed to settle, and then dried and melted down. (2) In order to prevent local action and to ensure that every particle of the ore is exposed equally to the action of chlorine, a revolving barrel containing a supersaturated soln. of chlorine in water is used in place of the stationary vat. The gas is kept in soln. by keeping the press. inside the barrel a few pounds per sq. in.[2] (3) W. Munktell leached the roasted ore with hot dil. hydrochloric or sulphuric acid to remove iron and copper, and then treated the residue in a vat with a 0·6 to 0·7 per cent. soln. of chloride of lime mixed with an equal volume of dil. sulphuric or hydrochloric acid (sp. gr. 1·002–1·003). A. Étard[3] recommended treating the ore with a soln. containing about 45 lbs. of commercial hydrochloric acid and 12 ozs. of potassium permanganate. In H. R. Cassel's process a soln. of common salt is electrolyzed, and the chlorine which is generated attacks the gold in the ore. The soln. of gold chloride so obtained is simultaneously decomposed, and the metal is deposited on the cathode.

Bromine has been recommended in place of chlorine. It is claimed that bromine acts more rapidly on gold; gives a higher percentage extraction with a less proportion of base metals; and is more readily handled.[4] Both the bromination and chlorination processes fail to deal with the silver of gold-silver ores, and attempts to extract, say, the silver chloride by subsequently leaching the tailing from the chlorine process with sodium hyposulphate soln. have not been satisfactory. The chlorination process has been gradually displaced by the cyanide process of extraction. The latter was first used to supplement the recovery of gold from the tailings of the plate amalgamation process; but with the introduction of improved grinding, and filtration, it has become so formidable a rival that the chlorination process is almost obsolete.

The alchemists of the eighteenth century knew that gold is soluble in an aq. soln. of potassium cyanide, and the early jewellers probably utilized the fact in gilding. C. W. Scheele, in his memoir, *De materia tingente cœrulei Berolinensis* (1783), noted the solvent action of aq. soln. of the alkali cyanides on gold, silver, copper, etc. In 1843, P. Bagration [5] showed that gold—*metallorum rex*—which resists attack by the strongest acids, dissolves quietly and quickly in an alkaline soln. of potassium or sodium cyanide, and less rapidly in soln. of alkali ferrocyanides. He also noticed that the action is more rapid in warm soln., and that the free circulation of air accelerated the speed of dissolution.

The facts are illustrated by placing a fragment of gold-leaf in each of two vessels containing a one per cent. soln. of potassium cyanide. Agitate one by stirring with a glass rod, and bubble a current of air through the other soln. In about 15 minutes, the gold in the latter vessel will be dissolved, and scarcely attacked in the other. A piece of gold-leaf submerged in dil. soln. of potassium cyanide also dissolves less rapidly than a *similar piece* of gold-leaf floating on the surface of the soln.

The solubility of metals, etc., in aqueous potassium cyanide.—Other metals are dissolved by the potassium cyanide soln.—mercury and platinum are attacked very slowly if at all. Silver sulphide, arsenate, antimoniate, and chloride are dissolved by the menstruum. According to G. Gore's experiments, the amount of metal, expressed in mgrm., dissolved per sq. cm. of surface by a 1·86 per cent. soln. of potassium cyanide, is indicated in Table I. This shows that the rate of dissolution of gold is increased nearly twenty-five-fold by raising the temp. about 55°. The numbers for aluminium are probably rather high—possibly owing to the potassium cyanide being contaminated with some potassium hydroxide. W. A. Caldecott [6] found that the cyanide soln. is more active in light than in darkness, and M. Berthelot showed that this is probably due to the increasing rate at which oxygen is absorbed by potassium cyanide soln. exposed to light.

TABLE I.—THE DISSOLUTION OF METALS IN AQUEOUS SOLUTIONS OF POTASSIUM CYANIDE

Metal.	Milligram dissolved per sq. cm. of surface.	
	15·6°	71°
Aluminium	0·096	4·510
Zinc	0·054	0·552
Copper	0·053	1·263
Silver	0·016	0·069
Cadmium	0·014	0·031
Gold	0·009	0·229
Tin	0·006	0·042
Nickel	0·005	0·027
Iron	trace	0·010
Platinum	nil	nil
Lead	—	0·031

In 1846, L. Elsner [7] showed that the presence of oxygen—either free or in soln.—is necessary for the dissolution of gold in potassium cyanide soln., and the reaction is said to occur in accord with the equation: $4Au+8KCy+O_2+2H_2O=4KAuCy_2+4KOH$. L. Elsner also obtained colourless octahedral crystals of potassium aurocyanide, $KAuCy_2$, by the evaporation of the soln. The necessary oxygen was stated by L. Elsner to be obtained from the water by the metals iron, copper, zinc, and nickel, and hydrogen was liberated; while the metals gold, silver, and cadmium were stated to get the required oxygen from the air, and to dissolve only when oxygen had access to the soln. W. A. Dixon gave a similar equation to that employed by L. Elsner. In confirmation of L. Elsner's equation, W. Skey, and J. S. Maclaurin proved that for every 130 parts of potassium cyanide, 8 parts of oxygen suffice for the dissolution of 196·8 parts of gold; and therefore, the amount of oxygen normally dissolved in liquids, and adhering to the surface of a solid, is sufficient for the dissolution of relatively large amounts of gold. J. S. Macarthur cited experiments to show that gold can be dissolved by the alkali cyanide in the absence of oxygen—*e.g.* if the crushed ore contains basic ferric sulphates which can form ferricyanide—and it has been suggested by L. Janin that the reaction should accordingly be represented by the equation: $2H_2O+2Au+4KCy=2KAuCy_2+2KOH+H_2$; but it is very doubtful if this equation can be correct because free hydrogen has not been detected, although it might be formed and immediately unite with the oxygen in soln. producing hydrogen peroxide. According to G. Bodländer, the chemical action should be represented by the equation: $2H_2O+2Au+4KCy+O_2=2KAuCy_2+2KOH+H_2O_2$, and he was able to detect as much as 72·3 per cent. of a substance acting like hydrogen peroxide as an intermediate product when gold is rapidly dissolved in aërated cyanide lye. The hydrogen peroxide leads to the dissolution of more gold by a reaction symbolized: $4KCy+H_2O_2+2Au=2KAuCy_2+2KOH$. The result of these two reactions is eq. to the one represented by L. Elsner's equation. W. Bettel considers that potassium auricyanide, $KAuCy_4$, not hydrogen peroxide, is the intermediate product, and he represents the reaction: $2H_2O+2Au+O_2+6KCy=KAuCy_2+KAuCy_4+4KOH$, followed by $KAuCy_4+2Au+2KCy=3KAuCy_2$. The equation given by J. S. Macarthur and R. W. and W. Forrest: $Au+4KCy+2H_2O=K_2AuCy_4+2KOH+H_2$, cannot be right because no hydrogen is evolved during the reaction, and the fundamental part played by oxygen is not explained. D. Reichinstein assumed that the oxygen slowly unites with the gold, and the cyanide ions then react quickly on the product.

The action of cyanide lye on pyrites is rather complex. According to W. A. Caldecott, the roasted pyrites contains undecomposed pyrites, FeS_2 ; ferrous sulphide, FeS, and sulphur ; ferrous sulphate, $FeSO_4$, and sulphuric acid, H_2SO_4 ; ferric sulphate, $Fe_2(SO_4)_3$, or basic ferric sulphates ; and ferric oxide, Fe_2O_3. The sulphuric acid liberates hydrogen cyanide, $2KCy+H_2SO_4=K_2SO_4+2HCy$; the ferrous sulphate forms ferrous cyanide, $FeCy_2$, which reacts with potassium cyanide, forming potassium ferrocyanide, K_4FeCy_6, and this may react with more ferrous sulphate, forming a pale blue precipitate, $K_2Fe_2Cy_6$, which is oxidized by air to Prussian blue, $3FeCy_2.4FeCy_3$—both these precipitates are decomposed by potash, forming potassium ferrocyanide and ferrous hydroxide, $Fe(OH)_2$, in the former case, and ferric hydroxide, $Fe(OH)_3$, in the latter. The ferric sulphates are decomposed by potassium cyanide, forming hydrogen cyanide and ferric hydroxide. Ferrous hydroxide, not ferric hydroxide, is decomposed by potassium cyanide: $Fe(OH)_2+6KCy=K_4FeCy_6+2KOH$. With roasted cupriferous pyrites, copper sulphate forms cuprous cyanide, $CuCy$, a precipitate soluble in excess of potassium cyanide, forming an unstable compound, $K_2Cu_2Cy_4$.

Application to the extraction of gold and silver from their ores.—The solvent action of potassium or sodium cyanide has been skilfully applied by metallurgists to the extraction of finely divided gold or silver from their ores. It has been stated [8] that A. Parkes applied for a patent in 1840 for "the separation of gold or silver from their ores by digestion with a 3 to 6 per cent. soln. of cyanide of sodium, potassium, or ammonium for 3 days at 150° F. to 180° F." It was proposed to recover the gold by fusing the residue obtained by the evaporation of the soln. This process would involve the loss of a large proportion of the cyanide soln., and the recovery of the gold would be expensive. J. H. Rae,[9] in 1867, patented a process for extracting gold and silver from their ores by digestion with suitable chemicals, such as potassium cyanide, and simultaneously precipitating the dissolved gold on copper plates by means of an electric current; J. W. Simpson patented a process for removing gold, silver, and copper from their ores by leaching them with an aq. soln. containing 3 per cent. of potassium cyanide, and 0·19 per cent. of ammonium carbonate. The gold was subsequently precipitated by metallic zinc. J. W. Simpson appears to have believed that the cyanide soln. in J. H. Rae's process did its work only when stimulated by the electric current, and that the addition of ammonium carbonate rendered the electric current unnecessary. Neither J. H. Rae's nor J. W. Simpson's process appears to have been employed on a large scale. Several other patents were obtained by inventors working along similar lines, but it is entirely due to the enterprise and skill of J. S. Macarthur and R. W. and W. Forrest of Glasgow that the practical success of the cyanide process for extracting gold from its ores was assured. J. S. Macarthur and R. W. and W. Forrest did not like the chlorine process because of the preferential action of chlorine on the sulphides of the base metals, and its unsuitability for the extraction of silver. They tried a number of solvents—ferric chloride, ferric bromide, etc.—and finally decided that a dil. soln. of potassium cyanide possessed advantages over all the other solvents because it exercises " a selective action " on gold and silver in preference to sulphides and other compounds of the base metals. They emphasized the use of a very dil. cyanide soln., " containing cyanogen in the proportion not exceeding 8 parts of cyanogen to 1000 parts of water," because the solvent action is then confined more to the precious metals ; conc. soln. act also in the base metals. J. S. Maclaurin (1893) and J. J. Andrejeff (1908) showed that the rate of dissolution of gold increases with decreasing conc. to a maximum rate with a 0·25 per cent. soln., and thereafter decreases with decreasing conc. According to S. B. Christy, the solvent action of potassium cyanide in 0·00065 per cent. soln. is virtually nil, and for all practical purposes ceases when the conc. falls below 0·001 per cent. of potassium cyanide.

The precipitation of gold from cyanide solutions.—Some time after J. S. Macarthur and R. W. and W. Forrest's patent was issued, further patents were issued to them for the use of zinc, preferably filiform or thread-like, as a precipitating agent; and for the use of caustic alkalies or lime for neutralizing ores containing acids or acid salts which caused undue losses by the decomposition of the cyanide. It is said that a patent is very easy to obtain, but very difficult to retain if a powerful company wants to appropriate an idea, and the validity of the Macarthur-Forrest patents has been the subject of much litigation. J. S. Macarthur once quoted sympathetically Isaac Newton's remark:

> If I get free of this present business, I will resolutely bid adieu to it eternally, except what I do for my private satisfaction or leave to come out after me ; for I see a man must either resolve to put out nothing new or to become a slave to defend it.

A. P. Price (1883), and J. W. Simpson (1885) had previously used zinc as a precipitation agent, but J. S. Macarthur and R. W. and W. Forrest found that sheet zinc is not nearly so efficient as zinc filaments or lead in conjunction with zinc—the lead zinc couple. The zinc precipitation is represented by the equation : $2KAuCy_2+Zn=K_2ZnCy_4+2Au$. There are also side reactions due to the direct action of the cyanide soln. on the zinc, resulting in the evolution of hydrogen and the formation of potassium zincate. If an excess of potassium cyanide be not present, a layer of zinc cyanide, zinc hydroxide, or potassium zinc ferrocyanide may be formed on the surface of the metal preventing further action.[10] Zinc-dust or zinc fume has been recommended by H. L. Sulman and used for the purpose in some plants.[11] Instead of precipitating the gold from the cyanide soln. by zinc, E. W. von Siemens and J. G. Halske [12] recommended electrolysis ; W. Moldenhauer, aluminium ; and W. D. Johnston, charcoal. According to G. Gore,[13] the voltaic order of the metals in aq. soln. of potassium cyanide is that indicated in Table II. The position of the metals in the table represents their relative tendency to dissolve under the conditions of the experiments ; and when two metals are in contact, the metal on the negative side accelerates the soln. of the more positive metal, and is itself protected from dissolution by the latter. A metal tends to precipitate from soln. another metal which is on the negative side, and to replace it in soln.

According to C. Engler and J. Weissberg,[14] the dissolution of the gold is attended by the formation of gold peroxide as an intermediate product. Feebly ozonized oxygen was found by J. J. Andrejeff to increase the speed of the dissolution, and this from about one and a quarter to one and three-quarter times the observed rates in air. Increasing the proportion of ozone in the air accelerated the action. The gold plate gradually acquires a brick-red film which slows down the solvent action of the cyanide. Hydrogen peroxide was found to act in a similar manner. Lead or manganese dioxide exert very little influence on the speed of the action, but they favour the action of hydrogen peroxide. J. Michajlenko and M. Meschtscherjakoff found that oxidation agents accelerate the rate of dissolution of the gold, and that OH'-ions retard, and $H^{\cdot}$-ions stop the action. Among the accelerating agents he includes potassium perchlorate, periodate, permanganate, sulphate, ferricyanide, and carbonate ; sodium sulphate and peroxide ; ammonium sulphate ; and bromine —the most marked action occurs with potassium or sodium sulphate, sodium peroxide, and potassium ferricyanide. The speed of dissolution increases with increasing conc. of the oxidizing agent up to a certain limiting value. Scarcely any acceleration was observed with potassium chlorate, bromate, or iodate, or sodium stannate ; while no appreciable change occurs with sodium, cobalt, cupric chloride, or with mercuric cyanide. E. Noelting and G. Forel also noted that ammonium persulphate accelerates the action, while potassium nitrite and ammonium vanadate are indifferent ; they found that many organic substances with oxidizing properties raise the solvent action of alkali cyanide on gold—*e.g.* nitroso-β-naphthol, nitrobenzene, *o*-nitrophenol, or picric acid.

A. Parkes patented a mixture of bromine or a bromide with potassium cyanide, potassium dichromate, and sulphuric acid ; W. H. Gaze and W. E. Field patented a haloid cyanide ; and H. L. Sulman and F. L. Teed patented the use of a small quantity of a haloid cyanide, say, cyanogen bromide, BrCy, with the soln. of potassium cyanide in order to give greater activity to the solvent, and to reduce the loss due to the decomposition of the cyanide. It is supposed that the reaction was symbolized : $3KCy+2Au+BrCy=2KAuCy_2+KBr$. The haloid cyanide acts as a mild oxidizing agent possibly : $2BrCy+3KCy+2H_2O=2KBr+KOCy+4HCy+O$, and hence accelerates the cyanidation of ores. It therefore offers advantages with sulpho-tellurides and certain other ores where a rapid dissolution of the gold is necessary in order that other associated minerals may not have time to destroy the solvent. In most cases, however, the improvements which have attended the development of cheap and efficient processes for roasting of otherwise refractory ores, mechanical agitation and aëration, and fine grinding of raw ores, have eliminated the need for special accelerators. Several attempts have been made to hasten the rate of dissolution of the gold by the addition of oxidizing agents. J. Michajlenko and M. Meschtscherjakoff recommended ozone; J. C. Montgomerie, and J. H. Burfeind, sodium peroxide; E. Schering, and W. Görlich and A. Wichmann, persulphates; W. H. James and co-workers, S. B. Christy, and G. Göpner, hydrogen peroxide; and W. Moldenhauer, chromates, permanganates, ferricyanides, chlorine, bromine, or iodine. Artificial oxidation, however, is employed only when some substance—*e.g.* soluble sulphide—is present in the ore or in the water and which acts as a reducing agent by the absorption of oxygen. It was formerly supposed that oxygen and potassium cyanide could not remain together in soln. without the immediate formation of potassium cyanate; observations have shown that the oxidation of cyanide to cyanate is a relatively slow process.

The work of a cyanide plant.—The application of the cyanide process comprises in general four operations although there are numerous modifications[15] at various stages of the process. A diagrammatic sketch of the process is given in Fig. 4; the dissolving and solution tanks *A* and *B* for preparing the cyanide lye of the required conc., are, if practicable placed so that the liquid runs by gravitation through the leaching vat *C* provided with false bottoms, and containing the ore to be treated; from the leaching or percolating vat to the settling tank *D* for the soln. of gold in the cyanide, the zinc extractors *E*, and thence to a sump *F* below the floor level, whence the lye is pumped back either to the storage tanks or directly into the leaching vats. If the plant has to be built on level ground more pumping and elevating appliances are needed than when the soln. can circulate in one direction wholly by gravity.

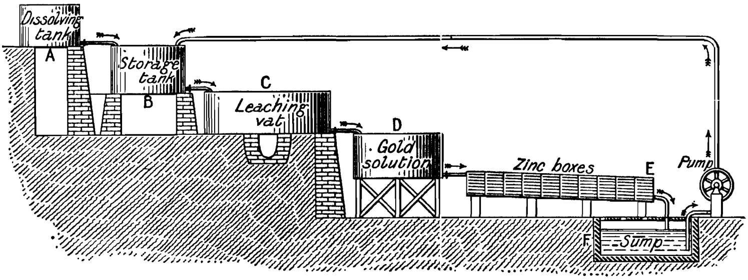

FIG. 4.—Diagrammatic Representation of Cyanide Plant.

(1) *The preparation of the ore.*—The tailings from the amalgamation process may be treated directly. If the ore is not already crushed fine enough, it must be reduced to a fine enough state of subdivision. If the particles of gold are coarse, they would occupy too long a period to dissolve in the cyanide lye, and a preliminary amalgamation may be advisable. Ores containing tellurides, arsenides, or antimonides may require a preliminary roasting; acidic ores are mixed with lime; and ores containing reducing agents are treated with oxidizing agents—potassium ferricyanide or permanganate, peroxides, bromine, etc. The object is to prevent losses in the cyanide by secondary reactions. The consumption of cyanide with ores containing sulphide, oxide, or carbonate of copper is so great that even if but a small proportion is present, the process may be impracticable. The ore for the leaching vats is sometimes washed with alkali lye and water to remove organic matters, acid salts, etc.

(2) *The leaching of the prepared ore with the cyanide lye.*—The ore is first leached with a 0·15 to 0·05 per cent. soln. followed by a 0·05 to 0·10 per cent. lye repeated as often as may be economically necessary. In one plant, the leaching of the ore with the more conc. soln. occupies 8 to 16 hrs., and each of four leachings with the

dil. soln. occupies about 4 hrs. The ore is then washed with water—8 hrs. The object of using the dil. soln. and water is to make sure that no dissolved gold is left in the vat. The soln. of gold in the cyanide lye is run into vats, and allowed to settle. The clear liquid is decanted or filtered. The filtration is effected by lowering canvas-covered wire frames into the lye, and when suction is applied, the mud is sucked free from the cyanide soln., which passes to the storage tank. The frame is then raised from the tank, and the suction is continued until the cake is dry. The cake soon breaks up and falls into the vat, where it is sluiced by water from a discharge door in the side of the vat, and the vats are recharged with ore. The cyanide lye is then run to the zinc boxes.

(3) *The precipitation of the dissolved gold.*—The zinc boxes are wooden or iron vats capable of treating 50 to 150 tons of soln. *per diem ;* the zinc boxes are divided into about ten compartments by partitions ; eight of the compartments are packed with trays containing zinc shavings, or lead-coated zinc shavings—lead-zinc couple—and so arranged that the soln. flows upwards through the shavings. The first and last compartments have a sand filter to clarify the soln. on entering and leaving the "precipitation boxes." The conc. and dil. soln. are treated separately. As the cyanide lyes percolate through the masses of zinc shavings or filaments, the gold is precipitated as a fine powder. The soln. pass into the sumps and a large proportion of their cyanide is available for more extractions. A clean-up of the black mud (precipitated gold) in the zinc boxes is made every week, fortnight, or month. A current of water is passed through the zinc extractors to remove the cyanide soln. The coarse fragments of zinc are picked out, and the residual slime is pumped into filter presses.

(4) *The conversion of the precipitated gold into bullion.*—The solid residue is finally collected and roasted at a red heat. It is then treated with hydrochloric acid to dissolve the zinc, washed, dried, and mixed with a flux—say, a mixture of sodium carbonate, glass, borax, fluorspar, and sand—and fused in a graphite crucible. The metal is re-melted, and cast into ingots of about 1000 ozs. each. The bullion so obtained is sold to the refiners. In P. S. Tavener's process,[16] the slimes are mixed with fluxes and litharge, and smelted in a reverberatory furnace. The product is cupelled, melted in graphite crucibles, and cast into ingots.

A. Goerz estimated that in the Transvaal, prior to the introduction of the cyanide process, 50 per cent. of the theoretical yield of gold was obtained by the amalgamation process, 5 to 10 per cent. was recovered by treating the tailings by Plattner's chlorination process, and the remaining 40 per cent. was lost in the tailings. No economical process for extracting the gold was then known. To-day, the cyanide process enables at least 90 per cent. of the gold to be profitably extracted from the tailings. J. S. Macarthur estimated that the cyanide process has directly added 20 per cent. to the world's output of gold, and indirectly enabled gold mining and amalgamation to be carried on under conditions where without this auxiliary they would not have yielded enough profit to stand alone.

§ 4. The Purification and Refining of Gold

The crude bullion is not commonly suited for use in the arts, and the bullion is therefore refined to bring it up to the standard degree of purity. Gold retorted from the amalgamation process contains 2 or 3 per cent. of copper, iron, mercury, and other base metals. More or less silver may also be present. Most gold is brittle before it is refined, and in refineries, the removal of impurities from gold and silver is called *toughening* the metal, and the term *refining* is reserved for the *parting* or separation of gold from silver. When cupellation is not practised, the bullion may be toughened by a preliminary treatment to remove the base metals. A large proportion of the more volatile metals can be removed by merely melting the bullion, and this the more the higher the temp., and the longer the time the metal is heated. Traces of the volatile metals, however, still remain after this treatment.

Refining by oxidation.—A large proportion of the base metals can be oxidized, say, by directing a blast of air over or below the surface of the bullion melted in a crucible; the oxidized metals form a scum on the surface, and can be skimmed off. Other oxidizing agents have been used—nitre, manganese dioxide, cupric oxide, potassium permanganate, etc.[1]

Refining by sulphurization.—The base metals have also been sulphurized instead of oxidized—particularly when iron is the chief impurity. This is done by sprinkling sulphur on the surface of the metal melted in a graphite crucible, and then stirring with a graphite rod. The gold is not affected, iron and silver form sulphides, and can be separated as matte when the contents of the crucible are allowed to cool. The silver does not sulphurize very much until the iron has all been converted into sulphide. Stirring the molten metal with an iron rod for a few minutes has been recommended to remove arsenic, antimony, sulphur, etc., since arsenides, antimonides, sulphides, etc., are formed, and these can be removed by skimming. Melting the metal under charcoal removes oxygen.

Refining by cupellation.—In refining by cupellation, the bullion is alloyed with an easily oxidizable metal like lead. The alloy of lead and gold is heated in a stream of air in a furnace with a shallow hearth made of bone ash. The lead is oxidized to litharge, PbO, and the base metal impurities are simultaneously oxidized. The oxides are then partly blown from the surface of the molten metal, and partly absorbed by the bone ash. Finally, when the gold appears as a bright disc, the operation is stopped, and the gold removed. If silver be present, the two metals remain alloyed after the cupellation, and they must be parted by some other process.

Refining by chlorination—In 1838, L. Thompson[2] stated that "it has long been known to chemists that not only has gold no affinity for chlorine at a red heat, but it actually parts with it at that temp. although previously combined. This is not the case with those metals with which it is usually alloyed. . . . It therefore offers at once an easy and certain means of separation." About thirty years later, 1870, F B. Miller applied this property of chlorine to the separation of gold and silver on a large scale at the Sydney Mint; the process was well suited to the local conditions—high price of sulphuric acid, and the absence of auriferous silver suited for parting. The gold is melted in crucibles, and chlorine (from liquid chlorine in cylinders or otherwise prepared) is forced through clay tubes dipping in the molten metal. The gas is absorbed by the base metals and silver, their chlorides rise to the surface and are skimmed off. These chlorides are not appreciably decomposed at this temp. The process yields gold of a high degree of purity—99·5 per cent. gold. Instead of chlorine gas, alternate additions of nitre and sal ammoniac have been used in former times; and in another old process, frequent additions of corrosive sublimate, $HgCl_2$, were made in small quantities at a time.

The electrolytic process of refining.—The anode is the alloy to be purified; the electrolyte a soln. of gold chloride in hydrochloric acid; and the cathode, a sheet of pure gold. On electrolysis fairly pure gold is deposited on the cathode, silver forms silver chloride which remains as a deposit about the anode. This process was brought out by E. Wohlwill,[3] in 1874. If the gold has a large proportion of silver, B. Mobius' process by electrolysis with silver nitrate as the electrolyte is used. The main objection to the electrolytic process is the length of time required for the treatment, and this involves interest on the metal lying idle. The advantages are: absence of acid fumes, platinum and palladium are easily recovered from the anode mud. The working cost of the process is said to be about 1*d.* or 1½*d.* per ounce of gold. Metal to the value of about £15,000,000 is said to be treated annually by electrolysis.

The separation or parting of gold and silver.—During the operation, the base metals are removed from both the precious metals, but to avoid the waste of acids, etc., the base metals are first removed by refining or toughening. In Pliny's time, the granulated metal was heated with a mixture of salt and brick dust for about 36 hours. The alloy was not melted. The silver was converted into chloride. The silver chloride, brick-dust, etc., were separated from the gold by washing, and the silver recovered by amalgamation. This method of parting is sometimes called the *cementation process.* Melting the alloy of silver and gold with sulphur or antimony sulphide are old and obsolete methods called *sulphurization processes.* In both cases, silver sulphide is formed as a scum; with antimony sulphide an alloy of antimony and gold is simultaneously formed, and the antimony subsequently removed by oxidation. The chlorine and electrolytic processes of refining can also be used for parting.

In the thirteenth century, Albertus Magnus mentioned the parting of silver and gold by *nitric acid,* and the process was described by V. Biringuccio in his *De la pirotecnica* (Venice, 1540), and by G. Agricola in his *De re metallica* (Basil, 1556). It was used in the Paris mint about 1514, and in the London mint about 1594. Silver is soluble in nitric acid, gold is not. If an alloy of silver and gold be digested in nitric acid, silver and not gold is dissolved, provided that at least twice as much silver as gold be present, and the acid has a sp. gr. of not less than 1·26. In parting silver and gold, it is necessary to alloy the gold with up to about 75 per cent. of silver, if this proportion be not already present. The operation is called *inquartation.* The alloy is then treated with nitric acid free from chlorides. The silver dissolves as silver nitrate, and the gold remains behind as a brown powder.

J. Kunckel used *sulphuric acid* [4] in place of nitric acid, about 1760; the process was mentioned by H. T. Scheffer in his *Historie vom Scheiden,* in 1753, and parting with sulphuric acid was used in the Paris mint by C. d'Arcet, nephew of J. P. F. d'Arcet, in 1802; the process is now comparatively common, because it is cheaper. Here the alloy is boiled with sulphuric acid and then with nitric acid. The gold is not appreciably attacked, and remains behind as a brown porous mass. This is washed, dried, and fused into a compact mass with sodium carbonate and charcoal. Any copper present is dissolved with the silver. The mixture of copper and silver sulphates is subsequently treated with scrap copper, when silver is precipitated: $Ag_2SO_4+Cu=CuSO_4+2Ag$; the copper sulphate is electrolyzed for copper, or crystallized and sold as *bluestone.* The sulphuric acid process is said to furnish a less pure metal than either the chlorine or the electrolytic process; the alloy may contain lead and tellurium, while the platinum and palladium, if present, are not recovered. With care, the method gives satisfactory results in most cases, and metal to the value of about £70,000,000 is refined annually by this process. Allowing for the sale of the copper sulphate obtained as a by-product, the operation is said to cost from 3*d.* to 4*d.* per ounce of gold.

The same principle is applied in assaying gold ores. A weighed portion of the ores is fluxed along with borax, and lead oxide and a little charcoal. Some metallic lead is reduced. This lead gathers the gold and silver in the ores and collects as a button at the bottom of the crucible. The button is cupelled and the bead of silver and gold is weighed. The bead is inquarted with silver and parted with nitric acid. The resulting gold is weighed. These data—weight of ore, weight of contained gold and silver, and weight of gold—enable an estimate to be made of the gold and silver in the ore.

The preparation of highly purified gold.—In 1887, G. Krüss[5] prepared highly purified samples of gold by the following process: Commercially refined gold is heated with hydrochloric acid in a flask on a sand-bath, and conc. nitric acid dropped into the liquid, in small quantities at a time. When all the metal is dissolved, the soln. is evaporated in a porcelain dish over a water-bath until a drop of the red liquid solidifies to a solid mass on cooling. The soln. must be protected from dust during the evaporation or some gold will be reduced from the soln. Distilled water is added and the silver chloride filtered off. The soln. is then treated with an excess of ferrous chloride soln. and the brown precipitate allowed to settle. The clear liquid is decanted off and the residue washed with dil. hydrochloric acid, and finally with water until all the iron is removed. If much platinum be present the precipitation is best made with oxalic acid; and if palladium be present, with sulphurous acid. The washed precipitate of gold is dried between 170° and 180°, and heated with conc. sulphuric acid in a platinum dish until the acid begins to give off dense white fumes. The object of this treatment is to remove traces of silver. In his work on the at. wt. of gold, G. Krüss repeated the digestion with sulphuric acid. The mixture, when cold, is poured into an excess of water, washed, dried, and fused with potassium bisulphate in order to remove any traces of palladium. The product is washed with water, dried, and fused with nitre in order to remove any platinum or iridium. If the cold flux be colourless, it may be assumed that these metals are absent. G. Krüss further dissolved the product in aqua regia, and precipitated the gold with sulphurous acid; and yet again dissolved the product in aqua regia, and precipitated the gold with oxalic acid.

§ 5. The Physical Properties of Gold

Gold in mass is yellow; it appears red if the light be reflected from the surface of the metal many times before it reaches the eye. According to M. Faraday,[1] gold-leaf 0·00009 mm. thick is yellow by reflected light and green or bluish-green in transmitted light; this is best seen by placing a sheet of leaf-gold between two sheets of glass, holding it up to the light, and viewing it through a magnifying lens. L. Houllevigne produced films almost colourless by reflected light, and in transmitted light they varied in colour from rose to violet. H. L. Barvir produced films which appeared red when very thin, and bluish or greenish when thicker. The hard and soft states of a metal are regarded by G. T. Beilby as two phases—the former is amorphous, the latter crystalline. The different mechanical, optical, electrical, and thermoelectric properties indicate that there is a transition temp.—amorphous gold began to soften at 250°, and was quite soft at 280°. According to J. W. Mallet, the maximum thickness for translucency is 0·20 mm.; G. Quincke gives 0·00816 mm.; and C. G. Ehrenberg, 0·00109 mm. H. L. Barvir produced thin mirror-like films on glass by slowly evaporating two or three drops of auric chloride, moistening the residue with clove oil, and warming; N. Castoro produced films by reducing neutral dil. soln. with acrolein; C. Schuyten warmed a soln. of auric chloride with one of mercuric bromide containing some antipyrine; C. Statescu electrolyzed with 2·5 to 30 milliamps. for a few seconds a soln. of 15 grms. each of potassium ferrocyanide and sodium carbonate with 2 grms. of gold as chloride in a litre of water; H. L. Barvir heated a thin layer of a gold compound with ammonium chloride; etc. G. Rümelin, and W. Beetz studied the formation of mirrors by the disintegration of gold and silver electrodes in vacuum tubes. The properties of thin films have been studied by J. C. Chapman and H. L. Porter, L. P. Wheeler, etc. M. Faraday showed that when a film is heated, it breaks up into beads; and H. Schottky observed that films 0·087μ thick begin to break up when heated in air or hydrogen over 400°. According to T. Turner, gold-leaf does not undergo any change at 500°, but rapidly becomes transparent at 550°; microscopic examination showed that the film, originally translucent, becomes aggregated to opaque masses with clear spaces between. Soft gold, which has not been mechanically strained, does not show this sudden change of properties. G. Tammann found the recrystallization temp. of gold to be 750°–800°. Gold precipitated in a fine state of subdivision, varies in tint from red to dark brown; very thin films of gold are crimson or purple in transmitted light—*vide* colloidal gold.

J. B. L. Romé de l'Isle (1783), and R. J. Haüy (1801)[2] showed that the **crystals** of gold belong to the cubic system; it occurs in nature in the form of cubes, octahedra, rhombic dodecahedra, trapezohedra. The crystals are rarely isolated and detached, but rather in the form of branching, dendritic masses composed of microscopic octahedra. The isolated crystals occur in drift deposits, or in cavities left by the removal of iron pyrites or other soft materials from the quartz rocks, or they are found in the upper ferruginous or argillaceous crust of the reef. The gold which is embedded in massive quartz does not usually show any marked signs of crystallization. A. Liversidge obtained Widmanstätten's figures, by etching the sliced and polished surface of gold nuggets. The surface of a slowly cooling mass of gold sometimes shows the faces and angles of octahedral crystals. G. W. A. Kahlbaum and co-workers obtained octahedral crystals by sublimation; L. Knaffl prepared good crystals by heating an amalgam with 95 per cent. of mercury to 80° for some time and removing the excess of mercury with nitric acid of sp. gr. 1·35; F. Rinne, by crystallization from a gold-lead alloy; N. Averkieff also obtained hexahedral crystals by reducing gold chloride with formaldehyde, or, according to L. Knaffl, amyl or methyl alcohol. The gold appears mostly in cubes and octahedra. J. M. Maclaren studied the effect of organic matter on the gold crystals; A. Ditte found that on placing a piece of quartz in a soln. of gold in molten sodium thiosulphate, the gold was deposited on the edges and corners of the mineral. Feathery crystalline flakes were obtained by C. G. Lindböm by the electrolysis of a soln. of ammonium aurichloride. Z. Jeffries and R. S. Archer give 200° as the lowest temp. at which the recrystallization of the cold-worked metal has been observed. According to A. Liversidge, it is no uncommon thing to find natural gold in the form of capillary threads—**moss, filiform, or hair gold**—which are often interlaced and twisted into beautiful and fantastic shapes; also as thin plates or scales, having a more or less fibrous surface, and at times in scales so exceedingly thin that they are not thicker than ordinary gold-leaf. A. Liversidge obtained moss gold by roasting auriferous mispickel ores in a muffle—*vide* moss silver. **X-radiograms** of crystals[3] of native gold show that the structural units are arranged after the pattern of a face-centred cubic lattice, with sides 4·08 A., and the closest approach of the atoms 2·88 A. P. Sherrer's measurements give $4·06 \times 10^{-8}$ cm. for the length of the edge of the elementary cube. N. Gross also described the structure of gold crystals. K. F. Slotte estimated the edge of the elementary cube of liquid and solid gold to be $6·6 \times 10^{-9}$ cm. E. Beckmann and O. Liesche found that gold dissolves in boiling mercury as monatomic mols. M. N. Saha made estimates of the at. radius.

In the Arabian *Book of the Best Things for the Knowledge of Mineral Substances*, by Abu-r-Raikan, written towards the end of the tenth century, the **specific gravity** of gold is stated to be 19·05, a number very close to the value accepted at the present time; another Arabian writer, Al-Khazini, in his *Book on the Balance of Wisdom*, written in the twelfth century, gives this same number for the sp. gr. of gold. R. Boyle,[4] in 1690, gave 19·64 for the sp. gr. of gold. D. G. Fahrenheit (1725) gave 19·081; G. Rose gave numbers between 19·2689 and 19·3336 (17·5) for sixteen samples of cast and pressed gold. M. Holzmann, 19·265 (13°); W. C. Roberts-Austen, 19·2945 for gold before rolling, 19·2982 for gold after once rolling. According to W. A. Tilden, hammered or rolled gold has a slightly greater sp. gr. than cast gold—cast gold at 18° has a sp. gr. 19·227, and hammered or compressed gold between 19·30 and 19·34; G. W. A. Kahlbaum and others have found similar results; according to the latter, cast gold has a sp. gr. 18·8840 at 20°, and hammered or compressed gold 19·2685. F. C. A. H. Lantsberry found that cold work affects the mechanical and physical properties of metals generally, and that the sp. gr. of annealed gold is 19·2601, that of cold-worked gold is 19·2504. According to T. M. Lowry, when gold is annealed at different temp. rising to 100°, it changes in volume, there is a small initial contraction followed by an expansion so that the original volume is restored; and T. M. Lowry and R. G. Parker found that while the sp. gr. of gold *en masse* is 19·2818, that of the filings is 19·2169. According to N. Averkieff, gold precipitated by formaldehyde has a sp. gr. 19·43095 at 20°, and, according to G. Rose, gold precipitated by ferrous sulphate has a sp. gr. 19·55 to 20·72; and with oxalic acid, 19·49. The best representative value of the sp. gr. of gold is 19·3. According to G. Quincke, the sp. gr. of liquid gold at 1120° is 18·38.

The **hardness** of gold lies between that of zinc and tin or between 2·5 and 3 on Mohs' scale; if the hardness of steel be 100, that of fine gold is 27; and, according to B. Kerl,[5] iridium and osmiridium augment the hardness of gold. The Brinell hardness of cast and slowly cooled gold is 44·5, but, according to A. Hanriot, the value is too high; C. A. Edwards gave 33·01. C. Calvert and R. Johnson found the hardness of gold as related to that of silver and copper is 4 : 5 : 7·2; the ratio on J. R. Rydberg's scale is 2·5 : 2·7 : 3·0; on F. Auerbach's scale, 97 : 91 : 95; and on S. Bottone's scale, 979 : 990 : 1360.

The **malleability** and **ductility** of gold are very high. Pliny was wrong in stating in his *Historia naturali* (**33**. 19) that these qualities with gold are inferior to those of lead, and he seems to contradict this later by saying that "gold possesses above all other metals the property of being spun and woven into garments like wool." According to J. W. Mallet, thin sheets can be made 0·08μ to 0·12μ thick. According to J. Fournet,[6] it has been made into sheets nearly 0·00001 mm. thick, and drawn into wire so thin that a gram of metal is extended to 2000 metres. A film of gold $0·23 \times 10^{-8}$ mm. thick appears under the microscope as a continuous film. Pulverulent gold may be welded like platinum, and rolled into sheets. S. Kalischer stated that rolled gold is not crystalline, but becomes so when heated to redness. These qualities are greatly influenced by the presence of foreign metals. Lead, for example, was found by F. Mylius to make gold very brittle, while, according to E. Vigouroux, small quantities of copper, lead, arsenic, antimony, or bismuth considerably diminish the malleability of gold, while zinc, nickel, tin, and platinum behave similarly, but to a smaller degree. Less than 0·015 per cent. of silicon makes gold very soft. According to F. A. and C. L. Lindemann, gold is brittle at the temp. of liquid hydrogen or liquid air.

According to G. Quincke,[7] the **surface tension,** σ, of gold is 581 dynes per cm.; A. Heydweiller gives for the surface tension of gold at 1070°, 612·2 dynes per cm., and for the **capillary constant,** a^2, 6·90 sq. mm. at 1120°; S. W. Smith gives respectively $\sigma = 1018$ dynes per cm. and $a^2 = 11·29$ sq. mm. He also shows that the surface tensions and capillary constants of the metals fit in with the periodic law. I. Traube gives for the **intrinsic pressure** of the solid 178,500 megabars. A. Masson[8] gives $20·816\times10^4$ cms. per sec. for the **velocity of sound** in gold; and G. Wertheim gives for annealed gold, $17·413\times10^4$ cms. per sec. between 15° and 20°, and $21·122\times10^4$ cms. per sec. for annealed gold at 10°. C. E. Guye and co-workers have calculated the internal **viscosity** of metals from the logarithmic decrement of oscillating wires, and M. Ishimoto from tuning-forks and oscillating pendulums. A. Johnsen found the **plastic flow** of gold is diminished by cooling the metal in liquid air. W. C. Roberts-Austen found that the **diffusion coefficient** of gold in molten lead corresponds with 3 cms. in one day at 492°, or 0·023 cm. per day at 251°; and he estimated that at 18°, it would diffuse 7 mm. in four years. C. E. van Orstrand and F. P. Dewey found that if k represents the coeff. of diffusion, v_0 the initial conc. of gold in solid lead, then, at 100°, $k=0·0002$, when $v_0=0·0023$ per cent.; at 150°, $k=0·004$, when $v_0=0·0074$ to 0·0123; and at 197°, $k=0·0068$, when v_0 ranges from 0·0155 to 0·0223; they also found at 150°, with v_0 ranging from 0·006 to 0·012, $k=0·005$ when the press. p is one atm. per sq. in.; $k=0·011$, when $p=1·65$ atm. per. sq. in. W. C. Roberts-Austen found that the coeff. of diffusion, k, in cals. per cm. cube per day, for gold in mercury is 0·72 at 11°; for gold in bismuth, 4·52 at 500°; and for gold in tin at 500°, 4·65. W. Fraenkel and H. Houben found the coeff. of diffusion of gold in silver at 870°, *i.e.* 100° below the m.p. of silver, to be 0·000037 per sq. cm. per day.

According to T. W. Richards,[9] the **compressibility** of gold is $0·64\times10^{-6}$ at 20°, *i.e.* $0·64\times10^{-6}$ is the average fractional change of the original vol. caused by a press. of one megabar, or 10^6 dynes per sq. cm., between 100 and 500 megabars. L. H. Adams, E. D. Williamson, and J. Johnston give $0·57\times10^{-6}$, and they represent the change in vol. between the press. p_0 and p by $-0·000005+0·000000568(p-p_0)$. J. Y. Buchanan gave $0·260\times10^{-6}$ per atm. for the linear compressibility.

According to G. Wertheim, the coeff. of resistance of gold to extension, *i.e.* the **modulus of elasticity,** or **Young's modulus** for drawn wires, is 81·31 kgrms. per sq. mm., and for the annealed metal 55·84 kgrms. per sq. mm. S. Katzenelsohn[10] gave 98·00 kgrms. per sq. mm., and G. S. Meyer, 86·30 kgrms. per sq. mm. for the drawn wire, while W. Voigt gave 75·80 kgrms. per sq. mm. for cast gold. The usually accepted value is $8·0\times10^{11}$ dynes per sq. cm., or 760 grms. per sq. cm. at 15°, with a maximum 980 and a minimum 559 grms. per sq. cm. The values at different temp. have been determined by G. Wertheim, who obtained 55·84, 54·08, and 54·82 respectively for the metal at 15°, 100°, and 200°, and S. Katzenelsohn obtained 2·92 for the percentage decrease between 0° and 100°. A. Wassmuth obtained a temp. coeff. 4·09. K. R. Koch and C. Dannecker found that the fall in the modulus of elasticity is gradual and uniform with rise of temp. A. Mallock obtained 1·32 for the ratio of Young's modulus at 0° K. to its value at 273° K. N. S. Kurnakoff and S. F. Schemtschuschny have measured the *pressure of plastic flow* and shown that gold, along with other metals, behaves like liquids with high internal friction under slow deformation, and like elastic brittle solids under rapid deformation. G. Tammann gave 49 kgrms. per sq. cm. for the **elastic limit** of gold. The ratio of the lateral contraction to the longitudinal extension, or **Poisson's ratio** for gold, is 0·422. The **volume elasticity,** cubic elasticity, or bulk modulus of gold is 16·6 dynes per sq. cm. The resistance to shearing, or the **rigidity** or **torsion or shear modulus** of gold, is $2·77\times10^{11}$ dynes per sq. cm. S. Katzenelsohn gave 3950 kgrms. per sq. mm.; W. Voigt gives 2850, and F. Horton, 2495 kgrms. per sq. mm. F. Horton gives 2445 kgrms. per sq. mm. at 15°; 2430 kgrms. per sq. mm. at 34°; 2400 kgrms. per sq. mm. at 75°; and 2386 kgrms. per sq. mm. at 98°. He also gives 3·069 for the temp. coeff., or the rigidity n at $\theta°$ is $n=n_{15}\{1-2·45(\theta-15)\}\times10^{11}$ dynes per cm. C. Schäfer gives $-3·01$ for the temp. coeff. between atm. temp. and low temp.

A. Baudrimont[11] found the **tensile strength** of cast gold to be 14·45 kgrms. per sq. mm., 20·35 to 33·15 kgrms. per sq. mm. for the hard-drawn wire, and 17·10 to 18·80 kgrms. per sq. mm. for the annealed metal. The tensile strength of a gold wire, one mm. thickness before and after annealing, was as 1 : 0·69, and at 0° the tensile strength is 19 kgrms. per sq. mm.; at 100°, 15·8 kgrms.; and at 200°, 13·1 kgrms. per sq. mm. G. T. and G. N. Beilby gave 15·6 tons per sq. in. as the maximum tensile strength of gold at ordinary temp. F. A. and C. L. Lindemann found the tensile strength of a 0·0513 mm. thick wire to be 134 kgrms. per sq. mm. at —192°, and 98·6 kgrms. per sq. mm. at 170°. J. Dewar found the breaking stress of a gold wire 0·098 in. in diameter, to be 255 lbs. at 15°, and 340 lbs. at —182°. W. C. Roberts-Austen measured the tensile strength of gold alloyed with about 0·2 per cent. of various metals, and found that elements with a higher at. vol. than gold lower the tenacity very considerably, while elements with a similar or lower at. vol. than gold increase the tenacity. Silver, with nearly the same at. vol. as gold, has very little influence on the tenacity. W. C. Roberts-Austen's results are shown in Table III, where the tensile strength of the purified metal is 7 tons per sq. in.

TABLE III.—INFLUENCE OF IMPURITIES ON THE TENSILE STRENGTH OF GOLD.

Impurity.			Tensile strength in tons per sq. inch.
Element.	Per cent.	At. vol.	
Potassium	Below 0·2	45·1	Below 0·5
Bismuth	0·210	20·9	Nearly 0·5
Tellurium	0·186	20·5	3·88
Lead	0·240	18·0	4·17
Thallium	0·193	17·2	6·21
Tin	0·196	16·2	6·21
Antimony	0·203	17·9	Nearly 6
Cadmium	0·202	12·9	6·88
Silver	0·200	10·1	7·10
Palladium	0·205	9·4	7·10
Zinc	0·205	9·1	7·54
Rhodium	0·2 (nearly)	8·4	7·76
Manganese	0·207	6·8	7·99
Indium	0·290	15·3	7·99
Copper	0·193	7·0	8·22
Lithium	0·201	11·8	8·87
Aluminium	0·186	10·6	8·87

A. L. Lavoisier and P. S. Laplace,[12] in 1782, made the first exact measurements of the coeff. of expansion of gold, and found between 0° and 100°, 0·00001466 for fine gold; 0·00001552 for gold not annealed, and 0·00001514 for the annealed metal. According to H. Fizeau, the coeff. of linear expansion of gold between 0° and 100° is 0·00001451; A. Matthiessen gave 0·00001403 at 20°; W. Voigt, 0·00001390 at 30°; according to A. Müller, the coeff. of linear expansion α, at θ, is $\alpha=0{\cdot}000014157+0{\cdot}000000215\theta$ between 0° and 520°; W. Voigt gave $\alpha=0{\cdot}00001414+0{\cdot}00000239(\theta-30)$, and, according to A. Matthiessen, the volume v of gold at θ° is $v=v_0(1+0{\cdot}000040756\theta+0{\cdot}0000000336\theta^2)$, where v_0 is the volume at 0°, or the coeff. of cubical expansion is about 0·000043 at 20°. E. Grüneisen found the mean coeff. of linear expansion between —191° and 17°, $\theta=0{\cdot}00001316$; between —18·3° and 16·4°, $\alpha=0{\cdot}00001320$; between 16·1° and 100·6°, $\alpha=0{\cdot}00001434$; between 15·9° and 100·5°, $\alpha=0{\cdot}00001429$; and between 17·7° and 100·3°, $\alpha=0{\cdot}00001430$. J. C. Chapman and H. L. Porter suspended a piece of gold wire with a light load and found that when heated to 184°, the expansion is regular, and the length then remains constant up to 340°, whereafter there is an abrupt contraction. H. F. Wiebe found that the relation $\alpha A/D=0{\cdot}000121$ for copper, 0·000197 for silver, and 0·00047 for gold, when α denotes the coeff. of expansion, D the sp. gr., and A the at. wt. of the element.

According to G. Wiedemann and R. Franz,[13] the **thermal conductivity** of gold is about half as great as that of silver (*q.v.*). J. H. Gray found for the mean conductivity of copper, between 10° and 97°, numbers between 0·96 and 0·32 cal. per degree difference of temp. per cm. per sec.—the exact value depends on the purity of the metal; for silver and gold the respective values were 0·9628 and 0·7464. W. Jäger and H. Diesselhorst found for pure gold at 18°, 0·7003, and at 100°, 0·7027, which represents a temp. coeff. or an increase of about 0·03 per cent. For 99·8 per cent. metal 0·4278 at 18° and 0·4708 at 100°. E. H. Hall has studied this subject.

H. V. Regnault found the **specific heat** of gold between 12° and 98° to be 0·03244; J. Violle[14] found between 0° and 100°, 0·0316; G. W. A. Kahlbaum, K. Roth, and P. Siedler found a sp. ht. of 0·0309 for gold with 0·1 per cent. of impurity, and 0·03087 for the same metal after compression; W. A. Tilden found 0·03035 between 0° and 100°; H. Schimpff found 0·0302 at 0°; W. Voigt gave 0·0303 for a nearly pure sample between 18° and 99°; P. Nordmeyer and A. Bernoulli, 0·0348 between —185° and 20°; T. W. Richards and F. G. Jackson, 0·0297 at —188°; and J. Dewar, 0·0160 at about —223°. Below 0° the sp. ht. is:

	0°	−23°	−73°	—123°	—173°	—223°
Sp. ht. .	0·0302	0·0298	0·0288	0·0277	0·0260	0·0160

and above 0°:

	50°	100°	200°	600°	1000°	1063·5°
Sp. ht. .	0·03042	0·03065	0·03110	0·03288	0·03466	0·0349

Consequently, the **atomic heat** rises from 3·16 at —223° to 5·96 at 0°, and to 6·88 at 1063·5°.

According to T. K. Rose, when rolled gold is heated, the metal softens and, after passing through a pasty stage, it melts at a *cerise clair* heat just below the m.p. of copper, and above that of silver. The temp. at which the softening occurs is higher when impurities are present, *e.g.* 0·002 per cent. of hydrogen raises it from 150° to 300°; and 0·005 per cent. of copper raises it to 250°. Numbers between the 1035° of J. Violle[15] and the 1421° of L. B. G. de Morveau have been given for the **melting point** of gold. C. T. Heycock and F. H. Neville gave 1061·7°; A. Jaquerod and F. L. Perrot gave 1067° at 200 mm. press.; L. Holborn and A. L. Day gave 1063·9°; E. Tiede and E. Birnbräuer, 1060°; H. Callendar, 1061°; A. L. Day and J. K. Clement gave 1059·3° ± 1°; A. L. Day and R. B. Sosman gave 1062·4° ± 0·8°; W. C. Roberts-Austen and T. K. Rose, L. I. Dana and P. D. Foote, W. Guertler and M. Pirani, and K. Scheel gave 1063°, which happens to coincide with the best representative value deduced from the best of the modern determinations. According to L. Holborn and A. L. Day, the absorption of oxygen by gold had very little influence on the m.p., and does not exceed the error of experiment. C. S. M. Pouillet showed that there is a considerable expansion during the melting of gold, and, conversely, in freezing there is a large contraction, so that this metal is not suitable for casting in moulds. C. T. Heycock and F. H. Neville measured the lowering of the f.p. of sodium, cadmium, lead, and bismuth by the soln. of a gram-atom of gold in approximately 100 gram-atoms of the solvent. With tin as solvent there was a rise in the f.p.

Up to the beginning of the eighteenth century no one had noticed any signs of the **volatilization** of gold at a high temp. In 1709, W. Homberg[16] gilded a silver plate by holding it over gold strongly heated in the focus of a burning lens; and in 1802, R. Hare observed the rapid volatilization of gold heated by the ordinary blowpipe, and he found that in a few seconds the vapour stained violet a bone-ash cupel. H. St. C. Deville and H. Debray volatilized and condensed gold when melting it with platinum. E. Tiede and E. Birnbräuer noted volatilization begins at 970° in vacuo. J. Napier, W. Fuchs, C. F. Plattner, S. B. Christy, G. H. Makins, T. K. Rose, K. Friedrich, L. Elsner, W. Lampadius, etc., have studied the losses due to the volatilization of gold in the oxidizing and chloridizing roasting of ores, and in the cupellation of gold or of gold alloys. The loss of gold by volatilization during the melting of its alloys is the common experience of mints. T. K. Rose found the loss with pure gold is probably nil at the m.p.; it is insignificant at 1075°, being 0·09 part per 1000 per hour; at 1125°, the loss was 1·00 per 1000 per hour; and at 1250°, the loss was 2·60 per 1000 per hour—that is, the loss is about four times as great at 1250° as at 1100°. T. K. Rose further observed that the loss by volatilization is probably independent of the nature of the atm. provided it remains unchanged. There are, however, losses which appear to depend on the nature of the atm., thus, the loss appears to be twice as great in an atm. of carbon monoxide and six times as great in an atm. of coal gas as it is in air. Hence, a protective layer of charcoal on the surface of the molten metal increases the loss by volatilization. The losses in a reducing atm. are due to spirting where showers of globules of metal of all sizes are thrown up, and the smaller ones, especially those less than 0·001 mm. in diameter, are carried away by a draught, however slight, and are difficult to recover. They can be recovered by such a filter as cotton wool. It is this action which causes the unrecovered losses in the crucible melting of gold alloys without a covering of slag. It is therefore difficult to judge from published reports of the volatilization of gold which are due to true vaporization, and which are due to the mechanical transport of fine gold spray. The rate of volatilization was found by T. K. Rose to be augmented by the presence of metal impurities—even a non-volatile metal like platinum slightly accelerates the rate of volatilization; lead also has a slight effect; copper and zinc, a greater effect; while antimony and mercury are still more active. With 0·5 grm. of thin foil, 999·6 fine, containing 0·025 grm. of impurity, T. K. Rose found the loss of gold per 1000 was with the fine gold 0·12, and with gold alloyed with

	Pb	Ni	As	Sb	Bi	Hg	Cd	Zn	Cu	Pt
Loss . .	0·30	0·30	0·80	1·00	0·50	0·90	0·55	1·60	0·55	0·23

The loss with tellurium was between 3 and 4 per cent. According to J. H. Niemann, selenium also favours the volatilization of gold. T. K. Rose showed that tellurium does not cause the volatilization of gold at temp. below 1100°, and that the observed losses in roasting telluride ores are due to the mechanical transport of fine dust or absorption by the furnace bottoms. The metals most effective in reducing the surface tension of the molten gold increase the volatility in the greatest degree. The loss is greater when the liquid is thrown into waves by heating the metal in a jet of gas of considerable velocity such as occurs when the metal is heated by the blast blowpipe—probably some of the gold here passes off as spray. H. Moissan vaporized 60 grms. of gold in six minutes in his electric furnace, and he showed that when the vapour is condensed in a cold tube, small cubic crystals or filiform gold are produced. The vapour is yellowish-green. A. Schuller found that when gold is heated in a quartz tube in vacuo, it commences to vaporize at 1070°. W. Mostowitsch and W. Pletneff did not detect any volatilization when pure gold is heated between 1100° and 1400° for 25 mins. in air, oxygen, nitrogen, or in carbon monoxide or dioxide, but the volatility is noticeable in hydrogen at 1250°, thus:

	1250°	1300°	1350°	1400°
Percentage volatilized . .	0·055	0·090	0·105	0·250

The quartz boat was also coloured an intense red when heated in hydrogen, but not in other gases. It has been suggested that possibly *gold hydride* is formed, and that this breaks down immediately into hydrogen and gold; it is also possible that the evolution of occluded gas carries some of the metal mechanically as spray. J. W. Richards calculated the **vapour pressure** of gold in mm. of mercury to be:

	942°	1165°	1467°	1877°	2322°	2455°	2530°
Vap press. .	0 0002	0 013	0·0779	26·35	300	548	760 mm.

O. Ruff and B. Bergdahl observed 130 mm. at 2315°; 296 mm. at 2450°; 332 mm. at 2480°; 400 mm. at 2500°; and 760 mm. at 2600°. J. A. M. van Liempt represented the vap. press. p atm. by $\log_{10} p = 7{\cdot}20 - 20760T^{-1}$. F. Krafft and L. Bergfeld found the b.p. of gold in vacuo is 1800°, and they observed *d'un façon générale* that the difference between the temp. of commencement of vaporization and the b.p. in vacuo is the same as that which exists between the b.p. in vacuo and in atm. air. This makes the **boiling point** of gold 2530° at atm. press.; 3167° at 8 atm. press.; 4057° at 50 atm. press.; and 4858° at 162 atm. press. O. Ruff and B. Bergdahl give 2600° for the b.p. at atm. press.; E. Tiede and E. Birnbräuer, 2100° in vacuo; and J. A. M. van Liempt, 2611° at atm. press. J. W. Richards' estimate for the **latent heat of fusion** of gold is 16·3 cals. per gram. F. Wüst and co-workers found 15·87 cals., and J. W. Richards estimated the **latent heat of vaporization** of gold is 64·47 Cals. per mol, or 32·7 cals. per gram; J. A. M. van Liempt gave 95,060 cals. at the b.p. G. N. Lewis and co-workers give 11·0 for the **entropy** of gold at 25° and atm. press.

Gold, like copper, selectively emits a greenish or bluish light at a high temp. According to Kirchhoff's radiation law, the selective emission and selective reflectivity of these metals at ordinary temp. gives rise to the colour. If E denotes the emissivity of a surface at a temp. T°, and E_0 be the emissivity of a black body at the same temp., the absorptivity A is connected therewith by the relation $E/E_0 = A$; the ratio E/E_0, called the relative **emissivity**, has been measured for gold by C. M. Stubbs and E. B. R. Prideaux,[17] and a selection from their results is shown in Table IV. There is a sharp discontinuity on passing from the solid to the liquid state, so that the relative emissivity of solid gold for the red and yellow rays is weaker, and for the extreme blue rays stronger than for the molten metal. L. Holborn and F. Henning state that there is no change in the emissivity at the m.p., and that the emitted light was so uniform that the difference in the two phases could be perceived only by shaking the crucible. Hence, the solid phase is evident by its having a deeper blue colour. C. E. Mendenhall and L. R. Ingersoll also found that gold and other metals show a marked increase of radiation on melting. The shapes of the curves with different wave-lengths are different; the curve for solid gold at high temp. is similar to that obtained from absorptivity at low temp., but whether the two are identical, and whether $E/E_0 = A$, has not been determined on account of the change of structure which a polished surface undergoes on heating. A. G. Worthing has also studied this subject.

TABLE IV.—THE RELATIVE EMISSIVITY OF SOLID AND LIQUID GOLD.

λ	Solid gold.				Liquid gold.			
	949°	1040°	1061°	Mean.	1067°	1083°	1177°	Mean.
0·7014μ	0·164	0·134	0·103	0·103	0·202	—	0·174	0·184
0·6409μ	0·169	0·144	0·143	0·1435	0·226	0·226	0·226	0·232
0·5895μ	0·241	0·229	0·221	0·229	0·303	0·294	0·309	0·304
0·5418μ	0·379	0·371	0·366	0·371	0·393	0·381	0·388	0·390
0·4961μ	0·520	0·465	—	0·4945	0·485	0·418	0·490	0·473
0·4750μ	0·595	0·492	—	0·531	—	—	0·547	0·503

The optical constants of gold, namely, the **refractive index,** μ, and the **absorption index,** k, as well as the **extinction coefficient,** μk, have been defined in connection with the optical constants of copper; similar remarks apply to the **angle of principal incidence,** ϕ, and the **angle of principal azimuth,** ψ, of polarized light. A selection of these constants by K. Försterling and V. Fréedericksz [18] is indicated in Table V. The index of refraction has been studied by W. Meier, H. Rubens. P. Drude, G. Quincke, A. Kundt, A. Pflüger, H. du Bois and H. Rubens.

TABLE V.—OPTICAL CONSTANTS OF GOLD.

λ	ϕ	ψ	μ	k	μk
1·00μ	81° 45′	44° 00′	0·24	28·0	6·7
2·00μ	85° 30′	43° 56′	0·47	26·7	12·5
3·00μ	87° 05′	43° 50′	0·80	24·5	19·6
5·00μ	88° 15′	43° 25′	1·81	18·1	33·0

etc. D. Shea found for the α-Li-line, μ=0·29 (A. Pflüger gave 0·20); for the *D*-line, 0·66 (A. Kundt gave 0·58); for the *F*-line. 0·82 (A. Pflüger gave 1·04); and for the *G*-line, 0·93 (A. Kundt gave 1·03). W. Meier's values for the index of refraction, absorption index, and extinction coeff., are:

λ	0·2573	0·2981	0·3611	0·4413	0·5080	0·5893	0·6680μ
μ	0·918	1·100	1·300	1·175	0·908	0·469	0·355
k	1·243	1·239	1·346	1·572	2·574	6·030	9·034
μk . . .	1·420	1·374	1·750	1·846	2·075	2·826	3·206

E. Hagen and H. Rubens give for the reflecting power (per cent.), *i.e.* the percentage **reflecting power,** *R*, of gold in air, that is, the ratio of the intensity of the reflected ray to that of the incident ray for light of wave-length λ:

λ= 0·251μ	0·305μ	0·357μ	0·385μ	0·420μ	0·500μ	0·600μ	0·800μ	1·00μ	1·50μ
R=38·8	31·8	27·9	27·1	29·3	47·0	84·4	94·9	97·1	97·3

The reflectivity and other optical constants of gold were shown by J. Königsberger, A. Pflüger, and P. Drude to have no appreciable temp. coeff. in the visible spectrum. J. Conroy, and L. P. Wheeler have studied the reflecting power of gold in water and in carbon disulphide; and F. Henning has investigated the **emissivity** of gold. I. C. Gardner measured the reflection coeff. for Schumann's region of the spectrum. H. Knoblauch has measured the polarization angle of the heat rays—66·50°. The angle of principal incidence has been observed by C. Statescu, etc.; the angle of principal azimuth by K. Försterling and V. Fréedericksz, etc.; H. Knoblauch, and F. Schön have studied the anomalous dispersion. J. H. Gladstone gave for the **refraction equivalent** of gold $A(\mu-1)/D$=23·1, when *A* denotes the at. wt. of the metal, *D* the sp. gr., and μ the index of refraction. M. Faraday noted the action of thin films of gold on polarized light. Y. Björnstähl found that the colloidal particles of gold sol are magnetically anisotropic, while the crystals of gold are isotropic, hence it is concluded that the two forms of gold belong to different crystal systems.

According to L. de Boisbaudran,[19] gold chloride imparts a greenish colour to the Bunsen's flame, and the **flame spectrum** is indicated in Fig. 5. It consists of a series of lines stretching from the yellow to the bluish-green.

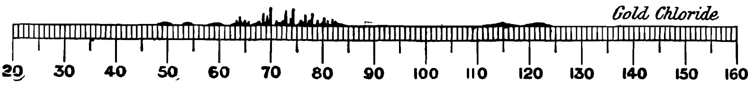

FIG. 5.—Flame Spectrum of Gold Chloride.

The spectrum is clearer if the auric chloride is volatilized in hydrogen. Hydrogen chloride is needed for the production of this spectrum, which is therefore regarded as due to the gold chloride, and not to gold alone. W. N. Hartley and H. W. Moss have studied the spark and the oxy-hydrogen flame spectrum. The **spark spectrum** of gold chloride, shown in Fig. 6, has some bands corresponding with the flame spectrum, and, in addition, there are brilliant sharp lines due to gold itself. B. de la Roche studied the effect of reducing gases—

hydrogen and coal gas—on the spectrum of gold. According to H. W. Vogel, the spectrum is clearer when the spark gap is large. W. Huggins, R. Thalen, G. Kirchhoff, A. de Gramont, F. Exner and E; Haschek, H. Kayser and C. Runge, F. M. Walters, and G. Krüss, have measured parts of the spark spectrum. The more prominent lines are 2932·3, 3029·3, and 3122·6 in the ultra-violet; 3898·0 and 4065·2 in the violet; 4437·4 and 4792·8 in the blue; 5064·7 in the green; 5656·0 and 5837·6 in the yellow; and 5957·2 and 6278·4 in the orange or red. J. M. Eder and E. Valenta have located 660 lines. H. Lehmann found the line $\lambda=7509{\cdot}8$ to be the most intense of those in the ultra-red emission spectrum, and $\lambda=10982{\cdot}3$ to be the weakest, while $\lambda=9208{\cdot}0$ is intermediate in intensity. J. M. Eder found $\lambda=2340{\cdot}22$ to be the most intense line in the ultra-violet spectrum. L. and E. Block studied the spectrum between $\lambda=1850$ and $\lambda=1401$ in the extreme ultra-violet. According to P. G. Nutting, the single and simple lines of the spark spectrum are broadened by increasing the intensity of the source of light. The arc spectrum has been studied by M. Quincke, etc. A. G. G. Leonard and P. Whelan have studied the spark spectra of dil. soln. of gold chloride with a view of detecting small quantities of the element. W. Hartmann, W. Michelson, and J. E. Purvis have studied the influence of a strong *magnetic field*—the Zeeman effect—on the spectral lines. W. G. Duffield found the lines are broadened by an increasing *pressure*. J. W. Mallet investigated the **absorption spectrum** of colloidal hydrosols of gold and ruby-coloured glass.

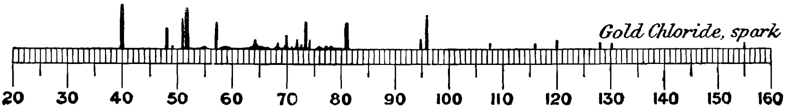

FIG. 6.—Spark Spectrum of Gold Chloride.

According to W. M. Hicks, the series spectra of copper, silver, and gold furnish clear evidence of being built on the same plan, although they seem defective in representatives of the ordinary series lines, and show some apparent deviations from relations exhibited by other groups. According to H. Kayser and C. Runge, there are two pairs of lines with a constant difference in the vibration frequency: the first pair of wave-lengths, 2676·05 and 2428·06, and the second pair, 6278·37 and 5064·75; the differences in the vibration frequencies are in both cases nearly the same. The first named corresponds with the isolated pair in the spectra of silver and gold, and was therefore regarded by J. R. Rydberg as the first member of a principal series. The second pair is possibly a member of a subordinate series. W. M. Hicks has shown the existence of a series in the ultra-red and one in the ultra-violet. The available data have been reviewed by A. Fowler.

According to B. C. Cobb,[20] gold becomes photographically active after it has been exposed to the discharge of a Ruhmkorff coil. For the radioactivity, see N. R. Campbell. For the action of α-rays, see H. A. Bumstead and A. G. McGougan, N. R. Campbell, H. Geiger, E. Marsden and co-workers, J. A. Gray, etc. According to W. H. Bragg, the stopping power s of substances for the α-**rays** is approximately proportional to the sq. root of the at. wt., A, and for gold, $s=4{\cdot}45$, and $\sqrt{A}=3{\cdot}70$. E. Rutherford and J. Chadwick found little if any evidence of the emission of long-range α-particles, charged hydrogen atoms, when gold is exposed to α-rays from radium-C. H. R. von Traubenberg found the range of α-rays in gold to be $14{\cdot}0\times10^{-4}$ cms. J. Crowther found the coeff. of absorption μ for the β-**rays** is approximately proportional to the sp. gr. D, and for gold, $\mu/D=9{\cdot}5$. For the heat developed during the absorption of radiations, see C. W. Richardson and H. L. Cooke. On the characteristics of the **X-rays** emitted by various metals, see C. G. Barkla and C. A. Sadler. The high frequency or X-ray spectrum has been investigated by D. Coster, A. Dauvillier, etc. E. Hjalmar, M. de Broglie, and W. Duane and co-workers measured the absorption of X-rays by gold. The **photoelectric effect** with gold has been measured by W. Ramsay and J. F. Spencer,[21] who arrange the copper family in the order Au, Cu, Ag ; K. Herrmann gives the order Cu, Ag, Au ; E. Ladenburg, and R. A. Millikan and G. Winchester give the order Cu, Au, Ag. W. Frese found that the photoelectric sensitiveness of gold is not affected by treatment with water or alcohol. E. Ladenburg [22] showed that a photoelectric effect can be obtained by passing ultra-violet light through a film of gold, and O. Stuhlmann found that the effect produced by the emergent beam is in general greater than that produced by the incident beam. M. N. Saha studied the **ionizing potential** of gold.

The **electrical conductivity,** λ, of gold has been the subject of many measurements. A. Mattheissen and A. von Bose [23] found that if the conductivity of mercury be unity at 0°, the conductivity of hard-drawn gold is 47·07 ; and of softened gold, 47·92 ; otherwise expressed, the specific conductivities in reciprocal ohms of hard and soft gold are respectively $46·8\times10^4$ and $47·6\times10^4$. If λ be the conductivity at θ between 0° and 100°, λ_0 the conductivity at 0°, $\lambda=\lambda_0(1-0·0036745\theta+0·000008442\theta^2)$. W. Jäger and H. Diesselhorst give for the conductivity of hard-drawn gold $41·28\times10^4$ rec. ohms at 18°, and $32·13\times10^4$ at 100° ; the conductivity is much reduced when the metal is impure, thus gold containing 0·1 per cent. of tellurium and 0·1 per cent. of copper had a specific conductivity of $24·68\times10^4$ rec. ohms at 18°, and $21·24\times10^4$ rec. ohms at 100°. J. Dewar and J. A. Fleming found that for gold 999-fine :

	−183°	−100·5°	0°	90·4°	194·5°
λ .	$146·8\times10^4$	$73·2\times10^4$	$45·5\times10^4$	$34·0\times10^4$	$26·5\times10^4$ rec. ohms

G. Niccolai also found the electrical conductivity decreases with a rise of *temperature,* and increases as the temp. is lowered. Conversely, J. Dewar and J. A. Fleming found the **electrical resistance,** R, to fall from 2197×10^{-9} ohms at 0° to 1849×10^{-9} ohms at 44° ; $1548·5\times10^{-9}$ ohms at −81·9° ; to $1366·8\times10^{-9}$ ohms at −106·1° ; and to $681·3\times10^{-9}$ at 197·1°. The temp. coeff. between 0° and 100° is $\alpha=0·00377$ in $R=R_0(1-\alpha\theta)$. L. Holborn gave 0·00400 for the temp. coeff. of the resistance per degree between 0° and 100°. E. F. Northrup measured the electrical resistance of gold in micro-ohms per c.c. between 20° and 1500°, and found :

	20°	300°	500°	800°	1000°	1063°	1063°	1200°	1300°	1500°
R .	2·316	4·72	6·62	9·94	12·45	13·50	30·83	31·76	34·17	37·00
	Solid.					Liquid.				

The change in the resistance of molten gold with rise of temp. is linear, and almost linear with the solid metal ; the ratio of the resistance of the solid at 20° and 1063° is 1 : 5·827, and at the m.p. the ratio of the resistance of the solid to that of the liquid is 1 : 2·28. According to H. K. Onnes, for still lower temp. if the ratio of the resistance at θ° to that at 0° steadily falls :

θ° . .	0°	−103·7°	−195·1°	−252·8°	−259·1°	−268·7
R_θ/R_0 .	1	0·593	0·219	0·008	0·003	0·002

Consequently, the electrical resistance of gold at the b.p. of helium in vacuo is less than the experimental error involved in the measurement, and therefore the electrical resistance of pure gold probably vanishes towards absolute zero, −273°. A. L. Feild estimated the resistance of *amorphous gold* to be 16·09 micro-ohms per c.c. at 20°. P. W. Bridgman found the general effect of *pressure* on the resistance of gold has the same general character as with silver. P. W. Bridgman found

	0°	25°	50°	75°	100°
R	1·0000	1·0977	1·1963	1·2960	1·3968
Press. coeff. 0 kgrm. . . .	$-0·0_5312$	$-0·0_5310$	$-0·0_5380$	$-0·0_5305$	$-0·0_5304$
Press. coeff. 12,000 kgrms. per sq. cm.	$-0·0_5276$	$-0·0_5275$	$-0·0_5276$	$-0·0_5279$	$-0·0_5282$

The initial press. coeff. at 0° is $-0{\cdot}0_5 3117$. B. Beckman found $-0{\cdot}0_5 527$. S. Pienkowsky found the electrical resistance of a thin sheet of gold is not perceptibly altered by *illumination*. G. Szivessy found the electrical conductivity is not altered by heating the metal in *oxygen*. F. Streinz and A. Wellick measured the electrical resistance at the limiting surface between gold and arsenical pyrites or galene. L. Grunmach and F. Weidert measured the increase of resistance in a *magnetic field*—*vide* silver. F. Credner observed a similar change in the resistance of a gold wire as was obtained with a silver wire, but the increase in resistance occurred at 300°. P. W. Bridgman found that the resistance of thin films of gold, at high current densities, is rather greater than corresponds with Ohm's law.

According to J. Thomsen,[24] three **allotropes of gold** are obtained by reducing auric chloride, hydrobromoauric acid, and aurous bromide with sulphur dioxide. E. Petersen confirmed this observation. The observed differences were :

	Source.	Specific gravity.	Atomic volume.	Heat of oxidation.
α-Au . .	$AuCl_3$	19·39 (19·31–19·45)	10·17	139·9 Cals.
β-Au . .	$HAuBr_4$	19·44 (19·40–19·50)	10·14	67·7
γ-Au . .	AuBr	19·72 (19·64–19·83)	10·00	37·9

J. W. van Heteren, however, does not agree with this conclusion, since the different modifications do not show any difference of potential, and he inferred that all three varieties are identical. C. E. Fawsitt, however, showed that if a portion of a rod of silver, gold, or platinum be softened by annealing, and the other portion of the rod of the same metal be hardened by polishing or hammering, there is a difference of potential when the two rods are placed in a soln. of an electrolyte—the hardened rod becomes the negative pole. Hammered gold has an electrode potential of 1·422 volts; polished gold, 1·446 volts; and the same specimen after annealing, 1·454 volts.

The **electrode potential of gold** in molten sodium hydroxide was found by P. Bechtereff[25] to rise from 0·328 volt at 386° to 0·537 at 620°, and the value is reduced if the metal has traces of selenium. F. H. Campbell found that the potential of gold in $\acute{N}$-$AuCl_3$ against a normal electrode is 1·5 volts. S. B. Christy gives for the e.m.f. in soln. of potassium cyanide :

Per cent. KCy .	6·5	0·65	0·065	0·0065	$0{\cdot}0_3 65$	$0{\cdot}0_4 65$	$0{\cdot}0_5 65$	0
E.m.f. volts .	+0·420	+0·265	+0·090	+0·340	−0·450	−0·565	−0·620	−0·720

L. Kahlenberg studied the potential in pyridine soln. of lithium chloride. J. Guyot, in soln. of alkali chlorides, cupric salts, and silver nitrate. P. Bechtereff found the cell $C \mid NaOH_{fused} \mid Au$ between 361° and 643° has an e.m.f. of 0·609 to 0·846 volt.

The so-called **electrolytic valve action** prevents the passage of the current in the direction of the flow so long as the applied potential does not reach a certain minimum value. G. Schulze[26] finds that the minimum potential of tantalum is 1·51 times that of aluminium when both metals have been prepared at the same potential. F. Giraud found that if two copper strips in electrical communication be dipped in a soln. of gold chloride and one of the strips be twisted or vibrated, it acquires a positive charge, the resting strip, a negative charge.

The hydrogen over-voltage with a gold cathode was found by J. N. Pring[27] to be greater than with platinum, and smaller than with zinc, copper, tin, nickel, or lead. G. Just and W. Berezowsky reported that gold electrodes are more readily polarized than those made of platinum, and that the previous history of the electrode is of great influence ; treatment with potassium ferrocyanide increases and treatment with potassium ferricyanide decreases the polarizability ; while G. Grube found an anode of gold in neutral or alkaline soln. of a mixture of the two last-named salts in the proportion 1 : 3 at 19° is not polarizable. A. Coehn and C. L. Jacobsen electrolyzed a soln. of auric chloride when gold is deposited at the cathode, and plotted the potentials against the current with a soln. of potassium gold cyanide. There is one break in the curve at −0·2 volt representing the discharge of $Au^{\cdot}$-ions at the cathode ; but there are several breaks with a soln. of auric chloride, thus above —0·905 volt only $Au^{\cdot\cdot\cdot}$-ions are discharged; in fresh soln. containing no aurous salt, the break at —1·1 volt indicated the change of $Au^{\cdot\cdot\cdot}$- to $Au^{\cdot}$-ions; and between —0·985 and —0·905 volt both $Au^{\cdot}$- and $Au^{\cdot\cdot\cdot}$-ions are discharged from soln. containing aurous and auric chloride. The gold anode is dissolved as a univalent metal in pure potassium cyanide soln., and does not become passive even in conc. soln. of the salt. In soln. of the commercial cyanide, however, it rapidly becomes passive, this being due to the presence of sodium salt as impurity. The passivity is attributed to the formation of a film of comparatively insoluble sodium gold cyanide on the anode. It is said that the passivation of the anode by sodium can be used to detect this metal in the presence of an excess of potassium. H. Kochan found that a gold anode polarized in dil. sulphuric acid is sensible to light of the visible spectrum, to ultra-red light, and to X-rays. W. Winter has studied the **electrolytic valve action** of gold anodes.

According to E. Wohlwill, soln. of gold in potassium cyanide cannot be utilized in electrolytic gold refining, because silver and copper are deposited along with the gold; with neutral soln. of auric chloride or hydrochloroauric acid, chlorine is evolved, and the gold anode is not attacked; and with hydrochloric acid alone, or acidified soln. of hydrochloroauric acid, no chlorine is evolved and the gold anode is dissolved—the alkali chlorides have the same effect as hydrochloric acid. Hence, in order that the gold anode shall dissolve it is necessary that the conditions permit the formation of $AuCl_4'$-ions. E. Wohlwill also studied the conditions which favour the dissolution of the anode, and the cathodic deposition of the gold. If only tervalent gold exists in the soln. 2·45 grms. of gold should be deposited per amp. hour; in practice more nearly 3 grms. are deposited; this is attributed to the presence of aurous chloride in the soln. The loss at the anode is greater than the gain at the cathode, because there is a loss due to the separation of fine particles of gold, most of which is found in the anode mud; part of the gold dissolved in the aurous state at the anode is decomposed into metallic gold and aurous chloride in the soln., and never reaches the cathode.

The reported values for the **thermoelectric force** of gold against platinum at 100° range from J. Dewar and J. A. Fleming's 0·56 volt to E. Wagner's 0·78 volt; the best representative value is 0·74 volt. L. Holborn and A. L. Day [28] give for the *gold-platinum* couple:

	−185°	−80°	100°	200°	400°	600°	800°	1000°
E.m.f. . .	−0·15	−0·31	+0·74	+1·8	+4·5	+7·9	+12·0	+16·8 volts

K. Noll obtained for *gold-mercury* couple between 0° and 100°, +713·2 microvolts for hardened gold, and +713·4 for annealed gold. According to P. W. Bridgman, the thermoelectric force of gold against lead, at atm. press. and θ°, is $E=(2\cdot899\theta+0\cdot00467\theta^2-0\cdot0000166\theta^3)\times10^{-6}$ volts; the **Peltier effect** is $P=(2\cdot899+0\cdot00934\theta-0\cdot0000398\theta^2)(\theta+273)\times10^{-6}$ volts; and the **Thomson effect**, $\sigma=(0\cdot00934\theta-0\cdot00000996\theta)(\theta+273)\times10^{-6}$ volts per degree. Table VI contains a selection

TABLE VI.—THE EFFECT OF PRESSURE ON THE SEEBECK, PELTIER, AND THOMSON EFFECTS.

Temp.	Seebeck effect. Volts × 10^6.			Peltier effect. Joules per coulomb × 10^6.			Thomson effect. Joules per coulomb × 10^6.		
	Press. in kgrms. per sq. cm.			Press. in kgrms. per sq. cm.			Press. in kgrms. per sq. cm.		
	2000	6000	12,000	2000	6000	12,000	2000	6000	12,000
10°	+0·080	+0·242	+0·485	+2·1	+ 6·4	+13·0	+1·5	+3·7	+5·5
40°	+0·354	+1·049	+2·061	+3·1	+ 9·1	+17·4	+1·7	+4·25	+6·3
60°	+0·564	+1·655	+3·213	+3·7	+10·5	+19·8	+1·8	+4·5	+6·7
100°	+1·052	+3·029	+5·760	+4·9	+13·8	+25·2	+2·0	+5·1	+7·5

from P. W. Bridgman's observations on the effect of press. on couples with compressed and uncompressed gold. All three effects are positive and increase regularly with temp. and press. E. Wagner also made some observations on the effect of temp. E. Sedström has studied the Peltier effect for couples of gold with silver, copper, cadmium, or zinc. G. Borelius and F. Gunneson found the Thomson effect, in microvolts per degree, to be 2·05 at 400° K., 1·61 at 300° K., 1·18 at 200° K., 0·71 at 130° K., and 0·29 at 100° K. A. Cöhn and A. Lotz studied the **contact electricity** of gold against glass in vacuo.

Gold is diamagnetic. According to J. Königsberger,[29] the **magnetic susceptibility** of gold is $-3{\cdot}1\times10^{-6}$ vol. units; and, according to K. Honda, $-0{\cdot}15\times10^{-6}$ mass units between 18° and 1064°; so that, as M. Owen showed, the value is not dependent on the temp. There is a discontinuity at the m.p., as shown in Fig. 8, Cap. XXII. According to M. Hanriot, ordinary yellow α-gold is more strongly diamagnetic than brown β-gold. The magnetization coeff. varies from $-0{\cdot}16\times10^{-6}$ to $-0{\cdot}23\times10^{-6}$. The change in the magnetization coeff. with temp. exhibits a break between 300° and 400° owing to the transformation of brown into yellow gold. H. Altherthum, and H. K. Onnes and B. Beckmann have studied the **Hall effect** with gold; and M. Owen, the thermomagnetic behaviour of this metal.

§ 6. The Chemical Properties of Gold

The general chemical behaviour of gold is connected with its relatively small affinity for the other elements. At the time Pliny's *Historia naturali* was written, gold was considered to be "the only substance in nature that suffers no loss by the action of fire; because it passes unscathed through the flames of the funeral pyre." Indeed, continued Pliny, "the oftener gold is subject to the action of fire, the more refined becomes the quality." Testing the goodness of gold by fire was known as *obrussa—obryza*, or obriza, from ὄβρυζον, pure gold.

Gold is not attacked by air or oxygen—moist or dry, hot or cold. Hence, the alchemists called gold a *noble metal* in contrast with the *base metals*—like lead, copper, tin, iron, etc.—which are oxidized and lose their metallic characters when heated in air. The fact that Moses (*Exod.*, 32. 20) was able to reduce Aaron's "golden calf" to ashes by fire led some of the early chemists to make conjectures as to what Moses actually did.[1] G. E. Stahl suggested that the gold was dissolved in a soln. of alkali sulphide; and W. Herapath that the metal was dissolved in aqua regia; J. D. Smith supposed that the idol was fused with an alloy which made the gold so brittle that it could be ground to powder, otherwise expressed, the gold of Aaron and his religious brethren was a kind of brass alloyed with some gold. Many other suggestions have been made, but in the absence of essential details, nothing is gained by prolonging the old discussion. The result, however, is a good illustration of *the influence of temperament on inquiry.* Two men may be presented with the same phenomenon and they may draw opposite conclusions, both of which are based on the different aspects of the phenomenon to which the men directed their attention. Still more is this the case when but a meagre report of a supposed phenomenon is available. Instinctive or acquired tendencies, temperament, and thought are so inseparably mingled that there is often a very real difficulty in applying purely logical reasoning. In such cases Socrates' advice is invaluable:

> What is the good of talking about something if you do not know clearly what it is, for all your observations may have been concerned with something different ? but you would be as unable to know this as a man who set out to find something without knowing what it was, would never be able to tell when he had found it.

J. Prinsep[2] found an increase in weight occurred when an alloy of gold and platinum is melted in a forge fire, although no residue of carbon appears when the alloy was dissolved in aqua regia. T. Graham found that gold cornets when strongly heated in vacuo gave up 0·2 per 1000 of their weight, or 2·12 times their volume of gas, the bulk of which was carbon monoxide, as shown by the analysis:

CO	CO_2	H_2	N_2	O_2
65·4	14·6	15·4	4·3	0·3 per cent.

T. K. Rose also showed that furnace gases are always absorbed by the molten metal, the amount varying in weight from 0·25 per 1000 in the case of gold heated to 1215° in air, to 7·8 parts per 1000 of gold heated to the same temp. in coal gas. T. Graham further observed that when gold was heated and cooled in a stream of air, the occluded gas amounted to 0·22 vol. per volume of gold, and contained 86·3 per cent. of nitrogen, 8·4 per cent. of carbon dioxide, and 5·3 per cent. of oxygen. The occluded gas was principally nitrogen, and, said T. Graham, "the indifference of gold to **oxygen** is remarkable and contrasts with the power of silver to occlude this same gas." G. Neumann found that gold can absorb about 32·78 to 48·49 times its vol. of oxygen. A. Sieverts and E. Bergner found that liquid gold at 1220° does not absorb **helium.** A. Sieverts also stated that hydrogen and nitrogen are not absorbed by solid or melted gold. T. Graham further showed that gold can absorb 0·3 vol. of **carbon monoxide,** 0·2 vol. of **carbon dioxide,** and 0·48 vol. of **hydrogen.** J. Trowbridge found gold absorbs 37·31 to 46·32 times its vol. of **hydrogen,** and G. Neumann, that molten gold can absorb 37·31 to 46·32 times its vol. of that gas.

Attempts by A. Sieverts, M. Major, and M. Thoma to make *gold hydride* have proved nugatory. The treatment of soln. of gold salts with hypophosphorous and phosphorous acids give precipitates of metallic gold.

According to H. Hartley, a gold surface acquires a negative charge during the catalytic combustion of gases in contact with it. The electrical effect is probably antecedent to combustion, and primarily due to occlusion. The occlusion of hydrogen or carbon monoxide results in the metal getting a negative charge; with oxygen the charge is positive.

According to H. Moissan,[3] gold is slowly attacked by **fluorine** at a red heat, but there is no appreciable action at ordinary temp. O. Ruff and A. Heinzelmann found that **uranium hexafluoride,** UF_6, has very little action on gold even when warmed; and O. Ruff and F. W. Tschirch found that when heated with **osmium octofluoride,** OsF_8, a protective black film is formed on the surface of the gold. Thoroughly dried **chlorine** does not act on gold at ordinary temp. G. Krüss found that at 140° to 150° dry powdered gold is transformed by chlorine into aurosoauric chloride; at 180° to 190° into aurous chloride; and a little volatile auric chloride, while over 300° the metal is not attacked—*vide* gold chloride. S. B. Christy studied the volatility of gold in air containing chlorine. J. Percy found that no reaction occurs when dry chlorine is introduced into molten gold. Liquid chlorine was found by F. Meyer to act but slowly on gold at ordinary temp., but the reaction is vigorous at 100°. E. J. Reynolds, J. Spiller, and A. H. Allen studied the dissolution of gold by chlorine water at ordinary temp. G. Krüss found **bromine** gas attacks gold superficially, forming a black film on the surface; while liquid bromine forms auric bromide. On the other hand, J. Thomsen and E. Petersen found aurosoauric bromide to be produced under these conditions, the discrepancy in the two statements was explained by G. Krüss and F. W. Schmidt by showing that the auric bromide is much decomposed at 60°. F. Meyer found that in a sealed tube a gram-atom of precipitated gold with two of bromine forms a crust of auric bromide which hinders further action, but after 12 hrs.' shaking, all the bromine forms auric bromide. T. Döring found that gold is soluble in an ether soln. of bromine; and in a mixture of bromine and hydrobromic acid. F. Meyer found that dry **iodine** does not react with gold at ordinary temp., but between 50° and the m.p. of iodine, aurous iodide is formed. J. Nicklès showed that nascent iodine unites with gold, and also in the presence of ether or in sunlight. At ordinary press. a soln. of iodine in water does not attack gold, but in a sealed tube a reaction does occur. T. Döring says that iodine does not react with gold—when the two elements are rubbed up with water, alcohol, or ether. T. Döring found that a 10–15 per cent. soln. of iodine in potassium or ammonium iodide readily dissolves gold; the action is much slower with a 5 per cent. soln., and exceedingly slow in more dil. soln.

C. W. Scheele found that **hydrofluoric acid,** either alone or mixed with nitric acid, will not dissolve gold. M. Hanriot and F. Raoult found powdered gold to be very slightly soluble in conc. **hydrochloric acid**—100 c.c. of acid dissolved 0·008 grm. of the metal. If access of air be excluded, hydrochloric acid has no action on gold. M. Berthelot said that fuming hydrochloric acid of sp. gr. 1·178 attacks gold when exposed to light, and particularly if certain salts—*e.g.* manganous chloride, $MnCl_2$—be present. No reactions in either case occurs in darkness. According to W. Spring, gold is dissolved when it is heated with conc. hydrochloric acid to 150° in a sealed tube; and the soln. seems to be reduced by the resulting hydrogen, for minute crystals are deposited on the walls of the tube. N. Awerkieff showed that precipitated gold is attacked by the conc. acid of sp. gr. 1·19, and particularly in the presence of many organic substances—*e.g.* various alcohols, cane sugar, formaldehyde, chloroform, etc. A. Bornträger also found a mixture of equal parts of conc. hydrochloric and nitrosulphuric acid is a good solvent for gold; and T. Fairley found a mixture of hydrogen peroxide and hydrochloric acid dissolves gold. O. P. Watts and N. D. Whipple studied the action of hydrochloric acid in the presence of soln. of various salts. The most convenient solvent for gold is usually **aqua regia.** The product of the action of aqua regia on gold was found by J. P. Prat to be dependent on the ratio of nitric to hydrochloric acid—an excess of the hydrochloric acid forms chloronitric acid, an excess of nitric acid acts on the chloride; to avoid the formation of chloronitric acid, the aqua regia should be diluted with an equal vol. of water. According to E. Priwoznik, a mixture of 200 c.c. of hydrochloric acid (sp. gr. 1·1946), 45 c.c. of nitric acid (sp. gr. 1·4), diluted with 245 c.c. of water, is the best solvent—one part of gold is dissolved by 4·3 parts of the mixture; and he represents the reaction: $Au+HNO_3+4HCl=HAuCl_4$

$+NO+2H_2O$. The alchemists were wont to represent the dissolution of gold in aqua regia by an animal devouring the sun or Apollo—*vide* Fig. 1, Cap. I. According to J. Nicklès, an ethereal soln. of **hydrobromic acid** does not dissolve gold; nor does **hydriodic acid** alone attack gold appreciably, but in presence of manganese dioxide, it does dissolve gold—the higher oxides of bismuth and other metals act similarly to manganese dioxide. An ethereal soln. of hydriodic acid dissolves gold. T. Döring also found gold to be readily soluble in hydriodic acid. According to J. P. Prat, **iodic acid** attacks gold slowly, and V. Lenher showed that if sulphuric acid be present, and the temp. 300°, the reaction is much faster; **periodic acid** also dissolves gold in the presence of sulphuric acid. O. P. Watts and N. D. Whipple studied the action of **perchloric acid** and of various acids and oxidizing agents on gold.

Gold is dissolved by mixtures containing **chlorides, bromides,** or **iodides** if they can generate the nascent halogens. For example, gold is dissolved by mixtures containing chloride, nitrates, and sulphuric acid or acid sulphates. A mixture of sodium chloride, nitre, and alum was the *menstruum sine strepitu* of the alchemists. Again, mixtures of hydrochloric acid with oxidizing agents like the nitrates; chlorates; permanganates; peroxides; with bleaching powder and an acid; and as J. Nicklès showed, with the easily decomposable **perchlorides, perbromides,** or **periodides** act similarly. C. Lossen also found that gold is dissolved by the products of the electrolysis of the alkali halide soln. According to T. Egleston, a soln. of **potassium chloride** or of **ammonium chloride,** has no action on finely divided gold when heated in a sealed tube for eight months or 5 hrs. at 150°–200°, **potassium bromide** under similar conditions gave a reaction. A. Hanriot and F. Raoult found that 100 c.c. of 25 per cent. hydrochloric acid containing 30 grms. of **auric chloride** dissolved 0·170 grm. of yellow and 0·745 grm. of brown gold. H. H. Morris made a similar observation and stated that aurous chloride is formed. F. Mylius found fuming hydrochloric acid containing some **cupric chloride** dissolves gold. W. J. McCaughey found that raising the conc. of the acid raises the speed of the action more than raising the conc. of the cupric chloride. The amount of gold dissolved seems to increase proportionately with the time of action without attaining a limit. Raising the temp. from about 40° to about 105° increases the speed of dissolution of the metal about 32 times. Doubling the conc. of the acid at about 40° increases the solvent action seven-fold, and at 105°, five-fold. Possibly the reaction of the cupric chloride is catalytic in the sense of the cuprous chloride in Deacon's process for chlorine, $2CuCl_2 \rightarrow 2CuCl+Cl_2$, and the cuprous chloride is oxidized by air and hydrochloric acid back to cupric chloride. The soln. of gold in the cupric chloride soln. at about 105° on cooling, and standing for about five days, does not deposit gold. According to P. C. McIlhiney, a boiling soln. of ferric chloride attacks gold in the presence of hydrochloric acid and air, but not if air be excluded. H. N. Stokes has also studied the solvent action of a soln. of ferric chloride and sulphate on gold. A hydrochloric acid soln. of a ferric salt—iron alum—was also found by W. J. McCaughey to dissolve gold, and the rate of soln. is increased more by raising the conc. of the acid than by raising the conc. of the salt. The rate of soln. is increased about eleven-fold by raising the temp. from about 40° to about 105°. The solvent action of the ferric salt occurs even when a ferrous salt is present, and decreases by increasing the conc. of the latter. Consequently, the precipitation of gold by ferrous sulphate can be complete only with a considerable excess of the latter. With an increasing conc. of the ferric salt a state approaching a balanced reaction may appear since, unlike the case with cupric chloride, the conc. of the dissolved gold approaches a limit. A soln. of gold obtained by boiling the alum soln. for two days with gold does not give evidence of the formation of a ferrous salt, when tested with potassium ferricyanide, but spangles of gold are deposited when the soln. cools. J. Nicklès found that ethereal soln. of **titanous chloride,** $TiCl_3$, **titanous bromide, manganic, cobaltic, nickelic chloride or bromide, ferric bromide,** and **plumbic chloride** dissolve gold;

so also does an ethereal soln. of **ferrous or ferric iodide**—on a water-bath or under the influence of light.

According to J. J. Berzelius, gold does not unite directly with **sulphur** or with **selenium**; but, according to H. Pélabon, at a temp. just below its m.p. selenium dissolves some gold. J. Margottet[4] found that the vapour of tellurium attacks gold, forming gold telluride, and, according to H. Pélabon, molten tellurium dissolves gold, forming the same compound. It has long been known that soln. of the **alkali sulphides** dissolve gold—*vide* gold sulphides. According to G. F. Becker, one part of gold dissolves in 843 parts of sodium sulphide, Na_2S, at ordinary temp. A. Ditte observed no action when gold was sealed in a tube for 18 months in the presence of an alkali sulphide sat. with sulphur. C. A. Stetefeldt and T. Egleston observed that soln. of potassium or sodium sulphide dissolve gold in the cold, and **ammonium sulphide** at 145° to 180°. C. A. Stetefeldt and E. H. Russell found gold to be soluble in a soln. of **sodium thiosulphate** and other thiosulphates of the alkalies and alkaline earths. The action takes place in the cold, but more readily if heated—a gold sulphide is probably first formed, and this is dissolved by the alkaline soln. J. Moir found gold to be dissolved by acid soln. of **thiocarbamide,** particularly in the presence of oxidizing agents. J. Uhl found that **sulphur dioxide** does not attack gold when heated therewith, but it is converted into sulphur trioxide and sulphur. Gold is not attacked by **sulphuric acid,** but, according to A. H. Allen, V. Lenher, H. Pélabon, and J. Pelletier, the metal is attacked if an oxidizing agent is dissolved in the acid—*e.g.* the higher oxides of manganese or lead, nitric acid, permanganates, periodic acids or periodates, iodic acid or iodates, chromium or nickel sesquioxide, chromic anhydride, telluric acid, lead or copper nitrates, etc. O. P. Watts and N. D. Whipple also studied the action of sulphuric acid in the presence of soln. of various salts on gold. E. Sulkowsky says dil. sulphuric acid, mixed with hydrogen peroxide, does not attack gold. V. Lenher and G. Kemmerer said a hot mixture of nitric and sulphuric acid dissolves gold far better than does a soln. of potassium cyanide. M. E. Chevreul suggested that ozone is formed, but M. Berthelot and V. Lenher found that neither oxygen nor ozone attacks gold-leaf suspended in conc. sulphuric acid when these two gases are bubbled through the liquid, but gold is dissolved in the presence of nascent oxygen liberated when oxidizing agents are heated with sulphuric acid. According to C. J. T. von Grotthuss, M. Berthelot, etc., gold is also dissolved at the anode when conc. sulphuric acid is electrolyzed with a gold anode; with dil. sulphuric acid, the anode is covered with a film of oxide. According to F. H. Jeffery, gold is also dissolved from the anode in sulphuric acid in the form of complex ions, but by the time the yellowish-brown stage is reached there is an appreciable formation of gold cations. These may possibly arise from the reduction of the anions by hydrogen. The anode soln. yields auric hydroxide with little of the aurous compound on dilution with water. According to E. Harbeck, M. Margules, and W. G. Mixter, a $\frac{1}{10}N$-soln. of sulphuric acid behaves like nitric acid towards a gold anode. Similar results were obtained with **alkali bisulphates.** T. Egleston found a soln. of **ammonium sulphate** exerted no action on spongy gold when kept in a sealed tube for 8 months, or heated between 150° and 200° for 5 hrs.; but W. G. Mixter found a soln. of **potassium sulphate** and V. Lenher and G. Kemmerer a soln. of potassium sulphate, **potassium hydrosulphate** or **sodium sulphate** attacks a gold anode during electrolysis. According to E. Mitscherlich and V. Lenher, conc. **selenic acid** in the cold does not attack gold appreciably, the action begins at about 230°, and proceeds more quickly at about 300°, when selenium dioxide is evolved, and gold selenate, $Au_2(SeO_4)_3$, passes into soln. According to V. Lenher, **telluric acid** attacks gold in the presence of sulphuric acid. According to M. Berthelot, **persulphuric acid** has no action on gold. H. B. North found that an excess of **sulphuryl chloride,** SO_2Cl_2, in a sealed tube at 160°, slowly dissolves the metal, forming anhydrous auric chloride; while **thionyl chloride,** $SOCl_2$, at 150°, has no appreciable action, but after heating the mixture ten days at 200°, gold is dissolved. According to A. Ditte, **pyrosulphuryl chloride** attacks gold.

According to J. J. Sudborough,[5] **nitrosyl chloride,** NOCl, does not attack gold after many hours' exposure to that metal at 100°. In 1748, G. Brandt showed that gold is slightly soluble in **nitric acid**, but the soln. readily deposits the gold. T. Bergmann discussed the phenomenon from the point of view of the phlogiston theory. In 1780, however, M. Tillet said that while it is true that nitric acid attacks gold, it does not really dissolve it, but keeps it mechanically in suspension, and he claimed that these suspended particles are visible under the microscope. T. Bergmann pointed out that this proved only that particles of gold may be suspended in the acid and not that gold cannot be truly dissolved. According to F. P. Dewey, gold is slightly soluble in highly purified nitric acid, and the yellow soln. deposits gold on standing for a few days; while M. Hanriot and F. Raoult found that when finely divided gold is boiled with nitric acid of sp. gr. 1·180, 0·002 grm. is dissolved; with acid of sp. gr. 1·285, 0·0119 grm. is dissolved; with acid of sp. gr. 1·332, 0·028 grm.; and with the monohydrated acid, 0·076 grm. G. J. Mulder found that nitric acid dissolves an appreciable quantity of gold (or platinum) when that metal is alloyed with a large proportion of silver. G. H. Makins attributed the action to the presence of nitrous acid. In any case, there is a small loss of gold during the parting of gold and silver by the nitric acid process. T. K. Rose found that the spent acid used in parting during the assay of gold at the Royal Mint contained 1·2 mgrms. of gold per litre. According to M. Margules, C. J. T. von Grotthuss, M. Berthelot, and W. G. Mixter, gold is readily attacked when used as anode in the electrolysis of nitric acid. The yellowish-green soln. thus obtained is reduced by hydrogen, forming a brown precipitate. According to F. H. Jeffery, if a porous pot be used in the electrolysis of nitric acid (1 : 2) the cathode cell remains clear, and the soln. in the anode cell passes from green to yellowish-brown, and if evaporated in vacuo over sulphuric acid and sodium hydroxide, yellow crystals of **hydroauri-nitric acid,** $HAu(NO_3)_4.3H_2O$, are formed. If the soln. of this acid be diluted with water, auric oxide accompanied by some aurous oxide is deposited. The more dil. the acid electrolyte, the less the amount of aurous oxide formed. If precautions are not taken to prevent the accumulation of ammonium nitrate formed in the anode cell with dil. acid (1 : 20), an explosive compound is formed at the anode. V. Lenher and G. Kemmerer found that a gold anode is attacked during the electrolysis of neutral soln. of **potassium nitrate** or **sodium nitrate.**

According to P. Hautefeuille and A. Perrey, melted gold absorbs **phosphorus** vapour, and gives it out again, with spitting, on the solidification of the metal. A. Granger found that phosphorus vapour does not attack finely divided gold at low temp., but a reaction occurs at 400°, and gold phosphide is formed. When gold is heated in a sealed tube with **phosphorus pentachloride** at 180° to 200°, L. Lindet observed the formation of aurous chloride, phosphorus trichloride, and a double compound, $AuCl_2.PCl_5$; with **phosphorus trichloride,** under similar conditions aurous chloride and phosphorus are formed. V. Lenher and G. Kemmerer found gold is readily dissolved by **phosphoric acid** in the presence of oxidizing agents. O. P. Watts and N. D. Whipple also studied the action of phosphoric acid on gold. According to F. H. Jeffery, the electrolysis of 15 per cent. phosphoric acid with a gold anode results in the formation of soluble gold complex anions, but not cations. When the resulting soln. is diluted with water, auric and aurous chlorides are formed, so that the soln. contains **gold phosphate.** According to A. Sieverts and M. Major, a boiling soln. of **sodium hypophosphate** is catalytically transformed into sodium phosphite by precipitated gold.

T. Bergmann, in his *De arsenico* (Upsala, 1777), showed that molten gold takes up scarcely $\frac{1}{60}$th of its weight of arsenic. According to A. Hatchett, **arsenic** does not combine readily with gold in open vessels, but the vapour readily alloys with gold at a red heat, forming a grey fusible mass which does not give off all its arsenic when fused for two hours in an open crucible. A. Liversidge found that if arsenic vapour be passed over heated gold, the latter readily melts and, when cooling, the mass spits, and ultimately furnishes yellow spangles of gold arsenide. The affinity between gold and arsenic, however, is not very great. A. P. Schleicher has worked out that portion of the equilibrium diagram which is possible by the ordinary thermal methods, and it includes alloys with between 100 and 74·53 atomic per cent. of gold. The m.p. of gold is lowered by arsenic down to what appears to be a eutectic with about 46 and 47 atomic per cent. of arsenic at 665°. On cooling, the evolution of arsenic occurs suddenly at the eutectic. V. Lenher and G. Kemmerer found that **arsenic acid** dissolves gold in the presence of oxidizing agents, but the action is much slower than with sulphuric acid. According to C. Hatchett, gold unites with **antimony** when the two elements are fused together, and likewise when the vapour is passed over the red-hot metal. Antimony makes gold brittle, even so little as 0·052 per cent. making gold lose its malleability. The antimony gradually oxidizes and volatilizes when it is fused for some time in an open crucible. The m.p. curve by R. Vogel is shown in Fig. 7; it explains itself; an unstable gold diantimonide, $AuSb_2$, is formed. These alloys were also studied by W. C. Roberts-Austen. Alloys of gold with **bismuth** were also prepared by C. Hatchett; he found gold is rendered brittle when alloyed with but 0·052 per cent. of bismuth. A natural alloy of gold and bismuth with a little adherent mercury was found in Rutherford County (U.S.A.), sp. gr. 12·4–12·9. Its composition corresponds with AuBi, and it has been called *bismuthaurite*. From R. W. E. McIvor's analysis, G. H. F. Ulrich's *maldonite* found at Maldon (Victoria) has the composition Au_2Bi; it has been also called *black gold*. It was investigated by C. U. Shepard, and W. Vernadsky. C. T. Heycock and F. H. Neville studied the lowering of the f.p. of gold by bismuth; E. Maey the sp. vol. of the alloys; and R. Vogel has worked out the fusion curve shown in Fig. 8, which is self-explanatory. It recalls the corresponding curve for silver. W. C. Roberts-Austen and F. Osmond also made some observations on these alloys.

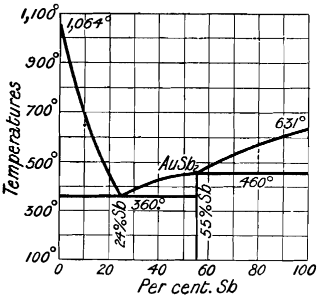

FIG. 7.—Fusion Curves of Mixtures of Gold and Antimony.

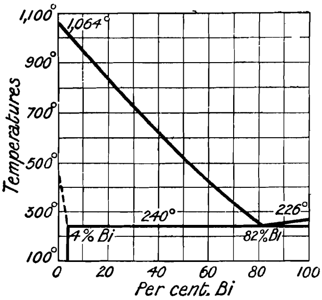

FIG. 8.—Fusion Curves of Mixtures of Gold and Bismuth.

O. Ruff and B. Bergdahl[6] found that molten gold can dissolve only traces of **carbon.** H. N. Warren found that **silicon** at the moment of its formation, so to speak, unites with gold much more readily than ordinary silicon, and a 5 per cent. alloy is best made by heating sodium and gold with potassium fluosilicate at a high temp. C. Winkler also made gold-silicon alloys and noted their brittleness. H. Moissan found that molten gold dissolves **carbon,** and rejects it as graphite on cooling. For gold acetylide, see acetylene. According to W. Muthmann and A. Schaidhauf, gold in the electrodes does not influence the decomposition of **carbon dioxide** in the electric arc. The solubility of gold in soln. of **alkali cyanides** has been previoulsy discussed. C. L. Jacobsen has discussed the passivity of gold in soln. of alkali cyanides. The electrolysis of amido-compounds, etc., which produce cyanides, also dissolve gold when they are electrolyzed. E. Beutel, and G. McP. Smith have studied the solubility of gold in soln. of **potassium ferrocyanide.**

The action is slow, but it is accelerated by heat. E. Beutel represented the reaction: $3Au+K_4FeCy_6+2H_2O+O_2=3KAuCy_2+Fe(OH)_3+KOH$. Soln. of the **thiocyanates** and many double cyanides also dissolve gold. According to W. Foster, and H. B. Giles, a neutral soln. of **potassium permanganate** is reduced by gold. H. H. Morris found gold is dissolved by soln. of **auric chloride** forming aurous chloride. H. von Euler studied the adsorption of silver ions from soln. of **silver nitrate and sulphate** by gold.

According to W. Dittmar,[7] fused **alkali hydroxide** does not attack gold to any appreciable extent, even when **alkali chlorate** is present, but the metal is attacked if an **alkali nitrate** be present. M. le Blanc and O. Weyl found that attack with dry potassium hydroxide begins below 670°, and small flecks of gold appear in the matrix. M. le Blanc and L. Bergmann found that in an atm. of nitrogen sodium hydroxide attacks gold but slightly. P. Bechtereff noticed that the molten sodium hydroxide is coloured yellow on account of oxidation. According to F. Meyer and W. L. Dudley, fused **alkali peroxide** readily attacks gold, forming the alkali aurate; **barium peroxide** attacks the metal to a less extent. The heat of the reaction with one gram of gold was found by W. G. Mixter to be 77 Cals., and for 2 grms., 30,400 cals. A Schiel, J. Spiller, M. Margules, and V. Lenher and G. Kemmerer found that a little gold is dissolved when soln. of the alkali hydroxides are electrolyzed with a gold anode; neutral salt soln. under similar conditions form a film of oxide on the anode. O. P. Watts and N. D. Whipple studied the action of soln. of sodium hydroxide and of various salts on gold; and also of **acetic acid** in the presence of oxidizing agents. A. Korczynsky studied the halogenation of aromatic hydrocarbons with gold as catalytic agent.

Reactions of analytical interest.—A soln. of gold trichloride acidified with hydrochloric acid is usually employed as a type to represent the gold salts. The action of potassium hydroxide, aqua ammonia, and of hydrogen sulphide are involved, and they are discussed in connection with auric chloride. The most important reactions depend on the ready reduction of auric salts to metallic gold, otherwise expressed, the auric salts are strong oxidizing agents—*e.g.* oxalic acid; ferrous sulphate; sulphurous acid; hydrogen peroxide; zinc with arsenic acid and ferric chloride; stannous chloride are oxidized. According to H. Rose,[8] stannous chloride produces a pale rose coloration with a dilution of 1 : 1,000,000; and the coloration is still recognizable with a dilution of 1 : 4,000,000. A. Stähler and F. Bachran found a drop of titanium trichloride colours a soln. of auric chloride an intense violet, and the reaction is almost as sensitive as the purple of Cassius' reaction. G. Armani and J. Barboni say that the coloration produced by formaldehyde in warm alkaline soln. is sensitive to 1 : 100,000. J. E. Saul found a $\frac{1}{10}$ per cent. soln. of *p*-phenylenediamine colours 10 vols. of a 0·005 per cent. soln. of auric chloride greenish-yellow. Several other organic compounds have been suggested as tests for gold.

Uses of gold.—Gold is largely employed in the manufacture of ornamental jewellery. The extensive use of this metal, said H. Sowerby,[9] wherever gorgeous ornament is required, as well as in the simplest designs of art—from the glittering crown of an emperor to the neat little wedding ring of the village maid—imparts to gold an interest in our eyes that other metals have failed to acquire. Gold alone is too soft to withstand wear and tear, and it is therefore alloyed with hardening metals like copper. Copper imparts a reddish tinge to gold, and this alloy was once called *red carat gold*. The term **carat** refers to a fractional part of 24, and is now used in stating the fineness of gold—*e.g.* pure gold is 24 carat; gold of 22-carats or 22-carat gold has 22 parts of gold and 2 parts of other metals. 22-carat gold is thus eq. to an alloy with 91·6 per cent. of gold and 8·3 per cent. of other metals. The British *gold coinage* is 22-carat gold. This alloy is termed *sterling or standard gold.* Brazil, Portugal, Turkey, India, Peru, Chili have the same standard; while America, France, Greece, Russia, Japan, and most other countries have a standard 90 per cent. of gold and 10 per cent. of baser metal, and this is therefore 21·6-carat gold. The gold coinage of the Sydney mint has the same amount of gold as the British, but silver is used in place of copper, so that the Sydney sovereign appears greenish-yellow beside that of Great Britain. The standard gold alloys recognized in the United Kingdom are 22-, 18-, 15-, 12-, and 9-carat. The percentage composition of these different standards is commonly :

	Gold.	Silver.	Base metals (mainly copper).
22-carat gold . . .	91·6	2·0	6·3
18-carat gold . . .	75·0	12·5	12·5
15-carat gold . . .	62·5	10·0	27·5
12-carat gold . . .	50·0	10·0	40·0
9-carat gold . . .	37·5	10·0	52·5

Articles made from these standard alloys can be *hall-marked*, or stamped with the imprimateur of certain Government offices to show that the metal is up to the standard claimed. 22-carat gold is mainly used for wedding rings; the best jewellery is made from 18- or 15-carat gold; and 9-carat gold is used for cheap jewellery which can be hall-marked. Much cheap jewellery is made from less than 9-carat gold, but it is not hall-marked. For gilding, gold-plating, and electroplating —see copper. The electrolyte for the electro-deposition of gold is made by dissolving 2·34 grms. of gold in aqua regia; evaporating the soln. on a water-bath to drive off the excess of acid; adding potassium cyanide soln. so long as a precipitate forms—avoiding an excess; washing the lemon-yellow precipitate by decantation; dissolving the precipitate in a soln. of potassium cyanide; and making the liquid up to about 500 c.c. For the properties of thin metal films—*vide* silver. W. Theobald has described the preparation of gold-leaf and thin metal films.

§ 7. The Atomic Weight of Gold

The early analyses of J. B. Richter,[1] J. L. Proust, A. Oberkampf, L. N. Vauquelin, and C. F. Bucholz gave rather discrepant results for the ratio by weight of gold to oxygen in the oxide of that metal. Of these, the analysis of A. Oberkampf comes nearest to that recognized at the present day. On the assumption that the at. wt. of oxygen is 5·5, J. Dalton wrote 105 for that of gold, and in his *A New System of Chemical Philosophy* (Manchester, **2**. 219, 1818), he wrote the at. wt. of gold 140, on the assumption that that of oxygen is 7. J. J. Berzelius assumed, in 1813, that the ratio of the atoms of gold to those of oxygen in gold oxide is 1 : 3, and he later regarded the ratio as being 2 : 3 ; he also discovered aurous oxide in which the ratio was taken to be 1 : 1. He obtained 2486 for the at. wt. of gold with oxygen 100 as standard ; with oxygen 16, this number becomes 2×198·8 ; and if the ratios of the atoms of gold in aurous and auric oxides be respectively 2 : 1 and 2 : 3, the at. wt. of gold is 198·8. J. J. G. Meinecke assumed the value to be 200 ; and L. Gmelin gave 66 for the eq. weight, which makes the at. wt. 198 when the formulæ of the two chlorides are AuCl and $AuCl_3$, and of the two oxides, Au_2O and Au_2O_3. The validity of the latter assumption was confirmed by the rule of Dulong and Petit; by Mitscherlich's isomorphic law; by J. H. van't Hoff's modification of Avogadro's rule; and by Mendeléef's periodic rule, whether gold be placed in the 11th series of the first group, or in the 10th series of the eighth group.

In 1813, J. J. Berzelius obtained the value 196·98 (assuming the at. wt. of mercury as 200·6), which is remarkably close to 197·2, the value accepted at the present day ; he obtained this result by weighing the gold precipitated by mercury from a soln. containing a known weight of auric chloride. In order to emphasize how far J. J. Berzelius was in advance of the chemists of his day, it may be mentioned that in 1819 J. Pelletier obtained 238, by weighing the gold remaining after a known weight of aurous iodide was calcined; that in 1821, J. Javal obtained 201 by the analysis of gold oxide, and 208 by the analysis of potassium chloroaurate ; and that in 1823, L. G. Figuier obtained 179, by the analysis of sodium chloroaurate. J. J. Berzelius, also in 1824, analyzed potassium chloroaurate, and calculating his result to present-day standards, he obtained 196·708 for the at. wt. of gold—a result not so good as his earlier determinations. In 1850, A. Levol reduced a soln. of auric chloride with sulphur dioxide, and determined the resulting sulphuric acid as barium sulphate. A gram of gold gave 1·782 grms. $BaSO_4$, which makes the at. wt. of gold 196·55. In 1876, J. Thomsen determined the ratio Au : 4Br=32·11 : 50 in hydrobromoauric acid, $HAuBr_4.5H_2O$, and this furnishes 197·48 for the at. wt. of gold.

In 1886, G. Krüss again opened up the subject in his memoir *Untersuchungen über das Atomgewicht des Goldes* (München, 1886). This memoir is often regarded as inaugurating the modern determinations of this constant. Hence the determinations of the at. wt. of gold may be conveniently grouped in three periods: (1) The inexact value obtained prior to J. J. Berzelius's investigations ; (2) the values obtained in the Berzelian era, which give as a best representative value 197·29 ; and (3) the modern era commencing with the work of G. Krüss. G. Krüss first determined the ratios $AuCl_3$: Au : 3AgCl, and obtained for the at. wt. of gold, 197·14 ; and in the remainder of his work he employed potassium bromoaurate from which five ratios were derived. In one set, the gold was reduced either by hydrogen or by sulphur dioxide and the consequent ratio $KAuBr_4$: Au gave 197·125 for the at. wt. of this element. In another set the bromine liberated during the sulphur dioxide reduction was determined as silver bromide and the resulting ratio Au : 4AgBr gave 197·156 for the at. wt. The weighing of the residue Au+KBr obtained after the hydrogen reduction gave the ratio Au : 3Br which furnishes the at. wt. 197·040 ; and when the resulting KBr in the residue was determined, the ratio Au : KBr enabled the at. wt. to be computed—the result was 197·077. The general mean of all G. Krüss's thirty measurements was 197·13. Independently of G. Krüss and partly overlapping, T. E. Thorpe and A. P. Laurie reduced the same compound by ignition, and the gold was determined by washing out the undecomposed bromide, and weighing the residue. This gave the ratio Au : KBr. The potassium bromide was also determined volumetrically by titration with a soln. of the silver salt for the ratio Au : Ag ; and also gravimetrically as silver bromide for the ratio Au : AgBr. These three ratios furnish the mean 197·25 for the at. wt. of gold.

In 1889, J. W. Mallet made seven series of determinations of the at. wt. of gold : (1) He analyzed auric chloride and obtained the ratio Au : 3Ag ; (2) likewise the bromide for Au : 3Ag ; (3) potassium bromoaurate, $KAuBr_4$, was then analyzed for the ratio $KAuBr_4$: Au : 4Ag ; (4) he also decomposed thermally the double salt trimethylammonium chloroaurate, $NH(CH_3)_3AuCl_4$, for the ratio $NH(CH_3)_3AuCl_4$: Au ; (5) he then electrolyzed potassium cyanoaurate, $KAuCy_2$, and potassium cyanoargentate, $KAgCy_2$, in the same circuit, and obtained the ratio Au : Ag ; (6) he also electrolyzed potassium cyanoaurate in circuit with the hydrogen voltameter for the ratio Au : H ; and finally, (7) he determined the hydrogen eq. of a given amount of zinc, and found the amount of gold this amount of zinc would reduce from a soln. of auric chloride or bromide. He thus obtained the ratio Au : 3H. The means in the different series were :

(1)	(2)	(3)	(4)	(5)	(6)	(7)
197·13	197·18	197·16	197·73	197·22	196·972	196·713

These results combined with the preceding give the general mean 196·722 ± 0·0129. The best representative value for all the determinations is 197·20 and the International value is 197·2. The **atomic number** of gold is 79.

§ 8. The Flocculation and Deflocculation of Colloidal Solutions

Adsorption by a liquid or solid is essentially specific, for the amount adsorbed necessarily varies with the nature of the adsorbing agent, the liquid, and the substance to be adsorbed. W. D. Bancroft[1] has compiled a large number of examples in his *Outlines of Colloidal Chemistry*, from which many of the following are selected. In illustration of selective adsorption L. and P. Wöhler and W. Pluddeman[2] found that charcoal and ferric oxide adsorb benzoic acid about ten times as strongly as acetic acid, while chromic oxide absorbs the two about equally well, and platinum black adsorbs acetic acid a little, and benzoic acid not at all. Salts generally have a tendency to adsorb their own ions—silver bromide adsorbs silver nitrate or potassium bromide, but not potassium nitrate ; charcoal adsorbs acid and basic dyes; alumina adsorbs acid dyes readily but not so with basic dyes; silica and tannin adsorb basic dyes the more readily; and wool adsorbs many dyes strongly without a mordant, while cotton adsorbs relatively few. G. T. Davis found that the order of adsorption of iodine from soln. of different substances was not the same with different kinds of charcoal.

A. Müller and H. Weiske have shown that filter paper adsorbs so much barium, strontium, or calcium hydroxide from dil. soln. as to interfere with the use of filter paper for certain quantitative work. T. Bayley, J. U. Lloyd, M. A. Gordon, L. H. Skraup, etc., have studied the adsorption of salts by filter paper. The general results show: (1) filter paper shows selective adsorption for water and for each constituent of the soln.; (2) if the solute is adsorbed relatively faster than the water there will be formed a water-ring; (3) if the water is adsorbed relatively faster than the solute, the latter will concentrate in the outer zone.

If a substance adsorbs a base more strongly than an acid, there will be a tendency for that salt to hydrolyze in soln. Similar remarks apply if the acid be adsorbed the more strongly. For instance, there is no doubt a slight hydrolysis of sodium chloride in aq. soln.: $NaCl+H_2O \rightleftharpoons NaOH+HCl$, but the action is so slight that it cannot be detected under ordinary conditions and the soln. appears neutral. If one product of the hydrolysis be removed from the system, say, the sodium hydroxide, the hydrolysis can go further, and the soln. will become acid. F. K. Cameron showed that if fuller's earth be shaken with water, the filtrate remains neutral to litmus or to phenolphthalein, proving that no soluble acid or alkali is present; but if the fuller's earth be shaken with a soln. of sodium chloride, the filtrate is acid to litmus and phenolphthalein. Moist fuller's earth will remove alkali from slightly reddened phenolphthalein, and the colour disappears; moist fuller's earth acts similarly when pressed against litmus paper, the paper is reddened by the earth adsorbing the base from neutral litmus.

J. E. Harris found that sandy loams, and china clay which had been treated with an acid, and the soluble acid removed by washing, adsorb the base from soln. of sodium acetate, potassium nitrate, or sodium chloride. L. Liebermann reported that animal charcoal will not remove the base from a soln. of sodium chloride, but that it will do so from soln. of sodium acetate or phosphate. Cupric or ferric hydroxides, so called, adsorb the acid; and boneblack adsorbs unchanged calcium or barium chloride from the aq. soln. P. Yorke also observed that filter paper adsorbs lead oxide from a soln. of lead oxide in lime water. L. H. Skraup noted that lead acetate soln. loses lead oxide and becomes more acid when passed through filter paper; L. Vignon obtained an analogous result by the action of cotton wool on soln. of mercuric chloride.

G. C. Schmidt found that in the simultaneous adsorption of iodine and acetic acid by charcoal from soln. of iodine in water and in ethyl acetate, less of each substance was adsorbed than if the other had been absent. H. Freundlich and M. Masius obtained similar results ~~with pairs~~ of organic acids, and they also found that the acid which is absorbed the more is displaced the less when the two acids are present in soln.

H. Lachs and L. Michælis found sodium hydroxide reduced the adsorption of potassium chloride from water, while the presence of sulphuric acid increased the adsorption in agreement with Y. Osaka's observation that ~~potassium~~ chloride is adsorbed more than potassium sulphate, and sodium chloride more than sodium sulphate. W. Skey also found that charcoal will remove traces of nitric acid from dil. but not from conc. sulphuric acid —otherwise expressed, with an increase in the conc. of the sulphuric acid there is an increasing displacement of nitric acid from the charcoal, so that less is adsorbed from the conc. acid. H. Freundlich and H. Kämpfer found that the presence of thorium salts reduce the adsorption of uranium salts by charcoal; P. Rona and L. Michælis, that acetone and acetic acid decrease the adsorption of glucose by charcoal; and D. B. Lake, that albumin and acetone have no effect each on the other.

H. Freundlich[3] assumes that adsorption by colloids is accompanied by a lowering of the surface tension of the absorbing phase. He bases his reasons on J. W. Gibbs' well-known formula $\mu = -(C/RT)(d\sigma/dC)$, but as W. D. Bancroft has shown this is a *mal*-application, because J. W. Gibbs' deduction refers to true soln., and not to suspensions. H. Freundlich's conclusion, however, is a valid empirical generalization, and it therefore follows that any substance A which is adsorbed by a second substance B lowers the surface tension of B, and will therefore tend to disintegrate it so as to form a colloidal soln. The term **peptization**—πέψις, digestion—was coined by T. Graham to denote the disintegration or deflocculation of a colloid so as to form a colloidal soln.; the converse coagulation or flocculation was also called *pectization*—πηκτός, curdled. The assumption now made is that every adsorbed substance tends to peptize the adsorbing substance.

W. D. Bancroft[4] has collected together a mass of evidence in support of this hypothesis from which the following examples are selected: We may have peptization by a liquid, by a non-electrolyte, by an adsorbed ion, by a salt, or by a peptized colloid. When a liquid is adsorbed by a solid, it will tend to peptize it, and in some cases will do so. Water peptizes tannin, amyl acetate peptizes pyroxylin, and fused salts peptize metals. At higher temp. the peptizing action increases, and we may get glass peptized by water or vulcanized rubber by various organic liquids. Gelatine is not peptized by cold water, but is by warm water. J. Weisberg found calcium silicate seems to dissolve in a sugar soln. What really happens is that it is peptized by the sugar soln. A conc. soln. of sugar in water will prevent the precipitation of calcium silicate. C. A. L. de Bruyn found that silver chromate and silver chloride are peptized by sugar; also T. Graham noted that lime is held in apparent soln. in the presence of sugar, and E. Riffard noted that sugar prevents the precipitation of the hydrous oxides of copper and iron by ammonia; and E. Grimaux noted that glycerol prevents the precipitation of hydrous ferric oxide by potassium hydroxide.

A. Lottermoser found that by adding a slight excess of $\frac{1}{20}N$-potassium chloride, bromide, or iodide to $\frac{1}{20}N$-silver nitrate, the silver halide remained in soln. Freshly precipitated silver chloride is peptized by silver nitrate or potassium bromide, and in each case the silver or bromide ions are adsorbed, and, as L. Cramer has shown, the peptization of silver iodide and silver bromide gels by the corresponding halogen ion takes place in a striking manner in the presence of gelatine. J. M. Eder said:

If we precipitate silver bromide from a cold aq. soln. containing no gelatine or other similar substance, we get a coarse, compact precipitate which can easily be washed on a filter. If we pour this precipitate into a warm soln. of gelatine and shake, the silver bromide disintegrates and forms a fine emulsion. Under these circumstances the silver bromide behaves differently, depending on whether it has been precipitated in presence of an excess of bromide or of silver salt. This difference is noticeable no matter how carefully the silver bromide is washed.

A. Müller peptized thorium hydroxide by a soln. of thorium nitrate, and zirconium hydroxide by zirconium nitrate; while B. Szilard peptized the rare earth hydroxides by soln. of the chlorides or nitrates of the same elements. C. F. Nagel showed that the apparent soln. of hydrated chromic oxide in chromic chloride soln. is a case of peptization. H. W. Fischer and W. Herz, and C. F. Nagel found the apparent soln. of chromic oxide in an excess of potassium hydroxide soln. is a case of peptization; A. Hantzsch found the apparent soln. of beryllium hydroxide in potassium hydroxide comes in the same category, so also O. Loew's and H. W. Fischer's observations of the action of caustic alkali on hydrated copper oxide, and C. Tubandt's on hydrated cobalt oxide with the same menstruum. Freshly precipitated zinc hydroxide was found by W. D. Bancroft to be peptized by caustic alkali, but the soln. is so unstable that it coagulates in half an hour, and the relatively small amount of zinc remaining in soln. is present as alkali zincate. This explains the results of A. Hantzsch, H. W. Fischer and W. Herz, and O. Klein with the same reagents. According to E. G. Mahin, D. C. Ingraham, and O. J. Stewart, alumina is peptized by alkali-lye, but the work of W. Herz, A. Hantzsch, J. Rubenbauer, M. H. Fischer, R. E. Slade, and F. Blum show that it goes into soln. mainly as sodium aluminate. T. Graham showed that gelatinous silicic or stannic acid is peptized by sodium hydroxide. A. Müller prepared colloidal soln. of aluminium, iron, cobalt, thorium, and yttrium oxides by peptization with $\frac{1}{20}N$-HCl; W. B. Bentley and R. P. Rose peptized alumina with 8 per cent. acetic acid.

Sulphides are peptized by hydrogen sulphide, for S. E. Linder and H. Picton found an excess of the last-named agent was necessary for the preparation of stable colloidal arsenious sulphide, and S. W. Young and W. R. Goddard showed that such sulphides can be repeatedly precipitated and peptized by removing or adding hydrogen sulphide, so that flocculation by electrolytes is not always an irreversible process W. Spring found that copper sulphide prepared from a dil. ammoniacal soln. of the sulphate, and free from ammonium salts is peptized to a brown soln. by hydrogen sulphide soln. J. N. Mukherjee and N. N. Sen made some observations in the same direction. E. Prost peptized cadmium sulphide in a similar manner. C. Winssinger prepared a colloidal soln. of zinc sulphide by the action of a soln. of hydrogen sulphide on freshly precipitated zinc sulphide.

J. Lefort and P. Thibault found that mercuric sulphide precipitates rapidly if mercuric chloride be added to the sulphur springs of Bagnères de Luchin, but no precipitation occurs if soln. of gum arabic, albumin, and other decoctions be present. Experiments with sulphides of lead, silver, iron, manganese, mercury, copper, zinc, antimony, and arsenic give similar results if the soln. of the salts be sufficiently dil. and enough gum arabic is added; metallic hydroxides behaved similarly. The formation of many other precipitates was also prevented by gum arabic. M. Lachaud found dextrine prevents the precipitation of ferric hydroxide by ammonia. C. Schiaparelli found saponin peptizes lead sulphate, barium carbonate, and other salts; W. Spring says soap peptizes rouge, charcoal, etc. These substances are often called *protective colloids* because they prevent the agglomeration and settling of finely divided precipitates. Caseine is not peptized by water, but is peptized by acids and alkalies, and then acts as a protecting colloid. C. F. Nagel, and A. B. Northcote and A. H. Church found that hydrous chromic oxide is peptized by caustic potash and can then prevent the precipitation of hydrous ferric oxide, etc. If too much ferric oxide is present, all the chromic oxide is carried down by it. M. Prud'homme found that colloidal copper oxide peptized by ammonia causes the peptization of chromic oxide by ammonia.

The particles in suspension in colloidal soln. are electrically charged, and in the majority of cases, if water be the dispersion medium, the charge is negative in agreement with A. Cöhn's rule[5] that when two substances are electrified by friction, the substance with the higher dielectric constant takes on the positive charge while the other substance takes the negative charge. Water has a relatively high dielectric constant, and hence, if the particles are charged by a process analogous to frictional electricity, the probability is, that they will be electrified with a negative charge. On the other hand, the dielectric constant is low, and G. Quincke found that with the exception of sulphur all the substances he tried were positive in this menstruum. E. F. Burton's experiments are also in agreement with the rule.

The electric change on colloidal particles can be conveniently demonstrated by S. E. Linder and H. Picton's experiment in which the liquid was placed in a U-tube fitted with electrodes charged to a high potential—say 110 to 220 volts. It was found that suspended particles of shellac, starch, sulphur, gold, silver, platinum, cadmium, metallic chlorides and sulphides, Prussian blue, silicic acid, stannic acid, clay, molybdenum blue, aniline blue, etc., travel to the anode, and therefore the particles are presumably charged negatively; on the other hand, particles of various metal hydroxides—*e.g.* ferric, chromic, aluminium, cadmium, zinc, thorium, zirconium, and cerium hydroxides—titanic acid; the metals lead, bismuth, and iron; methylene blue, etc., migrate to the cathode and presumably carry a positive charge.

W. B. Hardy showed that albumin in an alkaline soln. is negatively charged; in an acid soln., positively charged; and in a neutral soln. it is neutral; and J. Billitzer found that colloidal platinum in chloroform is positively charged, and in water negatively charged; and H. B. Weiser obtained colloidal soln. of positively and negatively charged barium sulphate. W. Pauli obtained similar results with proteids; J. Perrin, with many suspended powders and hydrosols; and F. Powis with ferric hydroxide. A. Cöhn observed that sugar migrates to the anode in dil. alkali soln., and to the cathode in dil. acid soln.

F. F. Reuss, in 1808, discovered the transport of both liquid and solid in a system composed of a liquid with a finely divided solid:

He inserted into a lump of moist clay two vertical glass tubes, filled them with water and dipped an electrode into each. On establishing a potential gradient between the electrodes, F. F. Reuss noticed to his surprise that the liquid rose in one tube and sank in the other, and that furthermore a decided turbidity developed in that tube in which the water-level sank. There had occurred, in short, a transfer of liquid to the cathode through the more or less porous clay diaphragm and, besides this, a simultaneous migration of some of the detached clay particles, the effects taking place in opposite directions.

H. Freundlich classified the electro-kinetic effects in a two-phase system of liquid and solid as follows:

> (1) A difference of potential sending a current through the system may produce a relative displacement of the phases: (*a*) if the solid is fixed in the form of a porous diaphragm the liquid may move through the diaphragm (*electrical endosmose*); (*b*) if the solid is in the form of a suspension and is free to move, the solid may migrate through the liquid (*cataphoresis*). (2) A relative displacement of the phases may produce a difference of potential and consequently an electric current through the system: (*a*) if the solid is fixed in the form of a porous diaphragm through which liquid is forced, a difference of potential and an electric current may be established between the extremes of the diaphragm (*G. Quincke's diaphragm currents*); (*b*) if the finely divided solid is dropped through the liquid, a difference of potential and a current may be set up between the upper and lower liquid strata (J. Billitzer's experiments).

The velocity of migration V of the disperse phase with a fall of potential E volts per cm., when the potential difference of the double layer is ϵ, and the dielectric constant and viscosity of the liquid are respectively K and η, is obtained from $V=\frac{1}{4}\epsilon EK/\pi\eta$. For glass and water with a fall of one volt per cm., M. von Smoluchowsky[6] calculated a velocity of migration of 34×10^{-5} cms. per second. Various measurements have been made by S. E. Linder and H. Picton, W. R. Whitney and J. C. Blake, E. F. Burton, A. Cotton and H. Mouton, etc., and the results for arsenious sulphide, quartz, gold, platinum, silver, iron, and ferric oxide range from 19 to 40×10^{-5} cms. per second with a fall of potential of one volt per cm. This means that the velocity is nearly independent of the size and form of the particles. The velocity of migration of the suspensoid is nearly the same as that of an average slowly moving ion—thus, for $Li^{\cdot}$, the velocity is 36×10^{-5} cms. per second with a fall of potential of one volt per cm. E. F. Burton estimated the magnitude of the charge on particles of gold and silver soln. and found for silver soln. $2{\cdot}8\times10^{-2}$ electrostatic units, so that the charge on a gram-eq. of colloidal silver is about 4 per cent. of the charge on a silver ion, $Ag^{\cdot}$. Calculations have also been made by W. C. McC. Lewis, by H. Lamb, and by H. Freundlich. The charge e on a particle is $e=6\pi\eta rV/E$, where r denotes the radius. The charge on a particle of colloidal platinum of radius 50 $\mu\mu$ and velocity 2μ is 297×10^{-10} electrostatic units, a quantity nearly eq. to that of 99 chloride ions.

In 1870, W. S. Jevons[7] assumed that the minute particles in a colloidal soln. acquire their electric charge by friction against the solvent as a dielectric, and he also supposed that the mutual repulsion of like charges prevented the coalescence of the particles. A. Cotton and H. Mouton, H. Lamb, and others interpreted this in terms of H. von Helmholtz's theory of the double electric layer formed by friction, so that the charged particle, with an opposing charge of opposite sign in the surrounding dispersion medium acts as a spherical condenser with oppositely charged concentric plates, Fig. 9. It is necessary to assume that there is a slip between the two coatings, for if they were fixed the particles would remain motionless in the electric field. This hypothesis may explain the origin of the electric charge in non-conducting soln., but in other cases the trend of opinion is that the disperse phase absorbs electrically charged ions from the soln., and, in the case of colloidal soln. of the metals formed by G. Bredig's process of sparking the metals under water, H. T. Beans and H. E. Eastlack believe that an oxide of the metal is formed and adsorbed during the sparking. The negatively charged platinum, gold, etc., are much more stable if chlorides, bromides, iodides, or hydroxides be present.

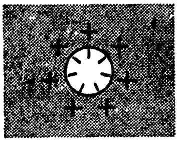

Fig. 9.

The electrical conductivity of colloidal soln. is very small, and is so little different from the liquid medium that it is not easy to decide what part of the conductivity is due to the medium, and what to the sol, or to the adsorbed impurities which cannot be removed from the colloid by washing or dialysis. For example:

	Specific conductivity in mhos.	
	Sol.	Medium.
Gold	$1{\cdot}4 \times 10^{-6}$	$0{\cdot}81 \times 10^{-6}$
Ferric hydroxide	$35{\cdot}7 \times 10^{-6}$	$2{\cdot}00 \times 10^{-6}$

W. R. Whitney and J. C. Blake[8] found the conductivity of gold hydrosol to diminish with repeated electrolysis, and finally approached a limiting value approximately that of the medium itself. When a soln. is placed in a U-tube, Fig. 10, fitted with suitable electrodes, during electrolysis, the suspended particles move through the liquid towards one electrode, and away from the other. The suspended particles move in the direction which reduces the electrical stress when a difference of potential is established in the liquid. This motion of the solid through the liquid is often called *cataphoresis* or *kataphoresis* (κατὰ φορά, a bringing down).

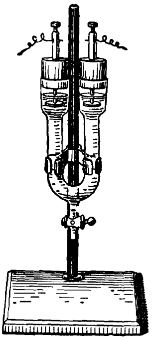

FIG. 10. — The Migration of Suspensoids during Electrolysis.

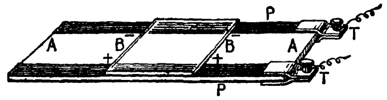

FIG. 11.—Microscopic Slide for observing the Migration of Colloids during Electrolysis.

A. Cotton and H. Mouton have designed a neat apparatus. Two strips of platinum foil *PP*, Fig. 11, to serve as electrodes, are cemented to a glass slip *AA*. These strips of foil are gripped by a pair of terminals *TT*. A drop of the liquid under examination is placed on the slide so that it touches both electrodes, and the cover glass *BB* is placed in position in the usual way. The preparation is then examined under the microscope. The movements of the particles towards one electrode and away from the other electrode can be readily observed.

Suspensoids can be ranged in two groups according as they migrate towards the anode or the cathode. S. E. Linder and H. Picton (1892) noticed that colloidal arsenious sulphide travelled towards the anode, and ferric hydroxide towards the cathode. It is therefore inferred that the particles in some sols are positively charged, and others negatively charged.[9]

Positively charged sols (to cathode).	Negatively charged sols (to anode).
Metal hydroxides	Metals and their salts
Titanic acid	Sulphur, selenium, iodine
Lead } are	Vanadium pentoxide
Iron } probably	Clay, quartz, felspar, asbestos
Bismuth } hydroxide sols	Starch, shellac, amber
Magdala red	Aniline blue, fuchsine, tungsten blue
Methyl violet	Gamboge, mastic, caramel
Methylene blue	Silicic and stannic acids
Albumen, agar-agar, hæmoglobin	

The solvents make a difference ; thus most of those substances which move towards the anode when suspended in water, travel in the opposite direction in turpentine.[10] The magnitude of the charge can be estimated from the rate of transit of the particles and the strength of the electric field. The velocity is independent of the size and shape of the particles, and is found to be of the same order of magnitude as the migration velocities of slowly moving ions, and is not far from 34×10^{-5} cms. per second with a difference of one volt in the fall of potential. The actual numbers are :

Silver.	Gold	Platinum.	Arsenious sulphide.	Ferric hydroxide.
19 to 33×10^{-5}	21 to 40×10^{-5}	20 to 30×10^{-5}	22×10^{-5}	30×10^{-5} cms. per second

The extraordinary sensitiveness of colloids to chemical reagents attracted attention very early,[11] In 1824, for example, J. J. Berzelius noted that colloidal boron is precipitated by acids and salts ; in 1846, H. W. F. Wackenroder noticed that colloidal sulphur was precipitated by the addition of an acid to a soln. of a polythionate; E. Frémy marked the precipitation of soln. of silicic acid by soluble alkalies; H. B. Weiser, the precipitation of some colloids by mixed electrolytes; W. Crum, the coagulation of colloidal alumina by salts and acids; T. Scheerer, the clarification of turbid soln. by strong acids and their salts. M. Faraday also noticed that his gold sols changed colour when treated by a salt; and T. Graham, discussing this very action, said:

> The colloid, although often dissolved in a large proportion of its solvent, is held in soln. by a singularly feeble force. Hence, colloids are generally displaced or precipitated by the addition to their soln. of any substance from the other class (crystalloids).

In general, the clarification of turbid soln., due to very small suspended particles which settle very slowly, if at all, is promoted by the addition of soluble electrolytes; non-electrolytes do not act in this manner. Thus, T. Schlösing found that the addition of 0·0001 or 0·00001 part of calcium or magnesium salts will clear water from suspended clay. This is supposed to explain the marked clarity of hard waters. A turbid suspension of clay which does not clear after standing for months will be clarified in half an hour after the addition of a trace of sodium chloride, or a drop of sulphuric acid. This partially explains the precipitation of mud at the mouths of fresh-water streams where they come in contact with the salt of the sea.

The susceptibility of colloids to the influence of electrolytes varies very much; some require large amounts of certain salts to effect precipitation, and are not affected by other salts. W. S. Jevons noticed, in 1870, the addition of acids, alkalies, or salts, independently of their constitution, stilled the Brownian movements, and coagulated the suspension. R. Zsigmondy thus described the effect of adding an electrolyte to a colloidal soln. with ultramicroscopic particles in suspension, as it appears under the ultramicroscope:

> The light cone first becomes visible; wavy nebulæ appear; the clouds thicken; and tiny individual particles with an active Brownian movement come into view. Where the particles unite, they turn about their common centre of gravity, and the Brownian movement begins again, but more sluggishly than before.

When the particles have settled, the Brownian movement ceases owing to the large size of the aggregates. The gradual discharge of the disperse phase has been followed by E. F. Burton, and T. Svedberg, and the latter showed that the amplitude of the Brownian movement was the same whether colloidal silver was neutral or charged positively or negatively, thus showing that the Brownian movement is not due to electrical causes.

A definite concentration of the electrolyte is necessary for the complete precipitation of the colloid, smaller or larger amounts may cause partial precipitation, or none at all. For example, H. Freundlich found that the addition of 1·219 and of 2·428 milligram-molecules of potassium chloride to a soln. containing 11·272 milligram-molecules of arsenious sulphide in suspension, produced very little result at the end of 340 days—about 1·8 milligram-molecules of the sulphide, at most, were precipitated—but with 3·9 milligram-molecules of potassium chloride, nearly the whole of the sulphide was precipitated. W. B. Hardy, H. Freundlich, E. F. Burton, J. Duclaux, A. Lottermoser, F. Powis, H. R. Kruyt and co-workers, etc., have studied the effect of traces of electrolytes on the stability of colloidal soln. W. B. Hardy showed that the flocculation of a colloidal soln. occurs exactly at that conc. of the electrolyte which can stop cataphoresis, but later observations have shown that this hypothesis requires modification. It is a curious fact that if the precipitating agent be added slowly, in small portions at a time, a larger amount is required for complete precipitation than if the reagent be added quickly. The difference is greater the slower the reagent is added. Thus, 2 c.c. of a soln. of barium chloride flocculated colloidal arsenious sulphide immediately when added at once, but if added to an equivalent soln. slowly, drop by drop, only a relatively small part of the colloid was precipitated in 45 days.[12] Using metaphorical language, it has been said that the sol becomes acclimatized to the reagent when the latter is added slowly.

It has been a favourite assumption[13] that the stability of a sol colloid is due to the formation of a chemical complex. For example, silver hydrosol has been regarded as $x\text{Ag}.y\text{AgOH}$; arsenious sulphide as $x\text{As}_2\text{S}_3.y\text{H}_2\text{S}$; etc.; and T. Graham has said that "the basis of colloidality may really be the composite character of the molecule." However this may be, V. Henri and A. Mayer consider that it is somewhat doubtful if the precipitating agent unites chemically with the sol colloid, because the amount of salt associated with the colloid varies with the conc. of the salt in the liquid, in agreement with the general law of adsorption of substances by colloids.

According to W. B. Hardy,[14] **the ion which is active in coagulating a given colloidal sol has a charge of opposite sign to that of the colloid**; consequently, the precipitating power of an electrolyte depends upon the valency of the ion whose electric charge is of opposite sign to that of the colloid. H. Freundlich calls this **Hardy's rule,** and it has been confirmed by the work of H. Freundlich, H. Picton and S. E. Linder, J. Perrin, and others. In 1882, H. Schulze showed that **the precipitating power of an electrolyte for a given colloidal solution depends upon either the anion or the cation, but never on both, and it increases rapidly with the valency of the active ion.** This has been called *Schulze's law.* The precipitating power of electrolytes falls into groups according to the valency of the active ion. Thus, with arsenious sulphide, which is a negative sol, the electrolytes with a univalent cation—$H^{\cdot}$, $Na^{\cdot}$, $K^{\cdot}$, . . .—fall into one group with the smallest precipitating power; the bivalent cations—$Ca^{\cdot\cdot}$, $Ba^{\cdot\cdot}$, $Mg^{\cdot\cdot}$, $Zn^{\cdot\cdot}$, . . .—fall into a second group; and the tervalent cations—$Al^{\cdot\cdot\cdot}$, $Fe^{\cdot\cdot\cdot}$, . . .—fall into a third group with the greatest precipitating power. Table VII shows the minimum conc. of the given salts required to coagulate the negative colloid in a sol containing 14·71 milligram-molecules of arsenious sulphide per litre. In this particular case, therefore, the precipitating power of ter-, bi-, and uni-valent cations is approximately as 1 : 8 : 500. N. Bach found the coagulating power of the alkali ions is in the order $Cs^{\cdot} > Rb^{\cdot} > NH_4^{\cdot} > K^{\cdot} > Na^{\cdot} > Li$; and the halogen ions, $Cl' > Br' > I'$. A. Westgren found that the coagulating power of an electrolyte to be independent of the size of colloidal gold particles; and that the velocity of coagulation is greater, the greater the migration velocity of the anion. O. Herstad showed that soln. of mercuric chloride with a comparatively small degree of ionization have a much greater coagulating power on gold hydrosols than most salts of the heavy metals, more strongly ionized. The coagulation is inhibited by hydrochloric acid. He supposes a film of mercury oxide is formed about the colloidal particles of gold which transform the negative colloid into a positive one. W. C. D. Whetham recast Schulze's law in the form:

> The coagulating power or the reciprocal of the minimal conc. of a series of ions of the same sign is proportional to a constant raised to the power representing the valency of each ion, so that if P_1, P_2, and P_3 represent the coagulating powers of a uni-, bi-, or tri-valent radicle, $P_1 : P_2 : P_3 = K : K^2 : K^3$, where K is a constant.

TABLE VII.—THE PRECIPITATING POWER OF ELECTROLYTES ON ARSENIOUS SULPHIDE

Univalent cations.		Bivalent cations.		Tervalent cations.	
Salt.	Mgrm. mols. per litre.	Salt.	Mgrm. mols. per litre.	Salt.	Mgrm. mols. per litre.
KI	67·1	$BaCl_2$	0·94	$AlCl_3$	0·13
KCl	69·1	$BeSO_4$	1·13	$Al(NO_3)_3$	0·14
KNO_3	69·8	$MgCl_2$	1·00	$\frac{1}{2}Ce_2(SO_4)_3$	0·13
LiCl	81·5	$CaCl_2$	0·905	—	—
HCl	42·9	$Ca(NO_3)_2$	0·945	—	—
NH_4Cl	59·1	$ZnCl_2$	0·956	—	—

H. B. Weiser and E. B. Middleton noted that in the precipitation of colloidal aluminium hydroxide, the most readily adsorbed ion precipitates in the lowest conc. and conversely. The order of adsorption deduced from the precipitation values, expressed in eq., is ferrocyanide, thiosulphate, ferricyanide, citrate, sulphate, oxalate, phosphate, chromate, dithionate, dichromate, chloride, nitrate, bromide, and iodide. H. R. Kruyt and co-workers have studied the flocculation of gold sols by thorium nitrate, by colloidal thorium oxide, and by potassium, barium, and aluminium salts; H. D. Murray, of colloidal sulphur; N. Bach, of colloidal arsenic sulphide and ferric hydroxide by the alkali halides; J. N. Mukherjee and N. N. Sen,[15] and J. Mukhopadhyaya, the effect of dilution and temp. on arsenic sulphide. H. D. Murray tried to get a general expression for the precipitating action of ions on colloids, and found, for univalent cations with the same anion, for negatively charged colloids $C=K.N^n$, where C is the minimum conc. for colloidal precipitation; N, the at. number of the cation; n, is a constant for the colloid at a given conc.; and K is a constant dependent upon the nature of the colloid, and on the anion.

W. D. Bancroft has emphasized the fact that the disperse phase in a colloidal soln. is electrically charged by the preferential or specific absorption of some ion; so long as all the particles are charged positively or negatively, they will repel one another and not coalesce. Neutralization of the charge causes precipitation through adsorption, and that in all probability the neutralization of an adsorbed ion is another case of specific adsorption. The precipitating power of an electrolyte depends on the degree of its adsorption by the disperse phase. According to this hypothesis, H. Schulze's law means that tervalent ions are adsorbed more strongly than bivalent ions, and bivalent ions more strongly than univalent ions. This is the usual state of things, but Y. Osaka has shown that charcoal adsorbs potassium salts in the following order: $KI > KNO_3 > KBr > KCl > K_2SO_4$ for eq. conc., therefore, the sulphate ion is adsorbed least of all. If selective adsorption be the cause of the action, it may be predicted that some univalent ions will be adsorbed by some substances more than some bi- or ter-valent ions. This is shown to be the case with S. Odén's experiments on the influence of different salts on the coagulation of colloidal soln. of sulphur. The eq. precipitating power of cæsium chloride is nearly five times as great as that of cadmium nitrate, zinc sulphate, or nickel nitrate, and greater than magnesium sulphate, manganese nitrate, or copper sulphate. H. Freundlich found bivalent lead has nearly the same precipitating power on colloidal platinum as tervalent aluminium; and mercurous nitrate, $HgNO_3$, a greater coagulating power on mastic than zinc sulphate, calcium chloride, or barium chloride. There are also exceptions to Schulze's rule to be observed in the work of N. Pappada, on Prussian blue and copper ferrocyanide; of H. Freundlich and H. Schucht, on arsenious sulphide and hydrated ferric oxide; of J. N. Mukherjee and N. N. Sen on the coagulation of sulphide soln. where adsorption of the electrolyte does not take place to any marked extent. W. D. Bancroft further showed that in the case of albumin there is not even a suggestion of Schulze's law in the observed results. Instead of the cations being alone effective in the coagulation of negatively charged sols, and anions in the coagulation of positively charged sols, W. D. Bancroft shows that in virtue of the preferential adsorption, the nature of both ions must be taken into consideration. Schulze's law is to be regarded as a first approximation because the precipitating power of an ion depends on its absorption by the disperse phase, and that the higher valent ions are adsorbed more than those of lower valency and have accordingly a greater coagulating power.

T. Graham, H. Picton and S. E. Linder,[16] and A. Lottermoser have noted the mutual precipitation of colloidal sols having opposite charges, and that if the charges be alike no precipitation occurs. W. Biltz showed that it is necessary for the admixture to be made in proper proportions, for if either one is in excess, there may be no precipitation, as in a case recorded by W. Spring. Thus, with 2 c.c. of a soln. of 0·56 mgrm. antimony trisulphide, and 13 c.c. of a soln. of ferric oxide, the product was turbid and homogeneous with 30·8 to 12·8 mgrms. Fe_2O_3; slow precipitation occurred with 8·0 mgrms. Fe_2O_3; complete precipitation with 6·4 mgrms. Fe_2O_3; and a yellow soln. with flocks with 4·8 and 3·2 mgrms. Fe_2O_3; and a yellow turbid soln. with no flocks with 0·3 mgrm. Fe_2O_3 per 13 c.c. of liquid. This conclusion was confirmed by H. Bechhold, M. Neisser and U. Friedemann, and V. Henri. W. D. Bancroft has emphasized the fact that adsorption may occur when two sols with charges of the same sign are mixed. "Since complete neutralization takes place only when one sol has adsorbed the amount of the sol carrying an *equivalent* amount of the ion having the opposite charge, it follows that the amount of one sol necessary to precipitate a given amount of another sol will vary with the degree of adsorption; it will therefore be a specific property and not an additive one," and he shows that the data of W. Biltz on the precipitation of colloidal gold, colloidal antimony, or arsenic sulphide fit in with this conclusion.

T. Graham observed that a rise of temp. of 1° occurred during the coagulation of a 5 per cent. soln. of gelatine; J. Thomsen could detect no measurable heat change during the coagulation of silicic acid, but E. Wiedemann and C. Lüdeking found 11·3 to 12·2 cals. per gram; and H. Picton and S. E. Linder reported that no measurable heat change attends the coagulation of ferric oxide or of arsenic or arsenious sulphides. According to F. Dörinckel, the heat of coagulation of silicic acid and of ferric oxide is always positive, and is not a linear function of the conc. of the colloid. The heat of coagulation is greater per gram of iron oxide in dil. soln. than it is in conc. soln. F. Dörinckel also found the heat of coagulation of colloidal silver with a protective colloid to be about 19 cals. per gram of the disperse phase; while J. A. Prange obtained with pure colloidal silver, 126·7 to 250·9 cals. per gram.

S. E. Linder and H. Picton noticed that during the coagulation and precipitation of a colloidal soln., the sol carries down with it part of the reagent—mainly the ion whose charge is of opposite sign to itself and the soln. becomes more acid or alkaline. Thus, when colloidal arsenious sulphide is precipitated with barium chloride, barium appears with the precipitate, and the supernatant liquid is acid with hydrochloric acid. The precipitate cannot be cleaned by washing. The ion with a charge of the same sign as the colloid, exerts an influence opposite to precipitation, and tends to make the suspension more stable—thus, G. Bredig's metal colloids become more stable when the medium contains a trace of alkali.

When an insoluble precipitate is formed in the absence of electrolytes by a reaction between two chemical compounds, it is almost always in the colloidal condition. Thus if aq. hydrogen sulphide be added to a soln. of arsenious acid, a turbid yellow soln. of colloidal arsenous sulphide is formed: $2H_3AsO_3+3H_2S\rightleftharpoons As_2S_3+6H_2O$. If the precipitate be made by adding an aq. hydrogen sulphide to a soln. of arsenious chloride, a coagulated precipitate of arsenious sulphide is formed. In the latter case, hydrochloric acid is produced by the reaction: $2AsCl_3+3H_2S\rightleftharpoons As_2S_3+6HCl$. If some hydrochloric acid be added to colloidal arsenous sulphide formed as just indicated, the suspended colloid is at once coagulated and precipitated. These facts illustrate a principle of great importance in quantitative analysis where successful work depends upon the formation of an insoluble precipitate which can be easily washed free from absorbed mother liquid. When a colloid is precipitated by an electrolyte, as when aluminium and ferric hydroxides are precipitated by ammonia in the presence of ammonium chloride, the salt, ammonium chloride, coagulates the colloidal hydroxides into the gel condition. During the washing of the gel precipitate, the gel passes into the sol condition, because the coagulating salt is removed by washing. Hence a soln. of ammonium nitrate is used for washing aluminium and ferric hydroxide precipitates in order to keep the colloid in the coagulated or gel condition. The ammonium nitrate is driven off during the ignition of the hydroxides prior to weighing. Gel colloids are said to be reversible colloids when they can be converted into the sol condition by restoring the original conditions, *e.g.* by washing out the coagulating electrolyte from precipitated aluminium hydroxide; M. C. Lea's soluble silver; etc. On the other hand, irreversible colloids cannot be reconverted into the sol condition once they have passed into the gel condition, *e.g.* stannic hydroxide, gold, etc. Some colloids are reversible when freshly precipitated, but become irreversible on standing.

Soln. must have a definite conc. in order that a precipitate may be formed in a given time. Certain conc. favour the formation of crystalline precipitates and with greater or less conc., the formation of crystals becomes less and less distinct until the crystalline structure cannot be recognized at all. When the conc. of the soln. decreases below that which favours the formation of a crystalline precipitate, the magnitude of the crystals decreases with increasing dilution, until colloidal suspensions are produced. There is no evidence of a discontinuity, and it is consequently inferred that the smallest particles have a crystalline character. According to P. P. von Weimarn's analysis of the phenomenon,[17] the earliest or initial stage in the separation or condensation of a solid from a soln. is the formation of nuclei or particles approaching molecular dimensions. These particles increase in size in two ways: (1) By aggregation as when two particles approach close enough to unite and form a larger particle—this P. P. von Weimarn calls *Aggregations-Kristallisation;* or (2) by abstracting molecules of the solute from the surrounding soln.—this P. P. von Weimarn calls *molecularen Kristallisation.* Consequently, the stability of a system will depend upon at least two factors: (i) the rate at which the nuclear particles separate from the soln.; and (ii) on the rate at which the particles can grow. In order that precipitation may occur, an amount P of the solute must be present in excess of that required for the saturation of the soln. P. P. von Weimarn calls this excess the *Kondensationsdruck*—that is, the condensation press. of the soln. Working against this factor is what P. P. von Weimarn calls the *Kondensationswiderstand,* or the resistance of the soln. to condensation; this varies with the nature of the solute and solvent. If C denotes the actual conc. of the supersaturated soln., and S the solubility or conc. of the sat. soln., $C-S=P$, the condensation press. For a given value of P, a few crystals of a very soluble solute (with S large) will be slowly formed under conditions where, for the same value of P with a very sparingly soluble solute (S small), a large precipitate will be immediately formed. Hence, it can be assumed that the resistance of the soln. to condensation is inversely proportional to the solubility S of the solute; the rate of condensation or separation of the nuclear particles will be equal to kP/S, where k is a constant; and the *spezifische Uebersättigung,* or the relative supersaturation of the soln. at the moment of condensation, will be P/S.

The behaviour of the system will be different according as the value of P/S is determined by a large value of P, or a small value of S. In the former case, a gel is likely to be formed, and in the latter case, a sol. Other things being equal, the duration of the phase of the initial condensation will depend on the magnitude of the supersaturation of the soln., and the smaller the value of P the slower the growth of the particles. The solubility of barium sulphate, approximately 0·0002 grm. per 100 c.c., is small in comparison with that of a soln. of barium chloride or nitrate, and of the ordinary sulphate precipitate in the laboratory, for on mixing such soln., $C-S$ or P for the resulting barium sulphate is not large enough to give large values of P/S, and an immediate precipitation occurs as is desired in the operations of analytical chemistry. By using soln. of barium thiocyanate, $Ba(SCy)_2.3H_2O$, and manganese sulphate, $MnSO_4.4H_2O$, P. P. von Weimarn was able to obtain a wide range of values of P/S for the formation of barium sulphate—$MnSO_4+Ba(SCy)_2=BaSO_4+Mn(SCy)_2$. The time required for the opalescence of barium sulphate to appear when soln. with different conc. of $Ba(SCy)_2.3H_2O$ and $MnSO_4.4H_2O$ are mixed: $MnSO_4+Ba(SCy)_2=Mn(SCy)_2+BaSO_4$, is indicated in Table VIII; and P. P. von Weimarn's results showing the nature of the precipitate are indicated in Table IX.

For very soluble substances, where S is large, the suspensoid stage is developed for large values of P/S, and the conc. suspensoid forms a gel. When P/S is small, the suspensoid stage is recognized with difficulty. For example, a test tube containing a sat. soln. of manganous sulphate, $MnSO_4$, when dipped in liquid air, forms a clear solid jelly or glass. For sparingly soluble substances, where S is small, the suspensoid stage is developed with both large and small values of P/S, but with large values of P/S, the suspensoid is a gel, and with small values of P/S a sol. Example, the formation of barium sulphate in aq. soln. For substances which are virtually insoluble, S is very small, and the suspensoidal stage is recognizable only with large values of P/S ; and P/S must be extremely large if a gel is to be obtained. Example, the formation of aluminium hydroxide by reactions in aq. soln. at room temp.

TABLE VIII.—THE TIME REQUIRED FOR THE PRECIPITATION OF BARIUM SULPHATE.

Conc. of the reacting soln.—normality.	Time required for the appearance of a marked opalescence after the mixing of the reagents.	Time required for the precipitation of most of the barium sulphate after the mixing of the reagents.
0·002	Some seconds	0·5 to 1 hr.
0·001	3 to 5 minutes	2 to 3 hrs.
0·0005	2 to 3 minutes	10 to 12 hrs.
0·0003	6 to 8 minutes	24 hrs.
0·0002	The opalescence and the appearance of the precipitate were not distinguishable	In about 30 days the formation of a precipitate on the walls of the vessel was noticed.

P. P. von Weimarn further states that however small the solubility of a substance, a crystalline precipitate is obtained if the volume of the sol and the interval of time are sufficiently great. Examples: the formation of crystalline minerals of sparingly soluble substances in nature ; and artificial processes for the synthesis of minerals. Again, every disperse system obtained by cooling a soln., by replacing one solvent by another, by reduction, oxidation, hydrolysis, or other chemical process, tends to diminish its dispersivity because the smallest particles are more soluble than the larger particles, and therefore the larger particles grow at the expense of the smaller. E. H. Buchner and J. Kalff hold that P. P. von Weimarn's theory is not confirmed by quantitative experiments.

F. W. Lüdersdorff (1833),[18] and M. Faraday (1857) found that the coloured soln. of gold are more stable in gummy gelatinous liquids. M. Faraday said that on evaporating such a mixture, the red did not change colour ; and A. Lottermoser found that the presence of albumin prevented the precipitation of silver sols by electrolytes, and stated : When the hydrosol of silver is mixed with a stable colloid —like albumin, gelatine, agar-agar, or gum arabic—the addition of an electrolyte does not precipitate the silver until all the stable colloid has been gelatinized. The less stable hydrosol of silver is thus protected by the more stable colloid against the electrolyte. The silver hydrosol when protected by the stable colloid is itself stable. Hence, as previously indicated, those colloids which have the power of preventing or retarding the coagulation of suspensoid particles are called **protective colloids,** or *Schutzkolloide.* According to H. Bechhold,[19] each particle of the suspensoid (silver hydrosol) surrounds itself with a film of the emulsoid (albumin), and then possesses the electrical properties of the latter. R. Zsigmondy considers that the relatively small dimensions of the particles of gold in comparison with those of gelatine or albumin molecules established by C. A. L. de Bruyn does not support this hypothesis ; and he favours the assumption that the gold particle either unites with many particles of the protective colloid, or that a particle of the protective colloid unites with many particles of gold. R. Zsigmondy determined the quantity of colloid which just fails to prevent 10 c.c. of a red gold hydrosol changing violet on the addition of 1 c.c. of a 10 per cent. soln. of sodium chloride. The numbers so obtained are called *Goldzahlen*, or the **gold numbers,** or gold figures of the protective colloid. The following gold numbers are selected from R. Zsigmondy's table:

Gelatine.	Egg-albumin.	Gum arabic.	Gum tragacanth.	Potato starch.	Sugar.
0·005—0·01	0·15—0·25	0·1—0·4	*c.* 2·0	*c.* 25	8

R. A. Gortner [20] has determined the gold numbers of protoalbic and lysalbic acids to be respectively 0·15–0·20, and 0·10–0·125; and for sodium oleate, 2–4. F. Küspert found that gold and silver hydrosols are protected by silicic acid; W. Biltz, by zirconium hydroxide; and R. Zsigmondy, by alumina, and stannic oxide. According to M. Beyer, colloidal silver protected by albuminous matters is found in commerce under the name *collargol.* It is employed in medicine as an antiseptic, but its power as a bactericide is rather feeble. E. Zung has studied the protective action of the albumoses; L. Lichtwitz, H. H. Salkowsky, E. Rählmann, and H. Much, the protective action of urine albumin; A. Gutbier and co-workers, the protective action of cetraria islandica (Irish moss), and of saponin; H. Freundlich and E. Löning, albumen; and T. Iredale, the protective action of soaps on colloidal gold. In purple of Cassius the gold is protected by stannic oxide; and finely divided chromic oxide forms a crimson lake with the stannic oxide.

TABLE IX.—THE INFLUENCE OF CONCENTRATION ON THE PRECIPITATION OF BARIUM SULPHATE.

Conc. of the reagents (normality N).	P The degree of supersaturation of $BaSO_4$ (grams per 100 c.c.).	P/S The relative supersaturation of $BaSO_4$ ($S=0·002$ grm. per 100 c.c.).	Nature of the precipitate.
0·00005 to 0·00014	0 to 0·0006	0 to 3	No precipitate formed in a year, but theoretically a precipitate can be expected in a few years with a large volume of solution.
0·00014 to 0·0017	0·0006 to 0·0096	3 to 48	It is probable that for $P/S=3$, over a year is needed for the formation of a suspensoid; for $P/S=48$, a precipitate forms in a few seconds.
0·0017 to 0·75	0·0096 to 4·38	48 to 21,900	A precipitate is formed in a few seconds when $P/S=48$; after this, precipitation is instantaneous, and the precipitate consists of crystal skeletons and needles. The nearer the concentration approaches 0·0017, the smaller the number of crystal skeletons.
0·75 to 3	4·38 to 17·51	21,900 to 87,500	There is an immediate precipitation of an amorphous precipitate which appears under the microscope to consist of spherical particles.
3 to 7	17·51 to 40·9	87,500 to 204,500	Clear jelly which changes in about 24 hours into a voluminous flocculent mass.

W. D. Bancroft identifies the so-called protective action of colloids with peptization. He supposes that the *Schutzkolloide* is absorbed, and, by lowering the surface tension, tends to disintegrate the precipitate, or prevent it forming. Consequently, the protective action is but a special case of peptization. Several examples have been previously discussed. For instance, the influence of sugar, gums, etc., in preventing the precipitation of, say hydrated ferric oxide from soln. of ferric salts by ammonia or potassium hydroxide; of gums in preventing the precipitation of mercuric and other sulphides; etc.

M. von Smoluchowsky, O. Klein, A. Westgren, etc., have discussed the mathematical theory of coagulation. The first named said:

> Perhaps the most simple view to adopt is, that the particles attract one another by capillary forces when they are sufficiently close together. The fact that no union takes place under normal circumstances, is to be attributed to the protective action of the electrical double layer, which can be likened to a kind of elastic cushion. The addition of an electrolyte, causes a partial or a complete destruction of the double layer through the absorption of ions as pointed out by H. Freundlich, so that at a certain conc. this protection is no longer sufficient to prevent the collision and adhesion of the particles. There is still a third factor to be considered, which favours the collision and hinders the permanent union of the particles. This is the mol. agitation which reveals itself in the Brownian movement; but, as taught by the statistic mechanics, this factor depends only on the temp., and, consequently, cannot be made answerable for the coagulation which follows the addition of an electrolyte.

§ 9. The Preparation of Colloidal Solutions

In the preparation of colloidal soln. a finely divided, peptized, dispersed, or deflocculated phase is kept from coalescing, coagulating, or flocculating into aggregates. In his *Outlines of Colloid Chemistry*, W. D. Bancroft[1] divides the available methods into two groups—condensation and dispersion—and he gives a long list of examples from which the following are selected. In the condensation methods there is a strong adsorption of some agent by the colloid, or a protective colloid is used, or else the conc. of the agglomerating agent is kept down by the use of suitable reagents or by dilution.

In illustration of the preparation of colloidal soln. in the presence of a strongly adsorbed substance, all the metals and many other substances can be kept in colloidal soln. by sodium protalbinate or lysalbinate.

Other examples are T. Svedberg's reduction of palladium salt soln. by hydrazine in the presence of gum arabic; J. Hausmann, sulphide soln. with gum arabic; silver chloride or bromide or Prussian blue in the presence of gelatin; E. Grimaux, ferric oxide with glycerol; T. Svedberg, cadmium sulphide, and H. Ritthausen, copper oxide with casein; T. Svedberg, mercurous chloride by albumen; C. Schiaparelli, lead sulphide by saponin; O. Gengou, alumina or barium sulphate with sodium citrate; T. Svedberg and E. Riffard, silver chromate, copper hydroxide, or ferric hydroxide by cane sugar or better invert sugar; M. C. Lea, silver by ferrous citrate or tartrate; C. Amberger, silver by wool-fat; A. Gutbier and E. Weingärtner, gold and silver by starch; P. Schöttlander, mercury and bismuth by stannic oxide, and gold by ceria; T. Svedberg and S. Odén, sulphur in acid soln. by sodium sulphate (not the potassium salt).

Precipitates obtained by coagulation from colloidal soln. owing to the use of an excess of the precipitating agent may reform colloidal soln. when the excess of the flocculating agent is removed by washing, etc. For example, when precipitated silver halide is washed, the salt is apt to run through the filter when the excess of precipitant is removed; zinc sulphide was found by J. Donau to form a colloidal soln. when the ammonium salt is washed out; and E. G. Berkeley and J. Hartley made a similar observation with respect to the washing of copper sulphate from precipitated copper ferrocyanide. If the coagulating agent cannot be removed by washing, or if the agglomeration has gone too far, the precipitate is not dispersed. The phenomenon is frequently observed in the washing of precipitates in analysis, and sometimes the precipitate is washed with a flocculating medium in order to prevent deflocculation. The flocculating medium employed is volatilized in a subsequent operation—*e.g.* alumina and rare earth precipitates are washed with a dil. soln. of ammonium nitrate; stannic oxide is washed with dil. nitric acid; etc. Instead of washing out the precipitating agent, a peptizing agent may be added—*e.g.* W. Skey found ammonia keeps clay in suspension, similar remarks apply to dil. soln. of the caustic alkalies.

T. Graham noted caustic hydroxide peptizes silicic acid, S. W. Young found hydrogen sulphide deflocculates the sulphides. A large excess of the peptinizing agent may be required, *e.g.* W. Fischer and W. Herz, and C. F. Nagel found that with chromic oxide a large excess of potassium hydroxide is needed to produce a green colloidal soln. F. Fischer found hydrated copper oxide; A. Hantzsch, cobalt oxide, and beryllium oxide are peptized by alkali; W. D. Bancroft found zinc oxide is partially peptized by alkali; E. Grimaux reported that similar remarks apply to the presence of an excess of ammonia on a soln. of a copper salt. The production of metal fogs in baths of fused metals, studied by R. Lorenz, is a case of peptization.

A. B. Northcote and A. H. Church say that the presence of chromic oxide with the oxides of iron, cobalt, nickel, and manganese makes them soluble in caustic alkali; M. Prud'homme made a similar observation with respect to chromic oxide in the presence of a copper salt; C. Lépéz and L. Storch, stannic oxide enables iron oxide to form a colloidal soln. with ammonia. F. R. M. Hitchcock, and L. Wöhler report molybdic acid is not precipitated by uranyl salts but is precipitated in the presence of tungstic acid. A. Müller found hydrochloric acid readily peptizes freshly precipitated oxides of alumina, iron, cobalt, thorium, and yttrium; T. Graham found soln. of their chlorides act similarly upon the oxide. H. W. Fischer and B. Szilárd, also give evidence showing that most oxides can be more or less peptized by soln. of their chlorides or nitrates. E. A. Schneider reported that ferric oxide is peptized by aluminium chloride; W. B. Bentley and R. P. Rose, that precipitated alumina is peptized by 8 per cent. acetic acid; and Prussian blue is peptized by oxalic acid or potassium oxalate.

Hence, adds W. D. Bancroft, "any substance will carry another into soln. when in sufficient conc. provided it is adsorbed by the second, but there is no direct experimental evidence of this."

Colloidal soln. are formed in reactions involving reduction processes.

T. Svedberg reduced silver oxide suspended in water at 50° by hydrogen; and dil. soln. of gold salts by carbon monoxide, sulphur dioxide, formaldehyde, etc.; A. Rasenfosse, a sulphuric acid soln. of copper sulphate by alcohol; T. Svedberg and A. Liversidge, gold by aspergillus oryzæ; J. Donau, reduction in flames. The reduction may be affected by electrolysis—*e.g.* T. Svedberg electrolyzed dil. soln. of gold, silver, and mercury salts; J. Billitzer, electrolyzed dil. soln. of the less noble metals; M. Lecoq, a dil. soln. of sodium arsenite; and A. Samsonoft. a soln. of uranyl chloride. T. Svedberg, and F. Hartwagner reduced gold sols by exposure to light; A. Wigand, sulphur; J. Amann, soln. of ferro- and ferri-cyanide; and A. Galecki, by the action of *X*-rays.

Colloidal soln. may be produced by metathetical reactions.

H. Picton and S. E. Linder passed hydrogen sulphide through a soln. of arsenious acid and obtained colloidal arsenic sulphide; T. Svedberg similarly acted on mercuric cyanide with hydrogen sulphide. Again, colloidal soln. of silicic acid can be made from sodium silicate and hydrochloric acid; stannic acid from stannic chloride; metastannic acid from sodium stannate; and tungstic acid from sodium tungstate. T. Svedberg obtained colloidal sodium chloride from sodium malonic ester and chloracetic ester in ligröin; A. Lottermoser obtained colloidal silver halides by the action of $\frac{1}{20}N$-silver nitrate on $\frac{1}{20}N$-soln. of potassium chloride, bromide, or iodide. Similarly reactions involving oxidations may furnish colloidal soln. *e.g.* A. Himmelbaur oxidized hydrogen sulphide in the presence of gelatine; L. Wöhler and W. Witzmann, sodium iridichloride. L. Vanino and L. Rössler, aurous chloride; and G. Bredig and A. Marck treated permanganates by hydrogen peroxide.

Colloidal soln. are also produced by hydrolytic reactions.

L. T. Wright boiled aq. soln. of ferric chloride; and generally soln. of acetates, nitrates or chlorides can be hydrolyzed to form colloidal oxides but not usually sulphates, although the chromosulphuric acids, according to H. G. Denham, are colloidal. T. Svedberg hydrolyzed silicon sulphide, ferric ethylate, and copper succinamide.

G. Wegelin found that some metals can be mechanically ground so as to form a colloidal soln., and the presence of a little gelatine is said to make disintegration easier. Quartz reduced to an impalpable powder by long grinding may form colloidal hydrated silica merely by boiling with water.

G. Bredig's and T. Svedberg's methods of forming colloidal soln. of the metals are cases of electrical disintegration by forming an electrical arc under water.

C. J. Reed, G. Bredig and F. Haber, M. Lecoq, and F. Haber and M. Sack report that cathodes of lead, tin, bismuth, antimony, arsenic, thallium, or mercury are disintegrated in soln. of sodium hydroxide when the current density exceeds a certain critical value. The soln. may be coloured as black as ink by the fine particles of metal. A. Müller similarly obtained colloidal soln. of tellurium; and F. Fischer obtained indications that colloidal copper may be formed by a high current density with a copper anode in sulphuric acid.

The disintegration of all electrodes by alternating currents of high density is attributed by F. Haber and R. G. van Name to the transient formation of a hydride or metal alloy.

§ 10. Colloidal Gold, Silver, and Copper

Soln. of gold salts are readily reduced to the metal by the mildest of reducing agents. The chemical inactivity of gold corresponds with the fact that it is precipitated from its salts by most of the metals, the metal sulphides, ferrous salts, and numerous organic compounds—oxalic acid, cane sugar, chloral hydrate, etc. Gold is also precipitated by many oxidizing agents, thus hydrogen peroxide precipitates the metal from its salts, and oxygen is evolved at the same time. Many of the peroxides reduce gold from alkaline soln.—*e.g.* manganese dioxide, peroxides of the alkaline earths, lead peroxide, ceric oxide, many of the manganiferous minerals, and even manganese carbonate, in alkaline soln., precipitate the metal. If a soln. containing 0·01 to 0·001 per cent. of gold chloride be made slightly alkaline by the addition of magnesia, and then a few drops of a dil. soln. of formaldehyde as reducing agent be added, the liquid will probably acquire a red or purple colour. *A red solution* of gold hydrosol is also obtained by mixing 4 c.c. of a one per cent. soln. of gold chloride with 100 c.c. of water, and stirring this up with an equal volume of a two per cent. soln. of tannin ; and a *blue solution* is obtained by mixing the gold soln. with three times its volume of the tannin soln. The main fact has been known for a long time, and was mentioned by J. Juncker in 1730, by P. J. Macquer in 1789, and by J. B. Richter in 1802,[1] before M. Faraday took up the subject in 1857. The liquid contains metallic gold in the form of minute particles which do not settle under the influence of gravity, but remain in suspension an indefinite time ; the soln. can be filtered through paper unchanged. The liquid is sometimes called **Faraday's gold** because of his early work on the subject in 1857. The suspended gold is in the colloidal condition ; the clear liquid may or may not appear opalescent by Tyndall's optical test ; and the particles can be perceived by the ultramicroscope. A. Connejo has surveyed the history of colloidal gold.

The *aurum potabile*—potable gold—of the alchemists was probably a hydrosol of gold.[2] This liquid was obtained by treating a soln. of gold in aqua regia with ether or ethereal oils. Fabulous medicinal virtues were attributed to this liquid ; it would cure " an infinity of diseases." The power of this medicine was explained somewhat as follows : " Gold receives its influence from the sun, which is, as it were, the heart of the world, and by communicating those influences to the heart, it serves to fortify and cleanse it from all impurities." Mrs. Fulhame, in *An Essay on Combustion* (London, 1794), described the production of red and purple colours on silk by dipping the fabric in soln. of gold salts, and subsequently precipitating the metal with hydrogen or a soln. of phosphorus in ether, and Mrs. Fulhame's method was patented nearly a century later.[3] The early book also described the production of red soln. of gold by reducing the chloride with phosphine, metallic tin, etc.

R. Zsigmondy's method[4] for preparing a red sol of colloidal gold.—25 c.c. of a soln. of hydrochloroauric acid, containing 6 grms. of the solid $HAuCl_4.3H_2O$ per litre, is dil. with 100 to 150 c.c. of distilled water (prepared by the re-distillation of distilled water, with say, a silver condenser), and made alkaline by adding 2 to 4 c.c. of a one-fifth normal soln. of potassium carbonate. The soln. is heated to boiling, and 4 c.c. of a soln. of one part of freshly distilled formaldehyde in 100 parts of water are gradually added to the boiling hot gold soln. In a short time, the liquid darkens, and acquires a dark red colour which does not change on boiling, or on standing for some months. Variations from these proportions give differently coloured soln.—purple, violet, or bluish-black turbid soln. may be obtained. The red liquid can be evaporated to half its volume without change, but further conc. causes the gold to precipitate as a black powder—possibly owing to the accumulation of salts in the soln. causing a precipitation of the metal. If the soln. be purified by dialysis at 40° to 50°, it can be conc. to one-twentieth of its volume—that is, a 0·12 per cent. soln. —in a few days. Further conc. leads to the precipitation of metallic gold.

A very great variety of other reducing agents have been recommended. M. Faraday[5] used yellow phosphorus, and also a soln. of phosphorus in carbon disulphide; J. Reitstötter, and others have employed a soln. of phosphorus in ether, alcohol, or other menstrua. F. Doerinckel, and T. Svedberg and K. Inouye used hydrogen peroxide; A. Gutbier R. Zsigmondy, J. Reitstötter, T. Svedberg, and E. Pozzi-Escot, hydrazine hydrate (1 : 2000); A. Gutbier and F. Resenscheck, phenylhydrazine hydrochloride; A. Gutbier, R. Zsigmondy, and J. Reitstötter, hydroxylamine hydrochloride; O. Brunck, sodium hyposulphite; M. C. Lea, sodium hypophosphite; A. Stähler, and F. Backran, titanous chloride; C. Winkler, E. Hatschek and A. L. Simon, sulphur dioxide;[1] J. Donau, and E. Hatschek and A. L. Simon, carbon monoxide; J. C. Blake, W. R. Whitney, and E. Hatschek and A. L. Simon, acetylene; A. L. de Bruyn, V. Kohlschütter, T. Svedberg, and W. Taylor, oxalic acid; L. Vanino, anhydro-methylenecitric acid (*i.e.* citarin); and E. K. Lenz, acetaldehyde, chloralhydrate, arsenic hydride, terephthalylaldehyde, benzaldehyde, and cinnamaldehyde.

A. Gutbier's process for red, blue, and violet gold sols.—Dissolve a gram of gold chloride in 1000 c.c of purified distilled water, and exactly neutralize the soln. with very dil.—say $0{\cdot}18N$-potassium carbonate. Then add a cold dil. soln. (1 : 4000) of hydrazine hydrate—say 1 c.c. of a 50 per cent. soln. in 2000 c.c. of water—drop by drop. The resulting sol is clear and stable, and is deep blue by reflected and transmitted light; but if too much reducer is added, the sol is not clear and sedimentation occurs. The colour readily depends upon the nature of the sol, for, according to W. W. Taylor, if the soln. is faintly acid the sol is bright blue; if almost neutral, violet or purple; and a brilliant red if alkaline. Thus, 100 c.c. water, 1 c.c. of one per cent. gold soln., 1 to 1½ c.c. of $0{\cdot}18N$-potassium carbonate, and 1 to 2 c.c. of hydrazine hydrate soln. (1 : 4000), gives a bright blue sol; if 2 c.c. of the potassium carbonate soln. are used, the gold sol is violet; and with 2·5 c.c. of the alkali carbonate and 3 c.c. of the hydrazine hydrate soln., the gold sol is bright scarlet. These sols are all very stable and easily reproduced.

The following is a demonstration experiment:

Dil. 5 c.c. of the 0·1 per cent. gold soln. with 300 c.c. of water, and run in from a burette, 0·2 to 0·5 c.c. of a freshly prepared 0·4 per cent. soln. of phenylhydrazine hydrate. When the liquid is stirred it becomes deep red. Now add more reducer drop by drop, when the colour changes to violet; after adding 5 c.c., the colour is violet blue, and a further quantity changes the colour to blue, and, finally, when 12 c.c. have been added, the colour is deep blue.

The reduction of a soln. of silver oxide by hydrogen seems to take place mainly on the walls of the vessel without there being any question of the solubility of the glass because the same results are obtained in the different glass vessels if an aq. soln. derived from ordinary ground glass is used instead of water in the different vessels. Walls of soft glass or quartz give yellowish-brown hydrosols; Jena glass, red, reddish-brown, violet, or blue sols; and with platinum, no sol formation occurs, but crystalline silver is formed. Hence, the surface of the vessel plays an important *rôle* in the form and size of the particles.

V. Kohlschütter's process for colloidal silver.—Hydrogen gas is bubbled through a sat. soln. of silver oxide contained in a round-bottom glass flask warmed between 50° and 60°; an excess of solid silver oxide is present in order to keep up the conc. A silver mirror is formed on the walls of the glass vessel simultaneously with the hydrosol. In 8 to 10 hrs. between half and one litre of intensely coloured sol is obtained. At temp. below 50° reduction is too slow; above 60°, the sol is unstable. The sol contains a little undecomposed silver oxide. This can be removed by passing hydrogen through a tube with a platinum tip, into 80 c.c. of silver hydrosol contained in a blackened platinum basin protected from air by a bell-jar. In about 12 hrs. the silver oxide is reduced to crystals of silver firmly adherent to the basin; at the same time the conductivity falls to between 4 and 8×10^{-6} reciprocal ohms—one-tenth its former value. The purification of hydrogen is useful because dialysis is liable to coagulate the sol. If carbon monoxide be used in place of hydrogen V. Kohlschütter found the resulting sol is not very stable.

Various organic substances[6] have been employed in the preparation of gold sols. Thus, according to L. Vanino, terpenes, alcohols, and carbohydrates for gold hydrosols; he also found that a little sodium anhydro-methylenecitrate gives colloidal solutions of gold, silver, etc., when added to soln. of salts of the respective metals—the gold sols are red. N. Castoro used acrolein, for colloidal gold, platinum, palladium, osmium, and ruthenium; and M. Müller used glycerol. C. Paal prepared hydrosols of selenium, copper, iridium, platinum, palladium, gold, silver, or silver oxide with protalbates or lysalbates as protective agents, and hydrazine, hydrogen, or sodium amalgam as reducing agent. F. Henrich used polyphenols as protective agents in preparing colloidal gold, platinum, silver, or mercury; L. Garbowsky used phenolic acids for gold, silver, and platinum; M. C. Lea, iron citrate for silver sols; A. Gutbier and co-workers, Irish moss; and A. Lottermoser, stannous salts for mercury, bismuth, or copper sols.

C. Paal's method for preparing solid colloidal gold and silver.—A soln. containing 8 parts of gold chloride are added to an aq. soln. of 10 parts of sodium lysalbate containing a great excess of sodium hydroxide. The pale yellow soln. is clear, it contains gold in the ordinary condition, and passes unchanged through a dialyser. If the soln. be treated with formaldehyde or other reducing agent, or gradually warmed with frequent stirring until a drop no longer reacts with hydrazine hydrate, the product is ruby red, and contains colloidal gold. A dark violet sediment may appear; the supernatant liquid can be washed by dialysis, and evaporated on a water-bath so as to furnish a lustrous dark brown powder resembling iron pyrites, and it contains about 90 per cent. of colloidal gold. The mass passes into the sol condition when treated with water or dil. alkaline lye. Sodium protalbate can be used instead of the lysalbate. Colloidal silver was prepared in a similar manner, and the sol is more stable than the commercial *collargol*, the soln. of which can be neither evaporated nor frozen without reversion to ordinary silver.

The early workers on electrical discharges noticed that metals were dispersed as an extremely fine dust from the cathode during an electrical discharge. M. van Marum,[7] for instance, mentioned the fact in 1787, and in 1857, M. Faraday obtained deposits ranging from a dark violet to a ruby-red colour by sparking gold terminals, and it is well known that when electrodes are used in vacuum tubes, the particles of gold which are shot from the cathode and deposited on the glass, form a film shading from red to purple according to its thickness. H. Davy also confirmed J. W. Ritter's observation (1808).

When tellurium is made the negative surface in water, the voltaic power being from a battery composed of a number of plates exceeding 300, a purple fluid is seen to separate from it, and diffuse itself through the water; the water gradually becomes opaque and turbid, and at last deposits a brown powder.

H. Davy supposed the purple fluid to be " a soln. of a compound of tellurium and hydrogen in water," and the brown powder to be a solid tellurium hydride. While thus early the metal sols formed by cathodic reduction were assumed to be metal hydrides, R. L. Ruhland, in 1815, and J. C. Poggendorf, in 1848, considered them to be metals in a very fine state of subdivision.[8] E. Müller and R. Lucas, however, showed that the purple liquid is a sol of tellurium; and G. Bredig[9] has employed the same fact in preparing sols of many of the metals—gold, silver, platinum, etc.

He made a direct current arc between the desired metals under water, and as in the case of tellurium, a hydrosol of the desired metal was formed.

G. Bredig's method of preparing colloidal metals by electrical dispersion.—Two wires of the metal, one millimetre thick and 6 to 8 cms. long, are dipped into water. For convenience in handling the wires, they are protected by narrow glass tubes. An electrical current of 5 to 10 amperes and 30 to 40 volts is passed through the wires, and the tips of the wires are separated 1 or 2 mm. so as to form a tiny electric arc about 1 or 2 cms. below the surface of the water. The arc is not easy to form at first but later on there is no difficulty in maintaining the arc for several seconds at a time. The arrangement will be evident from Fig. 12. While the arc is being maintained, dark clouds stream from the arc, and diffuse into the liquid. After a time, the liquid passes through various shades of colour, and finally in the case of platinum it assumes a brownish-black colour; with gold wires, the liquid appears reddish-purple; and with silver wires, yellowish-green. The liquid can be filtered to remove the larger particles, and the filtrate has all the properties of a colloidal soln.; or hydrosol of the given metal. During the experiment, very fine particles of the cathode metal appear to be torn from the wire and dispersed in the liquid. A trace of alkali in the water causes the formation of finer particles, presumably owing to a stabilizing action of the hydroxyl ions. Colloidal soln. of platinum, iridium, palladium, gold, silver, and cadmium are obtained in this way.

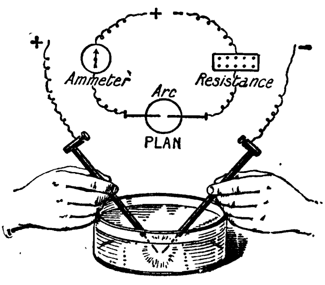

Fig. 12.—G. Bredig's Method of making Metal Sols by the Direct Current Arc.

G. Bredig's method does not give satisfactory results with organic liquids because too much liquid is decomposed. T. Svedberg found empirically that if the current density be made as small as possible this decomposition could be considerably reduced, and he therefore passed a current of high voltage (say 110 volts) and very low amperage between the electrodes placed between sheets of the required metal suspended in parallel or in series in the required medium. He obtained the best results with a large capacity, small self-induction, low resistance, and short arc. T. Svedberg also used oscillatory discharges in place of Bredig's direct current arc. The decomposition of the medium is not then so troublesome when organic liquids are substituted for water.

In one form of T. Svedberg's apparatus, the secondary terminals of a large induction coil (12–15 cm. sparks) were connected in parallel with a glass condenser 225 sq. cms. surface and the electrodes. The latter dipped in a porcelain basin of the required liquid, and small grains and fragments of the metal under investigation were spread on the bottom of the basin. The arrangement will be clear from Fig. 13. There is a vigorous sparking between the metal particles, and the required organosol is formed in a few minutes. Most of the metals—some 45 in fact—have been converted into colloidal soln. Liquid methane, ether, and isobutyl alcohol at a low temp. were especially satisfactory media for the metals of the alkalies and alkaline earths. The order of dispersion of some of the metals under similar conditions was found to be iron, copper, silver, aluminium, calcium, platinum, gold, zinc, tin, cadmium, antimony, thallium, bismuth, and lead, where the first member in the list was least rapidly dispersed, and the last member most rapidly. There is no perceptible relation between the order of the boiling points or the order of disintegration by cathode or canal rays and the dispersion in the organic liquid by T. Svedberg's process.

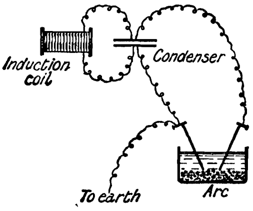

Fig. 13.—T. Svedberg's Method of making Colloidal Metals by the Oscillatory Discharge.

V. Kohlschütter also prepared colloidal metals by what he calls *discharge electrolysis* in which water is electrolyzed with either direct or alternating current combined with a condenser circuit.

The properties of gold hydrosols.—The particles of gold in suspension are assumed to be negatively charged because they migrate to the anode during electrolysis, and the liquid about the cathode becomes colourless while the liquid about the anode becomes darker and darker in colour, and finally almost black. A black film of gold deposits on the anode. If the two electrodes are separated by a membrane, the gold, like a true colloid, does not pass through the partition, but is deposited on the negative side. The behaviour of gold sols under the influence of a fall of potential has been studied by A. von Galecky,[10] J. Billitzer, J. C. Blake, and T. Svedberg. The adsorption of gold sol by dissolved dyestuffs depends less on the surface than on the number and size of particles, *i.e.* on the grain-size of the gold. The subject has been studied by R. Zsigmondy, W. Biltz, and L. Vanino. The gold can be removed from the colloidal sol by shaking it with precipitated aluminium hydroxide, stannic hydroxide, barium sulphate, animal charcoal, etc. The phenomenon resembles the decoloration of coloured soln. by shaking them with recently ignited charcoal. The gold is adsorbed by the precipitating agent. According to R. Zsigmondy (1898), a well-dialyzed and conc. gold hydrosol suffers no perceptible change after two or three days' shaking with mercury ; and after a few weeks' shaking, there is often a slight change in the shade of the soln., and an increased turbidity. Probably the mercury dissolves a little, forming an electrolyte which partially coagulates the hydrosol ; if mercury be boiled with the gold sol, the soln. is decolorized very slightly, and the precipitated powder amalgamates very slowly with the mercury. The addition of electrolytes—acids, salts, and bases—changes the red colour to blue, then violet, and then almost black. This is due to the coagulation of the suspensoidal gold into clots. The clotted gold settles to the bottom of the liquid in 8 or 9 hours as a bluish-black powder. With potassium ferrocyanide the colour changes to green, and in 24 hours the sol becomes yellow, but no gold is precipitated. Ammonia has no appreciable action ; alcohol in excess changes the colour to a dark violet and then precipitates the gold completely, but the precipitate still retains its property of re-forming a sol when treated with water. H. R. Kruyt and co-workers, and others have studied the coagulation of gold sols. E. Hatschek measured the velocity of coagulation of gold sols. The gold is precipitated by freezing and thawing the liquid ; and also by shaking in a centrifuge at 4000 revolutions per minute. The smaller the particles of colloidal gold, the more they incline to red, and the larger the particles, the more they incline to purple. When a few drops of a very dil. soln. of sodium hyposulphite,[11] $Na_2S_2O_4$, are added to hydrosols of gold of different conc., O. Brunck obtained the results shown in the first three columns of Table X. To these is added R. Zsigmondy's estimate of the size of the particles of suspended gold in sols of different colours. J. N. Mukherjee and B. C. Papaconstantinou[12] studied the effect of temp. on the coagulation of gold hydrosols by electrolytes. C. Bergholm and Y. Björnstahl found sols of vanadium pentoxide, gold, or silver are doubly refracting under the influence of an alternating electrical field. This is taken to imply that the particles of the sol are not spherical and do not possess spherical symmetry.

TABLE X.—THE EFFECT OF THE GRAIN-SIZE OF GOLD ON ITS COLOUR.

Conc. of gold sol.	Colour of liquid.	Opacity.	Average size of grain.
1 : 1,000	Deep purple-red	Opaque in thin layers	$75\mu\mu$
1 : 10,000	Purple-red	Opaque in 14 cm. layers	$38\mu\mu$
1 : 100,000	Rose-red	Perceptible in 1 cm. layer	$10\mu\mu$
1 : 200,000	Very pale rose	14 cm. layers rose colour	$6\mu\mu$
1 : 500,000	Scarcely perceptible	14 cm. layers perceptible	—
1 : 1,000,000	Colourless	Colourless	—

The colour of gold sols in transmitted light may be red, violet, or blue and occasionally yellowish-brown ; the submicrons of red soln. are green ; of the blue soln., yellow or reddish-brown ; and violet soln. contain submicrons of both colours. According to R. Zsigmondy, the blue obtained by the reduction of gold chloride soln. may be attributed to three causes :

> First, the reduction may be incomplete and colloidal gold oxide be formed instead of gold. Further reduction, perhaps at higher temp., might cause the blue to change to red. This condition has not been taken cognizance of up to the present time. Secondly, the reduction may be complete and the blue colour be attributed to the flocculent union of particles already spoken of ; or perhaps to the irregular growth, so that, instead of flakes or needles, husk-shaped bodies are called into being. These of course may be submicroscopic. Finally, the liquid may contain large massive gold particles that, according to the theory of G. Mie, would account for the blue colour.

As a rule, the layer particles are yellow or brown, and the smaller particles are green, but both green and brown particles may have all possible dimensions from a micronic dimension to over 120$\mu\mu$. R. Fürth studied the colour and Brownian movement of colloidal gold ; and B. Arakatsu and M. Fukuda, the limiting size of particles for the Brownian movement ; H. Freundlich and A. Nathansohn attributed the various colours to the formation of complexes, and W. Pauli has adopted a similar view.

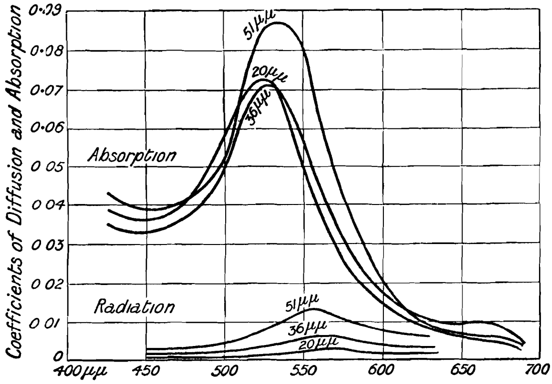

FIG. 14.—The Absorption and Radiation of Light.

F. Ehrenhaft explained the colour of gold sols by the optical resonance of the particles ; M. Garnett calculated the absorption spectra of gold hydrosols and ruby glass, and the theory has been extended by G. Mie, and the polarization, absorption spectrum, and the dispersion of light all are in agreement. W. Steubing found that the dispersion of light is only a fraction of the absorption, and the former is smaller as the size of the particles decreases, as shown in Fig. 14, per c.c. for a 0·0025 per cent. red gold sol with particles of different sizes. The absorption for liquids with submicrons of 20$\mu\mu$ and 36$\mu\mu$, is nearly the same, but there is a marked difference in the intensity of the radiation. The radiation is small for particles of 20$\mu\mu$, and immeasurably small for particles 2 to 4$\mu\mu$. Light reflected from the side is polarized by the submicrons, and this the more the smaller the particles. The polarization is linear, not elliptical or circular. According to G. Mie's theory, particles of gold of diameter 40$\mu\mu$ are green ; the theory is based on the assumption that the particle is spherical and a compact mass of metallic gold. The divergence from the theory probably means that these conditions are not fulfilled. When the small particles are brown this may mean that the shape is not spherical, that the entire space occupied by the submicron is not filled with metallic gold, or that an allotropic modification of gold is in question. The last assumption is unnecessary, and leads to contradictions. The assumed sphericity of the particles is made solely for convenience in the calculations, and is probably wrong because of the independence of the colour on the diameter. The submicrons are not isodimensional in their contour, and T. Svedberg believes that the dichroism of gold gelatine films show that the distance between the particles in the two directions is different, and it is assumed the particles are long and flat, or leaf-shaped. H. Siedentopf believes that the colours of the submicrons is determined by their shape, since the colour of gold and silver submicrons changed from green to brown when pressed between the cover glass and the platform of the microscope. The observations of H. Ambronn and

R. Zsigmondy showed that if the metal flakes are similarly oriented by spreading out the gelatine to form gold or silver gelatine films, the colour will be blue if the vibrations of the transmitted light are parallel to the direction of the distention of the gelatine; and red if the vibrations are at right angles to the distention. Hence G. Mie's theory must be adapted to include ellipsoidal particles.

The optical theory of metal colloids has not yet been completed, for it does not explain the colour change during coagulation. F. Kirchner supposes the particles act as resonators which, on coming into close contact with one another, displace the absorption maximum. G. Mie has raised objections to this hypothesis. The fact is that red gold sol changes to blue during coagulation, so that if a red colloidal gold sol with a very small amount of gelatine be evaporated, the dried residue is blue, and it becomes red when moistened. There is probably a flocculation of the particles during coagulation, but there is no relation between the size and colour because it occurs regardless of whether a micron or submicron unite. H. Siedentopf attributes the change to a change in the form of the particles rather than on their distance apart. The reversible change of colour indicates that an orientation of the particles parallel to the surface is more likely to occur than a change of form; and the distance apart of the particles also plays a part. The small amount of oxygen found on analyzing the gold precipitated by the addition of sodium chloride is not derived from aurous oxide, but is rather due to the condensation of air when the finely divided precipitate is dried—an eq. amount of nitrogen is simultaneously obtained.

The evidence that the gold is in the colloidal but elementary state is derived from: (i) The analysis; (ii) gold with a metallic lustre is deposited on slow evaporation, and there is no evidence of the decomposition of a compound; (iii) the red sol can be formed in a boiling hot soln. with a strong reducing agent where the probability is that aurous oxide would be decomposed; (iv) the colour of the gold sol resembles the colour of thin layers of gold viewed by transmitted light, and also that of ruby glass coloured with gold. The absorption spectra of the red gold sol, red film of metallic gold, and ruby glass; and of the blue and violet sols with blue and violet films of metallic gold, are almost identical.

Colloidal silver.—F. Wöhler [13] reduced silver citrate in a current of hydrogen at 100°, and obtained a product which gave a deep claret-red coloured liquid when treated with water. F. Wöhler assumed that he had prepared a subcitrate of silver, but W. Muthmann (1887) showed that the red liquid contains elementary silver, which is precipitated as black metallic silver when the liquid is treated with sodium sulphate, potassium nitrate, and other salts. H. Vogel also prepared amber-coloured soln. of silver in water by chemical processes. If F. Wöhler's subcitrate be treated with very dil. aq. ammonia, the liquid is green, but otherwise it behaves like the red soln. Both soln. are decolorized by charcoal, and if mixed with gum, and treated with alcohol, the colouring agent is precipitated with the gum. After freezing and thawing an opaque black liquid is obtained. The coloured liquid remains on the dialyzer, and ammonia and silver salts pass through the dialyzer. Colloidal silver can be obtained in an analogous manner to colloidal gold. For example, add ammonia to 5 c.c. of a one per cent. soln. of silver nitrate until the precipitate just disappears, and then add 100 c.c. of water. Mix this soln. with an equal volume of a 2 per cent. aq. soln. of tannin. The resulting hydrosol of silver forms a clear liquid—brown by transmitted light, and greenish-blue by reflected light. M. C. Lea [14] made an important contribution to the subject 1889–1891. It seemed remarkable that a metal so obviously insoluble in water should be produced in such a form that it could be dissolved in that menstruum, and hence M. C. Lea believed that the silver is in an allotropic form, and even to-day, M. C. Lea's hypothesis cannot be proved wrong. Indeed, on W. Ostwald's hypothesis that in the formation of a substance the unstable allotropic form appears first, it might be well argued that M. C. Lea's products are colloidal metals even though he never got them more than 97–98 per cent. purity. The assumption of allotropy, as C. Barus and

E. A. Schneider (1891) showed, is unnecessary and not so probable as the hypothesis that the metal is in a very fine state of subdivision. The reversibility of the silver sol and gel is explained by the formation of a protective colloid in M. C. Lea's process simultaneously with the production of the colloidal metal.

M. C. Lea's method of preparing colloidal silver.—Mix 200 c.c. of a 10 per cent. soln. of silver nitrate with a mixture of 200 c.c. of a 20 per cent. soln. of ferrous sulphate, 200 c.c. of a 40 per cent. soln. of sodium citrate, and 50 c.c. of a 10 per cent. soln. of sodium hydroxide. The resulting precipitate is a fine lilac colour; when filtered, it turns blue and does not become insoluble. It can be washed with ammonium nitrate, and it immediately forms a *blood-red solution* with highly purified water. It is precipitated by adding 5 to 10 per cent. of the same ammonium salt. It is purified by repeated re-solution, and re-precipitation, and finally washed with 95 per cent. alcohol. The precipitate contains about 97·2 per cent. of silver, and the remainder is iron oxide and citric acid. In another process, 40 grms. of sodium hydroxide and the same amount of ordinary brown dextrine are dissolved in 2 litres of water, and a soln. of 28 grms. of silver nitrate in a little water is gradually added. The resulting liquid is clear and black, although it contains less than one per cent. of silver. On dilution, the soln. becomes red, and with further dilution it forms a *yellow solution*. An insoluble *golden-yellow variety* is made by adding a freshly prepared mixture of 107 c.c. of a 30 per cent. soln. of ferrous sulphate, 200 c.c. of a 20 per cent. soln. of Rochelle salt, and 800 c.c. of distilled water, with constant stirring to a mixture of 200 c.c. of a 10 per cent. soln. of silver nitrate; 200 c.c. of a 20 per cent. soln. of Rochelle salt; and 800 c.c. of water. The red glittering precipitate soon becomes black, but looks like bronze on the filter paper. It is washed and then dried on a watch glass. The product has the colour of gold. If dried on glass it forms a beautiful gold mirror; if dried on glazed paper it looks like gold leaf. If washed too long it acquires the appearance of bronze. The product contains 99 per cent. silver.

J. A. Prange repeated M. C. Lea's experiments, and found that good silver hydrosols do not show the Tyndall effect, and K. Stöckl and L. Vanino therefore argued that the polarization of light by the silver sol is circular, but R. Zsigmondy showed that the polarization is always linear, never circular or elliptical. S. Odén showed that, like some gold hydrosols, silver hydrosols can be obtained optically homogeneous in Tyndall's beam. E. A. Schneider repeated M. C. Lea's experiments and used alcohol for the precipitation of the colloid, and he prepared the alcosol and glycerosol. The alcosols gave wine-red and green sols. Some non-electrolytes, like isopropyl alcohol, primary and secondary butyl alcohol, trimethyl alcohol, heptyl alcohol, octane, and formaldehyde precipitated the alcosol at once; but no coagulation occurred with propyl or isobutyl alcohols, a soln. of cetyl alcohol in alcohol, or glycerol.

The properties of silver sols.—The colloidal soln. of silver resemble in many of their properties the corresponding colloidal soln. of gold. The silver hydrosols prepared by precipitation with alkali sulphates, nitrates, and citrates are soluble, while the precipitates with iron, nickel, or manganese sulphate, and with barium or silver nitrate, are insoluble. The insoluble form can sometimes be peptized with borax or ammonium sulphate. The sols are decolorized by acids, bases, and salts, and, according to J. A. Prange, by indifferent bodies like quartz and graphite. Dialysis does not interfere with the colour, but a trace of a silver salt may pass through the membrane. Silver sols absorb light to a marked degree, and they become turbid on exposure—particularly to sunlight. Boiling and freezing and thawing decolorize the sols. Alcohol or ether precipitates the metal, but the precipitate again forms a sol with water, and hence the product was thought to be an allotropic water soluble form of silver before the colloidal nature of the product was established. Besides reducing silver nitrate with dextrine, and with a mixture of ferrous sulphate and sodium citrate, M. C. Lea also used a mixture of ferrous sulphate and Rochelle salt (*i.e.* sodium potassium tartrate). Golden-yellow colloidal silver is insoluble in water; it gives beautiful interference colours with oxidizing agents, alkali sulphates, and dil. potassium ferricyanide. Press. changes it to normal silver with the characteristic silver colour. Prolonged exposure to light, electricity, or shaking produces a similar result to press.—a sample tightly packed with cotton wool travelled 2000 miles without change, but a sample loosely packed turned to white silver *en route* These properties, and H. Ambronn's observations on the spontaneous crystallization of silver sols, are in favour of allotropy. The impure form is sometimes black, which becomes lighter coloured on warming. The unpurified red sol furnished a crystalline precipitate—short black needles and thin prisms after standing some weeks. Water changed the crystals without peptization, and on drying a green mass remained. W. R. Blake considered that M. C. Lea's experiments proved the existence of at least three, and possibly four, allotropic forms of silver—white, blue, red, and possibly yellow—but F. E. Gallagher [15] showed that all the colours—blue, red, green, purple, gold, brown, black—can be easily prepared from one set of reagents by simply varying the conditions, and the thickness of the soln. By dipping a glass plate in the dark reddish-brown liquid obtained by Lea's dextrine process (without precipitating or washing the product), allowing the film to dry, and dipping again so as to get a series of films, one superposed on the other, the result showed that with

Number of films	1	2	3	4	5	6	7
Colour . .	Blue	Blue	Green	Yellow and red	Yellowish-brown and red	Red	Red

The colours can be reversed by washing away the films showing that the change from blue to green, yellow, and red is not due to the further coagulation of the silver. F. E. Gallagher, therefore, concludes that the different colours of colloidal silver are due to variations in the thickness of the films under observation, or to a difference in the size of the suspended particles. The effect of light on the soln. is either to coagulate the suspensoid and thus increase the size of the particles, or else it affects the conc. of the particles in the sol by reducing to colloidal silver any silver nitrate which remains. R. Fürth studied the colour and Brownian movement of silver sols ; and B. Arakatsu and M. Fukuda the limiting size of particles for the Brownian movement. N. I. Morosoff measured the viscosity of silver sols ; and P. P. von Weimarn and co-workers, the reversible solubility of colloidal silver.

Colloidal copper.—A. Gutbier, and J. Meyer found brown hydrosols of copper are obtained when dil. soln. of copper sulphate or ammoniacal copper sulphate are reduced by hydrazine hydrate, hypophosphorous acid, or sodium hydrosulphite.[16] A. Lottermoser found that when a soln. of copper chloride in sodium citrate or tartrate is warmed with an alkaline soln. of stannous chloride, a white turbidity followed by a yellow, red, and black coloration is obtained ; a precipitate may also be formed and a hydrosol of copper remains in the liquid which appears blue in transmitted light and red by reflected light. F. Fischer obtained metallic copper in a soln. with a high current density and a copper anode in sulphuric acid —cuprous sulphate is formed, which breaks down to metallic copper and cupric sulphate—colloidal copper has not been so obtained, but W. D. Bancroft says that this probably could be done with a suitable protecting colloid. The disintegration of all electrodes by an alternating current with a high current density is attributed by F. Haber, and R. G. van Name to the temporary formation and subsequent breaking down of a hydrogen or metallic alloy. J. Billitzer prepared colloidal soln. of the less noble metals by the electrolysis of some of their salts, but F. Haber suggests the dispersed phase is probably the oxide, not the metal. Colloidal copper has also been obtained by forming an electric arc under water, using an iron wire dipped in copper sulphate as cathode. C. Paal and W. Leuze prepared a deep bluish-violet hydrosol of copper hydroxide by adding an alkali hydroxide to a suspension of copper protalbate or lysalbate, and if a conc. soln. be treated with hydrazine, an unstable blue hydrosol of copper is formed in cold soln., and in warm soln., containing not more than 25 per cent. of copper and a small amount of ammonia, a stable liquid hydrosol of copper is formed which appears red by transmitted light and black by reflected light. On evaporation of the liquid a solid red hydrosol is formed, which is stable in the absence of air, but rapidly acquires green, orange, and blue colorations when exposed to air. The red hydrosol is similar in tint to ruby glass obtained with copper as the tinctorial agent. A blue hydrogel is formed by adding an electrolyte to the red hydrosol. Red colloidal copper is formed by reducing colloidal copper oxide in the presence of sodium protalbate or lysalbate by hydrogen at 200°. For example :

Mix 20 grms. of powdered egg albumen and 20 c.c. of a 15 per cent. soln. of sodium hydroxide in water and dil. to 1 litre. Heat to boiling and filter. Boil again and add a 1 per cent. soln. of copper sulphate, drop by drop. The liquid turns red, then violet, then red-brown, and a precipitate settles. It is best to stop adding copper sulphate just before this precipitate forms. Dialyse the red-brown sol and filter. This sol of copper albuminate is almost neutral. Evaporate to dryness on the water-bath and dry further in a vacuum desiccator over sulphuric acid. Red-brown scales are left. They dissolve sparingly in water. Gold albuminate is made in similar manner.

The coloured varieties of colloidal copper are: brown (J. Billitzer); reddish-brown (A. Lottermoser); blue (A. Gutbier); olive-green (F. Ehrenhaft); green (C. Paal and W. Leuze); and C. Paal and H. Steyer describes two varieties of a ruby-red variety. B. Arakatsu and M. Fukuda studied the limiting sizes of particles of colloidal copper for the Brownian movement.

§ 11. Purple of Cassius, and Ruby Glass

I believe the purple of Cassius to be essentially finely divided gold associated with more or less oxide of tin.—M. FARADAY (1857).

If a soln. of stannous chloride be added to a very dil. soln. of gold chloride, hydrated stannic oxide is precipitated, and the gold is reduced, colouring the precipitate various shades of brown, purple, blue, green, yellow, or red. The precipitate is called **purple of Cassius,** and the tint depends upon the conc. and composition of the soln.—*e.g.* the proportion of stannous and stannic chloride and on the rapidity of admixture. The production of the colour is an extremely delicate test for gold. In making the test,[1] the soln. of gold chloride is heated to boiling, and poured into a beaker containing 5 to 10 c.c. of a sat. soln. of stannous chloride, and the mixture agitated to secure perfect admixture. A precipitate is at once produced which settles quickly. It will be purplish-red or blackish-purple if but one part of gold is present in 5,000,000 parts of water, and T. K. Rose has shown that the presence of one part of gold in 100,000,000 parts of water—that is, one grain of gold in 6 tons of water—can be detected by this means. The purple has long been used as a colouring agent for enamels, glasses, etc. The methods for making the finest and richest gold-red tints for porcelain and glass decoration are supposed to be trade secrets, although there is no difficulty in making colours to satisfy the less severe standards. One part of gold will tint about 100,000 parts of glass a rose-red colour ; and about half this amount of glass, a ruby-red.

The manuscript No. 3661 in the Sloane collection of the British Museum purports to have been copied by John Elyot in 1572 " out of an old copye by William Belyngslie which seemeth to be above 200 yers old ; " it contains a recipe for colouring glass garnet by means of gold oxide, and for colouring glass ruby by means of copper oxide. The deep carmine-red glass called *Gallien glass* was also coloured by copper as described by Eraclius in his *De artibus romanorum,* written in the tenth century. The term Gallien applied to red glass may have been derived from καλός, beauty, or from the Roman Galienus under whose reign the arabesque and other architectural ornaments were introduced into Rome.

Towards the end of the sixteenth century, A. Libavius, in his *Alchemia* (Francfurti, 1585), referred to the production of a hyacinth-red glass by using a mixture *ex vtraque Martis et terrea Solis ;* a little later, A. Neri, in his *L'arte vetraria* (Firenze, 1612), mentioned the coloration of glass by mixing the ingredients with the residue obtained by the evaporation of a soln. of gold in aqua regia ; J. R. Glauber, in his *Furnis novis philosophicis* (Amstelodami, 1648),[2] described how he prepared a ruby-red precipitate by treating a soln. of gold chloride with water-glass ; and in his *De prosperitate germaniæ* (1659), he mentioned the precipitation of a purple powder by the action of tin in a soln. of gold in aqua regia. In 1668, O. Tachen stated, in a tract called *De morborum principe,* that a purple colour is produced when glass is melted with fulminating gold ; and, in 1684, R. Boyle noticed that the bottom of a glass flask in which gold amalgam had been heated was stained ruby-red. The alchemists of this period speak of " the purple gold-soul," " the purple mantel of the king," [3] etc., without indicating their mode of preparation. About 1684, A. Cassius wrote a pamphlet entitled *De Auro* (Leiden, 1685), describing, for the first time, though somewhat incompletely, the preparation of the gold-tin purple colour, by mixing the chlorides of tin and gold. About the same time, J. C. Orschall, in his *Solis sine veste* (Augsburg, 1684), mentioned the use of Cassius' purple for colouring artificial stones and glass. In 1716, J. Kunckel [4] referred to the *præcipitatio Solis cum Jove,* prepared by Cassius, and stated that artificial rubies could be made by colouring crystal glass with gold precipitated from its soln. in aqua regia. He claimed to be able to make a colour *so schön das es schöner nicht sein kann.* About this time, the precipitate obtained by Cassius' process came to be called *purpura mineralis Cassii ;* and finally, *purple of Cassius.*

J. Kunckel stated that when attempts were made to colour glass by means of Cassius' purple, the product was often quite colourless, but when warmed in the blowpipe flame, the finest ruby-red tint was developed. There are, indeed, two types of ruby glass : the tint of the one is developed directly during fusion, and the tint of the other is developed when the glass is annealed below its fusion point. If the tint of the latter type be developed during the first fusion, it appears liver-coloured, and altogether lacks the fiery brilliance of the tint developed by the annealing process. The last-named phenomenon is very curious, and it can be illustrated by the following experiment :

A glass is made by fusing together an intimate mixture of quartz, 48 ; red lead, 80 ; nitre, 10 ; potassium carbonate, 10 ; crystallized borax, 30, for some hours. The product is ground, thoroughly mixed with stannic oxide, and antimony oxide, and moistened with a soln. of gold chloride containing the eq. of 0 0150 part of gold. The mass is dried, and fused so that when quickly cooled, the product has a pale yellow colour which turns ruby-red when warmed over the Bunsen flame.

It is supposed that the clear glass contains a soln. of gold, and on re-heating, the gold is reduced and surface tension brings the molecules of metal together and the aggregates separate from the soln. in the form of small particles; just as a film of metal on glass, at 300° or 400°, forms a number of minute spheroids without the metal melting. Coloured glasses have been prepared with copper or silver in place of gold. Methods of preparing ruby glasses, etc., industrially have been given by Arclais de Montamy in 1765, and by N. de Milly in 1771, by many others in later years.[5]

R. Zsigmondy's process for making purple of Cassius.[6]—300 c.c. of gold chloride containing the eq. of 3 grms. of gold per litre are mixed with 250 c.c. of a soln. of stannous chloride containing the eq. of 3 grms. of tin per litre, and a small excess of hydrochloric acid, and added to 4 litres of water with vigorous agitation. After standing three days, a dark violet-red powder collects as a sediment while the supernatant liquid is clear and colourless, for it contains no gold or tin. The precipitate is washed free from chlorides first by decantation, and then by suction on a filter. If the solid be treated with a warm soln. of dil. ammonia, a clear hydrosol of the purple of Cassius is obtained which can be re-precipitated by the addition of a little sulphuric acid.

When purple of Cassius is formed it is assumed that on the addition of stannous chloride to a dil. soln. of gold chloride the latter is reduced, and stannic chloride is formed: $2AuCl_3+3SnCl_2=2Au+3SnCl_4$. The stannic chloride is hydrolyzed into hydrochloric acid and colloidal stannic acid, and this prevents the aggregation of the gold particles. The hydrosol of stannic acid in soln. gradually changes into a hydrogel under the influence of the hydrochloric acid. A transformation from the soluble to the insoluble acid takes place at once on heating. The liquid usually becomes red, but the purple is not precipitated for some days unless the soln. is boiled.

The manufacture of special tints of purple of Cassius is attended by some uncertainty because the beauty of the tint depends upon details in manipulation not clearly understood. According to C. Buisson,[7] one cause of uncertainty in the results is due to the use of a mixture of stannic and stannous chlorides in indefinite proportions. Stannic chloride alone does not reduce the gold chloride, and C. Buisson considered that a mixture of one part of stannic chloride with three parts of stannous chloride is best for the precipitation of one part of gold. P. A. Bolley[8] used a soln. of 10 parts of ammonium chlorostannate, $2NH_4Cl.SnCl_4$, with 40 parts of water and 1·07 part of tin-foil, for reducing the gold chloride; and J. N. von Fuchs recommended the addition of a soln. of one part of ferric chloride liquor (sp. gr. 1·54) with three of water to a soln. of one part of stannous chloride in six parts of water until the product has a green tint. This, when diluted with six parts of water, was added to the soln. of gold chloride as nearly neutral as possible. W. A. Lampadius,[9] and J. Pelletier recommended a rod of tin or tin shavings as reducing agent. Colours analogous to the calcined purple of Cassius have been made by precipitating gold on the hydroxides of magnesium, calcium, barium, aluminium, antimony, bismuth, or zirconium; barium or lead sulphate; or on china clay, and calcining the product.[10] Purple of Cassius remains as a residue when alloys of gold and tin with a large excess of silver are treated with nitric acid;[11] and when a gold-tin alloy is vaporized in air, the tin burns to stannic oxide, and it is at the same time stained by the condensation of the vapour of metallic gold.[12] The silver[13] and platinum[14] analogues of purple of Cassius have been prepared. The platinum product has all the properties of a colloid; if it be prepared in a conc. soln. of hydrochloric acid, it will be soluble, or rather peptized, in ether or ethyl acetate; and the purple can be extracted from the acid soln. by one of these menstrua, and a water soluble jelly is left behind.

Prior to 1894, two views as to the chemical nature of purple of Cassius were rife, and in spite of the many investigations, no generally accepted decision had been reached. Analytical results ranging from gold 27 to 38 per cent., tin oxide from 48 to 64 per cent., and water from 7 to 15 per cent. have been reported. Formul d based on the analyses have been suggested, but with no satisfactory result, because chemical analysis cannot decide whether a substance is a chemical compound or a mixture. One view, held by J. J. Berzelius (1831) and others,[15] assumes purple of Cassius to be a chemical compound of a gold oxide with tin oxide, possibly with some stannic acid in excess; and the other view, advocated by J. B. Richter (1802) and others,[16] regards purple of Cassius as a mixture of stannic oxide with metallic gold. While recognizing with M. Macquer that *les faits prouvent que cette couleur est naturelle à l'or toutes les fois qu'il est extrêmement divisé*, certain difficulties were encountered, for the behaviour of the purple towards certain reagents was not like their behaviour with gold. Thus, J. J. Berzelius [17] argued that the solubility of purple of Cassius in ammonia, and the failure of mercury to extract the gold, favours the view that the gold is not present in the metallic state. By oxidizing stannous chloride, and allowing the dil. soln. to stand until a hydrogel of stannic acid separates, the addition of ammonia brings the product into soln. just as is the case with purple of Cassius, and there is therefore no sign of the formation of a salt. E. A. Schneider [18] considers that the ammoniacal soln. contains the hydrogels of gold and stannic acid, and R. Zsigmondy has shown that he is probably correct. A substance identical with purple of Cassius can be made by mixing the hydrosols of stannic acid and gold, and subsequently precipitating them by the addition of acids. The purple so synthesized has the same colour as the gold hydrosol from which it was prepared, and it is not probable that so inert a substance as gold would unite with stannic oxide under these conditions. The ultramicroscope shows that there is no essential difference between the gold particles in the synthesized hydrosol of purple of Cassius and the particles of the gold hydrosol. Neither the absorption spectrum nor the colour of the hydrosol of gold is changed in the least when it is converted into purple of Cassius, and this is not likely to be the case if the two components unite chemically. Purple of Cassius behaves like a typical colloid towards the electric current, and on dialysis; and in this respect it resembles the hydrogel of stannic acid. Hence, R. Zsigmondy argues that **purple of Cassius is a mixture of the hydrosols of gold and stannic acid** in which the latter imparts to the metallic gold the property of being dispersed in alkaline liquids. **Calcined purple of Cassius is a mixture of stannic oxide and finely divided gold; and ruby glass owes its colour to particles of extremely finely divided gold.** Still further, **the properties of purple of Cassius depend upon the properties of the protective colloidal—stannic acid—which makes the gold play a passive rôle towards reagents.** If the stannic acid is soluble in conc. hydrochloric acid, so is the purple; in the same manner, the solubility in ammonia and dil. alkalies depends upon the character of the stannic acid present. Generally, the great variations in the properties of the different varieties of stannic acid explain the many contradictions in literature with respect to the properties of purple of Cassius.

Instead of crystals being optically clear on solidification from a fused state, they are sometimes fogged.[19] An ultramicroscopic examination of the fogged crystals of the chlorides of lead, silver, and of thallium, and the bromides of silver and of thallium has shown that the fog is produced by metal particles so that the crystals have the character of ruby glass. If the fogged crystals of lead or silver chloride be fused in a stream of chlorine and hydrogen chloride gases, they solidify optically clear—thallous chloride has not yet been obtained in quite clear crystals.

§ 12. Allotropic Modifications of Gold and Silver

Gold is precipitated as a brown powder from its salt soln. by means of a stannous chloride, ferrous chloride, or sulphate, or by arsenious or antimonious acid; with oxalic acid and conc. potassium carbonate, gold is precipitated from boiling soln. as a soft yellow spongy mass. The more dil. the soln. the finer the state of the subdivision of the precipitate, and under certain conditions, red or purple soln. of colloidal gold are obtained without any precipitation of the metal. With conc. soln. the gold is often precipitated in flakes with a metallic lustre. J. Thomsen [1] found that pale yellow powdered gold is precipitated from neutral soln. of auric chloride by sulphur dioxide gas, and he symbolized this form of gold by the symbol Au; the same agent precipitates a fine dark powder from auric bromide, and J. Thomsen symbolized this form of gold by $\mathrm{Au}\alpha$ or α-gold; and gold with a metallic lustre is precipitated by the same agent from aurous halides, or by hydrogen chloride or bromide from aurous halides, and he designated this form of gold $\mathrm{Au}\beta$ or β-gold. J. Thomsen assumed that these three precipitates represented allotropic modifications of gold, and he found that the heats of the reactions corresponded with the relations $\mathrm{Au}\alpha=\mathrm{Au}+3{\cdot}21$ Cals.; and $\mathrm{Au}\beta=\mathrm{Au}+4{\cdot}7$ Cals. During the action of sulphur dioxide on auric bromide, J. Thomsen said that the bromide is reduced to aurous bromide, and then to $\mathrm{Au}\alpha$; but he also said that aurous bromide is reduced to $\mathrm{Au}\beta$ by the same agent, so that the two statements are not in accord. E. Cohen and J. W. van Heteren [2] found no difference of potential at 0° or 25° between these different varieties of gold, and concluded that there is a difference only in the state of subdivision of the precipitates. It is, therefore, inferred that the three allotropic modifications of gold postulated by J. Thomsen do not exist.

In studying the double refraction of gold, Y. Björnstähl found indications that gold crystals and particles of colloidal gold belong to different crystal systems—*vide supra.*

M. C. Lea, and J. C. Blake postulated different allotropic forms of silver for what are now regarded as colloidal forms of the metal. When A. J. A. Prage[3] observed a similar difference in the heats developed during the precipitation of colloidal silver from soln. of different conc. and in the conversion of colloidal silver to the metallic form: $Ag_{colloidal}=Ag_{metal}+(6\cdot48\times108)$ Cals., he, like J. Thomsen with gold, assumed that colloidal silver is an allotropic modification of that metal. C. Barus and E. A. Schneider, however, showed that work, or heat eq. to work, is necessary to transform a quantity of finely divided metal into a still finer state of subdivision, and heat is liberated during the converse process—the coagulation of the particles into larger grains. The energy difference between colloidal and finely divided silver is greater, per gram-atom, than between the allotropic modifications of phosphorus, sulphur, carbon, etc. *The development of heat during the transformation of a finely divided metal into more coarse-grained aggregates, is not conclusive evidence of the simultaneous conversion of one allotropic modification of an element into another.*

Attempts have likewise been made by M. Berthelot[4] to show that the differences in the heats of soln. of different forms of silver in mercury correspond with four *états allotropiques de l'argent.* Silver rolled into thin sheets gave a heat of soln. of 2·03 Cals. per gram-atom, and if heated to dull redness for 20 hours in oxygen, 0·47 Cal.; electrolytic crystalline silver from a 10 per cent. soln. of silver nitrate gave 0·10 Cal.; silver precipitated from a dil. soln. of silver nitrate gave 1·19 Cals. if dried at the room temp., and 0·76 Cal. if dried at 120°, or 0·08 Cal. if heated to dull redness. Even if M. Berthelot's assumption that these differences are due to allotropes of silver were correct, there would be no need to postulate four varieties, since various mixtures of two varieties of silver would explain the facts. E. Cohen and J. W. van Heteren, however, likewise failed to detect any difference in the potential difference of these different forms of silver, and they considered that M. Berthelot's allotropes to be *Silber nur in einer Form,* or identically the same form of silver. A. Matthiessen[5] said that "with silver it was not possible to get constant results for the sp. gr. although the metal was melted under borax, sodium chloride, and charcoal. The value 10·486 at 13·2° is the mean of thirteen different determinations varied between 10·424 and 10·511." W. D. Heldermann expressed the opinion that these differences cannot be ascribed to experimental error, but are rather due to changes in the metal itself, *i.e.* to different **allotropic forms of silver.** J. S. Stas obtained different values—9·8688 to 10·5537—for the sp. gr. of silver subjected to different treatment, and W. D. Heldermann also believed that different proportions of allotropic forms of the metal were present. He found the sp. gr. of silver, at 25°/4°, treated in different ways, varied from 10·3257 to 10·4978. He also found that when kept in contact with a soln. of potassium sulphate for different periods of time (days) at 25° the sp. gr. rose

	5	8	15	28
Specific gravity . .	10·4774	10·4867	10·486	10·4870

When kept for 6 days at 400° in contact with a molten mixture of sodium and potassium nitrates, and then chilled in cold water, the sp. gr. fell to 10·21608 at 25°/40°. The e.m.f. of different varieties in contact with a 10 per cent. soln. of silver nitrate ranged from 0·0000187 to 0·0000748 volt. Experiment showed that if silver be heated in a dilatometer with a soln. of silver nitrate, the rate of expansion of the system is comparatively slow between 76° and 78°, and the metal which has been heated with the soln. above 76° has a smaller sp. gr. than the metal which has not been heated to so high a temp. Accordingly, W. H. Heldermann concluded that silver exists in at least two allotropic modifications and that there is a transition temp. in the vicinity of 77°. Ordinary silver is therefore assumed to be in a metastable condition because the allotropic forms are not in a state of equilibrium. The physical constants excluding at. wt. refer to indefinite mixtures of the different allotropes, and hence must vary according to the proportions present in a given sample. It has been suggested, however, that the evidence is not decisive because the variations in the sp. gr. of silver observed by A. Matthiessen, and the movement of the liquid in W. D. Heldermann's dilatometer may be really due to the soln. permeating the pores of the metal; and the observed variation in the sp. gr. of the metal heated above and below 77°, due to a decrease in the apparent sp. gr. of the liquid confined in the pores of the metal—*vide* allotropic copper. Others have obtained evidence of allotropic modifications of silver. Thus, H. Lüdkte found that the electrical resistance of silver films increased with time. E. Jänecke [6] plotted the press. temp. curves of silver compressed to 20,000 kilograms per sq. cm. in steel cylinders on a rising and falling temp., and he found a break near 120° (at 118° on the cooling curve, and 120° on the heating curve), which he considered to represent the allotropic change. L. Pissarjewsky [7] could not get a constant value for the equilibrium constant in the reaction, $Ag_2SO_4+2FeSO_4=Fe_2(SO_4)_3+2Ag$; he found that the thermal values of the reaction in various solvents—water, normal sulphuric acid, 10 per cent. mannitol, or 24 per cent. glycerol—varied between 7·05 and 14·52 cals. per gram-atom of silver; and he also found that there is a difference of potential between the different precipitates in the reaction under consideration. Consequently, L. Pissarjewsky assumed that the precipitates are mixtures of at least two different modifications of silver. These results may be due to a difference in the state of subdivision of the different precipitates. Again, the curve showing the relation between the electromotive force of the silver-nickel thermocouple and the temp. coeff. between —80° and 920° shows a maximum value between 180° and 220°, and a minimum at about 370°. G. von Hevesy and E. Wolff [8] attribute the latter to an allotropic change in the nickel, and E. Jänecke attributes the former to an allotropic change in the silver.

According to D. Palitsch,[9] silver obtained by dissolving zinc from zinc-silver alloys by hydrochloric acid differs from ordinary silver in sp. gr., heat of soln. in mercury, and electrolytic potential, and is therefore considered to be an allotropic modification of ordinary silver. M. Hanriot studied the action of nitric acid on gold-silver alloys containing about 20 per cent. of gold, and he found that the residual gold always contained a little silver and much nitric acid; the latter is lost at 175°–200°, and on further heating, the product changes colour, and undergoes contraction; at 900°, a gas is evolved; and the residue melts at 1040°. He assumed that the residual brown gold is an allotropic β-form of gold, and, according to M. Hanriot and F. Raoult, the proportion of β-gold increases as the proportion of silver in the alloy increases. The last named measured the coeff. of magnetization and found $-0{\cdot}181\times10^{-6}$ for brown or β-gold, and $-0{\cdot}234\times10^{-6}$ for yellow or α-gold. The former begins to pass into the latter at about 350°, and the change is completed in about 2 hours at 400°. They found that nitric acid attacks both forms of gold, and that the best solvent for β-gold is a hot soln. of auric chloride containing hydrochloric acid. On cooling the soln. the dissolved gold crystallizes out in the metallic state, and a determination of its magnetization coeff. shows that, in this form, it consists almost entirely of the β-variety. This solvent has a much more marked action on the brown than the yellow gold, and it is the β-variety which passes into soln., thus leaving the insoluble residue enriched with the α-variety.

§ 13. Alloys of Gold, Silver, and Copper

H. Davy[1] said that when potassium "is heated with gold, or silver, or copper in a close vessel of pure glass, it rapidly acts upon them; and when the compounds are thrown in water, this fluid is decomposed, potash is formed, and the metals appear to be separated unaltered." G. S. Sérullas did not obtain any alloy of potassium with silver by igniting the metal with crude tartar. C. J. B. Karsten mentions a **sodium-copper alloy** with 0·13 per cent. of sodium, and H. Behrens made a **copper-potassium alloy**. There is some doubt about these statements, because molten sodium appears to be insoluble in copper at 500°, although when heated to the b.p. of sodium, copper absorbs a little sodium. According to E. Quercigh, and C. H. Mathewson, molten sodium and silver are miscible in all proportions, and the f.p. curve (Fig. 15) of the **sodium-silver alloys** has a single branch, although it is not certain if somewhere between 67 and 88 per cent. of silver there is not a separation into two liquid layers. There is probably a eutectic containing about 0·3 per cent. of silver, since G. Tammann found that the addition of this amount of silver lowered the f.p. of sodium 0·09°. This is represented in Fig. 15 by the area to the left of the dotted line. The little sodium which has been reported to be dissolved by silver in the crystalline state may be sodium which has been eutectically separated with the silver. Sodium dissolves virtually no silver in the solid state, for on cooling soln. of silver in sodium, octahedral crystals of silver are obtained. The equilibrium curve of **sodium-gold alloys** was found by C. H. Mathewson to show two eutectics (Fig. 16). The first eutectic with nearly ·6 atomic per cent. of gold and f.p. at 80°; the second eutectic has a f.p. at about

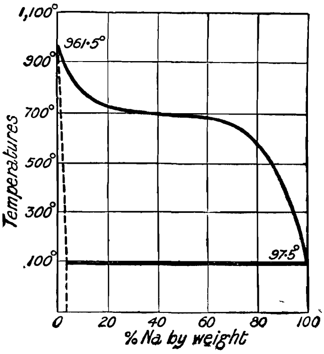

Fig. 15.—Freezing-point Curve of Sodium-Silver Alloys.

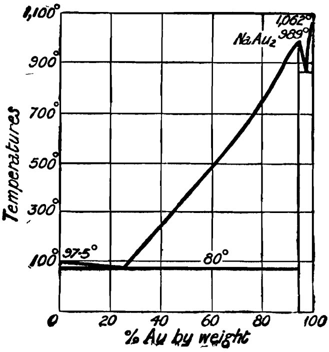

Fig. 16.—Freezing-point Curve of Sodium-Gold Alloys.

970° ; and there is a maximum in the f.p. curve at 989° corresponding with the formation of **sodium diauride**, $NaAu_2$. C. Vickers studied the use of sodium as a deoxidizer for copper.

According to P. Berthier,[2] native silver may contain up to 10 per cent. of copper ; and F. Field found the native copper of Coquimbo contained up to 7·6 per cent. of silver. W. Vernadsky also studied the native alloys of copper and silver. A. Levol, in his *Mémoires sur les alliages considérés sous la rapport de leur composition chimique*, stated that the two metals may be alloyed in all proportions, but only the alloy corresponding with Ag_3Cu is microscopically homogeneous ; but F. Osmond showed that even *Levol's alloy* is not homogeneous, but a polished surface rather has the pearlitic structure characteristic of eutectics ; alloys with more copper show copper crystals imbedded in the pearlitic mass under similar conditions, and alloys with more silver show crystals of that metal imbedded in the pearlitic mass. The segregation of these alloys was also noted by A. D. van Riemsdyk, H. Hahn, W. von Lepkowsky, K. Bornemann, and A. Bock. Standard silver (7·5 per cent. copper) containing more silver than the eutectic becomes on solidification richer in silver in the interior than on the outside. The difference does not usually exceed one or two parts per 1000, and does not usually cause trouble. Attempts by G. Jars, W. C. Roberts-Austen, and E. Matthey to cast uniform ingots of standard silver have proved abortive. To impart soundness, and deoxidize any copper or silver oxide, it is customary to add about 0·5 per cent. of cadmium after the alloy is melted. The cadmium is nearly all eliminated before the metal is cast. T. K. Rose, E. Pannain, G. Tammann, and W. H. Walker studied the microstructure of coinage silver during annealing. The standard alloy is annealed rapidly at 670°, and T. K. Rose showed that softening begins about 230° ; at 500° softening is completed in about half an hour ; and in less than a minute at 600°. It melts at 890°. When a strip of copper is immersed in a soln. of silver nitrate F. Mylius and O. Fromm observed that a dark-coloured alloy of copper and silver is first deposited, and this soon decomposes, and finally a layer of crystalline silver is formed. S. Field studied the electro-deposition of a copper and silver alloy from a mixed soln. of potassium cyanocuprite, and cyanoargentite ; G. Masing, the formation of alloys by compressing a mixture of the powdered metals at 4000 atm. press. W. Fränkel and H. Houben studied the diffusion of gold in a gold-silver alloy and found it to be 0·000037 sq. cm. per day at 870°.

The equilibrium curve of **copper-silver alloys** has been explored by C. T. Heycock and F. H. Neville, W. C. Roberts-Austen, W. von Lepkowsky, K. Friedrich and A. Leroux, and N. S. Kurnakoff. There is a eutectic with about 28·11 per cent. of copper at 778°–779°, and solid soln. are formed, as indicated in Fig. 17, represented respectively at the left and right of the dotted lines. F. C. Thompson and E. Sinkinson showed that the colour of the alloys is a linear function of the composition. K. Karmarsch studied the hardening and toughening of silver by alloying it with copper ; N. S. Kurnakoff, N. Puschin, and N. Senkowsky, and T. K. Rose studied the hardness of the copper-silver alloys. According t E. A. Smith and H. Turner, the addition of copper to silver renders it harder an

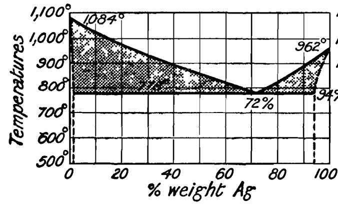

FIG. 17.—Freezing-point Curves of Copper-Silver Alloys.

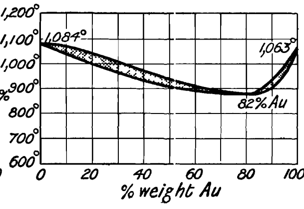

FIG. 18.—Freezing-point Curves of Copper-Gold Alloys.

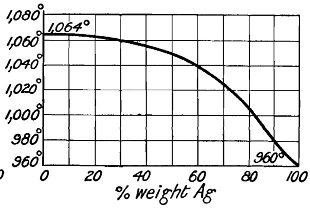

FIG. 19.—Freezing-point Curve of Gold-Silver Alloys.

better able to resist wear without sensibly impairing the malleability or ductility so that standard silver lends itself readily to rolling, stamping, spinning, and other mechanical operations employed in the manipulation of the metal in the arts. The plastic flow of a metal under press. is exemplified in the striking of coins whereby the metal is made to flow into the sunken portions of the die and so produce sharply defined impressions. T. K. Rose measured the hardness of standard silver at the successive stages of coinage. W. C. Roberts-Austen, and E. A. Smith and H. Turner measured some mechanical properties of some Cu-Ag alloys, including the tensile strength, compression, impact, and alternating bend test, see Table V, Cap. XXI. K. Karmarsch, and W. C. Roberts-Austen measured the sp. gr. of these alloys; E. Maey, the sp. vol.; the latter and also L. Weiller, N. S. Kurnakoff, N. Puschin, and N. Senkowsky, A. Matthiessen, and V. Strouhal and C. Barus, the electrical conductivity; and W. Meier, the refractive index, absorption coeff., extinction coeff., and the reflecting power. L. K. Oppitz also measured the optical properties of silver-copper alloys. D. Reicherstein showed that a silvered copper anode plate, in a conc. soln. of $KAgCy_2$, is not so readily polarized as a plate of amalgamated copper. When heated, A. Steinmann found that the surface is enriched in silver, and a film of copper oxide is formed which W. H. Walker showed can be avoided by heating the alloy in an inert gas. A. Sieverts showed that the absorption power of copper for hydrogen is scarcely influenced by alloying it with silver; and A. Sieverts and E. Bergner that the Cu-Ag alloy dissolves less sulphur dioxide than copper alone, and more than copper-gold or copper-platinum alloys. E. Pannain showed that an alloy of silver with one-sixth of copper is insoluble in dil. sulphuric acid. H. Moissan and T. Watanabe found that when the silver-copper alloy is heated in the electric furnace all but about 3 per cent. of the silver can be distilled from the copper. According to H. Rose, when the alloy is heated in air, only a small part of the copper is oxidized, but if a large excess of lead be added, the whole of the copper is oxidized by the cupel; and when fused with sodium chloride, cuprous chloride, but not silver chloride, is formed. According to W. R. Grove, nitric acid dissolves both metals, while a mixture of nitric acid with sulphuric acid acts slowly on copper, and serves to separate it from the silver. C. J. B. Karsten found that an alloy containing over 78 per cent. of silver has no action on silver nitrate, but if less silver be present the silver nitrate is reduced, and this more rapidly as the proportion of copper increases. Curiously enough, not only is the excess of copper simultaneously dissolved during the precipitation, but the reaction continues even after the proportion of silver in the alloy exceeds 78 per cent.

Gold and copper readily form alloys which are redder, harder, and generally more fusible than the gold alone. C. Hatchett found that pure copper does not injure the ductility of gold, but that the gold becomes brittle if alloyed with copper containing lead or antimony. According to G. Bruni and D. Meneghini, the two elements unite to form a solid soln. if a gold wire is heated with copper below the m.p.; and M. le Blanc and L. Bergmann obtained the same result by heating the two elements under fused sodium hydroxide below the m.p. A. Levol stated that only certain **copper-gold alloys** can be obtained homogeneous, Au_8Cu, Au_4Cu, Au_2Cu, AuCu, and $AuCu_5$. R. Pearce[3] reported the formation of compounds of the two elements, but the f.p. curves by E. Rudolfi, E. Jänecke, N. S. Kurnakoff and S. F. Schemtschuschny, and C. T. Heycock and F. H. Neville give no evidence of chemical combination. These are typical U-shaped liquidus and solidus curves as indicated in Fig. 18, with the minimum near 883° with 82·9 per cent. of gold by weight. The British sovereign has 91·66 per cent. of gold, 7·48 per cent. of copper, and a small amount of silver. The electrical conductivity or electrical resistance, and the hardness curves of the alloys of gold and copper, if rapidly cooled by quenching, confirm, fairly well, the results deduced from the f.p. curve, but the case is altogether different when the results are made on annealed or slowly cooled alloys. The electrical conductivity (or resistance) curve shows sharp cusps corresponding with definite **copper aurides,** Cu_3Au and CuAu—Table XI. Similar conclusions are drawn from the curve representing the hardness of slowly cooled alloys—Table XI. It is therefore inferred that definite compounds are formed by the decomposition of an isomorphous mixture or solid soln. of the two elements. There are indications of similar transformations taking place in solidified amorphous mixture of iron and nickel, manganese and nickel, copper and manganese, manganese and cadmium, etc. The sp. gr. of cast alloys of gold and copper have been determined by C. Hatchett, W. C. Roberts-Austen, and C. Hoitsema:

Gold . . .	100	91·7	75·0	58·3	25·0	0	per cent.
Sp. gr. . . .	19·31	17·35	14·74	12·69	10·03	8·7	„

If the alloy has been worked by rolling or hammering, the sp. gr. is greater. The mixture of the two metals contracts on alloying.

TABLE XI.—HARDNESS AND ELECTRICAL CONDUCTIVITY OF GOLD-COPPER ALLOYS.

Atomic per cent.	Electrical $K \times 10^{-4}$.		Brinell's Hardness.	
	Quenched.	Annealed.	Quenched.	Annealed.
0	58·83	58·83	35·30	35·3
10	13·51	13·80	54·50	51·9
20	8·55	9·26	54·35	60·1
25	8·07	17·66	60·45	44·2
35	6·33	6·75	64·52	109·5
50	6·61	17·75	115·40	126·3
70	7·06	6·65	83·10	81·1
100	31·81	31·81	18·64	18·6

P. van Muschenbroeck, C. Hatchett, N. Kurnakoff and S. F. Schemtschuschny have determined the hardness of these alloys; A. Portevin and J. Durand found the Brinell hardness rises to a maximum, and the force required to break a notched bar falls to a minimum with an alloy containing 20 per cent. of copper. The brittleness disappears on tempering at 400° owing to a transformation accompanied by an abrupt expansion. An alloy with 25·2 per cent. of copper, annealed at 700°, contracts when heated, and suddenly expands near 400°, it again contracts up to about 600°. An inverse curve is obtained by cooling, but the sudden change occurs at 350° when the heating and cooling curves intersect. W. C. Roberts-Austen and F. Osmond have measured the tensile strength and elongation of a few alloys; E. Nernst and F. A. Lindemann, and L. Rolla, the sp. ht.; and A. Matthiessen and E. Rudolfi, and A. L. Feild, the electrical conductivity. A. Sieverts found gold lowered the absorptive power of copper for hydrogen. Similarly, A. Sieverts and E. Bergner found gold-copper alloys dissolve less sulphur dioxide than copper or copper-silver alloys, and more than platinum-copper alloys. G. Tammann has also studied the galvanic polarization and the action of reagents on gold-copper alloys. R. Lorenz and co-workers studied the discharge potentials of the alloys. According to H. Moissan, copper first distils from the gold when the alloy is heated in the electric furnace. Copper cannot be completely separated from the alloy by calcining it in air, nor by cupellation with a large proportion of lead; when a triple weight of silver and a 24-fold excess of lead are simultaneously added to the gold-copper alloy, the whole of the copper can be absorbed by the cupel as copper and lead oxide. According to J. MacCulloch, copper may be superficially dissolved from the alloy by heating it with aq. ammonia; and alloys tarnished with cupric oxide may be cleansed by this reagent. G. Tammann studied the electrochemical behaviour of gold-copper alloys; he found that rolled or hammered alloys are more chemically active than annealed alloys.

Gold readily alloys with silver in all proportions, and the resulting products are harder, more fusible, and more sonorous than gold. As the proportion of silver increases, the colour of the alloy passes quickly through a pale greenish-yellow to white. J. Fournet[4] welded gold and silver powders by Wollaston's process for platinum, and obtained a damasked metal, with a true alloy at the surfaces of contact, thus showing that the metals are capable of uniting at a temp. below their m.p. Alloys were made by M. le Blanc and L. Bergmann, and by G. Bruni and D. Meneghini by a method similar to that employed for copper-gold alloys, and at a temp. below the m.p. of either component. A. Bock noted that if a bar be broken, the interior is paler than the exterior, showing that gold tends to segregate and accumulate near the exterior. Native **gold-silver alloys** are represented by auriferous silver, argentiferous gold, and electrum. The proportions are very variable, and the native alloys are therefore very diverse in colour and sp. gr.; but they have the same crystalline form as the parent metals. J. B. J. D. Boussingault assumed that the two elements occur in definite stoichiometrical proportions in his analysis of Columbian ores, but G. Rose has shown that this assumption is not in accord with facts. Analyses have been reported of specimens from different parts of the world made by many workers. S. Field studied the electro-deposition of gold-silver alloys.

Determinations of the f.p. have been made by W. C. Roberts-Austen and T. K. Rose,[5] C. T. Heycock and F. H. Neville, E. Jänecke, G. Bruni and D. Meneghini, U. Raydt, C. H. Mathews, A. Gautier, and T. Erhard and A. Schertel. The f.p. curve of silver-gold alloys lies entirely between the f.p. of the pure metals, Fig. 19. There is a continuous curve with what might prove to be an ill-defined minimum representing a continuous series of mixed crystals, but no compound. The m.p. of an alloy with less than 5 per cent. of silver is virtually the same as that of pure gold; further additions up to 35 per cent. of silver have very little effect, since the 35 per cent. alloy melts but 3° below the temp. of melting gold; with further additions of silver there is a more rapid decrease in the m.p. of the alloy. G. Tammann has studied the space lattice of mixed crystals of gold and silver. C. Hatchett showed that the sp. gr. of silver-gold alloys differs very little from the values calculated from the sp. gr. of the constituent elements. The sp. gr. of alloys of these two metals has been determined by W. C. Roberts-Austen, and C. Hoitsema:

Gold . .	100	91·6	75·0	50·0	25·0	16·7	0	per cent.
Sp. gr. . .	19·31	18·04	16·03	13·60	11·78	11·28	10·47	„

The sp. vol. of the silver-gold alloys was determined by E. Maey and C. Hoitsema; by W. C. Roberts-Austen and F. Osmond, the tensile strength and elongation; the hardness, by C. Hatchett, P. von Muschenbroeck, N. S. Kurnakoff and S. F. Schemtschuschny, and E. Rudolfi; by W. Nernst and F. A. Lindemann, and L. Rolla, the sp. ht.; by A. Matthiessen, V. Strouhal and C. Barus, E. Rudolfi, A. L. Feild, and N. S. Kurnakoff and S. F. Schemtschuschny, the electrical conductivity; by G. Tammann, the galvanic polarization; and by E. Rudolfi, the e.m.f. of the thermo-electric couple. Again, A. Sieverts found the solubility of oxygen in any particular alloy decreases with temp.; and for any given temp., it decreases with increasing proportions of gold. G. Rose and A. Levol noted the spitting of alloys with a preponderating proportion of silver. G. Tammann found that rolled and hammered alloys are more chemically active than annealed alloys. According to M. Hanriot, nitric acid dissolves all the silver from alloys with over 60 per cent. of silver, and gold with about 0·1 per cent. of silver remains behind; alloys with less than 60 per cent. of silver have a residue with a greater amount of this metal. Alloys with less than 50 per cent. of silver are difficult to dissolve in nitric acid and should be melted with more silver if they are to be parted with this acid—*vide* allotropic gold. W. B. Pollard has investigated the action of aqua regia on gold-silver alloys in the presence of ammonium salts and obtained indications of the formation of purple-brown crystals, $3AgCl.4AuCl_3.8NH_4Cl$, which decompose when water is added. G. Tammann has studied the action of reagents on gold-silver alloys. Alloys of silver and gold have long been used for jewellery and coins. The pale-coloured *electrum* has from 15 to 35 per cent. of silver. Coins of electrum were struck about 720 B.C. in Ægina, and a little later in Lydia; these coins were supposed to be three-quarters the value of pure gold coins. Gold and electrum coins were hardened by the addition of copper a few years before the Christian era. C. Hatchett[6] made some observations on the ternary **gold-silver-copper alloys.** E. Jänecke studied the thermal properties of the same alloys, and his results are shown in Fig. 20, arranged in isotectic lines. The curve *CBD* indicates the region where mixed crystals are formed; within that region two layers are formed. There is a minimum line passing from that of the binary eutectic of copper and gold, to the binary eutectic of copper and silver. The eutectic line passes from *E* to *A* in the diagram. The point *A* (42·5Cu, 36·5Ag, 21·0Au) represents a liquid mixture which is in equilibrium with a definite solid mixture, which is represented by *B* (42·5Cu, 33·5Ag, 24·0Au). The alloys were also studied microscopically.

§ 14. The Oxides and Hydroxides of Gold

Gold does not unite directly with oxygen. There are two well-recognized oxides of gold—*aurous oxide*, or *gold monoxide*, Au_2O, and *auric oxide*, or *gold trioxide*, Au_2O_3, which are derived from the corresponding halogen salts; and another, *aurosoauric oxide*, or *gold dioxide*, $(AuO)_n$, is generally regarded as a chemical individual although the evidence is not so satisfactory. It is possible that gold is a monad in aurous oxide; a dyad in aurosoauric oxide; and a triad in auric oxide. The distinction between the hydroxides and the anhydrous oxides in the published records is by no means always clear. Aurous oxide acts as a weak basic oxide, forming *aurous salts*, and possibly also as a very weak acidic oxide, forming *aurites*, $MAuO$. Auric oxide acts as an acidic oxide towards the strong bases, forming a series of salts—called *aurates*, $MAuO_2$; it also acts as a weak basic oxide, forming *auric salts* with the acids. It is doubtful if *gold tetroxide*, Au_2O_4 or the "gold dioxide" of J. P. Prat, and *gold pentoxide*, Au_2O_5, or the "perauric acid" of L. G. Figuier, can be regarded as homogeneous compounds. What was formerly known as *purple oxide of gold* has proved to be nothing more than finely divided gold—*vide* colloidal gold.

Gold monoxide or aurous oxide, Au_2O.—J. J. Berzelius[1] first prepared this oxide in 1811, by the action of a cold dil. soln. of potassium hydroxide on the aurous chloride, which he had discovered. It was called *gold suboxide* and *protoxyde d'or.* G. Krüss warmed aurous bromide with potassium hydroxide and obtained a dark violet precipitate of *aurous hydroxide,* AuOH. According to L. G. Figuier, the product is contaminated with a comparatively large amount of metal, if, as prescribed by J. J. Berzelius, the aurous chloride is prepared at 210° ; but if the latter be prepared at 150°, the aurous oxide is pure. L. G. Figuier also precipitated aurous oxide by treating a neutral dil. soln. of gold trichloride with mercurous nitrate : $2AuCl_3 + 4HgNO_3 + H_2O = Au_2O + 3HgCl_2 + Hg(NO_3)_2 + 2HNO_3$; if an excess of the precipitant is employed, the precipitate is contaminated with mercurous chloride. Aurous oxide was also obtained by mixing auric chloride with an excess of potassium hydroxide, and boiling the soln. with alkali tartrate, citrate, acetate, or other organic salt. If the soln. is neutral or acidic, metallic gold is precipitated. L. G. Figuier reduced auric chloride to aurous oxide by boiling the soln. for a long time with alkali hydroxide, alkali carbonate, or hydrocarbonate or with acetic acid. The non-evolution of oxygen led L. G. Figuier to suggest that a higher gold oxide is simultaneously formed. He also obtained aurous oxide by the prolonged boiling of a soln. of potassium aurate ; and F. Meyer heated a soln. of alkali aurate. According to E. Frémy, the black product with alkali hydroxide is not aurous oxide at all, but rather the finely divided metal, and its formation arises from the accidental presence of organic substances, or more generally from the decomposition of a certain quantity of aurous chloride which is mixed with the trichloride, and is converted by the action of the alkali into metallic gold and the alkali aurate. J. P. Prat, and P. Schottländer obtained what they regarded as *aurous hydroxide,* the former by warming a soln. of gold chloride with potassium hydroxide, the latter by decomposing the sulphate, $AuSO_4$, with water and drying at 100°. G. Krüss' preparation, and the product obtained by L. G. Figuier by the mercurous nitrate process, were regarded as hydroxides.

The analyses of L. G. Figuier, and G. Krüss correspond with what is required for Au_2O. According to the latter, the moist precipitate is dark violet, the dry powder is greyish-violet, and it loses water not oxygen when heated up to 200°. The evolution of oxygen begins between 205° and 210°, and is complete at 250°. According to L. G. Figuier, the dried product is insoluble and stable towards water and alcohol, while G. Krüss said the freshly precipitated oxide is " soluble " in water, forming an indigo-blue soln. with a brown fluorescence, which, according to L. Vanino, is *colloidal aurous oxide.* When the colloidal soln. is boiled, or treated with a salt, or allowed to stand for many days, the dark violet oxide is re-precipitated. H. Vogel and G. Krüss measured the absorption spectrum of the indigo-blue soln., and found the maximum absorption between $\lambda = 586 \cdot 5$ and $587 \cdot 5$. J. J. Berzelius found the oxide to be slightly soluble in a soln. of potassium hydroxide, and he considered that the soln. contained *potassium aurate,* AuOK. J. J. Berzelius also said the oxide he prepared was decomposed by long contact with a soln. of potassium hydroxide, forming dark brown auric oxide and metallic gold which gilded the vessel ; he also said that his oxide did not combine with acids ; L. G. Figuier said his oxide did combine with acids and also with the alkalies. Hence, it is obvious that two investigators worked with different products—J. J. Berzelius' oxide was probably a mixture of metallic gold and aurous oxide. According to E. Frémy, when the alkaline soln. is conc. it decomposes into gold and alkali aurate. L. G. Figuier found that hydrochloric or hydrobromic acids convert the oxide respectively into hydrochloroauric or hydrobromoauric acid ; hydriodic acid forms aurous iodide, and when the soln. is boiled, gold and iodine separate. Aqua regia readily dissolves aurous oxide, forming auric chloride ; but the oxide is not acted on by sulphuric, nitric, or acetic acid. According to F. Raschig, when aurous oxide is triturated with aq. ammonia a violet product is obtained which is less explosive than fulminating gold; it has the composition $NAu_3.NH_3$, and is not very explosive.

Gold dioxide or aurosoauric oxide, Au_2O_2, or $(AuO)_n$.—A hydrated product was obtained by J. P. Prat by dissolving gold in a quantity of aqua regia insufficient for its complete dissolution, and containing an excess of hydrochloric acid; the soln. was then heated with potassium hydrocarbonate until the precipitate first formed redissolved. When the orange-yellow filtrate is heated to 55°, it begins to appear turbid, at 60° it becomes pale green, and at 65°–95° a dark olive-green hydrate separates. The product loses its water in air and becomes almost black; it is completely decomposed when heated to 250°. It dissolves in hydrochloric acid, forming a dark green soln.; dil. hydrofluoric acid gives an insoluble mass; and conc. sulphuric acid unites with aurosoauric oxide especially when heated. According to F. Raschig, aq. ammonia forms a compound with the composition $Au_3N_2.5H_2O$, related to fulminating gold. G. Krüss prepared an oxide of the same composition, by gradually heating pure auric hydroxide up to 160° until the weight remained constant. It is a fine dark yellowish-brown, is very hygroscopic, and can be kept only over phosphoric anhydride. When heated above 173°, it gives off oxygen. W. L. Dudley prepared this oxide by heating auric oxide, Au_2O_3, to 160°. W. G. Mixter was unable to verify these results. P. Schottländer obtained *hydrated aurosoauric oxide*, $3Au_2O_2.2H_2O$, or $Au_3O_2(OH)_2$, or $3AuO.H_2O$, by the decomposition of the sulphate $AuSO_4$ by water. The properties of this hydrate do not agree with those of J. P. Prat's oxide. It forms a crystalline black powder, which is not acted on by boiling potash soln., whilst hydrochloric acid or nitric acid decomposes it into metallic gold and trioxide, the latter dissolving and forming a salt. Mercury removes no gold from this oxide. P. Schottländer is of the opinion that the gold acts as a true dyad, analogous to mercury, and is not to be regarded as a combination of monadic and triadic gold. If this hypothesis be correct, the inadequacy of the nomenclature is at once apparent, and a modification is necessary —possibly on the lines indicated by A. Werner.

J. P. Prat claimed to have made what was called *gold dioxide*, Au_2O_4, that is *gold tetroxide*, by dissolving gold in aqua regia containing an excess of nitric acid, and saturating the liquid with potassium hydrocarbonate. When the liquid is warmed an orange-yellow powder is precipitated. This is stable in light, but when heated towards 200°, it loses its oxygen. G. Krüss assumes that J. P. Prat here made auryl hydroxide, and not the alleged dioxide.

L. G. Figuier prepared a soln. of what he called *acide peraurique*, or *gold pentoxide*, Au_2O_5, by boiling auric oxide for a long time with a soln. of potassium hydroxide, whereby aurous oxide is precipitated, without the evolution of a gas, and potassium peraurate with a little aurate is formed. If sulphuric or nitric acid is added, some auric oxide is precipitated; there is an evolution of a little carbon dioxide, but not of oxygen. The bright yellow filtered liquid is decomposed in a few seconds at 60°–65°, becoming green and turbid, and depositing gold accompanied with the evolution of a little gas. L. G. Figuier added further that if a neutral soln. of auric chloride be boiled with an excess of potassium hydroxide until a considerable proportion of aurous oxide has separated, and then mixed first with barium chloride and then with baryta water, a yellow precipitate is first deposited, and afterwards a green one. If the latter be treated with sulphuric acid, auric oxide mixed with barium sulphate remains, and the liquid contains *acide peraurique*, J. J. Berzelius made this comment: "The verity of Figuier's results depends on whether or not he worked with alkali absolutely free from organic matter." G. Krüss could not confirm L. G. Figuier's results.

Gold trioxide or auric oxide, Au_2O_3.—It was known to the mediæval alchemists that a precipitate, called the *calx of gold*, is obtained when a soln. of gold in aqua regia is treated with sodium hydroxide. The precipitation was described by T. Bergmann at the end of the eighteenth century in his memoir *De præcipitatis metallicis;* while J. L. Proust,[2] and L. N. Vauquelin also prepared an oxide in a similar way; and A. Oberkampf showed that the product is *un peroxyd d'or*, Au_2O_3. The product obtained by precipitation is **auric hydroxide,** $Au(OH)_3$, or $Au_2O_3.3H_2O$;

and, according to G. C. Wittstein, when this is dried over calcium chloride at 100°, or, according to P. Schottländer, when it is heated to 205°, the water is expelled, and the anhydrous oxide, Au_2O_3, is formed—*vide infra.* G. Krüss says that the intermediate hydrate, $Au_2O_3.H_2O$, or $Au_2O_2(OH)_2$, or AuO.OH, *auryl hydroxide*, is formed by drying the normal hydroxide, $Au(OH)_3$, for a week over phosphorus pentoxide. P. Schottländer also found nitric acid of sp. gr. 1·4 transformed the aurosoauric hydroxide, $Au_3O_2(OH)_2$, into gold and auryl hydroxide, AuO(OH). While in aurous oxide, gold acts as a monad, and in auric oxide as a triad.

A. Oberkampf mixed a neutral soln. of auric chloride with less than an eq. of alkali hydroxide, and obtained a yellow precipitate which he regarded as *basic auric chloride*, since it formed a chloride with potassium hydroxide, and was thereby converted into black auric oxide; but J. Pelletier showed that A. Oberkampf's basic oxide was really auric oxide contaminated with auric chloride, since the latter may be washed out by boiling water and nitric acid. L. N. Vauquelin obtained a reddish-yellow precipitate by treating a soln. of gold in aqua regia with potassium hydroxide or carbonate; and J. Pelletier also regarded this as a mixture of auric oxide mixed possibly with potassium aurate. When an excess of potassium hydroxide was used for the precipitation of a hot neutral soln. of auric chloride, A. Oberkampf obtained brownish-black auric oxide, contaminated, according to J. Pelletier, with a little alkali. J. Thomsen mixed a soln. of one mol of auric chloride with three mols of sodium hydroxide and added some sodium sulphate to hasten the sedimentation of the precipitate. P. Schottländer showed that the resulting precipitate is contaminated with alkali which cannot be removed by washing. L. G. Figuier boiled a neutral soln. of auric chloride sat. with sodium carbonate so long as a precipitate was formed. To decolorize the filtrate completely, it was supersaturated with sodium carbonate and neutralized with hot sulphuric acid. L. G. Figuier added potassium hydroxide to a neutral soln. of auric chloride until the liquid was strongly alkaline; he then added barium chloride until the yellow precipitate of barium aurate acquired a whitish colour. The barium aurate was then decomposed with nitric acid, which removed the barium; the residue was well washed and dried in the dark. J. B. A. Dumas employed a somewhat similar process, but boiled the auric chloride with baryta water. J. Pelletier remarked on the difficulty of removing all the barium from the precipitated barium aurate, and he recommended the use of an excess of magnesia or zinc oxide instead of baryta water. C. Wittstein, G. Krüss, and V. Lenher recommended the magnesia process. E. Frémy recommended the following process:

> By adding to the soln. of auric chloride a sufficient quantity of potassium hydroxide to redissolve the precipitate first produced, boiling for a quarter of an hour, whereupon the liquid which is at first dark brown, gradually assumes a yellow tint—then adding sulphuric acid in slight excess—collecting the resulting precipitate on a filter, and washing it with water, till the wash-water no longer gives a precipitate with barium salts, auric oxide is formed. The first addition of the potassium hydroxide converts the auric chloride into an oxychloride, which then forms a soluble compound with the potassium hydroxide; if the soln. be treated with an acid without previous boiling, a precipitate is obtained consisting of the oxychloride, which may be distinguished from the auric oxide by dissolving slowly, but completely, in pure water. It is only by continued boiling that the compound of the oxychloride with potassium hydroxide is converted into the aurate of potassium, the conversion being attended with the change of colour above noticed. The auric oxide obtained in the manner just described is not quite free from potassium hydroxide, even after long-continued washing. It may be purified completely by treating it with very strong nitric acid, which dissolves it readily—mixing the soln. with water, which immediately precipitates the auric oxide—and washing the precipitate thoroughly with pure water.

P. Schottländer obtained auric oxide by the action on auryl nitrate or sulphate; and by dissolving gold in sulphuric acid mixed with manganese dioxide at 250° and decomposing the cold soln. with water. A good method of preparing auric oxide is to electrolyze a dil. soln. of nitric acid with a gold anode in a porous cell. The yellow liquid is decomposed with water as indicated in describing the action of nitric acid on gold. F. Meyer added precipitated gold to sodium peroxide melted in a nickel crucible, and raised the temp. to bright redness for ten minutes; leached the cold mass with water; filtered off the nickel oxide and the excess of gold; treated the green filtrate, a soln. of sodium aurate with dil. sulphuric acid, and dried the washed product in vacuo in darkness. In the electrolysis of dil. sulphuric acid with gold electrodes, A. Rundspaden found that the anode was covered with a thick yellowish-red crust of auric hydroxide. W. G. Mixter also prepared auric oxide by making gold the anode in an electrolyte—with potassium sulphate as an electrolyte, the auric hydroxide retains some potassium presumably as aurate; and with sulphuric acid as electrolyte, the deposit contains some basic sulphate which is not removed by cold water.

Auric hydroxide is a brownish-black powder, and, according to L. G. Figuier, that which is precipitated by conc. acid from potassium aurate is olive-green inclining to black, while that precipitated by acids of medium conc. is dark yellow, and he found that when dried under reduced press. or in dry air, it contained 24 per cent. of water—when $Au_2O_3.8H_2O$ corresponds with 24·6 per cent.; while G. C. Wittstein found that the hydrate precipitated by baryta water contained 11·1 per cent. of water, when dried over calcium chloride in vacuo—the theoretical value for $Au_2O_3.3H_2O$ is 10·9 per cent. L. G. Figuier found that a little oxygen is lost along with water in the drying of samples at 100°, and W. L. Dudley also found oxygen to be evolved at 110°, and at 160° the residue has a composition corresponding with Au_2O_2. W. G. Mixter also found oxygen is given off before all the water is expelled from auric hydroxide, that the decomposition is complete at 245°. W. G. Mixter heated 3·6907 grms. of auric hydroxide in a bulb 4 hrs. at 135°, and found its weight reduced to 3·6127 grms.; 18 hrs., 135°–148°, and found 3·5615 grms.; 20 hrs., 161°–168°, and found 3·5507 grms.; 24 hrs., 180°–204°, and found 3·504 grms.; 2½ hrs., 200°–215°, and found 3·497 grms.; 2 hrs., 218°–231°, and found 3·479 grms.; 2 hrs., 235°–244°, and found 3·417 grms.; 3 hrs., 240°–260°, and found 3·251 grms.; 2½ hrs., 250°–295°, and found 3·126 grms.; and above 360°, 3·083 grms. The loss with 80 hrs'. heating from 135°–213° was 5·7 per cent., which is practically the same as the amount of water in the original substance. The hydroxide is decomposed by light. J. Thomsen found the heat of formation of auric hydroxide, $2Au+3O+aq.=Au_2O_3aq.-11·5$ Cals. W. G. Mixter gave —12·3 Cals. for the heat of formation of auric oxide from its elements.

The hydroxide is readily reduced when warmed in a stream of **hydrogen,** and the gas first burns with a green, then a red flame. I. W. Fay and A. F. Seeker found an appreciable reduction occurs at 0° when the oxide is treated with hydrogen and with **carbon monoxide.** According to H. H. Morris, when gold hydroxide in a steel bomb is treated with **water** at 322°, metallic gold is formed; the presence of sodium or magnesium chloride favours the decomposition, while calcium chloride hinders the change. W. G. Mixter found auric hydroxide is reduced to the metal by **hydrogen peroxide** or a soln. of **sodium peroxide.** According to J. Pelletier and E. Frémy, auric hydroxide is easily soluble in **hydrochloric acid** and **hydrobromic acid,** but J. P. Prat found it to be insoluble in **hydrofluoric acid,** and this, added V. Lenher, even after digestion for a week in the presence of nitric acid. When warmed with water and **iodine,** it forms a turbid liquid from which a pale yellow powder settles—L. G. Figuier believed the product was a higher iodide, J. J. Berzelius an iodate. J. Pelletier found that with aq. **hydriodic acid,** aurous iodide and iodine are formed and the mixture deposits gold when warmed. Cold **alcohol** has no action on hydroxide, but with boiling alcohol some gold separates out. Auric hydroxide unites with the **alkali hydroxides** and with several other metal oxides, forming aurates—*vide infra.* According to J. Pelletier, when the hydroxide is treated with an aq. soln. of potassium hydroxide, part is reduced to the metallic state, and part is precipitated as black oxide. L. G. Figuier found the freshly precipitated hydroxide to be almost insoluble in a conc. soln. of potassium hydroxide, and it dissolves when heated, forming potassium aurate and some aurous oxide. J. Pelletier found that with an alcoholic soln. of potassium hydroxide it is reduced to hard shining gold scales, once used in painting miniatures. H. Rose found it to be insoluble in a soln. of **alkali bicarbonates**; and J. Pelletier found it to be sparingly soluble in boiling aq. soln. of **potassium, sodium, or barium chloride,** forming a yellow alkaline fluid.

The hydroxide, even when freshly precipitated, is very sparingly soluble in most acids; it is somewhat soluble in conc. **sulphuric acid,** but the oxide is re-precipitated by diluting the soln. J. L. Proust and E. Frémy noted the ready solubility of the hydroxide in **nitric acid,** and when the soln. is diluted with water, gold is quantitatively precipitated. H. Rose noted that fuming nitric acid dissolves very little hydroxide, and at the same time exerts a reducing action in virtue of the contained nitrous acid; **orthophosphoric acid** has very little action on the hydroxide; **oxalic acid** reduces it to the aurous oxide and gold; and of all the oxy-acids, **acetic acid** dissolves the hydroxides most readily, and the deep yellowish-brown soln. deposits some gold and some of the hydroxide on standing, and when the acetic soln. is boiled it deposits auric hydroxide again. In general, the **organic acids** reduce the hydroxide, and consequently do not form gold salts. Nor does auric hydroxide unite with **carbonic acid** or **boric acid.** According to E. Beutell, auric hydroxide dissolves in an aq. soln. of **potassium ferrocyanide** at ordinary temp., and rapidly when the soln. is boiled. Potassium cyanoaurate, $KAuCy_2$, is formed, and some ferric hydroxide is precipitated if the soln. is alkaline.

The action of **ammonia** on gold oxide or of alkali on an ammoniacal soln. of a salt of gold attracted much attention from the alchemists of the Middle Ages. In virtue of the fact that when rubbed, struck, heated, or exposed to an electrical spark, it detonates with a loud, sharp report, and a faint light, led to its being called **fulminating gold.** The anonymous writer, Basil Valentine,[3] in the seventeenth century, described its precipitation by the action of *sal tartari* on a soln. of gold in a mixture of nitric acid and ammonium chloride; and he added that the powder is so explosive that "when exposed to a little warmth, it ignites and does a great damage, for it then explodes with such great power and might that no man can withstand." It was called *aurum fulminans* by J. Begiun (1608); *aurum volatile* by O. Croll (1609); *pulvis pyrius aureus* by A. Kircher (1641); *aurum sclopetans* by J. Schröder (1641); *saffran d'or* or *or fulminant* by N. Lemery (1675); and various other names were assigned to it, for example, *magisterium ceraunochryson, pulvis chrysoceraunius,* etc. Observations on fulminating gold were also made by T. Willis (1659), A. Sala (1620), J. R. Glauber (1648), G. E. Stahl (1702), F. Hoffmann (1722), J. Juncker (1730), A. S. Marggraf (1745), J. Black (1755), A. Baumé (1763), J. F. Meyer (1764), etc. They thought the explosiveness was due to the evolution of fixed air. J. Kunckel (1716) first observed that *aurum fulminans* contained ammonia as an essential constituent. The compound was further investigated by T. Bergmann in his dissertation *De calce auri fulminante* (Upsala, 1769), and by C. W. Scheele in his *Chemische Abhandlung von der Luft und Feuer* (Upsala, 1777), and confirming J. von Löwenstein-Kunckel's observation, fulminating gold was found to be a compound of gold calx and ammonia, and the French chemists accordingly called it *oxide d'or ammoniacal.*

According to T. Bergmann, and C. W. Scheele, auric hydroxide is converted into fulminating gold by immersion in aq. ammonia, or in a soln. of ammonium chloride, sulphate, or nitrate; and he found a gain of 23·3 per cent. in weight in aq. ammonia, and T. Bergmann a gain of 20 per cent. in weight in the other soln., and at the same time, the liquid acquires an acid reaction. The auric hydroxide prepared by J. B. A. Dumas' process[4] yields green fulminating gold when immersed 24 hrs. in conc. aq. ammonia, and washed and dried at 100°. T. Bergmann also precipitated fulminating gold by adding aq. ammonia or ammonium carbonate to a soln. of auric chloride; and he observed that the greater the quantity of free acid in the gold soln. or a soln. of auric hydroxide in nitric or sulphuric acid, and the larger the excess of ammonia employed, the less the quantity of gold precipitated. The more completely the precipitated *aurum fulminans* is washed, the more readily and violently does it detonate; the detonating power is likewise increased by boiling the product with a soln. of potassium hydroxide or carbonate, and thoroughly washing it with water. The wash-water was found by J. B. A. Dumas still to give a turbidity with silver nitrate, even after three days' washing. J. J. Berzelius pointed out that the last traces of absorbed auric chloride can be removed by washing with hot water containing ammonia. W. G. Mixter found that when a soln. of ammonium carbonate is electrolyzed with gold electrodes, fulminating gold is deposited on the anode.

J. B. A. Dumas' analyses of fulminating gold can be represented by $Au_2O_3.4NH_3$, *gold tetrammino-oxide*, or $AuN.NH_3.1\frac{1}{2}H_2O$, or, according to F. Raschig, $HN:Au.NH_2$ *auric imidoamide*. If aq. ammonia is added to a soln. of auric chloride a mixture of fulminating gold and yellow *auric imidochloride*, $NHAuCl$, is formed, and the chlorine cannot be all removed by a prolonged digestion with aqua ammonia. Fulminating gold is resolved by detonation into gold, nitrogen, ammonia, and water, and, said T. Bergmann, silver or copper supports are gilded by the explosion. T. Bergmann obtained 11 c.c. of nitrogen from 0·625 grm. of fulminating gold; and C. W. Scheele obtained a volume of nitrogen gas equal in bulk to 1875 grms. of water from 0·06 grm. of fulminating gold. According to J. B. A. Dumas, when fulminating gold is kept for some hours at 100°, it becomes so sensitive that it can scarcely be touched without exploding. T. Bergmann found that the moist product does not detonate by heat until it becomes dry, and then not violently all at once, but in separate portions as they give off their water; it acquires a blackish tint when the temp. is raised just below the temp. of explosion, which J. B. A. Dumas places at 143°. Both T. Bergmann and J. B. A. Dumas noted that if care be taken to avoid friction, fulminating gold can be heated nearly to the explosion temp., then cooled a little, and more strongly heated, again cooled, and again still more strongly heated; it can finally be heated to redness without exploding, and all the gold remains behind in the metallic state. The explosion of fulminating gold is very violent, and T. Bergmann reports the bursting of the doors and windows of an apartment in which a mass exploded, and A. Baumé says that a dram of fulminating gold in a bottle, exploded while the stopper was being turned round, so that "the operator's two eyes were irrecoverably destroyed by the projected fragments of glass." A mixture of fulminating gold with finely divided salts of the alkalies or alkaline earths may be heated without explosion; and J. B. A. Dumas obtained nitrogen gas but no nitric oxide by heating a mixture of fulminating gold and copper oxide. A mixture of the explosive with one or two times its weight of sulphur does not explode, and T. Bergmann added fulminating gold in small portions at a time to molten sulphur without explosion. Basil Valentine first found that fulminating gold loses its explosiveness when heated with sulphur. Hydrogen sulphide and also stannic chloride were found by J. L. Proust to decompose fulminating gold without explosion. T. Bergmann found that fulminating gold can be gently heated with sulphuric acid without change, and at the b.p. of the acid, it is decomposed into metallic gold, etc., without explosion. It also forms an explosive sulphate, $4(HN:Au.NH_2)H_2SO_4$. It can be boiled with dil. sulphuric or nitric acid without decomposition. Boiling hydrochloric acid dissolves a little fulminating gold, $AuNH.NH_2+5HCl=AuCl_3+2NH_4Cl$; and potassium hydroxide precipitates fulminating gold from the soln., copper precipitates gold, and C. W. Scheele found the remaining liquid yields ammonium carbonate when distilled with potassium carbonate. Aq. alkalies, most acids, and alcohol, hot or cold, have no action on fulminating gold, but it is dissolved by a soln. of potassium cyanide, forming potassium hydroxide, ammonia, and ammonium cyanoaurate, NH_4AuCy_2. E. Beutell has studied the action of a dil. soln. of potassium ferrocyanide on fulminating gold, and found that at ordinary temp. hydrocyanic acid is formed; and when the mixture is boiled ferric hydroxide is precipitated, and all the gold forms potassium cyanoaurate, $KAuCy_2$.

Auric acid and the aurates.—Gold hydroxide unites with bases to form aurates. A soln. of gold hydroxide in soln. of alkali hydroxides or chlorides contains the corresponding aurate. J. J. Berzelius[5] noted that when aurous oxide is treated with an aq. soln. of potassium hydroxide it decomposes into metallic gold and potassium aurate; S. Tennant noted that when potassium nitrate is melted in a gold vessel, and the cold cake leached with water, a yellow soln. is obtained from which gold can be precipitated by potassium nitrite; J. Pelletier digested auric hydroxide in potassium hydroxide, and obtained a soln. of potassium aurate, which E. Frémy found, on evaporation in vacuo, furnished pale yellow masses and needle-like crystals of trihydrated **potassium aurate**, $K_2O.Au_2O_3.6H_2O$, or $KAuO_2.3H_2O$. F. Meyer represents its composition by $KAuO_2.2H_2O$. According to E. Frémy, potassium aurate is readily soluble in water, forming a pale yellow liquid with a feeble alkaline reaction indicative of hydrolysis, and on evaporation of the soln., much of the gold separates out. F. Meyer made potassium aurate by adding potassium sulphate to a soln. of barium aurate. H. Elkington, and E. L. Schubarth used the soln. of gold hydroxide in potassium hydroxide for gilding copper, brass, and bronze. E. Frémy found copper precipitated black pulverulent gold from a warm soln. of potassium aurate. Most metallic salts were found to give precipitates with potassium aurate, forming sparingly soluble metal aurates, although many redissolve in an excess of the precipitant. For example, calcium chloride precipitates *calcium aurate*, which is soluble in an excess of calcium chloride. Potassium aurate is decomposed by almost all organic substances, with the separation of gold.

F. Meyer prepared a green soln. of **sodium aurate** in connection with the preparation of auric hydroxide. He also digested auric hydroxide with an aq. soln. of sodium hydroxide, excluding access of atm. carbon dioxide, and evaporated the soln. in vacuo in darkness. The product was rapidly washed with alcohol. He also obtained a soln. of the same salt by adding sodium sulphate to a soln. of barium aurate, and filtering. The acicular crystals obtained by evaporating the aq. soln. are pale green; and are assumed to have a composition $NaAuO_2.2H_2O$. They detonate when heated with organic substances—*e.g.* paper. They are insoluble in alcohol. The aq. soln. is decomposed by heat and light; the soln. is reduced by sulphur dioxide. Alcohol furnishes gold and aldehyde. Hydrochloric acid converts the soln. into auric chloride. Dil. sulphuric or nitric acid converts the salt soln. into one containing **auric acid,** $HAuO_2$. According to W. G. Mixter, the heat of formation is $Au_2O_3+3Na_2O=100{\cdot}9$ Cals., and $2Au+3O+3Na_2O=88{\cdot}6$ Cals.

J. Pelletier obtained **barium aurate** by mixing a neutral soln. of auric chloride with baryta water. The precipitate dissolves in acetic acid, and the soln. furnishes crystals of the double acetate of gold and barium. F. Weigand said the filtrate from the preceding precipitate furnishes small green rhombic crystals of the composition $Ba(AuO_2)_2.5H_2O$. F. Meyer regarded the pale green powder which he obtained by adding baryta water to a soln. of sodium or potassium aurate, washing the gelatinous precipitate with water, and drying in vacuo in darkness, as having composition $Ba(AuO_2)_2.6H_2O$. The pale green powder gradually loses water in vacuo; it is decomposed by light; and is rather more soluble in water than the alkali aurate. E. Frémy prepared **calcium aurate** as indicated above, and F. Meyer also obtained a product, $Ca(AuO_2)_2.6H_2O$, analogous with the barium salt. J. Pelletier obtained **magnesium aurate** by a method analogous to that employed for the barium salt.

§ 15. Gold Fluoride

Gold does occur associated with fluorspar, particularly in telluride deposits, but gold fluoride itself does not appear to be capable of existence in the presence of water, nor under the ordinary conditions which obtain in nature. The gold halides are fairly well defined. Tervalent gold forms a relatively stable chloride, while the bromide and iodide are not so stable and are liable to break down into univalent gold halides. As a rule, the elements form halides whose stability is inversely as the at. wt. of the combined halogen. Fluorine is the most chemically active of all the halogens—if not of all the elements—and yet it appears to have but little affinity for gold. This might not be expected from a comparison of the relative stability of the other gold halides with the at. wt. of the halide, although the known properties of other fluorides have made chemists rather cautious in predicting the properties of the fluorides by extrapolation so to speak with the properties of the other halides. For example, contrast the solubility of the chlorides, bromides, and iodides of the alkaline earths with the insolubility of the fluorides; and the solubility of the thallium and silver fluorides with the insolubility of the chlorides, bromides, and iodides. H. Moissan[1] states that gold is not attacked by fluorine at ordinary temp., but when gold wire is heated to dull redness in a stream of fluorine, a crust of reddish-yellow powder is formed on the metal. This powder attracts moisture from the air with great avidity; it is volatile at a temp. a little higher than that at which it is formed, and decomposes into fluorine gas and the metal. J. P. Prat seems to have obtained a kind of basic fluoride, possibly a mixture of fluoride and oxide, as an insoluble product of the action of hydrofluoric acid upon gold sesquioxide ; but V. Lenher says that this oxide is not attacked by digesting it for a week in nitrohydrofluoric acid. According to O. Ruff, similar remarks apply to gold dichloride when heated up to the temp. of its decomposition with hydrogen fluoride ; or up to 280° with potassium hydrogen fluoride ; V. Lenher adds that when a soln. of silver fluoride is heated with auric chloride or hydroxide, if the double decomposition : $AuCl_3+3AgF=AuF_3+3AgCl$, does occur, the gold fluoride is immediately hydrolyzed by water, for gold hydroxide is quantitatively precipitated : $AuCl_3+3AgF+3H_2O=3AgCl+Au(OH)_3+3HF$. Many other processes were tried but without success ; nor was he able to find a non-aqueous solvent which dissolved both gold chloride and silver fluoride without decomposition.

§ 16. Gold Chlorides

The solvent action of aqua regia on gold is mentioned in Geber's *De inventione veritatis*, for he says that the addition of sal ammoniac accentuates the solvent action of *aqua dissolutiva* (nitric acid) because it then dissolves gold. The soln. of gold in aqua regia was known to all the succeeding alchemists, and called by them potable gold, to which many medicinal virtues were ascribed ; it was regarded as the elixir of life. Roger Bacon, in urging this terrestrial hippocrene to the attention of Pope Nicholas IV, related :

> An old man, when ploughing a field in Sicily, one day found some of the yellow potable gold in a golden phial, and, supposing it to be dew, drank up the liquor. He was thereupon transformed into a hale, robust, and highly accomplished youth. The youth was thereafter received into the service of the Sicilian king, where he served some eighty years.

There are relics of the mediæval ideas regarding the virtues of yellow golden water in some present-day quack medicines. Basil Valentine,[1] Robert Boyle, and O. Tachen refer to colour effects obtained by the soln. of gold with various reagents. Basil Valentine reported that mercury forms gold amalgam when mixed with the gold soln., and that the gold remains as a purple powder when the mercury is distilled off. R. Boyle, J. R. Glauber, J. Kunckel, and J. C. Orschall refer to the reduction of gold from its soln. in aqua regia by means of organic matters, mercury nitrate, and ferrous sulphate.

There are two well-defined gold chlorides—aurous chloride, AuCl ; and auric chloride, $AuCl_3$. Several investigators claim to have made an *intermediate chloride*. J. P. Prat stated that finely divided gold, or aurous chloride dissolves with the evolution of heat in a soln. of auric chloride, possibly with the formation of a compound of aurous and auric chlorides ; he also said that a *higher chloride* than the trichloride is produced when chlorine is passed over auric chloride. According to J. Thomsen,[2] if dry chlorine be passed over dried and finely divided gold, the mixture becomes heated, without the application of external heat, and **aurosoauric chloride,** or **gold dichloride,** Au_2Cl_4, is formed. This may be regarded as **aurous chloroaurate,** $Au.AuCl_4$. According to J. Thomsen, aurosoauric chloride is a dark red hygroscopic solid which decomposes at 250°. T. K. Rose says the sp. gr. is 5·1. Its heat of formation was measured by E. Petersen. J. Thomsen shows that the product is decomposed by water or by alcohol into aurous and auric chlorides. A. Meillet claims to have made a double sodium and aurosoauric chloride—*vide supra.*

According to G. Krüss, when finely divided gold is heated to 140° in dry chlorine, aurosoauric chloride is formed, which decomposes into aurous and auric chlorides at 180°–190°. At 220°–230°, some auric chloride is formed, and the aurous chloride decomposes; above this temp. the gold is not attacked by chlorine. On cooling these changes are said to be reversed. In a subsequent memoir, G. Krüss and F. W. Schmidt say that the only products of the reaction of chlorine on gold are the two chlorides, $AuCl$ and $AuCl_3$, and they maintain that the alleged compound, Au_2Cl_4, does not exist, for when made under different conditions, the product has a variable composition, never that of Au_2Cl_4; the ultimate product of the action is auric trichloride, and the alleged compound represents the product of a reaction arrested before it is completed, and is a mixture of auric chloride and unaltered gold. E. Petersen claims that G. Krüss and F. W. Schmidt washed their product with water and ether, and this is inadmissible, because J. Thomsen showed that it is decomposed by this menstruum. Even with alcohol at —20°, there is some decomposition. E. Petersen concludes from his synthetic and calorimetric experiments that this compound is a real chemical individual. G. Krüss and F. W. Schmidt repeated E. Petersen's experiments and again confirm their former conclusion.

Aurous chloride, or gold monochloride, $AuCl$.—J. C. Leuchs recommended heating the auric chloride, $AuCl_3$, between 230° and 300°; J. J. Berzelius[3] to the m.p. of tin, that is between 228° and 230°; L. Vanino and L. Rössler, to about 200°; J. Thomsen, to 185°; F. W. Schmidt, and F. Lengfeld, in a paraffin bath at 175°, for several days; L. G. Figuier, between 120° and 150°; and J. Löwe, in a thin dish at the temp. of a boiling water-bath for some days. The liquid should be protected from dust during the evaporation, otherwise some of the salt may be reduced to the metal. The auric chloride first acquires a reddish-brown colour, then dirty brown, yellowish-brown, greenish-yellow, and finally yellow. F. H. Campbell also claims to have made aurous chloride by heating auric chloride in vacuo to 170°, and washing the product with ether until the washings were no longer coloured by auric chloride.

F. Lengfeld showed that at 185° auric chloride slowly dissociates into gold and chlorine, and below 175° some auric salt escapes decomposition; and M. E. Diemer, that when ordinary auric chloride—in reality hydrochloroauric acid, $HAuCl_4$—is heated there appears to be no intermediate stage between auric chloride and metallic gold, and in consequence the formation of aurous chloride might be questioned. If, however, the auric chloride be prepared quite free from hydrochloric acid and water, it shows no loss in weight and not the slightest sign of decomposition at 100°; but if heated in an atm. of hydrogen chloride at 190° chlorine is evolved and the product assumes a yellowish-white colour and undergoes no further change when heated at this temp. for a long time. The curve showing the loss in weight at different intervals of time indicates a definite break about the point where the auric chloride is converted to the aurous salt. This indicates that aurous chloride is probably a definite compound, and not a mixture of auric chloride and gold. The important factor in the preparation of aurous chloride is the exclusion of water. If heated in dry air, the product is contaminated with metallic gold; and this dissociation is prevented by heating the auric chloride in an atm. of hydrogen chloride.

V. Lenher showed that not only can auric chloride be reduced to aurous chloride by heat, but in the presence of sodium, potassium, magnesium, zinc, and cadmium chlorides, the auric salt is reduced to the aurous condition by sulphur dioxide: $AuCl_3.nMCl_2+SO_2+2H_2O=AuCl.nMCl_2+H_2SO_4+2HCl$; and by arsenites: $AuCl_3.nMCl_2+Na_2HAsO_3+H_2O=AuCl.nMCl_2+2NaCl+H_3AsO_4$. M. E. Diemer also showed that a soln. of auric chloride or hydrochloroauric acid is bleached by sulphur dioxide before metallic gold begins to separate, and this is particularly the case in the presence of potassium, sodium, ammonium, or magnesium chlorides. When the soln. becomes colourless the electrode potential reaches a maximum, and there is a decided break at a point corresponding with the formation of aurous chloride, and this is the only break between auric chloride and the complete reduction to the metal. These soln. are more stable than those of auric chloride, and it is supposed that compounds of the type NaCl.AuCl are formed.

J. Nicklès prepared the salt by J. Pelletier's process and also by the action of manganese perchloride on the metal. He recommended separating aurous from auric chloride by treatment with ether which removes the auric chloride. J. C. Leuchs says that he obtained aurous chloride by heating auric chloride with conc. sulphuric acid, to 210°—decomposition begins at 170°. E. Bose has shown that in the presence of metallic gold, there is a state of equilibrium in aq. soln. of gold chloride: $2Au+AuCl_3 \rightleftharpoons 3AuCl$, which is displaced in favour of the aurous chloride by a rise of temp.; and E. Wohlwill found evidence of the formation of aurous chloride during the electrolysis of soln. of auric chloride with varying anodic current densities. Owing to the accumulation and decomposition of aurous chloride at the anode the loss at the anode is in excess of the gain at the cathode. The formation of aurous chloride decreases as the current density increases.

According to F. H. Campbell, aurous chloride is a dark red crystalline solid; and, according to M. E. Diemer, the colour is yellowish-white—possibly the difference is due to the former being contaminated with a minute quantity of very finely divided gold. T. K. Rose gives the sp. gr. as 7·4, and the mol. vol. 32. J. Thomsen gives the heat of formation from its elements as 5·81 Cals. F. Lengfeld says aurous chloride decomposes above 175° into the auric salt, and F. Meyer, that the dissociation begins at about 170°, and F. W. Schmidt, at about 210°. The dry salt, says M. E. Diemer, can be heated to 190° to 200° in an atm. of hydrogen chloride. F. Meyer says the dissociation press. at 207° is 65 mm., and F. Ephraim gave 289·5° for the dissociation temp. at atm. press.

F. Lengfeld says aurous chloride is insoluble in **water,** but, according to M. E. Diemer, it is immediately decomposed by water, even moist air quickly causes the separation of metallic gold: $3AuCl \rightleftharpoons 2Au+AuCl_3$; and the liquid becomes yellow owing to the formation of auric chloride. J. J. Berzelius and J. C. Leuchs say that in darkness, and in the cold, the decomposition is slow; but faster in light and when heated, and complete with boiling water. Aurous chloride is decomposed by **alcohol,** and, according to E. Petersen, the decomposition is slower with alcohol than with water; F. Lengfeld also says that this salt is slowly decomposed by **acetone** and by **ether.** F. H. Campbell found that dry **chlorine** converted it into auric chloride. M. E. Diemer says aurous chloride is decomposed when heated in an atm. of **nitric oxide** or **carbon monoxide**, forming metallic gold; with carbon monoxide, phosgene is formed; aurous chloride is slowly decomposed by **sulphur dioxide.** F. Lengfeld says that this salt is insoluble in dil. *nitric acid,* but decomposed, by conc. nitric acid—an auric salt passes into soln., and some gold remains as a residue. Aurous chloride dissolves in hydrochloric and hydrobromic acids, and in the alkali chlorides and bromides with decomposition; the decomposition is faster with bromides than with chlorides. J. Thomsen found aurous chloride to react with **hydrochloric acid:** $3AuCl_{solid}+HCl_{aq.}=HAuCl_{4aq.}+2Au+4·98$ Cals. According to F. Lengfeld, if aurous chloride be added to a soln. of **potassium bromide,** the resulting brownish-red liquid contains both potassium aurichloride and auribromide: $4KBr+12AuCl=KAuBr_4+3KAuCl_4+8Au$; aurous chloride also dissolves slowly in soln. of potassium chloride. According to M. E. Diemer, soln. of potassium, sodium, ammonium, magnesium, and calcium aurous chlorides can be made by adding sulphur dioxide to a soln. containing one mol of aurous chloride to one of the other chlorides until the soln. is decolorized—some gold is precipitated at the same time—with calcium chloride, however, an excess of about 40 mols is needed. The soln. in each case probably contain complex ions.

J. J. Berzelius obtained what is regarded as **potassium auro-chloride,** KCl.AuCl, or $KAuCl_2$, by melting potassium auri-chloride, $AuCl_3.KCl$, or $KAuCl_4$. The molten salt is brownish-black, and after cooling, yellow. It does not decompose when heated to redness in open vessels, but in water or hydrochloric acid, it forms gold, potassium, and potassium auri-chloride; it is decomposed by **potassium hydroxide** into aurous oxide and potassium chloride. By dropping an acid soln. of auric chloride into sodium thiosulphate, and evaporating the soln. over quicklime, in addition to sodium chloride, sulphate, and thiosulphate, fine colourless needles are formed which A. Meillet thought were **sodium auro-aurichloride,** $4NaCl.AuCl.AuCl_3$, or $4NaCl.Au_2Cl_4$. The crystals are separated by washing out the sodium aurochloride with alcohol, and recrystallizing. The product is soluble in alcohol and insoluble in water, and it is thought to be **sodium aurochloride,** NaCl.AuCl. F. Lengfeld says a soln. of sodium chloride dissolves aurous chloride with little decomposition, forming a colourless soln.—possibly sodium aurochloride—which is unstable, for on standing gold is deposited and the soln. becomes yellow, and then contains sodium chloroaurate, $NaAuCl_4$. The aurochlorides can also be called **chloroaurites.**

M. E. Diemer says that aurous chloride dissolves in aqua *ammonia* like silver chloride, and when the soln. is acidified with hydrochloric acid, a white crystalline precipitate is formed so unstable that it decomposes when dried—its analysis corresponds with **aurous ammino-chloride,** $AuCl.NH_3$. The same compound is precipitated when an ammoniacal soln. of one of the double aurous chlorides is acidified with hydrochloric acid. When the ammoniacal soln. of aurous chloride is treated with a conc. soln. of sodium or potassium hydroxide, there is deposited a white flocculent precipitate which is very unstable and darkens in a few minutes; the partially decomposed substance explodes if heated gently. F. Lengfeld also says a white curdy precipitate resembling silver chloride is formed when nitric acid is added to the ammoniacal soln. of aurous chloride; the precipitate during washing decomposes into auric chloride and gold. F. Herrmann also prepared aurous ammino-chloride, $AuCl.NH_3$, by the action of aqua ammonia or auro dibenzylsulphine chloride, $AuS(C_7H_7)_2Cl$, and extracting the soln. with ether. The evaporation of the aq. layer over sulphuric acid gives the salt in question. Aurous ammino-chloride decomposes at 150°–200° without melting. It is soluble in aqua ammonia, insoluble in water. According to F. Ephraim, **aurous diammino-chloride** has a dissociation temp. of 113·5°. N. S. Kurnakoff studied the constitution. F. Meyer prepared **aurous dodeca-ammino-chloride,** $AuCl.12NH_3$, by the action of ammonia on aurous chloride at —28°; by gradually raising the temp., it passes into **aurous triammino-chloride,** $AuCl.3NH_3$, which is a white powder, stable up to 180°, but at higher temp. it decomposes into gold, ammonium chloride, etc.; it is decomposed by water; dil. acids transform it into the corresponding ammonium salt and a white curdy substance resembling silver chloride, which is unstable, and is slightly soluble in hydrochloric acid and in aqua regia; conc. sulphuric acid first dissolves and then decomposes the white substance. Aurous triammino-chloride is decomposed by potassium hydroxide, forming a brown explosive substance and ammonia.

According to L. Lindet, 100 grms. of phosphorus trichloride dissolves a gram of aurous chloride at 15°, and about 12·5 grms. at 120°; he also obtained **aurous phosphoro-chloride,** $PCl_3.AuCl$ or $AuPCl_4$, by heating aurous chloride with an excess of phosphorous chloride in a sealed tube between 110° and 120°; prismatic crystals separate when the liquid cools. The salt is virtually insoluble in water, and the assumption that the ions are $Au^{\cdot}$ and PCl_4' is based on R. Abegg's valency theory—the positive valencies of phosphorus are balanced by the positive contra-valencies of chlorine. The compound has the characteristics of a derivative of phosphorous acid—*e.g.* it furnishes this acid when decomposed by water and the ester *aurous phosphoro-triethoxychloride*, $AuP(OC_2H_5)_3Cl$, when treated with alcohol.

Auric chloride, gold trichloride, $AuCl_3$.—J. Thomsen made auric chloride by treating finely divided gold at 200° with chlorine gas; H. Debray conducted the operation at 300°, and obtained sublimed auric chloride in red needle-like crystals. According to G. Krüss, H. Debray's estimate, 300°, is too high, for at that temp. he found the gold remains unchanged in a current of chlorine; and G. Krüss' description modified by T. K. Rose of the action of a continuous current of dry chlorine on gold at different temp. is as follows:

As the temp. rises to 140°, a small quantity of a reddish-brown vapour is formed; this condenses to a yellowish-red sublimate; if the temp. be maintained constant, the sublimation soon ceases, and the gold is converted into a mixture of aurous and auric chloride. When the temp. is raised to 180°–190°, this product decomposes, chlorine is evolved, green aurous chloride and a small quantity of auric chloride volatilize. As the temp. rises higher, the sublimed crystals form more rapidly in the cool part of the tube, and the part being heated darkens in colour, until, at 270°, it is almost black, and consists of lustrous crystals of auric chloride. At 285° there are signs of decomposition, but even at 300°, the rate of dissociation is slow. At 1100°, gold chloride distils slowly, when a current of chlorine is passed over metallic gold—the sublimation begins at 1000°, although gold chloride is completely decomposed at a much lower temp.

The excess of chlorine is removed from auric chloride, prepared by the action of chlorine on finely divided gold, by exposing the product for a day or two in a stream of air dried by sulphuric acid and phosphorus pentoxide, and allowing it to stand for several weeks over frequently renewed soda lime. C. Winkler removed the excess of chlorine by allowing the product to stand several days over potassium hydroxide contained in a desiccator. The aq. soln. forms a neutral soln. with water. According to F. Meyer, liquid chlorine converts gold completely into auric chloride. Finely divided gold dissolves in aqua regia, and L. N. Vauquelin recommended a mixture of two volumes of hydrochloric acid and one of nitric acid as a rapid solvent for the metal. According to J. J. Berzelius, the excess of acid cannot be all removed from the soln. in aqua regia by evaporation without transforming some of the auric into aurous chloride; a neutral soln. can therefore be obtained only by boiling the residue with water and filtering off the aurous chloride. The product of the action of aqua regia on gold is hydrochloroauric acid, $HAuCl_4$; M. E. Diemer converted this product into anhydrous gold chloride, by heating it to 200° in a stream of dry chlorine for half an hour. An ordinary soln. of gold chloride containing hydrochloric acid is gradually decomposed when heated to 100°, and the metal is formed; but if a soln. of gold in aqua regia be evaporated to dryness, and the residue heated to 200° in a stream of chlorine, auric chloride is formed free from hydrochloric acid.

In manufacturing gold chloride, fine gold is treated with aqua regia until the evolution of nitrogen oxides has ceased; and the soln. conc. to a syrup on a water-bath. It is then taken up with about five volumes of water, and allowed to stand 24 hrs., when a little silver chloride is deposited. The liquid is filtered and again evaporated on the water-bath, until a drop of the liquid solidifies to a mass of yellow crystals. The crystals which separate from the cooling soln. are sealed up for sale in "gram or five-gram tubes," and called "chloride of gold." The composition is not uniform since the crystals contain a variable amount of adsorbed water: $HAuCl_4.3H_2O+Aq$.

G. Krüss recommended dissolving the gold in chlorine water. C. Winkler passed a slow current of chlorine through water with gold, precipitated by sulphur dioxide, in suspension; the soln. was evaporated in darkness on a water-bath, taken up again with water, and filtered from the undissolved gold. Other mixtures which give off chlorine can be employed, thus, J. Nicklès[4] used aq. or ethereal soln. of manganese, cobalt, and nickel perchlorides; A. Baudrimont used phosphorus pentachloride and precipitated gold; L. Lindet heated finely divided gold with antimony pentachloride in a sealed tube at 200°. H. B. North heated the finely divided gold with an excess of thionyl chloride, SO_2Cl_2, for many hours at 160° on an oil-bath.

According to W. J. Pope,[5] auric chloride, $AuCl_3$, forms small prismatic crystals which are deep claret red by reflected light, with no pleochroism; but H. Ambronn says that conc. soln. between glass plates furnish double refracting crystals with a claret-red and bluish-green pleochroism. The crystals are deliquescent, or, as

Robert Boyle expressed it, they "run in air *per deliquium*." T. K. Rose gives the **specific gravity** 3·9 for the volatilized chloride, and he calculated 4·3 for the fused chloride, and the mol. vol. is 70; he also found the **melting point** to be 288° in chlorine at 2 atm. press., and that the presence of aurous chloride does not have much influence on this constant since a mixture of one mol. of aurous chloride with four of auric chloride, melted at 287°; and at 286° under a press. of 1·81 atm. of chlorine. Robert Boyle noted the **volatility** of gold chloride and obtained "a yellow and reddish sublimate" in the neck of a retort containing gold chloride heated on a sand-bath; and he added, "sometimes we had the neck of the retort enriched with numerous large, thin, red crystals, very like rubies, and glorious to behold." L. Thompson, F. B. Miller, and S. B. Christy noted the losses which occur in chloridizing gold owing to the volatility of the chloride. J. P. Prat, H. Debray, G. Krüss, L. Lindet, and T. K. Rose have investigated the volatilization and dissociation of gold chloride. If p denotes the partial press. of dissociated chlorine, and p' the vap. press. of the gold chloride, the press. $P=p+p'$ at different temp. is:

	70°	74°	115°	200°	248°	251°	258°	278°
$p+p'$ . .	0	2·05	9·0	138	682	755	893	1354 mm.

at 286° the press. was 1·81 atm., the chloride was molten and bubbling; and at 332° the press. was 4·1 atm. From the relation $\log P=-\frac{1}{2}Q/T+\text{constant}$, where Q denotes the heat of vaporization, or dissociation, and P the press. of vaporization or dissociation respectively, then if at 248°, $p=165$ mm. and $p'=538$ mm., and at 251°, $p=178$ mm. and $p'=577$ mm. M. Pellaton found the dissociation press. increases from 4·5 mm. at 140° to 931 mm. at 260°, and the results can be represented by $\log p=51{\cdot}6852-bT^{-1}-c \log T$, where $\log b=3{\cdot}841148$, and $\log c=1{\cdot}117057$. F. A. Henglein gave $p=-13{\cdot}2076T^{-1{\cdot}6375}+4{\cdot}6222$ atm. between 5·2 (415·6° K.) mm., and 992·3 (534·6° K.) mm. At atm. press. the dissociation temp. is 254°, F. Ephraim gave 256·5°, and added that if the salt be left under about 100 mm. press. at 225°, it acquires a pale yellow colour, and is changed into aurous chloride; and if the product be heated further in the atm. of chlorine, the vap. press. reaches one atm. at 289·5°. Hence, aurous chloride is stable in an atm. of chlorine only over the range of 33°. H. H. Morris found gold chloride may be heated to the critical temp. 370° before metallic gold appears; the presence of sodium, magnesium, or calcium chloride increases the stability, for the metal does not then appear until the temp. reaches 450°–460°. The increased stability is attributed to the formation of double chlorides. W. Biltz discussed the dissociation of auric chloride.

The **heat of vaporization** of gold chloride is 13·8 Cals., and the **heat of dissociation,** 12·7 Cals. By subtracting J. Thomsen's value for the heat of formation of aurous chloride (5·81 Cals.) from that of auric chloride (22·82 Cals.) the heat of dissociation is 17·01 Cals. The calculated value is obtained on the assumption that the heat of dissociation is constant and independent of the temp. T. K. Rose showed that auric chloride is formed and volatilized at all temp. above 180° up to, and probably far beyond, 1100°. G. Krüss stated that both J. P. Prat, and H. Debray were mistaken in stating that gold chloride is volatilized at moderate temp. because he observed no action between chlorine and gold between 220° and 300°, and at these temp. gold chloride is completely decomposed, while a reaction begins at 1000°, and is marked at 1100°. G. Krüss' observations do not agree with those of T. K. Rose, and the latter showed that the contradiction arises from the faulty method employed by G. Krüss. T. K. Rose showed that, like mercury, carefully dried gold is attacked by chlorine, but the presence of moisture accelerates the speed of dissociation, for with the dried chloride equilibrium between 194° and 204° is attained only after heating several hours while with undried chloride, less than an hour suffices. The amount of auric chloride volatilized in half an hour rises from 0·007 per cent. at 180° to 0·35 per cent. at 230°, to a maximum of 2·32 at 200°; it then falls to a minimum of about 0·58 near 590°, and rises again to 1·93 at 1100°. These results are taken to mean that the heat of formation of auric chloride changes from positive to negative between 800° and 1000°, and consequently exhibits a less tendency to dissociate as the temp. rises in accord with the rule that a rising temp. favours the system formed with an absorption of heat. J. Thomsen found the **heat of formation:** $Au+3Cl=AuCl_3+22{\cdot}82$ Cals ; the calculated values for the heat of formation, $AuCl_3+HCl+3H_2O=-3{\cdot}55$ Cals., and for $AuCl_3+HCl+4H_2O=-5{\cdot}83$ Cals. ; the **heat of solution,** 4·45 Cals., or $AuCl_3aq.+HClaq.=AuCl_3.HClaq. -4{\cdot}53$ Cals.

L. Lindet says 100 grms. of water dissolve 68 grms. of auric chloride. The conc. soln. is brownish-red, and the dil. soln. is reddish-yellow. The crust which forms on the surface of a neutral soln. of auric chloride, contains, according to J. Thomsen, dark orange crystals of **dihydrated auric chloride,** $AuCl_3.2H_2O$. The water of crystallization is lost over conc. sulphuric acid. According to W. Hittorf and H. Salkowsky,[6] the soln. contains the dibasic acid complex, $AuCl_3.H_2O$, *i.e.* H_2AuOCl_3 ; this acid forms with silver carbonate the silver salt, Ag_2AuOCl_3. The **transport number** of the anions for a soln. of approximately one mol per litre is 0·2316 ; for a soln. with 0·42 mol per litre, 0·233 ; and for one with 0·068 mols per litre, 0·227. It is therefore assumed that with conc. soln. the ionization is : $H_2AuOCl_3 \rightleftharpoons H^{\cdot}+HOAuCl_3{}'$, and with dil. soln.: $H_2AuOCl_3 \rightleftharpoons 2H.+AuOCl_3{}''$. This assumption has been also suggested as an explanation of the change of colour with increasing dilution. The **degree of ionization** is in any case small ; for $\frac{1}{15}N$-soln. F. Kohlrausch found the **equivalent conductivity** at 18°, $\lambda=128$ on the assumption that the acid is dibasic ; while if the acid is monobasic, the conc. is $\frac{1}{30}N$, and $\lambda=256$, and for a soln. a 100 times more dil., *viz.* $\frac{1}{5000}N$, $\lambda=315$, which in 10 hrs. rises to $\lambda=570$. F. Kohlrausch explains these high values—higher than hydrochloric acid—by assuming that the gold chloride becomes completely hydrolyzed.

According to L. Lindet,[7] both *arsenic trichloride* and *antimony trichloride* dissolve about 2·5 per cent. of auric chloride at 15°, and 22 per cent. at 160° ; *stannous chloride* dissolves about 4 per cent. of auric chloride at 160°, and a trace at 0° ; the solubility in *titanous chloride*, $TiCl_3$, is also small. According to E. C. Franklin and C. A. Kraus, auric chloride is slightly soluble in liquid *ammonia* ; and, according to H. B. North, it is soluble in *sulphuryl chloride*, SO_2Cl_2, and in a mixture of that compound with liquid *sulphur dioxide.* According to F. W. Schmidt, auric chloride is soluble in *alcohol, ether,* and *volatile oils,* but in these solvents it slowly decomposes with the reduction and separation of gold. V. Lenher found it to be insoluble in or decomposed by alcohol, ether, *carbon disulphide, turpentine, pentane, hexane, chloroform, carbon tetrachloride, ethyl nitrate, benzene, nitrobenzene, ethyl acetate, ethyl propionate,* and *pyridine.* F. Mylius, M. Frank, and R. Willstätter are not all in agreement as to the solubility of auric chloride in ether ; according to W. Hampe, when auric chloride is warmed with ether, a yellow gelatinous mass, soluble in water, is formed, and the gold is reduced to aurous chloride and gold. H. H. Morris found that gold chloride may be heated with water in a sealed tube up to the critical temp., 370°, before metallic gold appears. In presence of small quantities of sodium, magnesium, or calcium chloride, gold chloride is more stable, and the reduction to the metal is not observed until the temp. is raised to 450°–460°. The increased stability is attributed to the formation of double chlorides. Calcite and magnesite become plated with gold when heated with gold chloride soln. up to 310°. Sodium, magnesium, and calcium chlorides prevent this action from taking place until the temp. is raised to about 500°. Magnesium hydrocarbonate acts like the normal carbonate, but calcium hydrocarbonate appears to have no influence on the stability of a gold chloride soln It was also found that gold dissolves in hot hydrochloric acid containing auric chloride; and aurous chloride is formed. D. Avery studied the precipitation of gold from soln. of auric chloride, by charcoal: $4AuCl_3+6H_2O+3C=4Au+12HCl+3CO_2$.

If a neutral soln. of auric chloride be acidified with hydrochloric acid, or if gold is dissolved in aqua regia, a citron yellow soln. with a slight orange tinge is formed.

The soln. is supposed to contain **hydrochloroauric acid,** $HAuCl_4$. Whenever a soln. of auric chloride in the presence of hydrochloric acid, is conc. by evaporation, and allowed to stand over quicklime, long, yellow, deliquescent needles are deposited. According to F. Lengfeld,[8] P. Schottländer, and R. Weber, these crystals have a composition corresponding with hydrochloroauric acid, $AuCl_3.HCl.3H_2O$ or $HAuCl_4.3H_2O$; on the other hand, J. Thomsen's analyses correspond with $AuCl_3.HCl.4H_2O$, and he regards the trihydrated salt as partially effloresced tetrahydrated salt. The eq. conductivity of an approximately normal soln. of hydrochloroauric acid, $HAuCl_4$, is $\lambda=410$ at 18°, while for hydrochloric acid $\lambda=301$; and for $\frac{1}{100}N$-$HAuCl_3$, $\lambda=560$, and for $\frac{1}{100}N$-HCl, $\lambda=370$. The temp. coeff. of the conductivity is 0·016 in agreement with the values for other monobasic acids. Hydrochloroauric acid behaves as a monobasic acid and forms a series of well-defined salts—**chloroaurates.** In the electrolysis of the aq. soln. of the chloroaurates, say the potassium salt, the gold accumulates about the anode, the potassium about the cathode; hence the ions are taken to be $K^{\cdot}$ and $AuCl_4'$.

The chloroaurates.—The alkali chloroaurates are obtained by adding an eq. quantity of the alkali chloride to the solution of hydrochloroauric acid. The rubidium and cæsium salts are so sparingly soluble that they form precipitates in moderately conc. soln.; it is not material whether the soln. are acid or neutral, or whether the gold or alkali halide is in excess. The lithium salt is least stable and most soluble; the stability increases, and the solubility decreases with increasing at. wt. of the alkali metal in passing from potassium to cæsium. Citron-yellow deliquescent crystals of **dihydrated lithium chloroaurate,** $LiAuCl_4.2H_2O$, were obtained by U. Antony and A. Lucchesi[9] in 1890. The crystals lose their water at 90°, and decompose between 100° and 105°. **Tetrahydrated lithium chloroaurate,** $LiAuCl_4.4H_2O$, was obtained by R. Fasbender by adding ether to a soln. of gold and lithium chlorides. T. Rosenbladt's determinations of the solubilities of the alkali chloroaurates expressed in grams of the anhydrous salt per 100 grms. of soln. are as follows:

	10°	20°	30°	40°	60°	80°	100°
$LiAuCl_4$ . . .	53·1	57·7	62·5	67·3	76·4	85·7	—
$NaAuCl_4$ . . .	58·2	60·2	64·0	69·4	90·0	—	—
$KAuCl_4$ . . .	27·7	38·2	48·7	59·2	80·2	—	—
$RbAuCl_4$ . . .	4·6	9·0	13·4	17·7	26·6	35·3	44·2
$CsAuCl_4$ . . .	0·5	0·8	1·7	3·2	8·2	16·3	27·5

According to F. Mylius and G. Hüttner, and R. Fasbender, the sodium salt is soluble in alcohol and ether, but the sodium salt cannot be extracted from its aq. soln. by shaking out with ether; 100 parts of 98 per cent. alcohol dissolve 25 parts of the potassium salt, but the potassium salt is insoluble in ether which has been warmed to 100°–110° to expel the free acid. H. L. Wells and H. L. Wheeler find the rubidium and cæsium salts to be insoluble in ether, and soluble in alcohol. R. Fasbender says 100 parts of 98 per cent. alcohol dissolve 1·852 parts of rubidium chloroaurate. L. G. Figuier obtained large orange-yellow rhombic crystals of **dihydrated sodium chloroaurate,** $NaAuCl_4.2H_2O$, by evaporating the aq. soln. J. C. G. de Marignac gives the axial ratios $a:b:c=0{\cdot}7002:1:0{\cdot}5462$. The crystals are stable in air and lose their water of crystallization with difficulty. J. J. Berzelius, and J. F. W. Johnston found only 1·12 per cent. of water was lost at the m.p. At a red heat chlorine is given off. G. Krüss obtained a citron-yellow hygroscopic powder, which he thought to be $NaAuCl_4.\frac{1}{2}H_2O$, by drying the dihydrated salt for a week over phosphorus pentoxide. This may be a mixture of the anhydrous salt with a little dihydrated salt.

J. Javal made pale yellow rhombic crystals of **dihydrated potassium chloroaurate,** $KAuCl_4.2H_2O$, by the spontaneous evaporation of the aq. soln. H. Topsöe gives the axial ratios $a:b:c=0{\cdot}8586:1:?$. According to J. J. Berzelius, the salt effloresces at ordinary temp. in air, forming a sulphur-yellow powder, and at 100°, all the water of crystallization is expelled; the salt melts at a higher temp. and gives off chlorine. There is also a hemihydrate, $KAuCl_4.\frac{1}{2}H_2O$, analogous to the sodium salt, which is probably the anhydrous salt with a little of the dihydrate. H. L. Wells and H. L. Wheeler prepared the anhydrous **rubidium chloroaurate** and **cæsium chloroaurate**—the former in yellowish-red, the latter in golden yellow, monoclinic prisms; they also made golden yellow thin rhombic plates of **hemihydrated cæsium chloroaurate,** $CsAuCl_4.\frac{1}{2}H_2O$, by using an excess of the gold salt—say four mols of auric chloride to one of cæsium chloride—with not much free acid. The rhombic crystals of the hemihydrated cæsium salt have the axial ratios $a:b:c=0·625:1:0·24$. On exposure to dry air the crystals lose water and change to monoclinic prisms of the anhydrous salt. H. L. Wells and H. L. Wheeler say the "rearrangement is a beautiful sight when studied under the microscope in polarized light."

> The crystals at first show a uniform action on polarized light; then from different parts of the surface the rearrangement, which is marked by aggregate polarization, commences. It advances, shooting out in various directions in a manner resembling the growth of ammonium chloride crystals under the microscope, until the whole field is covered and light is finally no longer transmitted.

The axial ratios of the monoclinic prisms of potassium chloroaurate are $a:b:c=1·9180:1:1·3610$ and $\beta=95° 24\frac{1}{2}'$; the rubidium salt $1·1954:1:0·7385$ and $\beta=75° 22'$; and of the cæsium salt, $1·1255:1:0·7228$ and $\beta=71° 36'$. In these salts the replacement of one metal by another has a considerable influence on their form, particularly in the relation of the a-axis to the other axes, and in the angles β, while the replacement of cæsium and rubidium in the trihalides has very little influence on the crystal form. W. Hittorf has investigated the electrolysis of soln. of potassium chloroaurate. According to F. Ephraim, potassium chloroaurate melts at about 357°, but the cæsium salt melts at a rather higher temp. At 440°, however, both salts have vap. press. of about 350 mm. E. H. Duclaux studied the cæsium salts.

H. Ley and G. Wiegner, and W. Peters found that potassium chloroaurate, $KAuCl_4$, slowly absorbs the eq. of three mol. parts of ammonia, forming orange **potassium triammino-chloroaurate,** $KAuCl_4.3NH_3$. The compound loses the ammonia in vacuo. According to F. Ephraim, a mol of pale yellow potassium chloroaurate unites with about twelve mols of ammonia at −18°, forming a dark orange-red ammine which effervesces in water with the evolution of free nitrogen. The similarity in the behaviour of the alkali chloroaurates and auric chloride towards ammonia led F. Ephraim to suggest that they are dissociated by ammonia into their component halides. F. Emich, and E. Bayer have described a mixed **rubidium silver chloroaurate,** obtained by mixing a soln. of auric chloride with silver chloride and rubidium chloride; it appears in the form of blood-red prisms and plates, while **cæsium silver chloroaurate** forms non-transparent cubes and stars. This reaction is proposed as a microchemical test for cæsium and rubidium. The formulæ are of the type $Ag_nAu_{2-\frac{1}{3}n}Cl_63RbCl$.

Ammonium chloroaurates, NH_4AuCl_3, with $2\frac{1}{2}$ and $1\frac{1}{4}$ molecules of water, have been made—the former by the spontaneous evaporation or by cooling of aq. soln. of the two components, and the latter by using soln. with a large excess of acid. L. Darmstädter gave the formula for the first-named salt, $NH_4Cl.AuCl_3.3H_2O$, and he supposes the pale yellow plates are rhombic with axial ratios, $a:b:c=0·5059:1:?$ while the latter salt, according to H. Topsöe, forms pale yellow monoclinic plates with axial ratios $a:b:c=1·2190:1:1·2492$ and $\beta=102° 33'$. Both salts lose water at 100°. According to J. F. W. Johnston, the soln. of the yellow ammonium salts in aqua regia is almost blood-red, and on evaporation gives dark red or purple needle-like crystals. With alcohol, ammonium chloride and greenish-yellow particles of gold separate, and a red soln. is formed which on evaporation gives reddish-yellow prisms which melt when heated and on cooling give a mass of minute cubes. G. K. C. Storr has described a purple sublimate which is formed when a mixture of 15 parts of gold-leaf is heated. These substances have not been closely investigated.

Owing to the insolubility of silver chloride, attempts to make a *silver chloroaurate* by the action of silver carbonate or nitrate and gold chloride have been made. In both cases it was anticipated that the salt. $AgAuCl_4$, would be formed, but P. Schottländer, E. Wohlwill, F. Herrmann, F. W. Schmidt, and F. Lengfeld were not successful since the products of the reaction appear to be mixtures of gold oxide and silver chloride. W. B. Pollard[10] sat. a soln. of gold in aqua regia with ammonium chloride, and added silver nitrate. More ammonium chloride was added, and the silver chloride at once began to form brown crystals. When the mixture was heated silver chloride again appeared, but the brown crystals reappeared on cooling. The composition of his crystals corresponded with **ammonium silver auric chloride**, $3AgCl.4AuCl_3.8NH_4Cl$; they were holohedral and rhombic and had axial ratios $a:b:c$=0·5376 : 1 : 0·3210. The refractive index was 1·74. H. L. Wells modified the method of preparation, and the analysis of his product corresponded with $(NH_4)_6Ag_2Au_3Cl_{17}$; he failed to make the potassium salt, but he made several complex **cæsium silver auric chlorides.**

P. A. von Bonsdorff prepared the chloroaurates of the alkaline earths by mixing soln. of the component salts in eq. proportions; on evaporation yellow rhombic crystals are obtained which are stable in dry air, and deliquesce in ordinary air—*e.g.* **hexahydrated calcium chloroaurate,** $Ca(AuCl_4)_2.6H_2O$; **hexahydrated strontium chloroaurate,** $Sr(AuCl_4)_2.6H_2O$; and **hexahydrated barium chloroaurate,** $Ba(AuCl_4)_2.6H_2O$. The amount of water in the two last-named salts has been fixed rather by analogy with the calcium salt than by analysis. W. Crookes prepared **thallium chloroaurate,** and also **scandium chloroaurate,** $3ScCl_3.2AuCl_3$. S. Jolin, and M. Holzmann made **cerous chloroaurate,** $CeCl_3.AuCl_3.13H_2O$; F. Frerichs and F. Smith, **lanthanum chloroaurate,** $2LaCl_3.3AuCl_3.21H_2O$; and E. Alén, $LaCl_3.AuCl_3.10H_2O$; C. A. Matignon, yellow crystals of **praseodymium chloroaurate,** $PrCl_3.AuCl_3.10H_2O$, soluble in water; P. T. Cleve, and C. A. Matignon, orange prisms of **samarium chloroaurate,** $SaCl_3.AuCl_3.10H_2O$; C. Benedicks, yellow tablets of **gadolinium chloroaurate,** $GdCl_3.AuCl_3.10H_2O$; and P. T. Cleve, **yttrium chloroaurate,** $YCl_3.AuCl_3.16H_2O$. P. A. von Bonsdorff also prepared dark brown crystals of **magnesium chloroaurate,** $Mg(AuCl_4)_2.12H_2O$; **zinc chloroaurate,** $Zn(AuCl_4)_2.12H_2O$; dark yellow **cadmium chloroaurate,** $Cd(AuCl_4)_2(12H_2O?)$; **manganese chloroaurate,** $Mn(AuCl_4)_2 12H_2O$; and dark yellow cobalt and nickel chloroaurates. H. Topsöe, however, made crystals of the chloroaurates of these salts of the type $M''(AuCl_4).8H_2O$, as well as **cobalt chloroaurate,** $Co(AuCl_4)_2.8H_2O$, and **nickel chloroaurate,** $Ni(AuCl_4)_2.8H_2O$. The octahydrated salts of magnesium, nickel, and zinc are monoclinic and isomorphous, with axial ratios $Mg(AuCl_4)_2.8H_2O$, $a:b:c$ = 1·3441 : 1 : 1·7517 and $\beta=96°\ 1'$; $Ni(AuCl_4)_2.8H_2O$, $a:b:c$ =1·3411 : 1 : 1·7562 and $\beta=95°\ 42'$; and $Zn(AuCl_4)_2.8H_2O$, which resemble the magnesium salt, but the crystals are too deliquescent to permit of exact measurement. The crystals of octahydrated manganese chloroaurate are triclinic and isomorphous with those of the corresponding cobalt salt, but are too deliquescent for exact measurement; the axial ratios of $Co(AuCl_4)_2.8H_2O$ are $a:b:c$ =0·9238 : 1 : 0·9112, and $\alpha=101°\ 25'$, $\beta=103°\ 23'$, and $\gamma=92°\ 5'$.

W. Gibbs and F. A. Genth prepared crystals of double salts of auric chloride with luteo- and xantho-cobalt chlorides. The former precipitates as a yellow salt sparingly soluble in water, soluble in hydrochloric acid, and with a composition $[Co(NH_3)_6]Cl_3.AuCl_3$; the latter is obtained in brownish-yellow prismatic crystals by evaporation of a mixed soln. of the component salts. They have the composition $[Co(NH_3)_5NO_3]Cl_2AuCl_3$. Double salts of auric chloride with phosphorus pentachloride, $AuCl_3.PCl_5$, have been made by L. Lindet; R. H. Pickard and J. Kenyon made double salts of the type $2R_3PO_4.HAuCl_4$; where R denotes the organic radicles CH_3, C_2H_5, C_3H_7, C_6H_5, and C_7H_7. L. Lindet made a double salt with sulphur tetrachloride, $AuCl_3.SCl_4$; selenium tetrachloride, $AuCl_3.SeCl_4$; silicon tetrachloride, antimony pentachloride, tin chloride, and titanium chloride; and J. J. Sudborough, $AuCl_3.NOCl$. Numerous compounds of auric chloride with organic radicles are known.

The properties of acid and neutral solutions of auric chloride.—G. Massol and

A. Faucon[11] have measured the **ultra-violet** absorption spectrum of soln. of hydro chloroauric acid, and found the rays of the shortest wave length are absorbed; there is an absorption band between $\lambda=2900$ and $\lambda=3250$; and the transparency is a maximum between $\lambda=2600$ and $\lambda=2700$. T. Svedberg and N. Pihlblad observed that the maximum absorption with very dil. soln. of hydrochloroauric acid mixed with a soln. of phosphorus in ether, is at first displaced a little towards the ultra-violet, and then as time goes on the maximum absorption is slowly and continuously displaced towards the visible spectrum. There is a continuous change from gold soln. with a known degree of dispersion (size of particle) and absorption in the visible spectrum to hydrochloroauric acid which has maximum absorption in the ultra-violet. According to G. Besseyre, the neutral soln. gradually deposits flecks of metallic gold when it is allowed to stand in a closed vessel in the shade, but the acid soln. remains unchanged. According to E. Sonstadt, light decomposes very dil. aq. soln. of auric chloride with the separation of gold, and the formation of hydrogen peroxide. T. Svedberg says that prolonged illumination decomposes the soln., and that ultra-violet light reduces hydrochloroauric acid to colloidal gold at a speed proportional to the intensity of the light. E. P. Perman finds radium bromide reduces soln. of gold chloride to the metal. N. W. Fischer observed similar results in a closed vessel with an atm. of nitrogen. Soln. of gold chloride are very susceptible to reducing agents, some of which reduce the soln. to metallic gold, some to gold oxide, others to colloidal gold. A. Oberkampf reported that a neutral soln. of gold chloride is coloured purple-red by **hydrogen** without forming a precipitate. There are, however, other contradictory reports—J. L. Proust, and C. Schweigger-Seidel obtained neither a coloration nor precipitation; C. Buisson and L. G. Figuier, and W. J. Russell obtained a brown precipitate. F. Emich and J. Donau reduced the dil. hydrochloroauric acid by allowing a hydrogen flame to play upon it; E. Hatschek and A. L. Simon reduced a soln. of auric chloride in silicic acid by hydrogen and coal gas. E. Hatschek and A. L. Simon, and J. Donau obtained a red or violet colloidal soln. of gold by passing **carbon monoxide** into a 0·002–0·04 per cent. soln. of auric chloride. M. E. Diemer reduced the warm chloride to the metal with this gas.

L. Vanino and L. Seemann found that **hydrogen peroxide** in alkaline soln. rapidly precipitates the metal completely: $2AuCl_3+3H_2O_2+6KOH=2Au+6KCl+6H_2O+3O_2$. The precipitate appears bluish-black by reflected and bluish-green by transmitted light; 0·00003 grm. of gold in 10 c.c. of soln. gives a bluish-red coloration by this reaction. According to E. Knövenagel and E. Ebler, the precipitation is not complete in ammoniacal or acid soln.; and L. Rössler, the action in acid soln. is slow, but rapid and complete in the presence of lithium or potassium carbonates. F. Doerinckel, and T. Svedberg and K. Inouye prepared colloidal gold soln. by treatment with hydrogen peroxide. According to N. Dhar, auric chloride reacts more readily with reducing agents when an oxidizing agent is present, *e.g.* the reduction with hydrogen peroxide is effected in a few seconds if a few drops of a soln. of potassium permanganate be added. The action of a soln. of an **alkali percarbonate** is likewise affected by the permanganate.

N. W. Fischer found that **sulphur** is without action on soln. of gold chloride, but if hot some gold is precipitated. W. Skey reported that gold is precipitated from soln. of gold chloride as a thin skin of the metal on the **sulphides** of copper, gold, zinc, mercury, arsenic, bismuth, lead, tin, molybdenum, iron, and platinum; and P. V. Gladkoff found gold is precipitated by the addition of copper pyrites to soln. of auric chloride, and with dil. soln., iron replaces the gold in the soln. C. Palmer and E. S. Bastin noted that natural sulphides, **arsenides** and **antimonides** —*e.g.* pyrites stibnite, millerite, lead glance—precipitate gold from auric chloride soln. with very different velocities. A. Cossa has studied the action of molybdenum glance; V. Lenher, of calaverite, sylvanite, coloradoite, calgoorlite, and nagyagite. C. H. Pfaff found that **hydrogen sulphide** precipitates brown flakes of auric sulphide at ordinary temp. from soln. of auric chloride; with one part of gold in 10,000 parts of liquid, a brown coloration is produced ; the colour is fainter with 1 : 20,000 to 1 : 40,000 ; and scarcely perceptible with 1 : 80,000. When hydrogen or steam containing a very small trace of hydrogen sulphide is passed into a soln. of auric chloride, a purple-brown colour is first produced, then a purple-red, and finally a violet colour. According to A. Levol, and U. Antony and A. Lucchesi, aurosoauric sulphide is precipitated from cold soln., and metallic gold from hot soln. According to A. Ditte, hydrogen sulphide precipitates auric sulphide, Au_2S_3, only from acid soln. ; in neutral soln., the first few bubbles of hydrogen sulphide give a brown coloration and the sat. liquid is transparent and can be filtered without changing the colour, but after standing 24 hrs. in a closed vessel, the particles coagulate. The addition of hydrochloric acid to the brown liquid precipitates gold as a black powder. In general, hydrogen sulphide precipitates brown metallic gold from hot soln. of gold chloride : $8AuCl_3+3H_2S+12H_2O=24HCl+3H_2SO_4+8Au$; and, according to J. L. Lassaigne, black gold sulphide is precipitated from cold soln. : $8AuCl_3+9H_2S+4H_2O=24HCl+H_2SO_4+4Au_2S_2$; the disulphide is sparingly soluble in acids, but dissolves in aqua regia ; it is sparingly soluble in ammonium sulphide, but soluble in soln. of potassium sulphide, forming a soluble sulpho-salt, $KAuS_2$, from which hydrochloric acid precipitates yellowish-brown sulphide, Au_2S_3. **Ammonium sulphide** gives a black or brown precipitate of auric sulphide which is soluble in an excess—especially on warming ; **sodium thiosulphate,** said H. Fizeau, precipitates auric sulphide, Au_2S_3, from soln. of auric chloride. According to P. Berthier, and C. Winkler, **sulphur dioxide** reduces neutral or acid soln. of gold chloride, $2AuCl_3+3H_2SO_3+3H_2O=3H_2SO_4+6HCl+2Au$, so that the liquid in light appears to have a bluish opalescence ; on boiling, gold is deposited as a brown powder. H. Rose said that in the cold very dil. soln. are only decolorized, and when heated they are reduced ; and H. W. F. Wackenroder added that if very dil., and a great excess of hydrochloric acid is present, the soln. remains quite clear, and gold is precipitated when the soln. is diluted, or the acid neutralized with ammonia. M. E. Demier and V. Lenher showed that with many chlorides, aurous chloride is an intermediate stage in the reduction. N. Dhar found that the reduction of auric chloride by sulphurous acid is accelerated by potassium permanganate. According to A. Haase, if a conc. soln. of gold chloride, sat. with ammonia, is treated with sulphur dioxide, a voluminous flesh-coloured precipitate of **ammonium aurosulphite** is formed. P. Berthier said that **alkali sulphites** act like sulphurous acid ; and H. Rose, that the reduction occurs only with a prolonged boiling and if the soln. is sat. with hydrochloric acid. E. Hatschek and A. L. Simon prepared a gold sol by reduction of dil. auric chloride with sulphur dioxide. O. Brunck used **sodium hyposulphite** as a reducing agent in the preparation of colloidal soln. of gold. N. W. Fischer found **selenium** acts on gold only when the soln. is hot, while R. Hall and V. Lenher found that **tellurium** reduced cold soln. ; and V. Lenher, that **hydrogen telluride** reduces the salt to metal.

Aq. **ammonia** or **ammonium carbonate** precipitates most of the metal as dirty yellow fulminating gold, $[Au(NH_3)_2(OH)_2]OH$, which is the more soluble the greater the acidity of the soln. : $HAuCl_4+6NH_3+3H_2O=4NH_4Cl+[Au(NH_3)_2(OH)_2]OH$, the precipitate explodes when warmed or by concussion. H. Rose found that many organic substances—gum, glucose, cane sugar, etc.—retard the precipitation. According to C. Winkler, A. Lainer, and E. Knövenagel and E. Ebler, **hydroxlyamine** or **hydrazine** in alkaline ammoniacal or acid soln. reduce auric chloride to metallic gold. A. Gutbier and F. Resenscheck used **phenylhydrazine** for the preparation of gold hydrosols. A. Gutbier obtained blue, very stable gold hydrosol by adding a dil. soln. of hydroxylamine or hydrazine hydrate (1 : 2000) to a neutral soln. of auric chloride (1 : 1000), avoiding an excess of the reducing agent. The reduction by hydrazine has also been studied by T. Svedberg and K. Inouye, and E. Pozzi-Escot. N. W. Fischer found that **nitric oxide** or the fumes of nitric acid reduce neutral and acid soln. to gold. M. E. Diemer reduced auric chloride to the metal by warming it in a stream of **nitric oxide.** N. W. Fischer, and P. E. Jameson observed that **potassium nitrite** precipitates the gold from auric chloride soln. rapidly and completely; and, according to E. Frémy, **nitrous acid** or **arsenic acid** gives a precipitate with conc. soln. of gold chloride, and at 150° the mixture gives off chlorine, and forms aurous chloride and the metal; on account of its volatility **nitric acid** does not act in the same way. J. Juncker and P. J. Macquer observed that **phosphorus** precipitates gold, as also do **phosphorous acid** and **hypophosphorous acid;** the reactions were studied by A. Sieverts, and M. Major. M. C. Lea added 15 c.c. of a 10 per cent. soln. of **sodium hypophosphite** to 1 c.c. of auric chloride (0·1 grm. of gold), and a drop of sulphuric acid, and in 2–4 min., as the soln. darkens in colour, 30 c.c. of water. The resulting hydrosol of gold is first green and then blue. According to H. Rose, **phosphine** precipitates metallic gold, and he contradicts the statement of A. Oberkampf that if an excess of phosphine is used some gold phosphide is formed. P. Pascal found that the alkali **ferropyrophosphates**—*e.g.* $K_8Fe_2(P_2O_7)_3$—reduce gold salts in the cold, and with dil. soln. of the gold salt, the metal remains in the colloidal condition. E. Soubeiran, and V. A. Jacquelain say that **arsine** precipitates the gold after forming arsenious acid: $2AuCl_3+AsH_3+3H_2O=As(OH)_3+6HCl+2Au$; with **stibine,** the reaction is represented: $2AuCl_3+SbH_3=SbCl_3+3HCl+2Au$. A. Levol said that *arsenious oxide* in a soln. of hydrochloric acid precipitates gold slowly in the cold, rapidly when heated; and E. Rupp represented the reaction, $3As_2O_3+4AuCl_3+6H_2O=3As_2O_5+12HCl+4Au$. According to A. Carnot, if a few drops of a dil. soln. of gold chloride be treated with a drop of arsenic acid, a few drops of ferric chloride, and two or three drops of hydrochloric acid, and then dil. to 100 c.c. and a piece of zinc dropped in the liquid, the soln. around the zinc will assume a purple colour. The zinc should be moved about so as to disseminate the colour; 0·00003 grm. of gold in 10 c.c. of liquid can be readily detected in this way—with phosphoric acid in place of arsenic acid—the coloration is blue to violet. V. Lenher found that in the presence of **sodium chloride, manganous chloride,** etc., yellow soln. of auric chloride are reduced to a colourless soln. of a double salt of aurous chloride. **Antimonious chloride** precipitates a gold-coloured powder from dil. soln. of auric chloride, but a soln. of antimonious oxide in hydrochloric acid does not reduce the gold chloride. A soln. of **antimonic oxide** in hydrochloric acid does not reduce gold chloride soln. of **potassium or sodium hydroxide** gives a black precipitate which does not change on boiling. A. Stähler reduced a conc. soln. of auric chloride by adding a few drops of a soln. of **titanous chloride** and obtained a violet powder of titanic oxide coloured with colloidal gold.

From the position of gold in the electrochemical series it might be anticipated that most of the metals will displace the gold from soln. of auric chloride, and this is in accord with the behaviour of the base metals; even mercury, silver, palladium, and platinum precipitate the metal as a brown powder or as a surface gilding. According to V. Lenher, active metals like magnesium, aluminium, zinc, and iron, precipitate gold directly; while the inactive metals like antimony, bismuth, cadmium, lead, copper, and mercury, act more slowly, probably with the intermediate formation of aurous chloride. C. Boussin studied the precipitation of gold by **magnesium;** N. W. Fischer noted that **zinc** rapidly precipitates gold as a brown powder; **cadmium,** slowly; **mercury,** slowly with the formation of gold amalgam. N. W. Fischer also noted that **arsenic** precipitates gold rapidly; **antimony** and **bismuth,** slowly—with the two latter, gilding occurs. G. L. Lesage says that gold salts give a purple coloration with arsenic, antimony, or bismuth. N. W. Fischer and J. Pelletier say that **tin** precipitates metallic gold or purple of Cassius or both, and, according to N. W. Fischer, **lead** rapidly precipitates dendritic gold. According to M. Dauvé, **aluminium** forms colloidal gold. N. W. Fischer also noted that **manganese** reduces gold salts rather feebly; **iron** and **cobalt** rapidly precipitate gold as a brown powder; and **nickel** behaves similarly, but more slowly. C. Winkler found that spongy or strongly heated nickel or cobalt do not precipitate eq. amounts of gold, for the gold always contains some nickel or cobalt. Reguline cobalt or nickel which has been fused in the oxy-coal-gas flame, precipitates in 12 to 24 hrs. virtually pure gold, while if the nickel or cobalt contains iron, ferric chloride passes into soln., and if the soln. is warm, some basic ferric chloride may be formed, and the precipitated gold is contaminated with iron. N. W. Fischer found that **copper, silver,** and **palladium** precipitate gold, **platinum** reduces gold from neutral soln. and from soln. of sodium chloroaurate, but not from acid soln.; and he also found that the platinum is active after it has been boiled with hydrochloric or nitric acid or aqua regia, but not after boiling with sulphuric acid. E. F. Smith found finely divided **molybdenum** precipitates gold from soln. of gold chloride, and that finely divided **tungsten** acts slowly, but rapidly in alkaline soln. M. Lazowsky found soln. of auric chloride to be reduced by charcoal, and the gold is deposited on the **carbon.** The reduction has also been studied by A. Liversidge, W. O. de Coninck, A. Tingle, S. Brussoff, G. A. Koenig, D. Avery, M. Green, etc. H. Koch has shown that the gold is adsorbed by the various forms of charcoal when the quantities of gold in soln. are extremely small. The results with dil. soln. of sodium chloroaurate are in accord with the ordinary adsorption formula. This property of charcoal was employed by H. Koch to estimate the quantity of gold in sea-waters.

H. Rose, in his *Ausfuhrliches Handbuch der analytischen Chemie* (Braunschweig, 1851), stated that **potassium ferrocyanide** gives an emerald green coloration with soln. of gold chloride and **potassium ferricyanide** gives no precipitate; E. Frémy also said that no precipitate is formed, and E. Jordis, in his *Electrolyse wässeriger Metallsalzlösungen* (Halle a. S., 1901), gave the theoretical equation: $4AuCl_3+3K_4FeCy_6=Au_4(FeCy_6)_3+12KCl$. According to E. Beutel's study, the nature of the reaction between hydrochloroauric acid and potassium ferrocyanide is dependent upon the relative proportions of the reacting constituents. The colours produced—yellow, brown, blue, or green—are at first clear, and become turbid on exposure to light, and if the mixture be allowed to stand long enough, a precipitate is always formed. Direct sunlight accelerates the speed of the reaction in a very marked way. E. Beutel made up soln. A with 10 grms. of hydrochloroauric acid per litre, and soln. B with 10 grms. of potassium ferrocyanide per litre. Mixtures ranging from $25A$ to $3A+B$ give mainly aurous cyanide; with $A+B$, the soln. gradually changes from light green to dark brown; and it remains in this state a long time in diffused daylight without forming a precipitate, but on exposure to sunlight the colour changes to emerald green, dark blue and finally deposits a blue precipitate. The emerald green soln. obtained with $A+2B$ gradually deposits blue ferric ferrocyanide, leaving a yellow liquid containing an excess of the ferrocyanide; the reaction is hastened by warming. Similar results were obtained with $A+3B$ to $5B$, but the blue precipitate takes longer to form. Green soln. were obtained with $A+10B$ to $25B$, and these deposit small amounts of ferric hydroxide on exposure to sunlight leaving a yellow soln. of potassium ferro- and ferri-cyanide. The reaction with ferricyanide seems to be similar, but it has not been studied in detail. According to G. Mazzaron (1898), gold chloride gives chlorine not chromyl chloride when treated with potassium dichromate and sulphuric acid.

When **potassium or sodium hydroxide** is added to a conc. soln. of gold chloride, a reddish-brown precipitate of auric hydroxide is deposited: $AuCl_3+3KOH=3KCl+Au(OH)_3$. This precipitate looks like a ferric hydroxide precipitate; and it is soluble in an excess of the alkali lye as alkali aurate—*e.g.* $KAuO_2$. Dil. soln. of gold give no precipitate with alkali lye because the amount of alkali added suffices for the formation of the soluble aurate. According to A. Oberkampf, and J. Pelletier, **barium, strontium, calcium, or magnesium oxide** precipitates yellow auric oxychloride or, according to J. B. A. Dumas, auric hydroxide; the precipitate is contaminated with the alkaline earth. According to L. G. Figuier, and A. S. Duportal and J. Pelletier, cold soln. of the **alkali carbonates or bicarbonates** do not precipitate gold from soln. of auric chloride, but when boiled, L. G. Figuier found a precipitate of gold hydroxide. E. Desmarest found that when **calcium carbonate** (marble) is moistened with a soln. of gold chloride there are no signs of a reaction in daylight, but in sunlight, or when warmed, a purple colour appears. According to H. H. Morris, calcite and magnesite become plated with gold when heated with gold chloride to 310°; the presence of sodium, magnesium, and calcium chlorides prevent the action taking place until the temp. reaches 500°. Magnesium hydrocarbonate acts like the normal carbonate, but calcium hydrocarbonate appears to have no influence on the stability of a soln. of auric chloride. H. Rose found neither **barium carbonate** nor **sodium phosphate** is affected by gold chloride soln. According to H. H. Morris, a soln. of gold chloride is decomposed when heated in a steel bomb to about 365°, the critical temp. of water, but if sodium or magnesium chloride be present, the decomposition temp. is raised to 450°–460°. If heated in the presence of calcite or magnesite, the minerals become plated with octahedral dendritic crystals of gold. **Sodium orthophosphate** does not give a precipitate with soln. of auric chloride, and, according to J. F. Persoz, the latter soln. remains quite clear if it is mixed with **sodium pyrophosphate,** but the mixture is decolorized when heated. Alcohol precipitates sodium chloride, and, when the soln. is evaporated under conditions where organic matters are excluded, crystals of sodium chloride first separate, then sodium pyrophosphate, and finally a syrup is obtained containing sodium, gold, and pyrophosphoric acid in the proportions 26 : 92 : 75, possibly $Na_8Au_4(P_2O_7)_5$, *sodium pyrophosphato-aurate.* According to W. Gibbs, if this soln. is treated with aq. ammonia, a white precipitate appears which rapidly becomes yellow and crystalline. Its composition is given as $3Na_2O.14Au_2O_3.6P_2O_5.14NH_3.24H_2O$—*sodium ammino-pyrophosphato-aurate.* It is stable at ordinary temp., but explodes vigorously when heated to 170°. If a soln. of sodium aurate is poured into one of **sodium silicate,** P. P. von Weimarn found that after some minutes the yellow colour disappears, and a 0·1 per cent. soln. remains clear for some days. The reaction is here regarded as involving the *Selbstreduktion von Aurichlorid.*

According to V. Lenher, organic reducing agents—formic acid, formaldehyde, etc.—as a rule, reduce auric chloride to the metal, and not to aurous chloride; while the inorganic reducing agents—sulphurous and arsenious acids—reduce auric to aurous chloride, although some carry the reduction to the metal stage. Gold chloride soln. are reduced to metallic or colloidal gold by many organic substances. N. Dhar found that the reduction of auric chloride by organic acids—**oxalic, tartaric, citric, and malonic acids**—is hastened in the presence of an oxidizing agent like potassium permanganate. J. Pelletier and E. Priwoznik found oxalic acid, $(COOH)_2$ or **ammonium oxalate,** completely precipitates gold from neutral or acid soln., slowly in darkness, rapidly in light or when warm: $2AuCl_3+3(COOH)_2 =6HCl+6CO_2+2Au$, according to H. Rose, a large excess of hydrochloric acid or alkali chlorides hinders the precipitation. C. A. L. de Bruyn prepared colloidal soln. of gold by using a dil. soln. of gold chloride, gelatine, and oxalic acid. According to B. Morin and V. Lenher, **formic acid** and **potassium formate** do not precipitate all the gold from dil. soln.; and even if boiled with an excess of the potassium salt, about one-third of the gold escapes precipitation. V. Lenher noted that in acid soln. metallic gold is precipitated by formic acid only after long standing, while in alkaline soln. the action is quicker, but even then it is slow. Lactic, acrylic, pyroracemic, and phenylacetic acids behave similarly. J. J. Berzelius found that pyroracemic acid precipitates gold completely from hot soln. J. Pelletier found that **potassium tartrate, acetate, or citrate** precipitates metallic gold without the evolution of carbon dioxide; but, added R. Phillips, sodium tartrate requires heat to start the precipitation which then proceeds rapidly. N. Awerkieff, and J. Pelletier showed that the presence of an excess of hydrochloric acid retards the action of all these reagents. According to H. C. Neish, ***m*-nitrobenzoic acid** does not precipitate gold from a soln. of auric chloride. V. Lenher found that with acid soln. of gold chloride **formaldehyde** is without appreciable action even after the mixture had stood for some months, but with alkaline soln., gold is precipitated at once. R. Zsigmondy, F. N. Schulz, C. Thomae, F. Küspert, and A. Gutbier have prepared gold hydrosols by means of this reagent. According to G. Armani and J. Barboni, the violet coloration with formaldehyde is produced if one part of gold is present in 100,000 parts of liquid. Similar results were obtained with other aldehydes. For instance, F. Hartwagner found that **acetaldehyde** reduces acid and alkaline soln. of auric chloride, forming colloidal soln., and N. Castoro used **acroleïn** for the same purpose. According to V. Lenher, **valeric, anisic, benzylic, salicylic, and cinnamic aldehydes** are immiscible in water, and they extract the auric chloride from its aq. soln. as much as ether or carbon disulphide extracts bromine or iodine. The **ketones** behave like the aldehydes in acid and alkaline soln. and the immiscible ketones—**acetone, methyl-ethyl-ketone, methyl-butyl-ketone, acetylacetone, acetophenone,** and **pulegone**—extract gold chloride from its aq. soln. Some of the insoluble **esters—ethyl, isopropyl, butyl, and isobutyl acetates, diethyl oxalate, amyl formate, ethyl malonate, succinate, malate, or acetoxalate**—also extract gold chloride from its aq. acidified soln.; but with mixed esters—**methyl, ethyl, or amyl benzoates**; and **methyl or ethyl salicylate**—no extraction occurs. The immiscible **alcohols—butyl, isobutyl, capryl, amyl, tertiary amyl, benzyl, or valeryl alcohol** —extract auric chloride from its aq. acidified soln., with soln. of gold chloride. The partially miscible alcohols—**propyl, isopropyl, secondary butyl, or allyl alcohol**—which, on the addition of magnesium or sodium chloride separate into two layers, the gold salt collects in the alcohol layer. According to N. Castoro, allyl alcohol gives a pale red coloration with acid soln. of gold chloride. M. Müller used **glycerol** as reducing agent for gold hydrosols. L. Vanino prepared colloidal soln. of gold with **methyl alcohol** as reducing agent. L. Garbowsky, A. Hanriot, and F. Henrich found that the **phenols—hydroquinone, resorcin, paracresol,** etc. —quickly precipitate gold from acid or alkali soln. No reduction or extraction occurs with **methylene dichloride, methyl iodide, chloroform, carbon tetrachloride, amyl bromide, acetylene tetrachloride, or tetrabromide, monobromobenzene, benzoyl chloride, or benzyl chloride. Carbon disulphide** does not extract gold from its aq. soln.; **thiophene** does. K. Lederer obtained a feeble turbidity with **diphenyl selenide.** According to V. Lenher, the immiscible cyanides—**methyl, ethyl, or benzyl cyanide,** or **benzonitrile**—extract gold from its aq. soln., but they exert no appreciable reducing action. The aliphatic **amines** have not a pronounced reducing action, but the aromatic amines—**aniline, naphthylamine, dimethylaniline, ethyl-aniline, *o*- or *m*-toluidine**—precipitate gold from acid or alkaline soln. **Pyridine, piperidine,** and **picoline,** with sodium chloride or hydroxide, form two layers with aq. soln. of gold chloride, and the organic solvent retains the gold salt. According to J. E. Saul, a 0·1 per cent. soln. of ***p*-phenylenediamine** coloured a 0·0001 per cent. soln. of auric chloride greenish-yellow, and, according to R. J. Carney, **tetramethyldiaminodiphenylmethane** gave a purple colour in the presence of 0·0001 grm. of gold.

All the sat. **hydrocarbons** which have been tried exert no appreciable reducing or extracting powers on soln. of auric chloride. According to H. Erdmann and P. Köthner, *acetylene* colours soln. of auric chloride dark reddish-violet, and a black precipitate is formed which when heated gives a smell of aldehyde or paraldehyde; J. C. Blake obtained a colloidal soln. with acetylene as precipitant, and the same reducing agent was utilized by W. R. Whitney and J. P. Blake, and by E. Hatschek and A. L. Simon.

C. H. Pfaff found that **gallic acid,** and H. Rose that **pyrogallol** colour a soln. of auric chloride yellow, then brown, and finally precipitate the gold. According to Count Rumford, **ether** and **volatile oils** precipitate gold only in sunlight or when warmed, say to 100°. F. Mylius found that ether extracts over 90 per cent. of hydrochloroauric acid from its aq. soln. if at least 2 per cent. of hydrochloric acid is present. The solubility of auric chloride in the presence of copper is depressed; according to F. Mylius and C. Hüttner, this is due to the formation of $2AuCl_3.CuCl_2$. According to J. L. Proust, **sugar, mannite,** and decoctions of various dye-woods, form reddish-purple precipitates of gold.

According to B. Morin, at ordinary temp., **ferrous salts** completely precipitate the gold as a brown powder from neutral or acid soln.: $AuCl_3+3FeSO_4=Fe_2(SO_4)_3+FeCl_3+Au$. According to J. L. Lassaigne, a soln. with one part of auric chloride in 40,000 parts of liquid gives a brown coloration; with 1 : 80,000, a sky-blue coloration; with 1 : 160,000, a pale violet, even by reflected light; with 1 : 320,000, a pale violet; and 1 : 640,000 produces a scarcely perceptible violet tinge; and, according to B. Morin, hydrochloric acid favours the action, while in hot soln. the gold is coagulated. According to H. Rose, a very few ferrous salts reduce gold chloride soln. in the presence of alkali chlorides, and the addition of ferrous sulphate to a soln. of gold chloride in alkali lye gives a black precipitate of ferric aurous oxide; with very dil. soln. a purple colour is produced rivalling in sensitiveness that produced by stannous chloride. H. Rose also stated that **manganese, nickel, and cobalt sulphates** produce similar results. A. D. Brockaw (1913) observed that **manganous chloride** precipitated gold, while L. L. de Koninck (1881) showed that manganous sulphate or chloride reduces gold soln. rapidly in sunlight, slowly in darkness. W. O. de Coninck found that light or heat has very little influence on the reduction of gold salts by manganous sulphate, and that heat has very little action on the reduction with manganous chloride. **Stannous chloride** precipitates finely divided gold from dil. or conc. acid or neutral soln. of gold chloride. The precipitate—purple of Cassius—is at first reddish-purple and then changes to brown; the brown becomes purple again if nitric acid be added. Purple of Cassius is a mixture of tin oxide with very finely divided gold: $2AuCl_3+3SnCl_2=3SnCl_4+2Au$. According to J. L. Lassaigne, a soln. with one part of gold in 10,000 parts of liquid gives a red precipitate; with 20,000 to 40,000 parts of liquid a claret-red coloration; with 80,000 parts of liquid a brownish-red coloration; with 160,000 to 320,000 parts of liquid a pale brown coloration; and with 640,000 parts of liquid a scarcely perceptible coloration. According to C. Biusson, a mixture of auric chloride with antimony trichloride, or bismuth chloride and hydrochloric acid, gives a purple precipitate with ferrous sulphate or mercurous nitrate; but E. D. Desmarest says that a precipitate is produced, but no purple coloration. According to J. L. Proust, a soln. of **cuprous chloride** in hydrochloric acid, and, according to C. Löwig, a soln. of **cuprous bromide** in hydrobromic acid, precipitate gold—the former reagent was used by W. O. de Coninck for preparing a colloidal gold soln. J. L. Proust also stated that **mercurous nitrate** gives a dark blue flocculent precipitate, which, after calcination, is bluish-black gold powder containing gold, mercury, and chlorine; according to N. W. Fischer, mercuric oxide and red auric oxide; and, according to L. G. Figuier, aurous oxide. J. L. Proust also stated that the precipitate produced by **mercuric nitrate** is a mixture of auric oxide, mercurous chloride, mercuric oxide, and water. J. Pelletier noted that **silver nitrate** or **silver sulphate** precipitates a yellowish-brown mixture of auric oxide and silver chloride from neutral soln. of gold chloride. According to J. Jacobsen, the pale brown precipitate is $4AgCl.Au(OH)_3$. L. Vanino and L. Rössler reduced auric chloride to aurous chloride by heating it to about 200°; when a soln. of 0·055 grm. of auric chloride in a litre of water or acetone is heated on a water-bath for about half a day, a mirror of gold is formed by what is called the *Selbstoxydation von Aurochlorid*. J. Pelletier found **potassium iodide** precipitates yellow gold iodide, and A. Pleischl obtained a similar precipitate four hours after the addition of hydriodic acid to auric chloride. **Potassium cyanide** gives a yellow precipitate soluble in excess; **mercuric cyanide** gives no precipitate with aq. soln., but H. Rose said that a yellow precipitate is formed if mercuric cyanide be added to a soln. of auric chloride in aq. alcohol.

According to V. Lenher, the photographic developers—**pyrogallol, hydroquinone, eikonogen, metaquinone, edinol, ortol, glycine, dianol, metol, adurol,** and **amidol**—either acid or alkaline, instantly precipitate gold from auric chloride soln. V. Lenher further found that **ethylcyano-acetic ester, epichlorhydrin, acetic anhydride, paraldehyde, citral, guaiacol, acetone cyanhydrin,** and **amyl**

nitrate extract gold chloride from its aq. soln., while *amyl nitrate, nitrobenzene* partially extract gold chloride from its aq. soln.; and **ethyl dichloroacetate, ethyl trichloroacetone, ethyl chlorocarbonate, nitromethane, ethyl nitrate, nitrotoluene, allyl mustard oil, phenetole,** and **anethole,** are without extractive power; **tributyrin** distributes the gold chloride in two layers; while **pyrrol, anisidine, phenetidine, β-benzaldoxime,** and **phloroglucinol** more or less quickly reduce auric chloride soln. to metallic gold; and **vanillin, methylvanillin,** and **coumarin** precipitate gold from alkaline soln., but in acid soln. vanillin alone gives a reddish-brown precipitate which is insoluble in water and in dil. acid. K. A. Hofmann and D. Storm observed that **triformaltrisazine** reduces alkaline soln. of gold chloride. M. Wunder and V. Thüringer found **dimethylglyoxime** precipitates gold quantitatively from acid soln. of the chloride. A. Levol found that **chloral hydrate** precipitates gold quantitatively in alkaline soln., but, according to F. Hartwagner, reduction occurs in acid soln. G. Malatesta and E. di Nola say that a soln. of a gram of **benzidine** in 10 c.c. of acetic acid and 50 c.c. of water gives a deep blue coloration with dil. soln. of gold chloride, and that the colour gradually turns violet. M. Rogier and M. Fiore say that **sodium glycerophosphate** gives no precipitate with gold chloride.

§ 17. Gold Bromides

Gold forms two bromides, aurous bromide, AuBr, and auric bromide, $AuBr_3$, which are analogous in many respects with the corresponding chlorides. There is also an **aurosoauric bromide, or gold dibromide,** Au_2Br_4, or $AuBr_2$, or **aurous bromoaurate,** $Au(AuBr_4)$, which resembles the corresponding aurosoauric chloride, and concerning the individuality of which there is some doubt. J. Thomsen[1] claims to have made black or steel blue aurosoauric bromide by the action of bromine on finely divided gold, and subsequently evaporating off the excess of bromine. F. Lengfeld's directions are:

> Gold is first prepared by precipitation with ferrous sulphate, washing, and drying in vacuo over phosphorus pentoxide for two weeks. 6·1286 grms. of this gold are treated with an excess of bromine in a covered crucible, and the excess of bromine afterwards expelled by a stream of dry air. The product is kept over phosphorus pentoxide, in vacuo, until its weight is constant. The operation is repeated.

According to E. Petersen, aurosoauric bromide decomposes at 115° into bromine and aurous bromide, its heat of formation from aurous and auric chloride is —3·86 Cals.; it is decomposed by water, first into auric and aurous bromide, and the latter is then decomposed into gold and auric bromide; a similar result is obtained by the action of dry ether, according to F. Lengfeld; at 0° the attack by ether is slow, and it is readily decomposed by many organic solvents. F. Meyer denies the existence of aurosoauric bromide, and G. Krüss and F. W. Schmidt regard it as a mixture of auric bromide and undissolved gold. E. Petersen thinks that the thermochemical data do not support the view that it is a mixture of $Au+2AuBr_3$ or of $AuBr+AuBr_3$.

Aurous bromide or gold monobromide, AuBr.—J. Thomsen [2] prepared aurous bromide by heating hydrobromoauric acid up to the m.p., and after cooling, again raising the temp. to 200°; and F. Lengfeld heated hydrobromoauric acid for 3 hrs. on a water-bath, and then 12 hrs. at 105°; no auric salt is left, but usually a little gold remains. F. W. Schmidt obtained the same compound, by heating auric bromide with conc. sulphuric acid up to 200°—*vide* aurous chloride. Aurous bromide is a yellowish-grey crystalline powder which, according to F. W. Schmidt, decomposes when heated to 165°, or, according to J. Thomsen, 115°. F. Meyer says the dissociation temp. is 211° to 270°; and that it volatilizes at 270°, collecting on the cooler parts of the tube in fine needles. The heat of formation, according to J. Thomsen, is $Au+Br_{liq.}=AuBr-30$ cals. Aurous bromide is insoluble in water. The action of water on aurous bromide is similar to its action on aurous chloride. According to F. Lengfeld, gold bromide dissolves in soln. of potassium bromide, forming complex ions—possibly $AuBr_2$—and finally gold and potassium bromoaurate. The alkali chlorides act similarly. Aurous bromide is insoluble in nitric acid and sulphuric acid. It is soluble in aqua ammonia with partial decomposition and the ammoniacal soln. gives an unstable partially soluble precipitate when treated with nitric acid; with hydrobromic acid it forms gold and auric bromide, and, according to J. Thomsen: $3AuBr+HBr_{aq.}=HAuBr_4+2Au+3{\cdot}65$ Cals. aurous bromide and hydrochloric acid form gold, auric chloride, etc. Sulphurous acid reduces it to metallic gold and, according to J. Thomsen: $2AuBr+H_2SO_{3\,soln.}+H_2O=2Au+2HBr+H_2SO_4+42{\cdot}76$ Cals. The product dissolves in potassium cyanide soln. without decomposition; and is slowly decomposed by alcohol, ether, acetone, and moist chloroform. According to F. Meyer, when ammonia is liquefied over aurous bromide, at −40°, gold and ammonium bromide are formed, while if ammonia gas is passed over aurous bromide, gold, ammonium bromide, and nitrogen are formed with the evolution of much heat. If the temp. be maintained at 18°, **aurous diammino-bromide,** $AuBr.2NH_3$, is formed as a white powder which is decomposed by water, moist air, or heat. It is dissolved by aqua regia, and hydrochloric acid converts it into ammonium chloride and halogeno-auric acid. L. Lindet prepared colourless crystals of **aurous phosphinobromide,** $AuBr.PBr_3$, by heating auric bromide and phosphorous bromide in a sealed tube to 140° or 150°; and similarly, with aurous bromide and phosphorous chloride, colourless crystals of **aurous phosphorochlorobromide,** $AuBr.PCl_3$.

Auric bromide, or gold tribromide, $AuBr_3$.—In 1826, A. J. Balard [3] noticed that gold dissolved slowly in an aq. soln. of bromine, forming a liquid which colours the skin violet, and when evaporated forms yellow gold bromide, which when heated decomposes into bromine and gold. The compound was studied by W. A. Lampadius and by J. Nicklès and the latter prepared auric bromide by dissolving gold in ethereal and aq. soln. of the higher bromides of iron, manganese, or cobalt. G. Wilson obtained a dark red soln. of auric bromide by the action of hydrobromic acid on auric chloride: $3HBr+AuCl_3=3HCl+AuBr_3$, hydrochloric acid was evaporated, and the auric bromide extracted with ether. F. Meyer made it by heating precipitated gold with bromine to 100°, and repeating the treatment on the product for a number of times.

Auric bromide forms crystals of a brown colour. J. Thomsen gives its heat of formation as $Au+3Br_{liquid}=AuBr_3+8{\cdot}85$ Cals. According to F. H. Campbell, it decomposes at ordinary temp. into aurous bromide and bromine. F. Meyer says the dissociation temp. is 165°–220°; F. Ephraim, 181°, and the products are aurous bromide, etc., and the salt volatilizes in atm. of bromine at 300°. According to F. W. Schmidt, auric bromide passes into aurous bromide at 160°; and in conc. sulphuric acid it begins to give off bromine at 155°, and at 200° forms aurous bromide.

L. Lindet says that auric bromide dissolves slowly in water, and rapidly in ether, and it can be readily crystallized from its soln. in arsenious, antimonious, titanous, or stannous bromide. The conc. aq. soln. is almost black, and even dil. soln. have a viscous character and froth strongly when shaken. The aq. soln. of auric bromide is less stable than one of auric chloride, and on boiling is partially reduced. Auric bromide, says F. Meyer, is fairly soluble in bromine. F. Ephraim found dark brown auric bromide becomes brownish-yellow in an atm. of ammonia, and absorbs about 9 mols of the gas at ordinary temp., and about 23 mols when cooled by a freezing mixture. According to W. J. Pope and C. S. Gibson, ethyl magnesium bromide converts auric bromide into **auric diethylbromide**, $Au(C_2H_5)_2Br$.

If a conc. aq. soln. containing a mol of auric bromide and a mol of hydrogen bromide be cooled, dark scarlet crystals of **hydrobromoauric acid,** $HAuBr_4.nH_2O$, are obtained which melt in their own water of crystallization at 27°. J. Thomsen supposed the crystals were $HAuBr_4.5H_2O$, but F. Lengfeld considers that they are really $HAuBr_4.6H_2O$, and that J. Thomsen's $HAuBr_4.5H_2O$ is an effloresced product. J. Huber prepared an aq. soln. of this acid by dissolving 10 grms. of brown commercial gold chloride in about 100 c.c. of conc. hydrobromic acid (sp. gr. 1·78), and concentrating the soln. by evaporation to about 50 c.c. The crystals of hydrobromoauric acid can be recrystallized from ether or chloroform. Hydrobromoauric acid is reduced by sulphur dioxide to the metal, and, as F. W. Schmidt has shown, decomposed at 155° by conc. sulphuric acid into aurous bromide and bromine. F. Lengfeld found that if the hexahydrated acid be exposed in a desiccator over phosphorus pentoxide, sulphuric acid, or calcium chloride, or crystallized from dry ether, the trihydrated acid, $HAuBr_4.3H_2O$, is formed. This takes up moisture from the air, re-forming the hexahydrated salt. The tryhydrated salt loses water when heated, but simultaneously decomposes.

A. Gutbier and J. Huber prepared a dark red crystalline precipitate of **ammonium bromoaurate,** NH_4AuBr_4, from a conc. soln. of the component salts; recrystallization from the mother liquid acidified with hydrobromic acid, furnishes large bluish-black prismatic crystals. The corresponding **dihydrated potassium bromoaurate,** $KAuBr_4.2H_2O$, was obtained by P. A. von Bonsdorff by crystallization from aq. soln. of the component salts. P. Schottländer found the rhombic crystals had the axial ratios $a:b:c=0·7969:1:0·3510$, $\beta=94° 26'$; and, according to W. Muthmann, the pleochroism is carmine red and dark brown. The crystals are soluble in water, forming a reddish-brown soln.; they are also readily soluble in alcohol. P. A. von Bonsdorff also obtained the anhydrous **potassium bromoaurate,** $KAuBr_4$, by heating the dihydrated salt at 60°, and crystallizing from absolute alcohol, and G. Krüss by drying the dihydrated salt 14 days over phosphorus pentoxide. P. A. von Bonsdorff, and J. C. Leuchs prepared **dihydrated sodium bromoaurate,** $NaAuBr_4.2H_2O$, in a similar manner. H. L. Wells and H. L. Wheeler, and A. Gutbier and J. Huber likewise made large black monoclinic prismatic crystals of **rubidium bromoaurate,** $RbAuBr_4$, with axial ratios $a:b:c=1·1951:1:0·7256$, and $\beta=76° 53\frac{1}{2}'$, and of **cæsium bromoaurate,** $CsAuBr_4$, with axial ratios $a:b:c=1·1359:1:0·7411$, and $\beta=70° 24\frac{1}{2}'$; and, added S. L. Penfield, "there seems to be no regularity in the influence of the replacement of chlorine by bromine in these gold salts, for in the cæsium compound the chloride has a slightly shorter c-axis and a greater angle β than the bromide, while with the rubidium salts exactly the reverse is true in both cases." The potassium salt is alone hydrated; the rubidium and cæsium salts are anhydrous. The crystals are slightly soluble in water, and in alcohol, and insoluble in ether. According to F. Ephraim, cæsium bromoaurate behaves towards ammonia very like auric bromide. The similarity in the behaviour of the alkali bromoaurates and of auric bromide towards ammonia led F. Ephraim to suggest that they are dissociated by ammonia into their component haloids. P. A. von Bonsdorff prepared the **barium, zinc, and manganese bromoaurates**; J. C. Leuch, **magnesium bromoaurate**; S. Jolin, **cerous bromoaurate,** $CeBr_3.AuBr_3.8H_2O$; P. T. Cleve, **lanthanum bromoaurate,** $LaBr_3.AuBr_3.9H_2O$;

and **samarium bromoaurate,** $SaBr_3.AuBr_3.10H_2O$. L. Lindet obtained dark red crystals of **auric phosphobromide,** $AuBr_3.PBr_5$, by heating the components in a sealed tube at 150°. A. Gutbier and J. Huber have prepared a large number of organic bromoaurates.

§ 18. Gold Iodides

Aurous iodide, gold monoiodide.—According to J. Nicklès (1867),[1] gold is not attacked by iodine at ordinary temp., but leaf-gold is slowly attacked when heated with iodine in a sealed tube at 50°; a soln. of iodine in ether attacks gold in direct sunlight at ordinary press. F. Meyer (1904) synthesized aurous iodide from its elements by shaking precipitated gold with an aq. soln. of iodine in potassium iodide for 16–24 hrs., and by the action of gold on iodine—the action is very slow at 50°, but is completed in a few hours at 100°. F. H. Campbell agitated finely divided gold with a soln. of iodine in carbon tetrachloride. J. Pelletier first prepared aurous iodide by the action of hydriodic acid on auric oxide: $Au_2O_3+6HI=2AuI+3H_2O+2I_2$; J. P. Prat used potassium iodide and auric oxide. J. Pelletier also made aurous iodide by the action of a hot mixture of hydriodic and nitric acids on powdered gold, and also by treating a neutral soln. of auric chloride with an aq. soln. of hydriodic acid, potassium iodide, or ferrous iodide: $AuCl_3+3KI=AuI+3KCl+I_2$; if an excess of these reagents be employed some gold iodide passes into soln. The precipitate is washed by decantation with water, and freed from admixed iodine by warming it to about 35°. A. Meillet used ammonium iodide for the precipitation, and washed with alcohol; F. Gramp used iodine: $AuCl_3+2I_2=3ICl+AuI$; and F. H. Campbell, a soln. of potassium iodide in carbon tetrachloride. If hot water or alcohol be used for the washing, aurous iodide is decomposed. M. J. Fordos prepared this salt in an analogous manner in 1841. J. F. W. Johnston heated a soln. of a gold salt with a soln. of potassium iodide; on cooling, golden-yellow spangles of aurous iodide separated out. J. Thomsen treated auric bromide with potassium iodide. According to J. Nicklès, the higher iodides of many of the metals—iron, manganese, bismuth—attack leaf-gold, forming aurous iodide and a mixture of the oxide and iodide of the metal.

Aurous iodide forms a lemon-yellow crystalline powder or mica-like plates. A. Meillet obtained it as a white powder, and it is therefore possible that the yellow colour is due to the presence of a trace of iodine. When kept in a glass vessel, it acquires a greenish-yellow colour, owing to its slow decomposition into iodine and gold. F. Meyer says it dissociates slowly at 50° in vacuo, and the decomposition is complete at 190°. Aurous iodide, according to F. Meyer, is decomposed by moist air, and this the faster the more readily the iodine can escape; in the presence of iodine it is not decomposed by moist air; and it is stable in a sealed tube in the presence of water. The dissociation press. of aurous iodide is rather smaller than that of pure iodine at ordinary temp., otherwise it would not be possible to combine these two elements. When the two elements are in contact they will unite until the vap. press. of the iodine reaches the equilibrium value $2Au+I_2 \rightleftharpoons 2AuI$, and conversely aurous iodide will decompose so long as the press. of the iodine is less than the equilibrium value. The system $2AuI \rightleftharpoons 2Au+I_2$ is univariant, consisting of two solid phases, and a vapour phase. The vap. press. of the iodine is the only variable, and it is dependent on the temp. F. H. Campbell found that a soln. of 0·1088 mol of iodine in a litre of carbon tetrachloride soln. is in equilibrium with gold and aurous iodide at 25°. A sat. soln. contains 0·1156 mol of iodine, so that the press. of gaseous iodine in equilibrium with aurous iodide and gold is 0·1088/0·1156 =0·943 of that of pure iodine. Hence, any soln. of iodine is or is not able to act on gold according to whether it is or is not sat.; and the dissociation press. of aurous iodide at 25° is nearly 95 per cent. of the vap. press. of iodine. J. Thomsen gives the heat of formation: $Au+I=AuI+55$ Cals. It has not yet been determined whether the heat of formation becomes endothermal at higher temp., or whether the iodide then becomes more stable.

Warm water, or dil. sulphuric, hydrochloric, or nitric acid decomposes aurous iodide, but this salt is more stable towards these agents than the corresponding chloride or bromide. This is explained by the lower solubility of the iodide in these menstrua than is the case with the chloride or bromide. From the observations of J. Pelletier, and M. J. Fordos, chlorine water has no action, but bromine and chlorine respectively oxidize aurous iodide to auric bromide and chloride. Hydriodic acid forms hydriodoauric acid, $HAuI_4$, with the separation of gold; potassium and ferrous iodide similarly form gold and iodoaurates. The solubility of aurous iodide in water is not known, but F. H. Campbell found the solubilities in potassium iodide soln. to be approximately proportional to the conc. of that salt. Expressing conc. in mols of potassium iodide and gram-atoms of gold per litre:

KI . . .	0·1009	0·2508	0·4038	1·0096 mol
Au . . .	0·0096	0·0293	0·538	0·1170 gram-atoms

The aurous iodide is present in the soln. in the form of complex anions AuI_2' or AuI_4'''—probably the former. Iron in the presence of water and aurous iodide forms ferrous iodide and gold. The dissociation tension of aurous iodide makes it behave like free iodine; *e.g.* with potassium hydroxide it forms gold and a mixture of the alkali iodide and iodate. Many organic solvents also decompose the iodide, ether more quickly than alcohol. Gum retards the spontaneous decomposition of aurous iodide.

According to F. Meyer, **aurous hexammino-iodide,** $AuI.6NH_3$, is formed by the action of liquid ammonia on dry aurous iodide; when the excess of ammonia has evaporated off, white crystals of the hexammino-salt remain. It is also formed as an amorphous powder by the action of ammonia gas on aurous iodide at —28°. The dissociation press. at —28° is 760 mm. Between —28° and —15° it loses two molecules of ammonia, at —10° a third molecule, and at 20° it forms **aurous ammino-iodide,** $AuI.NH_3$. When heated, this salt loses ammonia and iodine; with water or moist air it forms gold and ammonium iodide, with dilute acids it forms aurous and ammonium iodides; it is dissolved by aqua regia; and with potash-lye it forms a black powder which burns with a hissing noise when heated by a flame.

Auric iodide, gold triiodide, AuI_3.—J. P. Prat[2] found that a soln. of aurous iodide with a sat. soln. of iodine in hydriodic acid furnished on evaporation small rhombohedral crystals of auric iodide. According to F. W. Schmidt, if aq. potassium iodide be gradually added to a neutral soln. of auric chloride, the liquid becomes dark green, and forms a dark green precipitate of auric iodide which dissolves when the liquid is agitated, forming soluble **potassium iodoaurate**: $AuCl_3+4KI=3KCl+KAuI_4$. If auric chloride be added to the soln. containing $AuCl_3 : KI=1 : 4$, the potassium iodoaurate is decomposed, and auric iodide is precipitated: $3KAuI_4+AuCl_3=3KCl+4AuI_3$. The precipitate can be washed without much decomposition, but it loses iodine when dried. It also decomposes slowly in air, forming yellow aurous iodide, which in turn decomposes as previously indicated. Auric iodide is decomposed by alkali and alkaline earth hydroxides. J. F. W. Johnston showed, in 1836, that auric iodide forms double salts with hydriodic acid and with metallic iodides. The soln. of auric iodide in hydriodic acid gives a dark brown precipitate when an excess of aqua ammonia is added, and with an excess of the gold soln. a black precipitate resembling fulminating gold. J. F. W. Johnston also obtained black prismatic crystals of ammonium iodoaurate by evaporating a soln. of auric iodide in aq. ammonium iodide. The evaporation of the dark reddish-brown soln. of finely divided gold in aq. potassium iodide and iodine (J. Pelletier), auric iodide (J. F. W. Johnston), or aurous iodide (M. J. Fordos), gives black crystals of what is considered to be **hydriodoauric acid**, $HAuI_4$. J. F. W. Johnston also prepared black crystals of **sodium iodoaurate**, and **barium iodoaurate**, in an analogous manner.

§ 19. The Sulphides of Gold

Gold does not unite with sulphur when the two elements are fused together. From J. R. Glauber's *De natura salium* (Amstelodami, 1658) it would appear that he found that the liver of sulphur, which he made by extracting with water a calcined mixture of sodium sulphate with carbon, had a solvent action on gold; and G. E. Stahl (1697) remarked on the solvent action of a boiling mixture of sulphur and potassium monosulphide, hydrosulphide, or carbonate on gold. U. Antony and A. Lucchesi found that the gold thiosalts obtained by treating auric chloride with soln. of alkali sulphides are very unstable, and cannot be obtained in the solid state. Gold is dissolved by molten alkali polysulphides. According to W. Skey,[1] gold is superficially attacked by a soln. of ammonium sulphide, by moist hydrogen sulphide, or by boiling with sulphur and water, whereby a film of gold sulphide is formed which prevents the metal amalgamating with mercury and which can be removed by calcination, by treatment with potassium cyanide, chromic anhydride, or nitric acid.

Gold monosulphide, or aurous sulphide, Au_2S.—J. J. Berzelius said that a brownish-black powder, gold monosulphide or aurous sulphide, is formed by passing hydrogen sulphide into a boiling soln. of auric chloride, part of the sulphur is at the same time converted into sulphuric acid. A. Levol said the precipitate is not gold sulphide, but rather metallic gold; the amount of sulphuric acid produced in the reaction corresponds with the equation: $8AuCl_3+3H_2S+12H_2O=8Au+24HCl+3H_2SO_4$. G. Krüss claimed that J. J. Berzelius' product is a mixture of sulphur and gold. This also is the conclusion of A. Schrötter and E. Priwoznik, V. A. Jacquelain, L. R. von Fellenberg, and of U. Antony and A. Lucchesi. The last-named worked with 1 per cent. soln. of gold chloride at 90°–100°. Further, they found that a 1 to 3 per cent. soln. at ordinary temp., about 8°, yields a black precipitate of aurosoauric sulphide, Au_2S_2. The temp. of the soln. continually rises during the precipitation proportionally to the strength of the soln., and if at any time the temp. approaches 40°, metallic gold is precipitated along with the sulphide. If the soln. is not fully precipitated and the sulphide is allowed to remain in contact with the soln. of auric chloride, these salts react according to the equation: $4AuCl_3+Au_2S_2+8H_2O=6Au+12HCl+2H_2SO_4$, metallic gold being formed. L. Hoffmann and G. Krüss also found that metallic gold is precipitated at 100°, and at lower temp. variable proportions of combined sulphur, but no definite compound, are precipitated. The free sulphur is retained very tenaciously by the precipitate, and cannot be removed by washing on a filter; they removed the sulphur by washing first with water, then successively with alcohol, ether, and carbon disulphide. They obtained no appreciable change when hydrogen sulphide was passed through a soln. of potassium cyanoaurate, but when an excess of hydrochloric acid was present and the whole heated, a steel-grey precipitate of aurous sulphide was precipitated; this was washed with dil. hydrochloric acid, alcohol, ether, etc., as previously indicated in order to remove free sulphur. When freshly precipitated, aurous sulphide is peptized by water to form a brown colloidal soln., hence the need for washing with dil. acid. A. Oberkampf said that aurous sulphide is precipitated when an acid is added to the reddish-yellow soln. obtained by dissolving finely divided gold in a boiling soln. of potassium sulphide, or carbonate and sulphur. From soln. of aurous sodium thiosulphate, hydrogen sulphide precipitates mixtures of gold, sulphur, and aurous sulphide which always vary in composition. A. Gutbier and E. Dürrwächter could not find the right conditions for making this sulphide. According to E. A. Schneider, **colloidal aurous sulphide** can be prepared by saturating a soln. of aurous cyanide in potassium cyanide with hydrogen sulphide, warming carefully with hydrochloric acid until a brown turbidity is produced, and then submitting the whole to dialysis; there remains in the dialyzer a deep brown, colloidal soln. of aurous sulphide which can be separated from the undissolved portions by decantation and filtration. The most conc. soln. that can be obtained in this way contains 1·74 grms. of the sulphide per litre. When the colloidal soln. is heated at 200° to 230°, sulphuric acid is formed, and gold is deposited; when the soln. is frozen and melted again, the aurous sulphide is precipitated.

P. Yorke prepared tetrahydrated **sodium thioaurite,** $NaAuS.4H_2O$, by heating to bright redness a mixture of one gram-atom of gold, 6 gram-atoms of sulphur, and two mols of sodium monosulphide; extracting the fused mass with water; and concentrating the filtered soln. in vacuo over sulphuric acid. The yellow crystals so obtained are colourless when purified by re-crystallization. He also obtained similar crystals by crystallization of a soln. of one of the gold sulphides in an aq. soln. of sodium monosulphide. According to P. Yorke, the crystals have the composition $NaAuS.4H_2O$, but A. Ditte's crystals obtained by evaporating in vacuo a yellow soln. of aurous sulphide in the least possible quantity of sodium monosulphide, are said to have had the composition $NaAuS.5H_2O$. The crystals obtained by P. Yorke were six-sided prisms, with trilateral or quadrilateral apices, and belonged to the monoclinic system. They rapidly turned brown in air, and when heated, first gave off water, and then sulphur. The crystals dissolve in water and alcohol, and when the aq. soln. is treated with acids, a yellowish-brown precipitate with Au : S=1 : 1 or 2 is deposited, and hydrogen sulphide evolved. The aq. soln. also decomposed slowly when exposed to air. The potassium salt treated under similar conditions furnishes a mass of indistinct crystals whose composition was not definitely established, but which were thought to be potassium **thioaurite,** $K_2S.Au_2S.nH_2O$, or $KAuS.nH_2O$.

According to P. Yorke, when gold sulphide is digested with sodium hydrosulphide, only a small quantity dissolves at ordinary temp., and on heating the soln., the gold sulphide is reduced. A. Ditte found aurous sulphide gradually dissolves in a soln. of sodium hydrosulphide, forming an orange-coloured soln. which, when evaporated in vacuo, deposits colourless needles, $2Na_2S.Au_2S.20H_2O$, or $Na_4Au_2S_3.20H_2O$, **tetrasodium trithioaurite.** These crystals are superficially blackened if organic matter be present.

U. Antony and A. Lucchesi dissolved finely powdered aurous sulphide in a soln. of sodium hydrosulphide of sp. gr. 1·021 or 1·029, and found the reddish-brown soln. to be rapidly decolorized, on the addition of absolute alcohol, owing to the formation of crystals of **trisodium dithioaurite,** Na_3AuS_2, or $3Na_2S.Au_2S$. It is suggested that unstable *trisodium trithioaurite*, Na_3AuS_3, is first formed, and this immediately decomposes into the more stable Na_3AuS_2; the corresponding **tripotassium dithioaurite,** $3K_2S.Au_2S$, or K_3AuS_2, was prepared in a similar manner. A. Ditte made yellow hygroscopic needle-like crystals of the composition, $4K_2S.Au_2S.12H_2O$, by evaporating in vacuo a soln. of auric sulphide in a small excess of potassium monosulphide. The crystals are coloured superficially grey by exposure to light. The crystals readily dissolve in water, forming a yellow soln. Silver nitrate precipitates **silver thioaurite,** Ag_3AuS_2, from soln. of the potassium salt.

Gold disulphide or aurosoauric sulphide, Au_2S_2, or $(AuS)_n$.—A. Levol[2] precipitated this product by treating a cold aq. soln. of auric chloride with hydrogen sulphide or an alkaline sulphide, and he represented the reaction: $8AuCl_3+9H_2S+4H_2O=4Au_2S_2+24HCl+H_2SO_4$, and this was confirmed by G. Krüss and L. Hoffmann. According to U. Antony and A. Lucchesi, the best conc. of the auric chloride soln. is between 1 and 3 per cent., and the temp. ought not to exceed 35° or 40°, otherwise some metallic gold is deposited. If the auric chloride is treated with ammonium hydrosulphide or an excess of yellow ammonium polysulphide, metallic gold is precipitated. They also made aurosoauric sulphide by adding a soln. of auric chloride to an aq. soln. of sodium aurous thiosulphate, and washing and drying the product. The preparation of this salt was also investigated by A. Oberkampf and by A. Schrötter and E. Priwoznik. A. Ditte made aurosoauric sulphide by passing hydrogen sulphide into an acid soln. of auric chloride. S. Odén prepared a colloidal hydrosol of auric sulphide by the action of a hydrosol of sulphur on an aq. soln. of auric chloride. A. Gutbier and E. Dürrwächter could not find the right conditions for making this sulphide.

Dried aurous sulphide is a brownish-black powder, and, once the precipitate has been dried, it is no longer peptized by water. A. Beutell has studied the formation of filiform gold by heating gold sulphide in vacuo, and obtained results like those obtained with silver sulphide under similar conditions (*q.v.*). It is not decomposed when boiled with dil. hydrochloric or sulphuric acids. Ozone was found by A. Mailfert to oxidize gold sulphide to the metal and free sulphuric acid. According to G. Krüss, aqua regia, chlorous oxide, and other oxiziding agents oxidize it easily. Bromine water slowly dissolves it with the formation of aurous bromide and sulphuric acid. Alkaline monosulphides dissolve it but slowly and slightly, polysulphides rapidly and completely, with the formation of green soln. of thio-salts. A soln. of potassium hydroxide does not attack it even at 100°, whereas the compound Au_2S_2 is, under like conditions, decomposed into gold, potassium gold sulphide, and potassium gold oxide. Potassium cyanide dissolves it readily, and the sulphide is reprecipitated by boiling the soln. with excess of hydrochloric acid. This reaction gives a good means of purifying the sulphide from free sulphur, as a slightly warmed soln. of potassium cyanide dissolves the former but not the latter. When heated in a tube, part of the sulphur distils off, and part passes off as sulphurous anhydride. The compound is completely decomposed at 240°, and ignites in oxygen at a low temp. When heated in a stream of hydrogen, hydrogen sulphide is formed, but in a stream of hydrogen chloride the sulphur sublimes without the formation of any hydrogen sulphide, and pure gold is left. The existence of a soluble aurous sulphide and a soluble aurous oxide is regarded by G. Krüss as evidence in favour of placing gold in the alkali group rather than in the platinum group.

K. A. Hoffmann and F. Höchtlen formed yellow rhombic crystals of ammonium trithioaurate, NH_4AuS_3, by shaking aurous chloride with a soln. of ammonium polysulphide, and allowing the mixture to stand some days at 5°. Aurosoauric sulphide is a reddish-brown or brownish-black powder, which, according to A. Oberkampf and A. Levol, begins to decompose at 140°, and the decomposition is complete at 250°–270°. When heated in hydrogen, G. Krüss found it to be reduced to gold. V. A. Jacquelain noticed that when kept for two days under an excess of the gold soln. in which it was formed, the precipitate decomposes, producing gold and sulphuric acid. A. Levol observed that although aurosoauric sulphide can be boiled in the liquid in which it was made, it cannot be prepared from boiling soln. When freshly prepared, E. A. Schneider, and C. Winssinger found it to form a colloidal soln. with water such that a litre of water may hold up to 0·8 grm. of the sulphide, but it was found by A. Levol to be converted by chlorine into sulphur chloride and auric chloride. According to G. Krüss, bromine water converts aurosoauric sulphide into auric bromide and sulphuric acid. It is insoluble in acids, but is dissolved by aqua regia. Soln. of the alkali monosulphides dissolve it sparingly in the cold, but when heated it first forms a brown and then a yellowish-green soln. According to A. Ditte, an excess of alkali monosulphide soln. forms an alkalithioaurite, while with an excess of aurosoauric sulphide, crystals of gold are formed. A very small excess of potassium monosulphide in the cold or at 30°–40° gives a residue of metallic gold. According to H. Hahn, soln. of the alkali polysulphides dissolve it easily in the cold, forming first a brown, then a green soln. A. Ditte says that it is insoluble in a soln. of sodium monosulphide sat. with sulphur; and sulphur gradually precipitates gold as black sulphide from aq. soln. of aurosoauric sulphide in aq. sodium monosulphide. Potassium hydroxide lye does not attack aurosoauric sulphide in the cold, but when heated a part is dissolved and part reduced to gold. Potassium cyanide rapidly dissolves aurosoauric sulphide, forming a colourless soln. E. A. Schneider found a soln. of auric chloride converts it into gold, slowly if cold, rapidly if heated.

Gold trisulphide or auric sulphide, Au_2S_3.—J. J. Berzelius[3] melted an excess of gold with potassium pentasulphide; extracted the cold mass with water; and precipitated by adding an acid, dark green flocculent auric sulphide which dried to a brown mass. According to G. Krüss, J. J. Berzelius' product was a mixture of sulphur and auric sulphide. K. A. Hoffmann and F. Höchtlen prepared auric sulphide by passing hydrogen sulphide into a soln. of auric chloride in anhydrous ether. U. Antony and A. Lucchesi prepared auric sulphide by passing hydrogen sulphide over dry lithium tetrachloaurate, $LiCl.AuCl_3$, or the hydrated salt, $LiCl.AuCl_3.2H_2O$, at $-10°$. The resulting brown mass was extracted with alcohol, and washed successively with carbon disulphide, alcohol, and finally ether; the product was dried at 70° in alcohol vapour until the weight was constant. U. Antony and A. Lucchesi, and A. Gutbier and E. Dürrwächter found that auric sulphide is decomposed by soln. of auric chloride, say: $Au_2S_3+6HAuCl_4+12H_2O=8Au+3H_2SO_4+24HCl$.

U. Antony and A. Lucchesi reported that auric sulphide was a black amorphous powder with a sp. gr. 8·754; it decomposes into its constituents between 197° and 200°. Neither fuming hydrochloric acid nor moderately conc. nitric acid attack auric sulphide, but conc. nitric acid (sp. gr. 1·370) oxidizes the sulphur and leaves the gold. Aqua regia attacks it slightly. A hot soln. of potassium or sodium hydroxide (1 : 6) gradually dissolves the sulphur, forming alkali sulphide, thiosulphate, and gold. Warm aq. ammonia acts extremely slowly. Auric sulphide readily dissolves in a soln. of potassium cyanide: $Au_2S_3+6KCy=2KAuCy_2+K_2S+2KCyS$; a soln. of auric sulphide in a hot 25 per cent. soln. of potassium cyanide, furnishes crystals of potassium cyanoaurite, $KAuCy_2$. Dil. acids precipitate gold sulphide and cyanide from a soln. of auric sulphide in one of potassium cyanide; while dil. acids precipitate aurous or aurosoauric sulphide unchanged from a soln. of the respective salt in the same menstruum. A cold soln. of ammonium hydrosulphide or monosulphide extracts sulphur from auric sulphide, and leaves the gold; the action is rapid with warm soln. A soln. of the alkali sulphides and polysulphides dissolve auric sulphide with difficulty, and the latter salt is partially decomposed; cold soln. of the alkali hydrosulphides readily dissolve auric sulphide, forming a brown soln., which when warmed becomes pale yellow, and when boiled the soln. deposits gold; when an acid is added to the soln., a pale yellow flocculent precipitate is formed and hydrogen sulphide is given off, and the precipitate becomes brown owing to the separation of auric sulphide.

Although sulphur vapour has very little action on gold, the case is different when that metal is alloyed with copper or silver, since what have been regarded as double **cuprous thioaurites** and **silver thioaurites** are formed. M. M. P. Muir's analysis, $5Ag_2S.2Au_2S_3$, of a product of the action of sulphur vapour on an alloy of gold and silver showed that the gold and silver are attacked, and a native sulphide of gold and silver is known. J. S. Maclaurin[4] confirmed M. M. P. Muir's observation and prepared a number of such alloys of gold and silver sulphides, but gave no evidence as to which were compounds and which were mixtures. J. S. Maclaurin made what he regarded as silver thioaurite, $Ag_2S.Au_2S$, or $AgAuS$. U. Antony and A. Lucchesi also prepared what they regarded as *trisilver dithioaurite*, $3Ag_2S.Au_2S$, or Ag_3AuS_2, by the action of silver nitrate on trisodium dithioaurite, Na_3AuS_2. Similar observations were made with respect to silver and cuprous sulphides.

§ 20. Gold Sulphates

J. P. Prat[1] prepared what is regarded as **aurosoauric sulphates,** $AuSO_4$, by heating finely divided gold with sulphato-iodic acid, $3H_2SO_4.2HIO_3$, to 300° until the mixture acquired a dark orange-yellow colour; he dissolved the mass in fuming nitric acid, dil. with water, and boiled. The brown precipitate was washed, dried, and preserved out of contact with light. P. Schottländer prepared what appears to be the same product by evaporating a soln. of auryl sulphate at 250° as rapidly as possible. The red hygroscopic prismatic crystals so obtained were blackened when treated with water, owing to the separation of auric hydroxide, and with a small quantity of moisture they formed a yellow substance. They are insoluble in cold conc. sulphuric acid, and with hot conc. sulphuric acid they are decomposed into gold and a soln. of auric sulphate.

J. Pelletier found that auric oxide is sparingly soluble in cold sulphuric acid, forming a yellow strongly acid liquid which, when gently heated or when mixed with water, deposits metallic gold. The acid liquid is thought to contain a soln. of **auric sulphate,** $Au_2(SO_4)_3$. J. P. Prat says the soln. crystallizes with difficulty, and that the dry crystals are purple-red, very hygroscopic, and decompose when treated with water into an insoluble aurous salt and a soluble auric salt. A. H. Allen obtained a similar liquid to that obtained by J. Pelletier, but he worked with hot soln. The soln. reacts with ferrous sulphate, oxalic acid, or stannous chloride like ordinary soln. of gold salts. A. Reynolds made similar observations, but he employed hot conc. sulphuric mixed with a little nitric acid for dissolving the auric oxide. A. H. Allen employed a mixture of chlorine-free potassium permanganate and conc. sulphuric acid as a solvent. J. Spiller obtained a soln. of auric sulphate by the electrolysis of a mixture of sulphuric acid with 10 per cent. of nitric acid with a gold anode and platinum cathode. The resulting soln. contains auric sulphate which is converted into auric chloride by hydrochloric acids or metal chlorides.

P. Schottländer heated auryl nitrate with conc. sulphuric acid to about 200° and obtained yellow, hygroscopic octahedra of **auryl hydrosulphate,** $AuO.HSO_4$. They form a yellowish-red soln. with 95 per cent. sulphuric acid which becomes almost black when heated. Boiling nitric acid does not appreciably affect the compound; hydrochloric acid forms auric chloride and sulphuric acid; and water immediately decomposes the salt into auric oxide and sulphuric acid.

According to J. P. Prat, an aq. soln. of gold sulphate unites with alkali sulphates to form a salt which crystallizes in octahedra resembling alum; and, according to P. Schottländer, a soln. of one part of potassium hydrosulphate with ten parts of auryl sulphate on evaporation at 200° furnishes pale yellow rhombic plates of **potassium disulphatoaurate,** $KAu(SO_4)_2$. These slowly turn brown on exposure to air, and when treated with cold water furnish auric oxide, potassium sulphate, and sulphuric acid. The corresponding **silver disulphatoaurate,** $AgAu(SO_4)_2$, was made in a similar way.

§ 21. The Gold Nitrates

According to T. Bergmann,[1] freshly precipitated gold dissolves in conc. nitric acid, but separates from it again when the liquid is agitated. S. Tennant also observed the formation of an orange-coloured soln, when finely divided gold is digested with fuming nitric acid, and found that the soln. deposits auric oxide when shaken up with water, while if an excess of fuming nitric acid is present, or if the water contains some potassium nitrate, metallic gold is precipitated. According to A. H. Allen, the aq. soln. decomposes slowly in the cold, and rapidly when heated. L. N. Vauquelin, J. Pelletier, E. Frémy, and A. H. Allen studied the yellowish-brown soln. obtained when auric oxide or hydroxide is digested with conc. nitric acid. On evaporation, the soln. deposits first auric oxide, and then a black mixture of gold and auric oxide. In the absence of hydrochloric acid, the addition of water precipitates auric hydroxide from the soln. of gold in conc. nitric acid; the soln. behaves towards reagents in a way which is characteristic of auric salts. It is generally assumed that the soln. contains **auric nitrate,** which is stable only in very conc. soln. of nitric acid. A. Hanriot and F. M. Raoult dissolved brown precipitated gold in nitric acid free from nitric fumes, and concentrated the soln. in vacuo, over calcium chloride, in darkness, first aided by heat, and then while cooling the soln. The residue was extracted with boiling dried acetone, and the soln., on evaporation, furnished needle-like crystals of the composition $Au(NO_3)_3.nH_2O$. They are decomposed by exposure to light and air, and this renders the determination of the water of crystallization impracticable. The crystals are soluble in boiling acetone, and are decomposed by water into nitric acid and brown auric oxide.

F. M. Campbell prepared **aurous nitrate,** $AuNO_3$, by shaking aurous oxide with nitric acid. He estimated that the solubility product, $[Au^{\cdot}][OH]'$, of the hydrolyzed aurous nitrate is $0{\cdot}52 \times 10^{-19}$ with $9{\cdot}13N$-HNO_3, and $0{\cdot}86 \times 10^{-19}$ with $11{\cdot}6N$-nitric acid. The discharge potential of $Au^{\cdot}$-ions is 1·5 volt. According to P. Schottländer, auric hydroxide is soluble in nitric acid of sp. gr. 1·40, when heated on a water-bath, and the soln. when evaporated in vacuo over calcium chloride and sodium hydroxide gives a dark reddish-brown gum-like mass of **auryl nitrate,** $AuO.NO_3.\frac{1}{3}H_2O$, or $5Au_2O_3.5N_2O_5.2H_2O$. If hydronitratoauric acid (*vide infra*) is dried on a water-bath at 98°, a reddish-brown amorphous powder is formed, whose composition corresponds with a basic auryl nitrate or **auryl oxynitrate,** $2Au_2O_3.N_2O_5.2H_2O$, or $Au_2O_3.2AuO(NO_3).2H_2O$. It is very slowly soluble without residue in nitric acid of sp. gr. 1·40, even at 100°. According to P. Schottländer, when a soln. of one part of auric hydroxide in 3·67 parts of nitric acid of sp. gr. 1·492 is cooled by a freezing mixture, it furnishes golden-yellow triclinic crystals of sp. gr. 2·84, and whose composition corresponds with **auric hydronitrate,** or **hydronitratoauric acid,** $HAu(NO_3)_4.3H_2O$, or $Au(NO_3)_3.HNO_3.3H_2O$. For F. H. Jeffery's preparation of yellow crystals of hydroaurinitric acid, $HAu(NO_3)_4.3H_2O$, see the action of nitric acid on gold. The crystals effloresce in dry air, and deliquesce in moist air. When warmed at 72°–73°, nitric acid is given off, and a brownish-black liquid is obtained. At 215° decomposition is complete. If a soln. of hydronitratoauric acid and ammonium nitrate in colourless conc. nitric acid, of sp. gr. 1·4–1·5, be evaporated in a desiccator, yellow prismatic crystals of **ammonium nitratoaurate,** $NH_4NO_3.Au(NO_3)_3$, or $NH_4Au(NO_3)_4$, are formed. The crystals are fairly stable when heated, but decompose as the temp. approaches 140°. P. Schottländer also evaporated in a desiccator a warm soln. of seven parts of ammonium nitrate and ten of hydronitratoauric acid in 25 parts of colourless nitric acid of sp. gr. 1·5. The yellow rhombic plates had the composition corresponding with $2NH_4NO_3.Au(NO_3)_3.HNO_3$, or $NH_4Au(NO_3)_4.NH_4NO_3.HNO_3$. They are decomposed by nitric acid of sp. gr. less than 1·4 and over 1·5. Corresponding salts—**potassium nitratoaurate,** $KAu(NO_3)_4$, and **rubidium nitratoaurate,** $RbAu(NO_3)_4$—were prepared by P. Schottländer.

§ 22. The Family Relationship of Copper, Silver, and Gold

These three elements are generally classed together in so-called "systematic chemistry," and they are furthermore considered to be related to the alkali metals. The copper group of elements is generally linked with the alkalimetals by the scheme indicated in the margin, which starts with the elements with the lowest atomic weights. The fault with the scheme is that it makes the relationship appear far closer than is indicated by known facts. If we recall the relationship between the members of, say, the alkali metals, and the halogen families, the relationship between the individual members of this so-called family and with the alkali metals is strikingly obscure. The student might well inquire why these elements are grouped together at all, and cogent reasons might be urged for grouping gold with platinum, silver with palladium, and copper with mercury. The reason why this is not done will appear when we take a general survey of *all* the elements. Returning to the elements copper, silver, and gold, the physical properties may be tabulated:

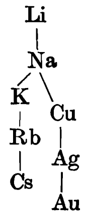

TABLE XII.—PHYSICAL PROPERTIES OF COPPER, SILVER, AND GOLD.

	Copper.	Silver.	Gold.
Atomic weight	63·6	107·88	197·2
Specific gravity	8·93	10·49	19·265
Atomic volume	7·07	10·29	10·11
Melting point	1082·6°	960·0°	1062·4°
Boiling point	2310°	1955°	2200°
Latent heat of fusion (cals.)	43	24·35	16·3
Specific heat	0·086	0·055	0·030

In malleability, ductility, and tenacity, silver is intermediate between copper and gold. While the large atomic volume of the alkali metals is associated with great chemical activity and affinity for oxygen, the low atomic volume of these elements is related with their weak affinity for oxygen, etc. Copper, for instance, is alone oxidized in air. The oxides of copper, silver, and gold are easily reduced, while the oxides of the alkali metals are reduced with great difficulty. The reduction of copper, silver, and gold by magnesium is the more energetic the greater the atomic weight of the metal—cuprous oxide reduces easily; silver oxide reduces with explosive violence, and gold oxide breaks down into its constituents below the ignition point of magnesium. Silver appears to be uni-, bi-, and ter-valent, but copper is both uni- and bi-valent, and gold is uni- and ter-valent. Hence these three elements have univalency in common with the alkali metals. Cupric salts are isomorphous with iron, cobalt, and nickel. The isomorphism of the silver and sodium sulphates and selenates indicates a relationship of some kind between silver and sodium. The alkali halides, like silver chloride and bromide, crystallize in the cubic system—silver iodide crystallizes in the hexagonal system and the crystals pass into the cubic system at about 146°—on cooling the reverse change takes place—sometimes with explosive violence. Silver seems to be related with copper through argentic oxide, AgO, where silver appears to be bi-valent; silver pyridine persulphate, $Ag_2S_2O_8.4Py$, is isomorphous with the analogous copper pyridine persulphate, $CuS_2O_8.4Py$; with gold, through silver sesquioxide, Ag_2O_3; and with the alkalies through argentous oxide, Ag_2O, and with the magnesium family through mercury. The more salient differences between copper and the alkali metals are: (1) The elements of the alkali metals have a small density, the other metals have a large density; (2) the alkali metals do not occur free; (3) the elements of the alkali metals are chemically active, the others not so; (4) the haloids of the alkalies are all soluble in water, and are not hydrolyzed by water; copper and silver form sparingly soluble haloids, and the haloids of copper and gold, not silver, are hydrolyzed by water. (5) The oxides and hydroxides of the alkalies are strongly basic; the oxides and hydroxides of copper and gold are feebly basic, and they accordingly form basic salts. (6) The alkali metals do not form complex salts, whereas copper, silver, and gold form many complex salts.

R. F. Heath[1] reported a radioactive element of monad valency, at. wt. 204·6, belonging to the first group in the periodic table. It was found in the uranite and monazite sand of Montana, U.S.A. The element itself is brownish-grey in colour, and it unites at a high temp. with the halogens, nitrogen, oxygen, and hydrogen; the compounds and salts are white. It was named *wilsonium* after the then President of the United States. The results have not been confirmed.

CHAPTER XXIV

THE ALKALINE EARTHS

§ 1. The History of Calcium, Strontium, and Barium

THE early chemists applied the term *earth* to those non-metallic substances which were virtually insoluble in water, and did not change when exposed to a high temp. When it was found that some of the earths resembled the alkalies in that they neutralized the acids, and gave an alkaline reaction when moistened with water, they were subdivided so as to form a class termed *terra alkalina.* The alkaline earths at first comprised magnesia and lime; baryta and strontia were afterwards included. It was subsequently found that the chemical properties of magnesia more nearly resembled those of zinc and cadmium oxides than those of the other three alkaline earths, and it was consequently removed to another sub-group so that this family now includes the three oxides—lime, strontia, and baryta. Radium has been included in the family of the alkaline earths.

Lime must have been long known, since it has been employed in making mortar from prehistoric times. Theophrastus (300 B.C.) mentioned in his Περὶ Λίθων, that the calcination of γύψος, gypsum, furnishes a product which has more the nature of a rock than an earth, and which develops heat and sets to a hard mass when wetted with water. He also stated that gypsum seems to have the nature of lime. Dioscorides (75 A.D.) described the preparation of caustic lime—ἄσβεστος, unslaked, as he called it—by calcining mussel-shells, limestone, or marble at a white heat. Contemporaneous with Dioscorides, the elder Pliny, in his *Historia naturali*, described the processes of burning and slaking lime.

G. E. Stahl [1] regarded salts as products of the combination of an earthy element with an aqueous element. N. Lemery said:

> Quicklime is a stone whose moisture has been dried up by fire and replaced by a great many igneous particles; the igneous particles can be driven from quicklime by the addition of a little water. . . . I am not of the opinion of those who suppose quicklime to contain an acid which is drawn out by water, and, meeting an alkali, effervesces when in the presence of water.

C. F. Dufay evaporated lime-water and obtained what he called *le sel de la chaux.* M. Malouin assumed that the *crême de chaux*, which formed as a film on the surface of lime-water exposed to air, contained vitriolic acid united with a particular earth. In 1747, H. L. Duhamel du Monceau prepared many *combinaisons de la chaux avec plusieurs acides.* The changes which occur during the conversion of limestone into caustic lime were not understood until J. Black published his thesis, *Experiments upon Magnesia Alba, Quicklime, and other Alcaline Substances* (Edinburgh, 1777).

Near the beginning of the seventeenth century, about 1602 or 1603, the mineral heavy spar, found in the secondary strata of the Monte Paterno, attracted the attention of V.Casciorolus or V.Casciarolus who dabbled in alchemy; he suspected from the weight and lustre of the stone that it contained a heavy metal; he therefore subjected the mineral to fire and was amazed to find the product glowed with a red light when viewed in a dark room. Hence the stone was called *lapis solaris*, and, owing to its having been first prepared at Bologna, it was called *Bolognian or Bononian stone.* It was mentioned by A. J. C. de Galla [2] in 1612, and in his *Andegavensis pharmacopœa* *spagyrica* (Coloniæ, 1625), P. Poterius described the method of making the phosphorescent stones. In 1748, F. M. Zanottus stated that in 1719 it had been demonstrated by J. B. Beccari and others that the Bolognian stone contained sulphur and an alkali.

The mineral from which the *lapis solaris* was made was also called the *Bologna stone* or *Bologna spar.* J. G. Wallerius regarded Bologna spar as a kind of gypsum, and he called it *gypsum spathosum;* and A. F. Cronstedt considered it a distinct species and called it *marmor metallicum.* In 1750, A. S. Marggraf found that this mineral contained sulphuric acid, but he regarded it as a compound of sulphuric acid with lime. About 1760, J. H. G. von Justi, commenting on the obscure nature of the mineral, said :

> Our analysis has here reached its limits, we know of no smelting operation which will enable anything to be obtained from the spar. Many skilled chemists and assayers have here tried their art in vain.

C. W. Scheele's investigation, *De magnesia nigra* (Stockholm, 1774), revealed the presence in manganese oxide of " an earth differing from all earths hitherto known," whose soln. in phosphoric, tartaric, or hydrofluoric acid gave an insoluble white precipitate with sulphuric acid ; and in his *De arsenico ejusque acido* (Stockholm, 1775), C. W. Scheele made further observations on this new earth which he called *terra ponderosa,* and stated that he had been informed by I. G. Gahn that the new earth is the basis of heavy or ponderous spar. C. W. Scheele made a special *Examen chemicum de terra ponderosa* in 1779, and it was soon identified with the Bologna spar.

T. Bergmann, in his *Sciagraphia regni mineralis* (London, 1783), assumed that a carbonate of *terra ponderosa* would occur in nature, and this was discovered in 1783 by W. Withering, at Leadhills (Scotland). A. G. Werner called the mineral *witherite.* A. F. de Fourcroy and L. N. Vauquelin (1797) prepared *terra ponderosa* by calcining the nitrate. L. B. Guyton de Morveau recommended the term *barote*—from *βαρύς*, heavy—in place of *terra ponderosa,* and this term was later changed into *baryta* in conformity with A. L. Lavoisier's nomenclature, and the metal was called *barium.* E. D. Clarke proposed calling the metal *plutonium,* but the suggestion was never adopted.

A mineral resembling heavy spar, found associated with the ore in the lead mines of Strontian in Argyleshire, attracted the attention of T. C. Hope.[3] In 1790, A. Crawford, basing his opinion on the experiments of his assistant, W. Cruickshank, emphasized the conspicuous difference in the form of the crystals of the chloride derived from this mineral, and from barytes ; and on the difference in the solubilities of the two chlorides ; and he conjectured that the mineral from Strontian differed from aërated barytes in containing a peculiar and hitherto unknown kind of earth. B. Pelletier reported that a sample of the Strontian mineral had been transmitted to a French chemist of note, who did not publish the result of his analysis because *elle ne m'avoit fourni rien de particulier.* T. C. Hope reported the results of his first experiments in 1792, and in 1793 he gave *An account of a mineral from Strontian and of a peculiar species of earth which it contains.* He added :

> Considering it as a peculiar earth, I thought it necessary to give it a name. I have called it *strontites,* from the place where it was found ; a mode of derivation, in my opinion, fully as proper as any quality it may possess, which is the present fashion.

In 1793, also, M. H. Klaproth compared the peculiarities of the two earths, and concluded from (i) the smaller sp. gr. of the strontian earth ; (ii) the difference in the crystals of the carbonates ; (iii) the difference in the crystalline form of the nitrates, acetates, and chlorides ; (iv) the difference in the water of crystallization ; and (v) the red colour imparted by the strontian earth to a flame, that strontian earth is *eine selbständige einfache Erde.* T. Bergmann believed that baryta is precipitated from soln. of its salt by potassium ferrocyanide, and this reagent was afterwards suggested as a means of distinguishing baryta from strontia ; but F. Meyer showed in 1786 that T. Bergmann's ferrocyanide must have been contaminated with sulphate, because the purified salt gives no precipitate with barium salts, and this was confirmed by M. H. Klaproth. R. Kirwan also investigated the properties of strontian earth. J. T. Lowitz found that strontian earth accompanied baryta in witherite.

The ideas of J. J. Becher, G. E. Stahl, and R. Boyle[4] on the relation of earthy substances to the metals were founded on the alchemical hypothesis that the metals were compounds of an earth with some igneous principle or phlogiston. About 1755, C. Neumann made some unsuccessful experiments to obtain a metal from quicklime. T. Bergmann suspected *terra ponderosa* to be a metallic calx from its high sp. gr.; and A. L. Lavoisier extended the hypothesis to all the metallic oxides:

> Il seroit possible à la rigueur que toutes les substances auxquelles nous donnons le nom de terre, ne fussent que des oxides métalliques, irréductibles par les moyens que nous employons.

M. Tondi and M. de Ruprecht stated that the earths can be reduced to metals by charcoal, but A. M. Savaresi, and M. H. Klaproth proved that the products were in reality mixtures containing phosphide of iron derived from the bone-ash and other materials used in the experiment. Consequently, the latter concluded: *la prétendue réduction des terres en métaux n'est qu'une pure illusion.*

H. Davy's decomposition of the fixed alkalies[5] led him to say:

> From analogy alone it is reasonable to expect that the alkaline earths are compounds of a similar nature to the fixed alkalies, peculiar highly combustible bases united to oxygen. I have tried some experiments on barytes and strontites; and they go far towards proving that this must be the case. When barytes and strontites, moistened with water, were acted upon by the power of the battery, there was a vivid action and a brilliant light at both points of communication, and an inflammation at the negative point.

H. Davy attempted to deoxidize the earths by heating them with potassium in glass tubes; he also modified the procedure employed in the deoxidation of the fixed alkalies, but was not very successful. While engaged on these experiments, H. Davy heard by letter from J. J. Berzelius that barytes and lime could be decomposed by negatively electrifying mercury in contact with them, whereby amalgams of the metals of these earths were obtained. Consequently, H. Davy repeated these experiments with barytes, strontites, and lime; and with perfect success. The resulting amalgams when thrown into water, disengaged hydrogen, mercury was set free, and an aq. soln. of the alkaline earth was obtained. H. Davy found the yield was improved by mixing mercuric oxide with the base. He then distilled the amalgams in sealed glass tubes filled with petroleum vapour, and found, as also did J. L. Gay Lussac and L. J. Thénard (1811), that it is very difficult to drive off the mercury. Although in some cases H. Davy obtained white metals, he never felt certain that a minute portion of mercury was not present. However, he claimed:

> The evidence for the composition of the alkaline earths is of the same kind as that for the composition of the common metallic oxides, and the principles of the decomposition are precisely similar. . . . On the same principles as I have named the bases of the fixed alkalies, potassium and sodium, I shall venture to denominate the metals of the alkaline earths, barium, strontium, and calcium.

T. J. Seebeck showed in March, 1808, that lime, baryta, magnesia, and alumina when electrolyzed in contact with mercury, furnished amalgams of the basic elements which behave with water like sodium amalgam; and when distilled in the vapour of petroleum furnished a metallic powder. About the same time, J. B. Trommsdorff verified these results; and J. F. A. Göttling obtained metal spherules by the electrolysis of barium carbonate, but calcium or magnesium carbonate did not yield the same result. Coherent masses of these different metals were obtained later—*vide infra.*

§ 2. The Occurrence of the Alkaline Earths

The metals of the alkaline earths do not occur free in nature. F. W. Clarke's estimate [1] of the relative abundance of these elements in the lithosphere or half-mile crust of the earth, is

	Calcium.	Strontium.	Barium.
Per cent.	3·47	0·02	0·08

The sea contains 0·05 per cent. of calcium ; this makes an average of 3·22 per cent. in the earth, air, and sea. Calcium is one of the most abundant of the elements, and it comes fifth in the list of elements arranged in the order of their relative abundance ; strontium is less abundant than barium, for it comes eighteenth on the list, while barium comes sixteenth on the list, and it is widely distributed though in small quantities. The average composition of the typical rocks shows the presence of

	Igneous rocks (95 per cent.).	Shales (4 per cent.).	Sandstones (0·75 per cent.).	Limestones (0·25 per cent.).	Weighted average.
Calcium oxide .	4·48	3·11	5·50	42·57	4·86
Strontium oxide .	0·04	—	—	—	0·04
Barium oxide .	0·10	0·05	0·05	—	0·09

N. Ljubavin has compared the relative distribution of calcium and magnesium in the earth's crust.

Calcium is an essential constituent of many rock-forming minerals—*e.g.* in the amphiboles, pyroxenes, and scapolite, as well as in epidote, garnet, and anorthite. The carbonate, $CaCO_3$, is widely distributed as *calcite* or *calcspar*, *aragonite*, *chalk*, *limestone*, *marble*, *coral*, etc. ; it occurs along with magnesium carbonate as *dolomite*, or, when crystallized, as *bitter-spar* ; and it occurs in isomorphous mixture with other carbonates as

Chalybite or *brown-spar*, $(Ca, Mg, Fe, Mn)CO_3$; *mangano-calcite*, $(Mn, Ca, Fe, Mg)CO_3$; *baryto-calcite* or *alstonite*, $(Ba, Ca)CO_3$; *calcio-strontianite*, $(Sr, Ca)CO_3$; *plumbo-calcite* or *tarnowitzite*, $(Ca, Pb)CO_3$; *gaylussite* or *natro-calcite*, $Na_2CO_3.CaCO_3.5H_2O$; *uranothallite*, $Ca_2U(CO_3)_4.10H_2O$; etc.

Calcium occurs in large quantities as sulphate, tungstate, and titanate :

Gypsum or *selenite*, $CaSO_4.2H_2O$; *anhydrite*, $CaSO_4$; *glauberite*, $Na_2SO_4.CaSO_4$; *syngenite* or *kaluszite*, $K_2SO_4.CaSO_4.H_2O$; *scheelite*, $CaWO_3$; *cuproscheelite*, $(Ca, Cu)WO_3$; *uranopilite*, $CaU_8S_2O_3$; *polyhalite*, $K_2SO_4.M_2SO_4.2CaSO_4.2H_2O$; *krugite*, $K_2SO_4.MgSO_4.4CaSO_4.2H_2O$; *wattevillite*, $(Na ,K)_2(Ca, Mg)(SO_4)_2.2H_2O$; *ettringite*, $Al_2Ca_6(OH)_{12}(SO_4)_3.24H_2O$; *perowskite*, $CaTiO_3$; etc.

There is a hydrated nitrate, *nitrocalcite*, $Ca(NO_3)_2O.nH_2O$; and several halides :

Chlorocalcite, $CaCl_2$; *fluorspar*, CaF_2 ; *gearksutite*, $Al(F, OH)_3.CaF_2.H_2O$; *pachnolite* and *thomsenolite*, $AlF_3.NaF.CaF_2.H_2O$; *prosopite*, $2Al(F, OH)_3.Ca(F, OH)_2$; *nocerite*, $(Mg, Ca)_3OF_4$; *tachydrite*, $CaCl_2.MgCl_2.12H_2O$; *yttrocerite*, $(Y, Er, Ce)F_3.5CaF_2.H_2O$; etc.

Calcium phosphate occurs combined with calcium chloride or fluoride as the well-known minerals *apatite*, $Ca_5(PO_4)_3(Cl, F)$, and *osteolite*, *phosphorite*, *staffelite*, *coprolite*, etc. In addition to the phosphates there are arsenates, antimoniates, niobates, tantalates, and vanadates :

Arseniopleïte, $(Mn, Fe)_2(Mn, Ca, Pb, Mg)_3.(MnOH)_6(AsO_4)_6$; *arsenosiderite*, $Fe_4Ca_3(OH)_9(AsO_4)_3$; *atopite*, $(Ca, Na_2, Fe, Mn)_2Sb_2O_7$; *berzeliïte*, $(Ca, Mg, Mn, Na_2)_3(AsO_4)_2$; *boryckite*, $Fe_4(OH)_6.Ca(PO_4)_2.3H_2O$; *brandtite*, $MnCa_2(AsO_4)_2.2H_2O$; *brushite*, $CaHPO_4.2H_2O$; *calcio-ferrite*, $(Fe, Al)_3(OH)_3(Ca, Mg)_3(PO_4)_4.8H_2O$; *caryinite*, $(Mn, Ca, Pb, Mg)_3(AsO_4)_2$; *cirrolite*, $Al_2Ca_3(OH)_3(PO_4)_3$; *collophane*, $Ca_3(PO_4)_2.H_2O$; *coppite*, $Ca_3(CaF)(Na, K_4).CeO.(Cb_2O_7)_3$; *dahllite*, $Ca_7(PO_4)_4CO_3.\frac{1}{2}H_2O$; *fairfieldite*, $(Ca, Mn, Fe)_3(PO_4)_2.8H_2O$; *fillowite*, $(Mn, Fe, Na_2, Ca)_3(PO_4)_2.\frac{3}{4}H_2O$; *goyazite*, $Al_{10}Ca_3P_{23}.9H_2O$; *haidingerite*, $CaHAsO_4.\frac{1}{2}H_2O$; *herderite*, $Ca\{Be(OH, Fe)\}PO_4$; *isoclase*, $Ca(CaOH)PO_4.2H_2O$; *calc-uranite* or *autunite*, $Ca(UO_2)_2(PO_4)_2.8H_2O$; *konichalcite*, $(Cu, Ca)(CuOH)(As, P, V)O_4.\frac{1}{4}H_2O$; *martinite*, $Ca_5H_2(PO_4)_4.\frac{1}{2}H_2O$; *mazapilite*, $Fe_4(OH)_6Ca_3(AsO_4)_4.3H_2O$; *microlite*, Ca_2Ta_2O ; *ornithite*, $Ca_3(PO_4)_2.2H_2O$; *pharmacolite*, $CaHAsO_4.2H_2O$; *picropharmacolite*, $(Ca, Mg)_3(AsO_4)_2.6H_2O$; *polysphärite*, $(Ca, Pb)_5(PO_4)_3Cl$; *romeïte*, $CaSb_2O_4$; *roselite*, $(Ca, Co, Mg)_3(AsO_4)_2.2H_2O$; *svanbergite*, $Na_3(CaOH)(AlO)_6(PO_4)_2(SO_4)_2.3H_2O$; *tavistockite*, $Al_2Ca_3(OH)_6(PO_4)_2$; *uranospinite*, $Ca(UO_2)_2(AsO_4)_2.8H_2O$; *volborthite*, $(Cu, Ca)(CuOH)VO_4$.

Calcium borate also occurs in nature associated with many other metallic borates :

Boracite or *bechilite*, $CaBr_2O_7.4H_2O$; *boronatrocalcite* or *ulexite*, $NaCaB_5O_9.6H_2O$; *colemanite*, $Ca_2B_6O_{11}.5H_2O$; *franklandite*, $Na_2CaB_6O_{11}.7H_2O$; *hydroboracite*, $MgCaB_6O_{11}.6H_2O$; *pandermite*, $Ca_2B_6O_{11}.3H_2O$.

Calcium silicate is an almost invariable constituent of all the silicates, as well as of calcium silicates like wollastonite, $CaSiO_3$; apophyllite, $(Ca,K_2)H_2Si_2O_6$; etc. In addition, calcium occurs as an accessory constituent in numerous minerals.

According to A. Cornu,[2] spectroscopic observations indicate the presence of calcium in the sun, and W. H. Julius, R. K. Young, and M. N. Saha likewise found calcium in some of the fixed stars. The same element was found by J. L. Smith in meteorites—*e.g.* as calcium sulphide.

Calcium salts occur in spring waters [3]—usually as calcium sulphate, or as calcium hydrocarbonate—and these salts as well as calcium phosphate and fluoride occur in sea-water. According to L. Dieulafait, the waters of the Mediterranean Sea contain 1·4 grms. of calcium sulphate per litre. The behaviour of the calcium salts during the evaporation of sea-water has been studied by J. H. van't Hoff.

The experiments of E. V. McCollum, N. Simmonds, and H. T. Parsons show that calcium is one of the limiting factors in a large proportion of our staple foods, and the amount of calcium required for normal human nutrition is estimated by H. C. Sherman to average about 0·45 grm. per 70 kgrms. of body weight per day. Calcium is invariably found amongst the mineral constituents of animals and plants. The calcium salts accumulate more in the leaves than in the roots of plants, and crystals of the oxalate, *whewellite*, $CaC_2O_4.H_2O$, are often present in the tissue. The ash of the rosaceæ are stated by F. J. Malaguti and J. Durocher to be particularly calcareous. Calcium occurs as phosphate along with a little fluoride in bones, teeth, etc. Eggshells and mollusc shells contain a large proportion of calcium carbonate. According to W. Reisinger, each of the following materials contains the indicated number of grams of calcium oxide per kgrm.: Beef, 0·31 ; white bread, 0·28; potatoes, 0·39; white of egg, 0·18; yolk of egg, 1·87; peas, 0·65; fruit, 0·34; beer, 0·08; cow's milk, 2·80; leaf vegetables, 2·50; and root vegetables, 2·04.

The most important strontium minerals are the sulphate, *cœlestine*, $SrSO_4$, and the carbonate, *strontianite*, $SrCO_3$. More or less strontium also occurs associated with other minerals of the alkaline earths. For example, *bromlite* or *baryto-calcite* was stated by F. J. W. Johnston[4] to contain up to 6·6 per cent. of strontium carbonate in addition to the calcium and barium carbonates; and A. Delesse found 1·10 per cent. The so-called *calcio-strontianite* or *emmonite* is an isomorphous mixture of calcium and strontium carbonates. G. R. Credner and L. Grandeau found almost all the varieties of aragonite which they analyzed to be strontianiferous, and E. Riegel found a specimen from Thurnberg to contain 2·2 per cent. of strontium carbonate, and S. de Luca found 7 per cent. in mossottite. G. Kirchhoff and R. Bunsen found strontium spectroscopically in numerous varieties of limestone and chalk, gypsum, heulandite, stilbite, etc. T. Engelbach reported its presence in calcites, marbles, dolomites, and limestones; J. S. Stas found strontium in marble. W. N. Hartley and H. Ramage also found traces of strontium in many iron ores and minerals. The mineral *baryto-cœlestine* is an isomorphous mixture of strontium and barium sulphates. Heavy spar was also found by L. Grandeau to contain strontium and calcium. Strontium aluminium pyrophosphate, $2SrO.3Al_2O_3.2P_2O_5.7H_2O$, is represented by the mineral *hamlinite* or *bowmanite* with between 18 and 20 per cent. of strontia. *Brewsterite* has been reported with up to 9 per cent. of strontium silicate. Indeed, strontium is very common as a minor constituent of minerals and rocks; and W. F. Hillebrand has emphasized the very wide distribution of strontium in natural silicates. J. N. Lockyer observed what he believed to be strontium lines in the solar spectrum; M. N. Saha has also discussed the subject. L. Collot studied the distribution of strontium in sedimentary rocks. The occurrence of cœlestine in limestones has been examined by W. H. Sherzer, E. H. Kraus and W. F. Hunt, A. Koch, H. Bauerman and C. le Neve Foster, M. Lachat, W. H. Phalen, etc.

Strontium was found by J. J. Berzelius in many mineral waters—*e.g.* Carlsbad, Eger, etc.; T. J. and W. Herapath found it in a spring water near Bristol; A. and F. Dupré, in certain chalky waters like that of the Thames basin; F. A. Reuss, in the waters at Bilin; L. Gmelin, in the waters at Enis; K. W. G. Kastner, at Marienfels; R. H. Davis, at Harrogate; J. Steinmann, at Marienbad; R. Brandes, at Pyrmont; O. Henry, at Selters, Vie-sur-Serre, and Galmier; L. Dieulafait, at Schinznach, and Contrexeville; F. M. Tripier, in Algiers; L. F. Bley, at Ernabrunn; J. N. Planiava, at Luhatschiwitz; S. Baup, at Lavey; J. Girardin, St. Allyre; H. Braconnot, at Bulgneville; etc. According to G. Kirchhoff and R. Bunsen, a litre of water from Dürkheim contains 19·5 mgrms. of strontium sulphate, and 8·1 mgrms. of strontium chloride; that from Theodorshall, 2·86 mgrms. of strontium chloride; and that from Ungemach (Baden-Baden), 2·3 mgrms. of strontium chloride. Deposits from mine waters containing barium and strontium sulphates have been studied by G. Lattermann, and J. T. Dunn. A. Naupert and W. Wense found a small amount of strontium in carnallite and kaïnite; L. Grandeau, in the salts from Meurthe, the salt of St. Nicolas-Varaugéville, glauberite, etc. The presence of strontium in sea-water has been reported by G. Forchhammer, G. Kirchhoff and R. Bunsen, L. Dieulafait, etc.; in mollusc shells by L. Dieulafait; in the boiler scale of transatlantic liners, and in the ash of seaweeds—*fucus vesiculosus*—by G. Forchhammer.

The chief mineral form of barium is *heavy spar*, *barite*, *barytes*, or barium sulphate, $BaSO_4$, in which the barium may be more or less replaced by strontium or calcium, forming respectively *cœlestobarite*, or *baryto-cœlestine*, $(Ba, Sr)SO_4$, and *calceobarite* $(Ba,Ca)SO_4$; and with all three bases *calstronbarite*, $(Ca, Sr, Ba)SO_4$. The mineral *witherite*, or barium carbonate, $BaCO_3$, is also an important source of barium. When the barium is partly replaced by calcium, the mineral is called *alstonite*, *bromlite*, *neotype*, or *barytocalcite*, $(Ba, Ca)CO_3$. The so-called *baryta saltpetre* or barium nitrate, $Ba(NO_3)_2$, occurs as a mineral; there is also a phosphate in *barytapatite*, $3Ba_3(PO_4)_2.BaCl_2$; *uranocircite* or *bariumuranite*, $Ba(UO_2)_2(PO)_2\ 8H_2O$; and a vanadate, *volborthite*, $\{(Cu, Ca, Ba)OH\}_3VO_4.6H_2O$. Small quantities occur in *psilomelane*, $(Mn, Ba)O.MnO_2$, as barium manganite, and in many other manganese ores. The same element occurs as an essential constituent in many silicates, for example, *brewsterite*, $(Sr, Ba)H_4Al_2Si_6O_{18}.3H_2O$; *harmotome*, $(K_2,Ba)H_2Al_2Si_5O_{15}.4H_2O$; *hyalophane*, or *baryta-felspar*, $(K_2, Ba)_2Al_2Si_8O_{24}$; *edingtonite*, $H_6BaAl_2Si_3O_{13}$; etc. Small quantities were shown by R. Delkeskamp,[5] and W. F. Hillebrand to occur in an extraordinary number of rocks and minerals—*e.g.* felspar, phillipsite, chabasite, mica, granite, gneiss, clays, marls, limestones, etc. G. C. Wittstein discussed the occurrence of barium in silicate rocks. H. Lutterkorth also found barium in many sandstones. F. Clowes, W. Mackie, C. B. Wedd, J. T. Dunn, and C. C. Moore observed its action as a cement in sandstones, and A. Koch in bituminous limestones. W. Knop found barium in the Nile mud; G. H. Failyer, in soils, and H. Schwarz, in the dust from blast furnaces. L. Collot has examined the distribution of barium in sedimentary rocks. The solar spectrum lines led G. Rayet to infer the presence of barium in the sun. M. N. Saha has also discussed the occurrence of barium in the sun and stars. Traces of barium salts have been found by R. Brandes, and R. Fresenius in the water of Pyrmont; by C. Löwig, in the waters of Kreuznach; by H. Braconnot, in the waters of Luxeuil; by J. N. Planiava, in the waters of Luhatschivitz; and by T. S. Hunt, in other mineral waters. T. W. Richards found 41 parts of barium chloride per 100,000 in the spring waters of Boston Spa; J. White found nearly the same quantity in the artesian water of Ilkeston; R. H. Davis in waters at Harrogate; and T. E. Thorpe, 6·6 grains of barium chloride per gallon in the old sulphur well at Harrogate. P. Carles has studied the equilibrium between barium hydrocarbonate and the soluble sulphates in the presence of carbon dioxide under press. in the waters of Néris. A small proportion of barium was found by G. Forchhammer in sea-water, and it accordingly finds its way into sea-plants, and in the shells and skeletons of sea-organisms. C. W. Scheele found this base in the ashes of trees; G. E. Eckard, and R. Homberger have verified this, but U. Suzuki did not find any in phanerogams. P. P. Bedson, T. Richardson, and F. Clowes have observed the presence of notable amounts of barium in colliery waters, and in deposits therefrom. The pipes carrying water from the mines were often choked by deposits in which barium is rarely absent, and often the predominant constituent. Barytic sinters formed by the deposition of barium sulphate from the brine spring at Doughty Springs (Colorado) have been examined by W. P. Headden; and at Lautenthal, by G. Lattermann.

§ 3. The Preparation of the Metals of the Alkaline Earths

The three general methods for the preparation of calcium are: (1) the reduction of calcium compounds by the metals of the alkalies; (2) the electrolysis of conc. aq. soln. with a mercury cathode; and (3) the electrolysis of fused calcium halides. The unsatisfactory results obtained by H. Davy's and analogous processes for preparing calcium in all but minute quantities, led R. Bunsen [1] to investigate the electrolysis of a boiling soln. of calcium chloride acidified with hydrochloric acid, by a process analogous to that which he had found successful with magnesium. He obtained the metal, but the yield was not satisfactory because the metal, liberated at the high temp.—calcium chloride fuses at 780°—readily ignited, and made the fused mass basic. Calcium alone fuses at about 800°, and ignites in air not far above this temp. There is, therefore, but a narrow range of temp. for the safe working of electrolytic processes. The molten metal also readily forms a metal fog. If the calcium chloride be contaminated with small amounts of salts of sodium, magnesium, or aluminium, these metals are deposited along with the calcium, and at some stage of the process, lower the m.p. of the calcium making it impossible to maintain the cell in operation. It is, moreover, difficult to make the anhydrous chloride from the hydrated salt because, during the expulsion of the water, hydrolysis occurs, and what is regarded as a hydroxychloride, HO.CaCl, is formed. The calcium chloride is dehydrated by evaporating the aq. soln. with an excess of hydrochloric acid, and a few per cent. of ammonium chloride. The white porous cake is pulverized, mixed with more ammonium chloride and heated out of contact with moist air for several hours at 500°–600°. With the incompletely dehydrated electrolyte, hydrogen is evolved at the cathode, and oxygen is liberated at the anode whereby the latter is disintegrated; the liberated metal is slowly attacked by the fused salt, hydrogen is evolved, and a sparingly soluble oxychloride is formed. This thickens the bath, the conductivity decreases, and the yield of metal falls. R. Bunsen prepared mixtures of the alkaline earth chlorides with a lower m.p., and using high current densities, succeeded in preparing impure finely divided calcium. P. H. Brace tried a mixture of calcium chloride and fluoride, of calcium and potassium chloride, and calcium chloride alone as electrolytes, and concluded that if the last named be properly dehydrated, it forms a most suitable electrolyte. There is a difficulty in completely drying the amalgam without some oxidation; it is exceedingly difficult to remove all the mercury by distillation of the amalgam; and at best the product is a finely divided metal of rather indefinite composition which presents so much surface to the surrounding medium as to offer difficulties in working up into a satisfactory mass.

A. Matthiessen obtained a coherent mass of the metal by the electrolysis of a molten mixture of calcium and strontium chlorides with a small amount of ammonium chloride, contained in a porcelain crucible and with a carbon rod as anode and a thin iron wire as cathode. A high current density was employed. B. von Lengyel used a graphite cell with a porous cathodic cell. A. Feldmann electrolyzed a haloid salt or a mixture of the haloid salt with an alkali halide, and a metal oxide. L. P. Hulin obtained an alloy of the metal by using a heavy metal or a mixture of carbon with a heavy metal oxide as cathode. The economical production of large quantities of calcium was an unsolved problem until it was recognized that the temp. of the fused salt must be kept above the m.p. of the electrolyte and below that of the metal. O. Ruff and W. Plato kept down the temp. of the bath by using a mixture of calcium fluoride and chloride, melting at about 655° or 660°. The objection to R. Bunsen and A. Matthiessen's process is that external heat is required in addition to that afforded by the current; as a result, it is very difficult to regulate the temp. so that a crust of chilled chloride will always cover the bath. W. Borchers and L. Stockem avoided this difficulty by collecting the metal at the bottom of the bath. The metal did not combine with the chloride to such an extent as to invalidate the method. The bottom of the furnace was, however, cooled by means of a water-jacket. The apparatus finally employed was rather complicated. K. Arndt used as electrolyte a mixture of calcium fluoride and chloride, and P. Wöhler used a mixture of calcium chloride and fluoride (1 : 0·17) with a m.p. of 660°; the temp. bath was 665°–680°; a carbon rod was used as an anode and an iron rod as cathode. The current density was 50 to 250 amps. per sq. dm. The current efficiency was 82 per cent. C. Bürgel discussed the electrolytic preparation of calcium, and B. von Lengyel prepared calcium of 99·2 per cent. purity by electrolysis in a cell with a porous diaphragm.

W. Rathenau obtained fairly large quantities of calcium by the electrolysis of calcium chloride very little above its m.p. The iron cathode just touched the surface of the bath, and the calcium solidified on the rod. The rod was gradually raised, and as a result, a stick of the metal with a little adherent chloride was produced. The end of the calcium rod, dipped in the fused chloride, then forms the lower end of the cathode. J. H. Goodwin recommended a similar process with a carbon crucible as anode. F. C. Frary, H. R. Bicknell, and C. A. Tronson used a graphite crucible which was water cooled at the bottom as anode; a water-cooled iron cathode; and fused calcium chloride as electrolyte. The heat due to the current sufficed to keep the salt melted in the upper part of the cell. The cathode rod was regularly and continuously raised. The current density was 9·3 amps. per sq. dm. The e.m.f. averaged 25 volts, and the current efficiency usually exceeded 80 per cent. Consequently, the energy efficiency is $80 \times 3{\cdot}24/25 = 10$ per cent., where 3·24 volts represents the decomposition voltage of molten calcium chloride at 800°. Consequently, the production of a kilogram of calcium required 42 kilowatt hours. W. Moldenhauer and J. Andersen made calcium practically free from potassium by the electrolysis of a fused mixture of calcium chloride with 15 per cent. of potassium chloride, by W. Rathenau's process, and a current density of 60–110 amps. per sq. dm. The current efficiency was 75–90 per cent. An electrolyte of calcium chloride with 60 per cent. of potassium chloride did not give a coherent stick of calcium—probably due to the formation of a calcium potassium alloy. A. R. Johnson, S. O. Cowper-Coles, and P. H. Brace have also described electrolytic processes for making calcium. G. O. Seward and F. von Kügelgen have patented the cell illustrated in Fig. 1, for the production of calcium by the electrolysis of calcium chloride.

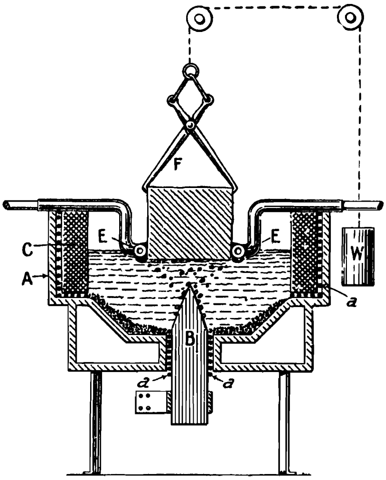

Fig. 1.—G. O. Seward and F. von Kügelgen's Electrolytic Cell for Calcium.

The cell consists of a circular iron box, *A*, through the bottom of which projects a conical iron cathode, *B*, insulated from the box at *aa*. The carbon *C*, insulated from the box, serves as anode. A water-cooled collecting ring, *E*, separates the metal which rises to the surface of the molten chloride. The metal accumulates till the ring is full. The top layer is cooled solid by the air, while the bottom is soft or melted. The solid part is fastened to a hook, *F*, which is gradually raised. The heat due to the current keeps the salt molten. The metal is protected from oxidation by the layer of fused salt.

The reduction of calcium iodide or phosphide at an elevated temp. was proposed by R. Hare as a means of preparing calcium; H. Caron and E. Sonstadt proposed reducing calcium chloride by sodium in the presence of zinc; C. Winkler, calcium oxide or carbonate by magnesium; and H. Moissan, calcium oxide or carbonate by carbon. The last named, however, reported that all these suggestions offered practical difficulties, *plus ou moins graves*. E. Stansfield did not succeed in getting Goldschmidt's thermite process to work with a mixture of calcium oxide and aluminium, using a mixture of calcium peroxide and aluminium for starting the reaction. Lies-Bodart and M. Jobin reduced calcium iodide with sodium, but the product obtained was really an alloy of calcium and sodium. H. Moissan modified the process, and obtained white hexagonal crystals of calcium of 98·9 to 99·2 per cent. purity.

A mixture of 600 grms. of anhydrous calcium iodide, with 240 grms. of small fragments of sodium, was placed in an iron crucible about a litre capacity. The crucible was closed and kept for an hour at a dull red heat. The contents were agitated from time to time. The calcium dissolved in the excess of heated sodium, crystallized out on cooling, and the excess of sodium was removed by treatment with absolute alcohol.

T. Curtius and J. Rissom obtained calcium by heating calcium azide, CaN_6, for a long time to 120° or 130°. J. Malovich heated a mixture of calcium oxide or a calcium salt with sulphur and the sulphate or sulphite of another metal, between the m.p. and b.p. of the calcium. There is first formed a polysulphide of the added metal which by its decomposition reduces the calcium oxide. H. Moissan and G. Chavanne found commercial calcium with 99·3 to 99·6 per cent. of calcium, and the impurities were calcium chloride, silicon, aluminium, and traces of iron and sodium. K. Arndt found 0·2 per cent. of silicon and 0·3 per cent. of aluminium, and some calcium oxide and chloride.

Strontium, as previously indicated, was obtained by H. Davy. R. Bunsen, and A. Matthiessen also prepared pieces weighing less than half a gram by the electrolysis of a fused mixture of strontium and ammonium chlorides with a thin iron wire as cathode; and W. Borchers and L. Stockem, R. Hare, B. von Lengyel, C. Winkler, J. Malovich, T. Curtius and J. Rissom, applied the process employed for calcium to this element. B. L. Glascock tried the method employed by J. H. Goodwin for calcium, but found it impossible to prevent the strontium either burning, or combining with the electrolyte. He obtained 76 grms. of the metal by electrolyzing fused strontium chloride in an iron mortar 15 cms. diam. at the top, 15 cms. high, and a litre capacity. A carbon anode 8 cms. × 8 cms. was used; and the iron vessel itself served as cathode. A current of 125 amps. and 40 volts was employed for 7 hrs. The current efficiency was 5·3 per cent. If the current passed longer than 8 hrs., the current efficiency was diminished. The metal was separated from the cold mixture in the iron vessel, by crushing the contents on an iron plate, and sieving out the metal. M. Trautz electrolyzed a mixture of 2 mols of strontium chloride and 1 mol of potassium chloride contained in a tapering crucible at a bright red heat. A pointed iron cathode was cooled externally by water, and a thick carbon cylinder was used as anode. With 30 amps. and 10 volts, the current efficiency was 29–48 per cent., 90 grms. of strontium containing 97·3 per cent. strontium, 0·3 per cent. chlorine, and 0·84 per cent. potassium were prepared. Only small masses of barium could be obtained by this process. B. Neumann and E. Bergve obtained strontium in sticks by the general method employed for calcium, by the electrolysis of a fused mixture of strontium chloride with 15 per cent. of potassium chloride which melts at 628°. A current density of 20–50 amps. per sq. cm. cathode was used, and a current efficiency of 80 per cent. was obtained.

R. Böttger,[2] and B. Franz prepared *strontium amalgam* by heating a sat. soln. of strontium chloride to 90° with a 20 per cent. sodium amalgam, but it is more conveniently prepared by A. Guntz and G. Röderer's process, namely, by electrolyzing a soln. of strontium chloride with a mercury cathode, washing the product with water, pressing between folds of filter paper, and heating to 150°. B. Franz placed the amalgam in an iron crucible, and heated it to redness in a stream of hydrogen, but the last traces of mercury are retained by the metal with great tenacity. A. Guntz and G. Röderer first heated the amalgam with about 8 per cent. of strontium in vacuo to 700° and then to 1000° in hydrogen. The mercury is thus completely removed and a mass of *strontium hydride* is formed. This is then heated in vacuo in small quantities in an iron tube contained in a porcelain tube. The hydride decomposes, and the strontium volatilizes. The vapour is condensed on a hollow polished steel tube cooled by a stream of water. The metal thus obtained is 98·6 to 99·0 per cent. purity, and it may be obtained 99·4 per cent. purity by redistillation in vacuo. A. Guntz and M. Galliot heated a mixture of strontium oxide with the calculated quantity of aluminium for four hours at 1000° in a steel tube placed inside an evacuated porcelain tube, and they obtained silver-white crystals of 99·4 per cent. strontium as a crust on the walls of the steel tube. The yield was 75 per cent.

The isolation of barium or the preparation of barium amalgam was effected by H. Davy,[3] J. J. Berzelius, R. Hare, A. Matthiessen, R. Bunsen, A. Feldmann, L. P. Hulin, T. Curtius and J. Rissom, J. Malovich, S. Kern, and C. Winkler, as indicated in connection with calcium and strontium. The electrolysis of the molten barium chloride furnished A. Matthiessen, and R. Hare with some globules of barium; C. Limb used a fused mixture of barium and sodium chlorides as electrolyte. R. Graetzel used the chloride and fluoride. A. Guntz said that some chlorine is evolved in the early stages of the electrolysis, and that barium subchloride is the main product. These results were not very satisfactory, although it is quite easy to make solid crystalline amalgams, containing over 5 per cent. of barium, by the electrolysis of a sat. soln. of barium chloride with a mercury cathode. R. Bunsen, W. Crookes, J. Donath, R. Böttger, and E. Frey prepared the amalgam by the electrolysis of a sat. soln. of the chloride, and subsequently obtained the impure metal by distilling off the mercury. B. Neumann and E. Bergve obtained barium by the electrolysis of a fused mixture of barium and potassium chlorides as indicated in connection with strontium.

S. Kern's process in which barium iodide or chloride is reduced with sodium, and the metal extracted with mercury was found by A. Guntz to give what he regarded as a subhaloid complex, NaI.BaI, or NaCl.BaCl; and C. Winkler's process of reduction of barium oxide with magnesium was found by A. Guntz to furnish what he regarded as a suboxide. E. D. Clarke reported the formation of barium by heating the oxide or nitrate in a cavity in a piece of charcoal or slate before the oxyhydrogen blowpipe, but this is considered to be incorrect. C. Matignon observed that barium is readily obtained by heating barium oxide with silicon, in vacuo, in a steel tube at 1200°. The metal distils and condenses in the cooler part of the tube: $3BaO+Si=BaSiO_3+2Ba-37$ cals. The silicon was also replaced by ferrosilicon (95 per cent. silicon). The metal prepared by the distillation of mercury from the amalgam is invariably impure, because of the difficulty in drying the amalgam; in removing all the mercury by distillation; and in working up the powder to a compact mass. E. Stansfield obtained an impure alloy of zinc with about 12 per cent. of barium by H. Caron's process of reducing barium chloride with zinc and sodium; and he also heated barium oxide with aluminium by Goldschmidt's thermite process, using a mixture of barium peroxide and aluminium for starting the reaction, and working under reduced press. The product furnished an alloy of aluminium with up to 60 per cent. of barium. The substitution of magnesium for aluminium gave too violent a reaction. A. Guntz obtained barium by converting the amalgam into hydride, and, subsequently proceeding as indicated in the corresponding process for strontium.

§ 4. The Properties of Calcium, Strontium, and Barium

The metals calcium, strontium, and barium obtained by the earlier workers —A. Matthiessen,[1] R. Bunsen, Lies-Bodart and M. Jobin, B. von Lengyel, J. Donath —were tinted yellow. E. Frey first prepared calcium of a white **colour** which he likened to that of aluminium. H. Moissan's calcium was described as lustrous almost silvery white. According to H. Moissan, the metals are yellow when they contain the nitride, *e.g.* Ca_3N_2; and, according to O. Ruff and W. Plato, the metal is yellow when it is contaminated with silicide. A. Guntz and G. Röderer, and W. Borchers and L. Stockem obtained silvery white strontium. H. Davy described barium as silvery white; W. Crookes as white; and A. Guntz, white like tin or silver.

L. Doermer noticed that a freshly fractured surface of electrolytic calcium showed small aggregates of the appearance of ice crystals embedded in the main bulk of metal. These aggregates are more readily acted on by moisture and less affected by hydrochloric acid in absolute alcohol than the ground mass; they are not observable in specimens of the metal which have been melted and allowed to resolidify. They are probably due to impurities. According to J. H. Goodwin, the fractured surface of calcium is more brilliant than steel, and it has a greyish-white colour. The metallic lustre of the metal is retained under petroleum. H. Moissan obtained hexagonal growths in the form of platelike **crystals** or distorted rhombohedra, as well as dendritic six-rayed stars resembling snow crystals, making it appear as if the crystals belong to the trigonal or hexagonal system. Analogies between the calcium and magnesium families favour the latter. A. W. Hull found that the **X-radiograms** of calcium show that the crystals are cubic with a face-centred cubic lattice, and that there are 4 atoms per elementary cube the side of which is 5·56 A., and the smallest distance apart of the atoms, 3·93 A. W. L. Bragg gave 1·70, 1·95, and 2·10 Angström units for the at. radius of the at. spheres respectively of calcium, strontium and barium.

The **specific gravity** of calcium was stated by Lies-Bodart and M. Jobin not to exceed 1·55; R. Bunsen and A. Matthiessen found 1·5778; H. Caron, less than 1·6; J. H. Goodwin, 1·5446 (28·1°); B. von Lengyel, 1·5540 (18°); W. Muthmann and co-workers, 1·4153; H. Moissan and G. Chavanne, 1·548; P. W. Bridgman, 1·5563 at 21°; W. Biltz and G. Hohorst, 1·542 at 22°/4°; P. H. Brace, 1·46 at 22°; O. Ruff and W. Plato, 1·59; and K. Arndt found for the distilled metal, 1·59. The best representative value for calcium may be taken as 1·53 (20°); and the **atomic volume,** 25·0. For strontium, R. Bunsen and A. Matthiessen gave a sp. gr. of 2·504 to 2·58; M. Trautz, 2·50; and B. Franz gave 2·4. H. Davy said barium is heavier than sulphuric acid; E. D. Clarke gave 4 for the sp. gr., and A. Guntz 3·78 for purified silvery crystalline barium. C. T. Heycock and F. H. Neville attempted to determine the **molecular weight** of calcium from its effect on the f.p. of tin. M. N. Saha calculated the **atomic radii** of barium, strontium, and calcium from the ionization potentials.

Calcium is a soft metal which like sodium can be cut with a knife. The **hardness** of calcium is stated by Lies-Bodart and M. Jobin to be greater than that of tin, and less than that of lead; and it can be cut with a knife. R. Bunsen and A. Matthiessen found their sample was scratched by strontium, but was harder than lithium or lead; O. Ruff and W. Plato found the hardness of their sample to be 2·2 to 2·5 on

Mohs' scale, and was therefore softer than gold and bismuth, and harder than lead. According to J. H. Goodwin, calcium is harder than sodium, lead, or tin, almost as hard as aluminium, and softer than cadmium or magnesium. He found that calcium is not hardened by heating it red hot and plunging it into water; at 300°–400° it is as soft as lead; and when hot it can be filed and polished without losing its lustre but not when cold. R. Bunsen and A. Matthiessen stated that strontium is harder than lead or calcium, while W. Borchers and L. Stockem said it is as soft as lead; and B. L. Glascock that it is harder than sodium and softer than calcium. A. Guntz found that barium is a little harder than lead, and if a little mercury is present the barium is brittle. P. H. Brace found the Brinell hardness to be 42·5 with a load of 500 kgrms., and the Shore hardness 19–20. M. von Wogau found the velocity of **diffusion** of calcium in mercury to be k=0·45 sq. cm. per day at 10·2°; for strontium, k=0·47 sq. cm. per day at 9·4°; and for barium, 0·52 sq. cm. per day at 7·8°.

E. Frey found calcium to be brittle, and its **malleability** and **ductility** small, while Lies-Bodart and M. Jobin found it could be hammered into plates; and H. Moissan and G. Chavanne drew it out into wires 0·5 mm. diameter. B. Franz also found that strontium could be hammered to thin plates, and E. Frey that it could be rolled or drawn into wires. A. Guntz reported that barium is malleable like lead. J. H. Goodwin found the **tensile strength** of calcium to be 8710 lbs. per sq. in., or 612 kgrms. per sq. cm. T. W. Richards found the average **compressibility** of calcium at 20° to be $5·7\times10^{-6}$ between 100 and 500 megabars per sq. cm. According to J. H. Goodwin, if some of the red-hot molten metal be collected on a wire, and struck smartly on the table, it will fly in all directions with a hissing sound, and burn violently with a blinding light. Similar energetic action takes place when the red-hot metal comes in contact with asbestos or other reducible substance. L. Doermer stated that the explosions which occur when electrolytic calcium either in the form of powder or shavings is struck on an anvil seem to be due to the presence of iron oxide. Calcium powder when heated evolves hydrogen which is reabsorbed when the temp. of the metal is lowered. O. Ohmann observed similar explosions with sodium, potassium, lithium, and phosphorus; and small ones with aluminium and magnesium; and he says it cannot be due to rust because similar results are obtained if granite or quartz be used in place of iron. The sparking which occurs when calcium is detonated is attributed to the evaporation of the metal, and subsequent chemical action. When the detonation is conducted in an atm. of oxygen, the light evolved is more intense than air.

P. W. Bridgman found the **coefficient of cubical expansion** of calcium from 0° to 21° to be 0·000717. According to R. Bunsen and A. Matthiessen, calcium melts at a red heat. H. Moissan found commercial calcium to soften between 790° and 795°, and to melt at 810°; O. Ruff and W. Plato give 780° for the **melting point** of calcium; K. Arndt gives 800°. A. Guntz and G. Röderer give 800° for the m.p. of strontium; and A. Guntz gives 850° as the m.p. of barium. W. Guertler and M. Pirani give for the best representative values: calcium, 809°; and barium, 850°, with strontium an intermediate value. H. Caron reported that the **volatility** of calcium is not marked at a red-heat, but when zinc is distilled from a zinc-calcium alloy, some calcium volatilizes. K. Arndt found calcium volatilizes in vacuo even below its m.p.; G. Bartha observed that calcium volatilizes in vacuo at 720°; and H. Moissan sublimed the metal. N. B. Pilling calculated the **vapour pressure** of calcium from the rate of evaporation in vacuo, and found:

	300°	400°	500°	600°	700°	800°	900°	1000°
p mm. .	$9·6\times10^{-8}$	$4·2\times10^{-6}$	$3·7\times10^{-4}$	$1·2\times10^{-2}$	0·19	1·8	10·6	47·2

and at the **boiling point**, 1240°, 760 mm. The vap. press. at the m.p. was 2·0 mm. He represented the vap. press., p, at T° K., by $\log p=-10170T^{-1}+9·73$ mm. for the solid, and $\log p=-9670T^{-1}+9·27$ for the liquid. A. Guntz and G. Röderer found strontium evaporates considerably at 950°; and A. Guntz that barium volatilizes at 950°, rapidly at 1150°, and it can readily be boiled in vacuo. E. Tiede and E. Birnbräuer noted that in a vacuum furnace calcium volatilizes from a carbon boat at a red heat, and the vapour is rapidly oxidized in air, but if passed into dry petroleum, by a current of carbon dioxide, spherulitic aggregates are formed.

The **specific heat** of calcium between —180° and +20° was given by P. Nordmeyer and A. L. Bernoulli as 0·1574, and for barium, 0·0681; while A. Bernini gave 0·145 for the sp. ht. of calcium between 0° and 20°; 0·1453 between 0° and 78°; 0·149 between 0° and 100°; and 0·152 between 0° and 157°. At the temp. of liquid air, J. Dewar found the sp. ht. of calcium to be 0·0714; of impure strontium, 0·0714; and of impure barium, 0·0350; the corresponding at. ht. for calcium is 2·86; for strontium, 4·80; and for barium, 4·80; R. J. Brunner gave for calcium at $T°$ K.:

	−273°	−200°	−100°	0°	100°	200°	400°	500°
Sp. ht. . .	0·0971	0·1209	0·0416	0·1523	0·1599	0·1672	0·2023	0·2398
At. ht. . .	3·884	4·836	5·664	6·092	6·396	6·688	8·092	9·592

E. D. Eastman and W. H. Rodebush also determined values for C_p and C_v at temp. ranging from 676°–393·5° K. The **entropy** of calcium is given by G. N. Lewis and co-workers as 10·64 for the solid, and 36·71 for the vapour at 25° and one atm. press. W. Muthmann, L. Weiss, and J. Metzger found the **heat of combustion** of calcium to be 80·097–81·32 Cals. per gram-eq.—*vide* heats of formation of the oxides.

According to J. H. Gladstone,[2] the **refraction equivalent** $A(\mu-1)/D$ for calcium is 10·0, when A denotes the at. wt., and D the sp. gr. of the element. The value for strontium is 13·0; and for barium, 15·8. W. J. Pope gave 13·95 for strontium and 18·94 for barium. J. Kannonikoff found the refraction eq. of calcium in its salts for rays of infinite wave-length to be 9·11; strontium, 12·2; and barium, 15·40. R. Pohl and P. Pringsheim, and T. W. Case studied the **photoelectric effect** with calcium; the last-named also measured the effect of temp. with barium and strontium cells. W. Crookes found that calcium gives an orange-yellow **phosphorescence** in the cathode ray tube. H. R. von Traubenberg found the range of the α-**particles** in calcium to be $78·8\times10^{-4}$ cm. M. N. Saha gives 8000°–10,000°, 1500°, and 4000° for the estimated temp. of complete ionization, or the temp. of luminescence of barium, strontium, and calcium vapours. R. Whiddington studied the emission of electrons by the action of X-rays on strontium.

The Bunsen flame is coloured a brick-red by calcium chloride and similar remarks apply to the alcohol flame. Strontium salts colour the flame a magnificent crimson; and barium salts, a yellowish-green. The **flame spectra** of the metals of the alkaline earths[3] are not so simple as those of the alkali metals. G. Kirchhoff and R. Bunsen's chart is illustrated by Fig. 2. When first introduced into the flame, certain bands appear which are different according to the particular salt introduced into the flame, and these spectra are supposed to be due to the particular compound employed. The final spectra are the same with all the different salts of a given metal, and these

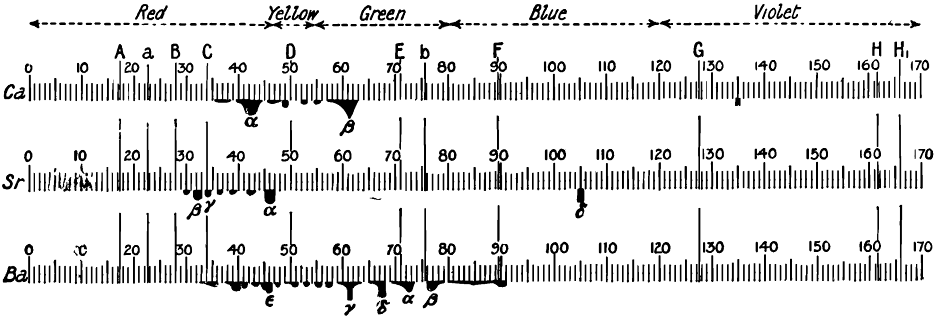

FIG. 2.—G. Kirchhoff and R. Bunsen's Spectral Chart of the Alkaline Earths.

are accordingly attributed either to the metal oxide or the metal itself. The spectral lines due to any particular compound are maintained and strengthened by introducing into the flame a gas which hinders the dissociation of the compound. This is the case, for instance, with a current of hydrogen chloride or chlorine in the flame coloured with the chloride; of hydrogen bromide or bromine in the flame coloured with the bromide; and similarly with the iodide—*vide* the flame spectrum of copper. Some non-volatile salts—*e.g.* the phosphate or silicate—may require a preliminary treatment with hydrochloric acid or ammonium fluoride before the spectrum can be obtained. W. N. Hartley and H. W. Moss have studied the spark and the oxy-hydrogen flame spectra; and J. H. Pollok and A. G. G. Leonard the quantitative

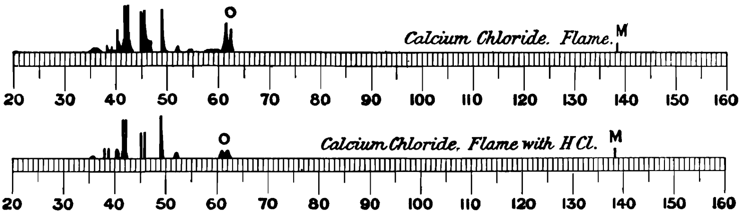

FIG. 3.—Flame Spectra of Calcium Chloride.

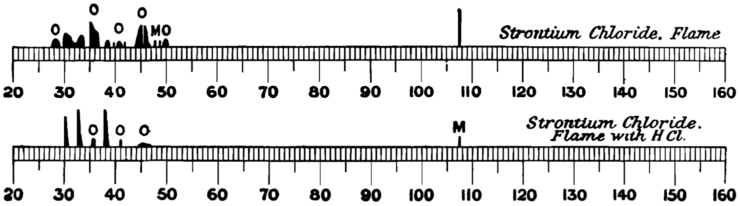

FIG. 4.—Flame Spectra of Strontium Chloride.

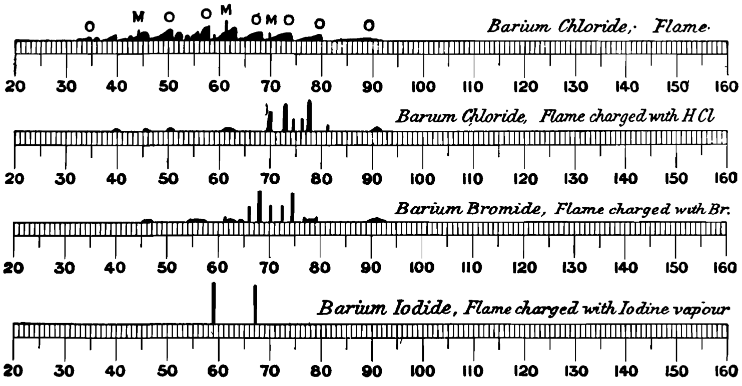

FIG. 5.—Flame Spectra of Barium Halides.

spectra of the alkaline earths. The diagrams, Figs. 3 to 5, illustrate the flame spectra of calcium, strontium, and barium chlorides, and of the same salts with the flame charged with hydrogen chloride. The letters *M* and *O* respectively denote lines attributed to metal and oxide, the others are due to the halide. In the calcium spectrum, the one line marked 138·2 is due to the metal; the lines 61·2 and 62·1 are due to the oxide; and the lines 41·75, 42·25, 45·0, 45·7, 48·8, and 52·2 are due to the chloride. In the strontium spectrum, the two lines 47·7 and 107·6 are due to the metal; the lines 30·3, 33·0, and 38·25 are due to the chloride; and the remainder are due to the oxide. In the barium spectrum, the three lines due to the metal are 44·0, 61·6, and 69·9; the lines 69·8, 72·9, 74·5, 76·0, 77·6, and 81·0 are due to the chloride; and the remainder are usually attributed to the oxide. Hence it would appear from the spectra of the chlorides, that calcium has a greater affinity for chlorine than either strontium or barium; and that barium has a greater affinity for oxygen than either strontium or calcium. According to W. N. Hartley, the oxides of the alkaline earth metals are not dissociated by heat alone because they show no spectrum in the carbon monoxide flame; they are, however, reduced by the combined action of heat and hydrogen in the oxyhydrogen flame, and by the action of cyanogen in the cyanogen flame. The flame coloration is due to the metal because not only is the flame spectrum from lime essentially the same as that of the metal calcium, but also the heats of formation of the three oxides have nearly the same value, and where calcium oxide can be reduced, the other oxides could undergo a similar reduction. As W. D. Bancroft and H. B. Weiser have emphasized, it is dangerous to base arguments on thermochemical data when dealing with reversible reactions.

The spectrum of the calcium salts, said G. Kirchhoff and R. Bunsen, shows numerous lines in the orange and green; the most prominent are the green line Ca_β, and the orange line Ca_α. The latter is nearer the red end of the spectrum than the yellow sodium and the Sr_α-line. The spectrum of strontium was first described by H. F. Talbot in 1825; G. Kirchhoff and R. Bunsen stated that the spectrum of strontium shows numerous lines, but the eight most prominent ones include six in the red, one in the orange, and one in the blue. Of these, the line termed Sr_α in the orange, Sr_β and Sr_γ in the red, and Sr_δ in the blue are the most characteristic, and are considered by E. H. Reisenfeld and H. E. Wohlers to be the most valuable in detecting this element. The spectrum of the barium salts is the most complex of the alkalies and alkaline earths. G. Kirchhoff and R. Bunsen say that the green lines Ba_α and Ba_β are by far the most distinct; the line Ba_γ is not so prominent, but it is still well marked and characteristic. The spark spectra closely resemble the flame spectra of the metals. From R. Bunsen's experiments, quantities as small as 0·00006 mgrm. of calcium chloride; 0·000006 mgrm. of strontium chloride; and 0·001 of barium chloride can be detected spectroscopically. With over 500 parts of calcium oxide to one of barium oxide, T. Engelbach failed to recognize the presence of barium spectroscopically. According to G. Merz, the calcium flame through green glass appears yellowish green; the strontium flame vanishes; and the barium flame appears bluish-green. When viewed through a blue glass, greenish-grey; and the strontium flame appears purple or violet. According to R. Cartmell, when viewed through the indigo prism, the calcium flame appears olive-green; and the strontium flame appears intensely red. A. S. King studied the absorption spectra of calcium and barium vapours. B. E. Moore studied the excitation stages in the arc spectra of calcium, barium, and strontium.

In their study of the **series spectra**, H. Kayser and C. Runge found that 36 out of the 106 calcium lines can be represented by two series of triplets corresponding with the following formulæ—each equated to $10^8\lambda^{-1}$:

$$\text{I}\ \begin{cases} 33919{\cdot}51-123547n^{-2}-961696n^{-4} \\ 34022{\cdot}12-123547n^{-2}-961696n^{-4} \\ 34073{\cdot}82-123547n^{-2}-961696n^{-4} \end{cases} \qquad \text{II}\ \begin{cases} 34041{\cdot}17-120398n^{-2}-346097n^{-4} \\ 34146{\cdot}95-120398n^{-2}-346097n^{-4} \\ 34199{\cdot}09-120398n^{-2}-346097n^{-4} \end{cases}$$

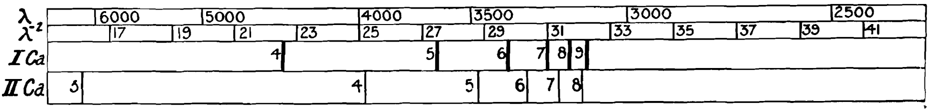

FIG. 6.—Series Spectra of Calcium.

Numerous other regularities were observed by J. R. Rydberg. The arrangement of the lines in the series spectra of calcium, with n ranging from 4 to 9, is shown in Fig. 6. H. Kayser and C. Runge found only one series in the spectral lines of strontium, but H. Lehmann found a second. These formulæ, each equated to $10^8\lambda^{-1}$, are:

$$\text{I}\begin{cases}31030{\cdot}64-122328n^{-2}-837473n^{-4}\\31424{\cdot}67-122328n^{-2}-837473n^{-4}\\31610{\cdot}58-122328n^{-2}-837473n^{-4}\end{cases}\qquad\text{II}\begin{cases}31226-120300n^{-2}-301000n^{-4}\\31618-120300n^{-2}-301000n^{-4}\\31806-120300n^{-2}-301000n^{-4}\end{cases}$$

Their graphic representation furnishes a diagram like that for calcium. J. R. Rydberg, L. Börsch, and F. A. Saunders noticed some other regularities. H. Kayser and C. Runge did not succeed in finding any formula for the 162 barium lines, although some triplets with constant differences were found. The series spectra of the alkaline earths were also studied by W. M. Hicks, B. Götze, and A. Fowler. C. M. Olmsted studied the band spectra of the halogen salts of the alkaline earths. A. S. King and F. A. Saunders studied the arc spectra of calcium, strontium, and barium. O. Holtz studied the arc spectrum of calcium; H. Hampe, that of strontium; and K. Schmitz, and H. George, that of barium. E. Fries compared the spark spectra of the alkaline earths, and the arc spectrum of the alkalies, and showed that the results agree with the hypothesis that when an electron is removed from its outer sheath by ionization, the spectrum of the element is displaced to that of the element occupying the preceding position in the periodic system.

L. F. Miller, M. Ritter, and W. Huggins and Mrs. Huggins have studied the effect of *pressure* on the *H* and *K* violet spectral lines—respectively 3968 and 3934—obtained in the spark spectrum of metallic calcium. With dense calcium vapour, the *H* and *K* lines as well as 3706, 3737, and 4227 lines are diffuse; as the density of the vapour is diminished the lines are gradually enfeebled until the *H* and *K* lines alone appear. J. R. Rydberg has studied the effect of *magnetism* on the spectral lines of calcium, barium, and strontium; and T. Takamine and N. Kokubu, the effect of the *electric field* on those of calcium. J. Stark and G. von Wendt investigated the effect of the **canal rays** on the alkaline earth metals; and E. Hjalmar, D. Coster, and R. A. Sawyer and R. L. Becker, the effect of **X-rays**, and the X-ray spectrum.

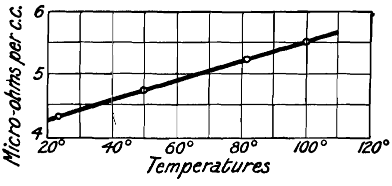

FIG. 7.—The Electrical Resistance of Calcium.

According to J. H. Goodwin,[4] the specific **electrical resistance** of calcium at 0° is 3·43 micro-ohms per cm. cube, the temp. coeff. is 0·00457; and P. H. Brace found a metal with 1·08 per cent. of chlorine had an electrical resistance of 6·77 micro-ohms per cm. cube at 22°. The resistivity or electrical resistance of calcium in micro-ohms per cm. cube, at different temp., has been also determined by E. F. Northrup. The results are indicated in the graph, Fig. 7. C. L. Swisher obtained 4·6 micro-ohms per cm. cube, and a temp. coeff. of 0·0034 per degree; J. H. Goodwin obtained a temp. coeff of 0·00457. P. W. Bridgman found that with press., p, in kgrms. per sq. cm., the electrical resistance at $\theta°$ is:

	$\theta°$	0	1000	3000	5000	7000	9000	12,000
Ca	0°	1·0000	1·0107	1·0330	1·0569	1·0827	1·1103	1·1550
	50°	1·1552	1·1668	1·1912	1·2171	1·2451	1·2749	1·3229
	100°	1·3327	1·3589	1·3865	1·4008	1·4311	1·4631	1·5146
Sr	0°	1·0000	1·0516	1·1622	1·2850	1·4196	1·5670	1·8160
	50°	1·1768	1·2320	1·3519	1·4842	1·6280	1·7852	2·0446
	100°	1·3828	1·4341	1·5539	1·6936	1·8527	2·0272	2·3144

The press. coeff. of calcium increases with rising temp.; that of strontium decreases very slightly at 0° with rise of press., but at 50° it increases with rise of press. to 2000–3000 kgrms., then shows a flat maximum, and then decreases; at 100° the behaviour is like that at 50° except the maximum is sharper, and occurs at 700 kgrms. The temp. coeff. of both metals falls with rise of press. The **electrical**

conductivity of calcium at 20° is 45·1 if that of silver of the same area and length is 100; and the conductivity is exceeded only by that of silver, copper, gold, and aluminium; for the same weight and length of metal, the conductivity of silver is 32·5 when that of calcium is 100; for strontium the conductivity is 6·71. R. Bunsen and A. Matthiessen say that strontium is more electropositive than magnesium and more negative than calcium and the alkali metals. M. Born estimated the **heat of hydration** of Ca''-ions to be 344 Cals.; K. Fajans gave 475 Cals. H. Grimm estimated the **ionic radii** of barium, strontium, and calcium ions, and W. P. Davey gave 1·25 A. for the $Ca^{\cdot\cdot}$-ion, 1·42 A. for the $Sr^{\cdot\cdot}$-ion, and 1·56 A. for the $Ba^{\cdot\cdot}$-ion.

E. F. Northrup determined the **thermo-electromotive force**, or the **Seebeck effect,** of the calcium-aluminium couple, and found, in micro-volts:

	0°	24°	51·2°	56°	89°	90·4°	92°	96°	100°
E.m.f. .	0	218	514	558	940	968	1000	1027	1080

The results at 335°—*viz.* 3080 micro-volts—on wire protected from oxidation, were not consistent owing to oxidation of the calcium at the joint. The direction of the current was through the hot joint from the calcium to the aluminium. C. L. Swisher found calcium is thermoelectrically positive towards lead giving 8–9 micro-volts per degree at 50° and 14·0 micro-volts at 400°. The **Thomson effect** is positive for calcium. P. Pascal studied the diamagnetism of the metals of the alkaline earths.

A **resonance potential** represents the intensity of the energy of an electron which is capable of bringing a change in the molecule of the gas—*e.g.* the dissociation of hydrogen into electrically neutral molecules: $H_2 \rightarrow 2H$. On the other hand, the **ionization potential** represents the intensity of the energy which must be imparted to an electron, in order that by its collision with an atom or molecule it may cause an electron to be eliminated—*e.g.* $H_2 \rightarrow H^{\cdot}_2 + \ominus$ or $H \rightarrow H^{\cdot} + \ominus$. F. L. Mohler and co-workers[5] found that the ionization potential of calcium vapour is 6·01 volts, and there are two resonance potentials,one at 1·90 volts and another less pronounced one at 2·85 volts. J. C. McLennan and J. F. T. Young obtained 6·12 volts for the ionization potential of calcium vapour; 5·7 volts for that of strontium vapour; and 5·21 volts for that of barium vapour. P. D. Foote and F. L. Mohler found that calcium vapour is not ionized by heating it to 700°; and they gave 1·90–2·85 volts for the resonance potential. H. Greinacher studied **flame ionization** by strontium salts. E. Rutherford and J. Chadwick obtained little if any evidence of the emission of long-range particles, detected by scintillations on a zinc sulphide screen, when *α*-**particles** pass through calcium. B. Gudden and R. Pohl measured the electrical conductivity of phosphorescent calcium under a field strength of 16,000 volts per cm. V. L. Chrisler studied the **potential gradient in the arc** with electrodes of barium, strontium, and calcium. P. Pascal determined the **magnetic susceptibility** of the alkaline earth metals and their compounds.

According to H. Davy,[6] finely divided calcium oxidizes rapidly when exposed to the **air** at ordinary temp., and H. Caron found the metal is covered with a grey film after it has been exposed to dry air. H. Moissan found extremely finely divided calcium, such as is obtained by the evaporation of a soln. of calcium in liquid ammonia, inflames spontaneously on exposure to air. H. Davy, and B. Franz likewise found strontium oxidizes in air. H. Davy, A. Matthiessen, E. D. Clarke, and W. Crookes made similar observations with respect to barium. When the clean, bright metal is exposed to air, A. Guntz and G. Röderer found the surface immediately becomes dull, then yellowish-brown, and later grey, owing to the formation of oxide and nitride. A. Guntz made similar observations with respect to barium. According to H. Davy, when calcium is heated in air, it burns with a brilliant flame. J. H. Goodwin heated the metal red hot without ignition, and he found it to be quite soft at this temp. R. Bunsen and A. Matthiessen found strontium burns when heated in dry oxygen. A. Guntz found that finely divided 98·35 per cent. barium ignites spontaneously in air. Barium also readily burns when heated in air. Lies-Bodart and M. Jobin found that when calcium is heated by the blowpipe flame, it is covered by a film of oxide which protects the metal and renders combustion difficult. H. Moissan found that when calcium is heated to 300°, it burns vigorously in **oxygen** gas, and the heat of combustion is so great that some calcium oxide is volatilized, but no peroxide is formed. Dry oxygen has no action at ordinary temp. W. Strecker and H. Thienemann studied the action of **ozone** on soln. of calcium and barium in liquid ammonia; they found that ozonates analogous with those of the alkali metals were formed, contaminated with products of the action of ozone on ammonia. Calcium is one of the most active of elements and it seems to combine with all excepting the inert gases. According to L. Maquenne, **nitrogen** is absorbed by the hot metals of the alkaline earths forming a nitride. O. Ruff and co-workers found that the pure calcium is passive towards nitrogen, while metals more strongly positive—*e.g.* barium, strontium, sodium, and potassium—accelerate the absorption of nitrogen; some metals—*e.g.* magnesium, lead, and tin—have no effect; others —*e.g.* arsenic and antimony—retard it; and some—*e.g.* bismuth, copper, and zinc —inhibit the action. It is hence concluded that the heteropolar nature of a metallic surface favours the combination with a homopolar gas. H. Moissan observed that when calcium is heated to dull redness in air, oxide and nitride are formed. A. Guntz and G. Röderer likewise found that when strontium is heated in air, oxide and nitride, but no peroxide, is formed. When the metals of the three alkaline earths are heated with **hydrogen,** the gas is absorbed and hydrides are formed (*q.v.*). F. H. Newman noted the absorption of hydrogen and nitrogen by calcium in the electrical discharge tube.

Calcium was found by Lies-Bodart and M. Jobin to be rapidly covered with calcium hydroxide and carbonate when exposed to moist air. H. Davy's preparation of calcium vigorously decomposed **water,** but H. Moissan showed that with cold water the action is slow, in consequence of the formation of a protective layer of calcium hydroxide; since the last-named compound is soluble in a soln. of sugar, calcium is dissolved more rapidly by a soln. of sugar than by water. Strontium was also found by R. Bunsen and A. Matthiessen to react turbulently with water; and A. Matthiessen, H. Davy, and E. D. Clarke noted that barium reacts with water at ordinary temps. The action of water on calcium is more vigorous if a little ferric chloride, auric chloride, or platinum chloride be present—a galvanic couple is possibly here formed. Lies-Bodart and M. Jobin found a soln. of sodium carbonate attacks calcium very slowly. According to J. H. Goodwin, when calcium made in an iron vessel is treated with water, it sometimes gives hydrogen with an odour of acetylene; this is probably due to the calcium extracting some carbon from the iron. Calcium can also extract sulphur and phosphorus from iron.

According to H. Moissan calcium is vigorously attacked by **fluorine** at ordinary temp., the mass glows with a red heat, and cubic crystals of calcium fluoride will be found in the molten product; at 400° **chlorine** likewise attacks calcium with incandescence, forming fused calcium chloride. A. Guntz and G. Röderer found strontium is not changed by cold chlorine, but when warmed, the metal is attacked, and at 300°, the metal burns with incandescence. The combustion of strontium in chlorine was noted by R. Bunsen and A. Matthiessen. According to H. Moissan, liquid **bromine** has no action on calcium, but with bromine vapour, combustion occurs at a dull red heat. Strontium was found by R. Bunsen and A. Matthiessen, and by A. Guntz and G. Röderer, to burn in bromine vapour at 400°, forming molten strontium bromide. According to R. Bunsen and A. Matthiessen, B. von Lengyel, and H. Moissan, **iodine** can be heated to its b.p. without acting on calcium, but at a higher temp., a vigorous reaction occurs. A. Guntz and G. Röderer found iodine unites with strontium below a red heat. According to H. Moissan, when calcium is heated to dull redness in a stream of **hydrogen chloride,** it glows, and forms calcium chloride. A. Guntz and G. Röderer found strontium behaves similarly at 500°. B. von Lengyel, and R. Bunsen and A. Matthiessen found dil. or conc. **hydrochloric acid** reacts turbulently with calcium with the evolution of hydrogen. A. Guntz and G. Röderer found strontium behaves similarly. H. Moissan observed that the **alkali chlorides** are reduced by calcium at a red heat—W. Muthmann, L. Weiss, and J. Metzger say at 950° to 1200° or 1600°. F. M. Perkin and L. Pratt found that the alkali metals volatilize and burn during the reaction. H. Moissan found the **alkali iodides** under similar conditions are not attacked; and **calcium chloride or iodide** are reduced to the corresponding subhalide. W. Muthmann and L. Weiss say that **cryolite** at a red heat is reduced to aluminium; and that **strontium and barium chloride** furnish alloys which are readily oxidized in air. F. M. Perkin and L. Pratt obtained similar results. According to L. Hackspill, when calcium is heated with **silver chloride or cuprous chloride** at a red heat, the corresponding metal alloy is formed; **chromic chloride** is reduced to chromium, but **ferric chloride** is not reduced. F. M. Perkin and L. Pratt found **lead chloride** to react explosively with calcium, forming an alloy; **aluminium chloride** under similar conditions also yields an alloy. According to H. Moissan, calcium reduces **boron bromide or boron nitride**, forming boron and the corresponding calcium salts.

B. von Lengyel found that calcium burns in **sulphur** vapour with a very brilliant white flame, and, according to H. Moissan, the reaction begins about 400°. F. M. Perkin and L. Pratt say that a mixture of calcium and sulphur, fired by a taper, reacts explosively; and that **lead sulphide** (galena) does not give lead, but a grey solid which gives off hydrogen sulphide when treated with hydrochloric acid. R. Bunsen and A. Matthiessen found that strontium like calcium burns in sulphur vapour forming, according to A. Guntz and G. Röderer, strontium sulphide. H. Moissan found that **selenium and tellurium** react like sulphur with calcium at a dull red heat. Gaseous **hydrogen sulphide** reacts vigorously with red-hot calcium, forming calcium sulphide, CaS. According to A. Guntz and G. Röderer, strontium behaves similarly. H. Moissan found that calcium at a dull red heat burns in **sulphur dioxide**, forming calcium sulphide. R. Bunsen and A. Matthiessen found that calcium and strontium are attacked vigorously by dil. **sulphuric acid**, and slowly by the conc. acid, forming, according to H. Moissan, sulphur dioxide, sulphur, and hydrogen sulphide, while fuming sulphuric acid reacts similarly, but furnishes no hydrogen sulphide. According to A. Guntz and G. Röderer, with the cold acid, a layer of solid strontium sulphate is formed which hinders the attack by the acid. H. Davy noted the action of sulphuric acid on barium.

F. H. Newman studied the absorption of **nitrogen** by calcium at the cathode of a vacuum tube. H. Moissan found that calcium does not react with nitrogen at ordinary temp., but at 900° a nitride is formed; he also found that **ammonia** does not react in the cold with calcium; liquid ammonia dissolves the metal, forming at −40° the so-called calcium-ammonium. A. Guntz and G. Röderer observed that strontium, and A. Guntz, that barium, behave similarly. According to H. Erdmann and H. van der Smissen, **ethylamine** reacts with calcium at 250°, forming calcium hydride and nitride. Calcium heated to dull redness burns vigorously in **nitrous oxide**, forming molten calcium oxide, free from the nitride. According to A. Guntz and G. Röderer, when strontium is heated to dull redness with **nitrogen peroxide,** the metal is oxidized less energetically than in air and strontium nitride is formed. They also found that dil. hot conc. **nitric acid** was found by B. von Lengyel to dissolve calcium, while R. Bunsen and A. Matthiessen and H. Moissan noted that the reaction with fuming nitric acid is very slow, but if the acid be diluted the reaction is faster. A. Guntz and G. Röderer found strontium behaved similarly. Calcium reacts with **phosphorus**, forming the phosphide; with **arsenic** forming the arsenide; and with **antimony or bismuth,** alloys are formed. A. Guntz and G. Röderer observed that strontium reacts with the vapour of arsenic at 450°, forming—possibly a black arsenide—which reacts with water giving off arsine, and leaving behind a dark brown powder. H. Moissan observed that at a red heat, **phosphorus pentoxide** reacts explosively with calcium. At about 600°, **boric oxide** is reduced to a brown mass without producing calcium boride;

calcium borate is reduced to a mixture of boron and calcium boride, CaB_6. According to F. M. Perkin, a mixture of boric oxide or of sodium borate with calcium, when ignited with a fuse of sodium peroxide and calcium, furnishes a mixture of what appears to be boron and calcium boride, which can be used in place of boron for making boron trichloride.

Calcium was found by H. Moissan to react vigorously with **carbon**; the reaction is attended by the evolution of much heat—and it begins with soot at a dull red heat, and with graphite at a rather higher temp. A. Guntz and G. Röderer found that when heated with strontium, carbon forms a grey product which develops acetylene when treated with water. According to H. Moissan, liquid **acetylene** does not react with calcium, but when calcium is warmed in the gas, a layer of carbon is formed on the metal, and the remaining gas is polymerized. When heated in a stream of acetylene, the metal burns, forming calcium carbide and hydride. A. Guntz and G. Röderer found strontium is blackened by acetylene at 600°, and the metal is covered by a protective layer of carbon, but very little carbide is formed. The reaction with **ethylene** begins at a dull red heat, and a layer of carbon is formed on the metal which hinders the reaction; acetylene is simultaneously formed; **methane** reacts similarly. R. Bunsen and A. Matthiessen observed that calcium burns brilliantly when heated in **carbon dioxide.** O. P. Watts represented the reaction as furnishing carbon and calcium oxide; and H. Moissan found that if the temp. is not so high, the metal is covered with a layer of carbon and calcium carbide and carbonate which hinders the reaction—some carbon monoxide is also formed. R. Bunsen and A. Matthiessen found strontium reacts similarly with carbon dioxide. A. Guntz and G. Röderer said that strontium burns as energetically in carbon dioxide or coal gas as in air, but not so vigorously as calcium. H. Moissan said that calcium at a dull red heat decomposes **carbon monoxide**, forming carbon and calcium carbide; and A. Guntz and M. Mantrel observed a similar reaction with barium. A. Guntz and G. Röderer found strontium behaves in carbon monoxide as it does in carbon dioxide. Dil. **acetic acid** dissolves the metal vigorously with the evolution of hydrogen, and H. Moissan made a similar observation with calcium and acetic acid. Lies-Bodart and M. Jobin say that absolute alcohol is without action on calcium. F. M. Perkin, and L. Pratt found calcium must be used with care as a drying agent for alcohol, because after half an hour's contact, a turbulent action occurs, hydrogen is evolved and calcium ethoxide is formed. Calcium was also found by H. D. Law and F. M. Perkin to react with **ketones.** According to A. Guntz and G. Röderer, absolute alcohol dissolves some strontium, but dry **ligroïn, toluene, turpentine,** etc., have no action on the metal. J. A. Wanklyn found calcium attacks **zinc ethyl.** Calcium and **silicon** combine at a red heat, forming a silicide; while **silica** is reduced by calcium or strontium, forming the silicide and a little silicon. R. Bunsen and A. Matthiessen found **glass** and **poreclain** are vigorously attacked by calcium or strontium at a red heat. A. Guntz and G. Röderer said that strontium does not reduce **silicon tetrachloride.**

H. Moissan found that **sodium** dissolves calcium at a high temp. and that the calcium cystallizes out again on cooling; **potassium** possesses this quality in a smaller degree. According to W. Muthmann and L. Weiss, when a heated alloy of calcium and sodium is cooled it forms two layers, and potassium behaves similarly. H. Moissan found that calcium forms brittle alloys with **magnesium, zinc,** and **nickel,** and these alloys decompose water; A. Guntz and G. Röderer observed that nickel alloys with strontium. A. Guntz found that nickel is attacked by barium more than is the case with iron. H. Moissan found that calcium reacts vigorously with **tin,** but the alloy retains only a little calcium, and it too decomposes water slowly. W. Muthmann and L. Weiss say that calcium does not alloy with **lead** or tin; and L. Hackspill that it forms no alloy with **chromium,** but it does so, under press., with **iron.** A. Guntz found iron is but little attacked by barium. H. Moissan found that when calcium is rubbed up with **mercury,** an amalgam is produced;

A. Guntz and G. Röderer observed that strontium, and R. Bunsen and A. Matthiessen that barium, forms an amalgam under similar conditions. The **alkali oxides**—lithium, sodium, and potassium—are reduced to the metals when heated with calcium; and the **alkali hydroxides** are similarly reduced with detonation. This agrees with the heats of formation of the oxides, (Ca, O)=145 Cals., (2K, O)=98·2 Cals., and (2Na, O)=100·9 Cals. F. M. Perkin and L. Pratt could not obtain metals from the hydroxides of the alkalies or the alkaline earths. No strontium was obtained with strontium oxide and calcium although there is a vigorous reaction; with calcium oxide and calcium, a suboxide is formed. F. E. Weston and H. R. Ellis partly reduced lime and magnesia by calcium, but in the latter case, a nitride is the chief product. H. Moissan found that **uranic oxide,** UO_3; **titanic oxide,** TiO_2; and **vanadium pentoxide,** V_2O_5, are reduced to a lower state of oxidation by calcium. A. Burger obtained uranium of a high degree of purity by the calcium reduction, and likewise also titanium and zirconium—the latter from **zirconium oxide.** F. M. Perkin and L. Pratt found titanic oxide is reduced to a metallic powder; **tungstic oxide** is reduced to the metal, and the reaction is so vigorous that both the metal and the calcium oxide are fused; **alumina** is reduced to a metal powder. F. E. Weston and H. R. Ellis also reduced alumina by calcium. A. Burger likewise obtained molybdenum from **molybdic oxide**. According to F. M. Perkin, a mixture of calcium with ferric oxide gives the corresponding metal; similar remarks apply to mixtures of calcium with **manganese dioxide,** or with **chromic oxide.** The chief objections to the use of calcium for reducing the oxides to the metal are the great violence of the reaction, and the infusibility of the calcium oxide. According to A. Burger, the reduction by calcium is unsatisfactory with **silica; cerium dioxide** is reduced to the sesquioxide; and **thorium dioxide** is not reduced.

Some reactions of analytical interest.—The chlorides of the alkaline earths may be regarded as typical. Aq. **ammonia** free from carbonate gives no precipitate with salts of calcium, strontium, or barium, although if the ammoniacal soln. be exposed to air, carbon dioxide is absorbed, and the carbonate of the alkaline earth precipitated. An ammoniacal soln. of commercial **ammonium carbonate** contains ammonium carbonate and carbamate. This soln. gives a flocculent precipitate of, say, calcium carbonate which becomes crystalline on standing, and more rapidly on heating. The reaction: $CaCl_2+(NH_4)_2CO_3 \rightleftharpoons CaCO_3+2NH_4Cl$, is reversible so that an excess of the precipitant is needed, and the soln. should not be boiled longer than is needed to change the flocculent precipitate into a crystalline one. If a large proportion of ammonium chloride is present, and only a small proportion of the carbonate, no precipitation may occur. A soln. of ammonium carbamate alone gives no precipitate because the carbamates are soluble, but if the soln. be warmed over 60°, ammonium carbamate forms carbonate, and the alkaline earth carbonate is precipitated. F. Jackson[7] gives as the limits of the reaction with barium 1 : 4000, with strontium 1 : 16,000, and with calcium 1 : 8000. R. Fresenius gave 1 : 163,000 for calcium, and 1 : 201,000 for barium. Soln. of **sodium carbonate** precipitate the carbonates of the alkaline earths from soln. of their salts, much as is done by ammonium carbonate. According to J. L. Lassaigne, sodium carbonate gives a slight cloud, appearing only in a few minutes with calcium nitrate diluted 1 : 25,000; a very slight turbidity appearing only after standing some time when the dilution is 1 : 50,000; with 1 : 100,000 there was a scarcely perceptible turbidity after standing a long time; and with 1 : 200,000, no effect could be detected. Neutral or alkaline soln. of the salts of the alkaline earths give a precipitate of the oxalate when treated with **ammonium oxalate**. The crystalline precipitate formed in cold soln. is difficult to filter, but that formed in hot soln. consists of large crystals more readily filtered. The precipitated calcium oxalate is very sparingly soluble in acetic acid, the strontium salt is rather more soluble, and the barium salt readily dissolves in the hot acid. The solubility of the oxalates increases with increasing mol. wt., so that while the calcium salt is virtually insoluble in water, the barium salt is more soluble, 100 parts of water dissolve 0·0386 part of barium oxalate. The oxalates of the alkaline earths are soluble in the mineral acids, and the addition of aq. ammonia reprecipitates the oxalates; boiling the oxalates with a soln. of sodium carbonate changes them into carbonates. According to J. L. Lassaigne, one part of strontia in 10,000 parts of water gives a scarcely appreciable turbidity, and with more water, no turbidity is visible; with calcium a precipitate is obtained with 1 : 25,000; a very slight precipitate is obtained with 1 : 50,000; and with 1 : 100,000 an opalescence appears in five minutes; and with 1 : 200,000, 1 : 400,000, and 1 : 800,000 a slight opalescence appears in five, eight, or fifteen minutes respectively. P. Harting obtained a turbidity with a soln. of calcium chloride at a dilution of 1 : 400,000. According to F. Jackson, the reaction with ammonium oxalate is sensitive to 1 : 64,000 with calcium, 1 : 32,000 with strontium, and 1 : 2000 with barium.

Conc. soln. of a calcium salt give a precipitate with **sulphuric acid**; but dil. soln. give no precipitate since calcium sulphate is sparingly soluble in water. Calcium sulphate is far less soluble if alcohol be added to the soln. Strontium sulphate is less soluble than calcium sulphate, and more soluble than barium sulphate. The latter is very sparingly soluble in water. Hot conc. sulphuric acid dissolves the precipitate because a soluble hydrosulphate is formed—*e.g.* with barium, $BaSO_4+H_2SO_4=Ba(HSO_4)_2$—this is decomposed into sparingly soluble barium sulphate when the soln. is diluted with water. Hot dil. hydrochloric acid dissolves calcium and strontium sulphate, and barium sulphate is but sparingly soluble in the hot acid. Calcium sulphate is soluble in a soln. of ammonium sulphate owing to the formation of a soluble double salt: $CaSO_4.(NH_4)_2SO_4$. This soln. is decomposed by water and the calcium sulphate is reprecipitated. Barium sulphate is slightly soluble in a soln. of sodium thiosulphate. A soln. of **calcium sulphate** gives no precipitate with a soln. of a calcium salt; but in a neutral or feebly acid soln. of a strontium salt, a precipitate of strontium sulphate is formed when the soln. has stood for some time, but with a soln. of a barium salt, precipitation of barium sulphate occurs at once. According to J. L. Lassaigne, a soln. of barium nitrate containing one part of baryta in 25,000 parts of water gives a very distinct cloudiness with sulphuric acid or sodium sulphate; with 1 : 50,000 or 1 : 100,000, a slight turbidity appears; with 1 : 200,000 to 1 : 400,000, a turbidity appears in some minutes; and with 1 : 800,000 there is no reaction. According to P. Harting a soln. of barium chloride with one of bartya in 71,000 parts of water becomes turbid with sodium sulphate in half an hour, and the limits of the reaction is 1 : 79,300. J. L. Lassaigne found a soln. of strontium nitrate with one of strontia in 2500 parts of water gives a precipitate with sulphuric acid or sodium sulphate; with 1 : 5000, a slight cloudiness; with 1 : 10,000, a very slight turbidity; and with 1 : 20,000, a very slight turbidity in a few minutes; with 1 : 40,000 there was a scarcely appreciable turbidity in a few minutes. F. Jackson gives the limits 1 : 256,000 with barium; and with strontium the limits are 1 : 8000, and with calcium 1 : 2000. R. Fresenius gives 1 : 23,100, or 1 : 25,200 for the limits with strontium. The limits of the reaction with calcium sulphate as precipitant are, according to F. Jackson, 1 : 64,000 with barium, and 1 : 1000 with strontium.

When a neutral soln. of a calcium, strontium, or barium salt is treated with a soln. of **sodium phosphate,** a white flocculent precipitate is produced: $Na_2HPO_4+CaCl_2=2NaCl+CaHPO_4$; and if aq. ammonia be added to the mixture, normal calcium phosphate, $Ca_3(PO_4)_2$, is formed. Both the calcium phosphates are soluble in mineral or acetic acid. According to J. L. Lassaigne, a precipitate is obtained with sodium phosphate in soln. of calcium nitrate diluted 1 : 25,000; a slight precipitate with a dilution of 1 : 50,000; and with 1 : 100,000 there was an opalescence in a few minutes, but no effect with a dilution 1 : 200,000. The limits of the reaction are given by F. Jackson as 1 : 16,000 with calcium, 1 : 8000 with strontium, 1 : 4000 with barium. No precipitation occurs when a soln. of a calcium salt is treated with **potassium chromate,** nor does precipitation occur with a dil.

soln. of a strontium salt; but a conc. soln. of a strontium salt does give a precipitate of strontium chromate. A neutral dil. or conc. soln. of a barium salt gives a yellow precipitate of barium chromate which is very sparingly soluble in water and acetic acid, but it is readily soluble in mineral acids. Consequently, potassium dichromate is not so good a precipitant since an acid is then formed: $2BaCl_2+K_2Cr_2O_7+H_2O=2BaCrO_4+2HCl+2KCl$. The presence of sodium acetate diminishes the solvent action of the mineral acids and the reaction is then quantitative. The limits of the reaction, according to F. Jackson, are 1 : 256,000 with barium, and 1 : 200 with strontium. Barium salt soln. give a white crystalline precipitate of barium fluosilicate, $BaSiF_6$, when treated with **hydrofluosilicic acid**, H_2SiF_6. The precipitation takes some time. The precipitated fluosilicate is sparingly soluble in water and dil. acids, and virtually insoluble in alcohol. According to P. Harting, one part of barium chloride in 3800 parts of water gives a precipitate with this acid, F. Jackson gives 1 : 2000. Neither calcium nor strontium salts give a precipitate with this reagent even in fairly conc. soln., and this even if the calcium soln. is mixed with half its vol. of alcohol. C. F. Rammelsberg found that **sodium iodate** precipitates baryta quantitatively as iodate, and the precipitate dissolves in hydrochloric acid, consequently G. Denigès recommended a 10 per cent. soln. of iodic acid as a reagent for the microdetection of calcium, strontium, or barium salts all of which give finely crystalline iodates.

The separation of barium, strontium, and calcium.[8]—Salts of the alkaline earths can be separated from the alkalies by precipitation as oxalates. Calcium can be separated from the other two elements (1) by treating the nitrates with a mixture of alcohol and ether in which the calcium salt readily dissolves, while the other two salts are very sparingly soluble (F. Stromeyer, H. Rose, R. Fresenius); (2) by extracting the calcium nitrate with amyl alcohol (P. E. Browning); (3) by treating the nitrates with nitric acid of sp. gr. 1·42–1·46, in which the calcium salt is readily soluble, and the other two salts are very sparingly soluble (S. G. Rawson); (4) by boiling the three sulphates with a soln. of an alkali or ammonium carbonate, which converts calcium and strontium sulphates into carbonates, leaving the barium sulphate virtually unchanged. The carbonates are then removed with dil. acid (H. Rose, J. L. R. Morgan, F. W. Küster); (5) by treating the sulphates with an alkali tartrate, when calcium sulphate is alone converted into tartrate which is soluble in hydrochloric acid (M. Dupasquier); (6) by precipitating the barium as chromate, the strontium as sulphate, and the calcium as oxalate (H. Robin); and (7) by the indirect method in which the mixture is converted into mixtures of different weighable salts (O. Knoblauch).

The separation of calcium and strontium.—(1) By treatment of the nitrates with the alcohol-ether mixture or amyl alcohol in which the calcium alone dissolves (*vide supra*); (2) by treatment of the soln. with a mixture of ammonium sulphate and oxalate, whereby the strontium is converted into sulphate, the calcium into oxalate (D. Sidersky); (3) by treatment of the chromates with alcohol in which the calcium alone dissolves (W. Fresenius and F. Ruppert).

The separation of calcium and barium.—(1) By precipitation of the barium as chromate or as fluosilicate (R. Fresenius); (2) by treatment of the nitrates with alcohol-ether or amyl alcohol which extracts the calcium salt alone (*vide supra*); (3) by extracting the chlorides with an ethereal soln. of hydrogen chloride which extracts the calcium salt alone (F. W. Mar); (4) by treating a dil. soln. with sulphuric acid, which precipitates the barium as sulphate; (5) by digestion with a mixture of potassium sulphate and carbonate, which converts the barium into sulphate, and the calcium into carbonate—the latter is removed by treatment with dil. hydrochloric acid (E. Fleischer); (6) by digestion with a mixture of ammonium sulphate and oxalate which converts the barium into sulphate and the calcium into oxalate—the latter is alone soluble in dil. acid; and (7) by digesting the sulphates with a soln. of sodium thiosulphate in which the calcium salt alone dissolves (W. Diehl).

The separation of strontium and barium.—(1) The barium can be precipitated as chromate, the strontium salt remains in soln. (R. Fresenius); (2) the barium can be precipitated as silicofluoride (R. Fresenius); (3) barium chloride is alone insoluble in absolute alcohol (P. E Browning); (4) by boiling the alkali carbonate which converts strontium sulphate into the carbonate and leaves the barium salt almost unattacked. The carbonates are removed with dil. acid (H. Rose).

The accuracy of analytical processes is generally affected by the assumption that precipitates are insoluble when they are but sparingly soluble; by the precipitation of one substance in the presence of another whereby a substance assumed to be wholly in soln. is partly carried down with a precipitate; and by the assumption that one component of a mixed precipitate is insoluble in or inert towards a given menstruum, when in reality it is slightly soluble, or not quite inert. Many of these proposed methods are faulty when closely examined. The methods which have proved most satisfactory are (i) treatment of the mixed nitrates with ethereal alcohol to remove calcium nitrate, and the subsequent separation of barium and strontium by the chromate process; (ii) treatment of the soln. in acetic acid with an alkali chromate; barium chromate is precipitated, redissolved, and again precipitated; the salts in the filtrate are precipitated as carbonates; converted into nitrates; and the calcium nitrate removed from strontium nitrate by the ether alcohol mixture. The separated products are converted into sulphates and weighed.

The uses of alkaline earths.—Calcium is a powerful reducing agent, and it has been used to a very limited extent as a deoxidizer and for removing nitrogen from alloys. It has been used as an absorbent for gases—hydrogen and nitrogen—in gas-analysis. The fine-grained metal is a faster absorbent than the coarsely crystalline metal obtained by slow cooling. The use of metallic calcium is thus summarized by H. P. Brace [9]:

> Calcium is used as a reducing agent in the preparation of metals and alloys from their oxygen and halogen compounds; as a reagent in the purification of the inert gases; as a scavenger for non-ferrous metals and alloys; as a scavenger, decarburizer, and desulphurizer for ferrous alloys; as a dehydrating agent in the treatment of oils and alcohols, etc.; as a means of fixing atm. nitrogen; as a source of pure calcium carbide by direct reaction with pure carbon; as a stiffening filling for hollow metal structural members; as a constituent of a light aluminium alloy having useful properties; and as a hardening component in certain lead-base antifriction alloys.

Calcium alloys have been proposed for bearing metals. Lime or limestone is used in the preparation of mortars; cements; sand-lime bricks; glass; glazes; the purification of water; the manufacture of soda; bleaching powder; calcium carbide; calcium cyanamide; calcium nitrate; etc.; the purification of coal gas; the manufacture of insectides and sprays; the manufacture of sugar; the distillation of wood; the manufacture of paper; paints; and in tanning. Strontium salts are used in the manufacture of fireworks, signal lights, and signal shells; and to a limited extent in medicine. Strontia is used in the recovery of sugar from beet-sugar molasses. Barium carbonate is used in glass making; in rendering soluble sulphates in clays inert; in making wall-paints, etc. The chloride is used in the purification of salt; in certain medicinal and photographic preparations; for rendering soluble sulphates in clays more or less inert; as a chemical agent; the nitrate is used as a chemical agent, in certain medicinal preparations; in pyrotechnics and in making green signal lights; and for certain explosive mixtures. Barium peroxide is used as a bleaching agent. For the uses of the sulphates of the alkaline earths,[10] *vide infra.*

§ 5. The Atomic Weights of Calcium, Strontium, and Barium

In 1809, J. J. Berzelius[1] made a determination of the at. wt. of calcium by treating a known quantity of calcium chloride with silver nitrate, and weighing the precipitated chloride. This gave the ratio $CaCl_2 : 2AgCl$, from which it follows that the at. wt. of calcium is 40·46. J. J. Berzelius first assumed the formula of the oxide is CaO_2, but this was later altered to CaO, with a corresponding change in the at. wt. The last-named formula would make the at. wt. of calcium approximate to 40, the former to 20. The former value is in harmony with Dulong and Petit's sp. ht. rule; with Mitscherlich's isomorphic law; with Mendeléeff's periodic law; and with J. H. van't Hoff's extension of Avogadro's hypothesis to soln. J. J. Berzelius' value is rather too high. In 1841, S. Baup made some interesting analyses of some calcium salts of organic acids, and obtained the at. wt. 39·98 for calcium when that of oxygen is 16. This result, however, is usually regarded as being too much affected by errors to have much weight in comparison with more modern measurements. J. L. Gay Lussac and L. J. Thénard quote 40·3 for the at. wt. of calcium. T. Thomson discussed the at. wt. of strontium, barium, and calcium. A. Salvétat made a statement without details, of some results he had obtained by measuring the amount of carbon dioxide obtained from a given amount of calcium carbonate. The other determinations of this constant include:

1. *Evaluation of the ratio $CaO : CaCO_3$.*—In 1842, J. B. A. Dumas ignited Iceland spar, and determined the amount of CO_2 evolved and of the calcium oxide remaining. A correction was made for the impurities in the spar. As a result he obtained 40·171 for the at. wt. of calcium (O=16). The same year O. L. Erdmann and R. F. Marchand made similar determinations with native carbonate and with artificial carbonate. They obtained 40·005. J. J. Berzelius pointed out that the artificial carbonate retains moisture even at 200°, and some chloride from the mother liquid also adheres to the precipitate. These errors act in opposite directions and tend to balance one another. In 1844, the same investigators, working with Iceland spar, obtained 40·068 for the at. wt. of calcium; and in 1850, they obtained 39·996. They also observed that carbon dioxide is liable to be retained by the lime after ignition. In 1897 and 1901, A. Herzfeld, with artificial calcium carbonate, obtained 39·996; and F. W. Hinrichsen, 1901–02, obtained 40·142 with Iceland spar and 40·137 with a sample from the Crimea.

2. *Evaluation of the ratio $CaCO_3 : CaSO_4$.*—In 1842, O. L. Erdmann and R. F. Marchand treated calcium carbonate with sulphuric acid, and weighed the resulting calcium sulphate. They obtained 40·02 for the at. wt. of calcium. In 1843, J. J. Berzelius by an analogous method obtained 40·22; and in 1913, W. O. de Coninck 40·12.

3. *Evaluation of the ratio $CaCl_2 : 2AgCl$.*—J. J. Berzelius' determination of this ratio in 1809, *vide supra*, furnished 40·46; in 1843, J. C. G. de Marignac obtained 40·21; J. B. A. Dumas in 1859, 40·103; and T. W. Richards in 1902, obtained 40·126. The general mean of all the determinations is 40·13; and the International Atomic Weight Commission recommend 40·1 or 40·07 as the best representative value.

The at. wt. determinations for strontium resemble in general procedure those employed for calcium and barium, but they are fewer in number. F. Stromeyer[2] in 1817, and A. Salvétat in 1843, measured the volume of carbon dioxide evolved from a given amount of strontium carbonate. From the ratio $SrCO_3 : CO_2$ the former obtained 87·3, and the latter 88·0 for the at. wt. of strontium. With the exception of these results, and J. C. G. de Marignac's determination of the ratio $SrCl_2.6H_2O : H_2O$, and of $SrCl_2 : SrSO_4$, where the former gave 87·41, and the latter 87·1 for the at. wt. of this element, and T. E. Thorpe and A. G. Francis' 87·677 from the ratio $SrBr_2 : SrSO_4$, and 87·668 from the ratio $SrBr_2 : SrSO_4$, investigations have centred about the ratio $SrX_2 : 2AgX$, or $SrX_2 : 2Ag$, where X represents an atom of chlorine or bromine. In 1816, H. Rose evaluated the ratio $SrCl_2 : 2AgCl$ and found 87·31 for the at. wt. of strontium; T. J. Pelouze (1845), 87·70; J. C. G. de Marignac (1858), 87·49; J. B. A. Dumas (1859), 87·53; T. W. Richards (1894), 87·617; T. W. Richards (1905), 87·616; and T. E. Thorpe and A. G. Francis (1910), 87·632. The general mean of the best determinations is 87·6; the International Atomic Weight Commission recommends 87·63 as the best representative value.

During the earlier part of the nineteenth century a number of determinations of the at. wt. of barium were made with widely varying results, namely, 134 to 143, The at. wt. has been computed from the results obtained by the analysis of barium carbonate; by converting the barium chloride or nitrate into the sulphate; and by converting barium halide into the corresponding amount of silver halide, or silver. A. Levol[3] reduced auric chloride with sulphur dioxide, and determined the resulting sulphuric acid with barium chloride, and thus obtained the ratio Au : $BaSO_4$; from his data, the at. wt. of barium would now be represented by 139·3. J. C. G. de Marignac obtained some ratios including water of crystallization, but the results were poor, for they varied from 130·7 to 138·5. P. A. Guye and D. E. Tsakalotos critically examined this method and concluded the process is not suited for the determination in question. T. Andrews also gave 137·6 for the at. wt. of barium without indicating how that result was obtained. In 1883, F. W. Clarke selected 137·0 from all the available data; in the same year, L. Meyer and K. Seubert selected 137·2; in 1885, W. Ostwald, 137·04; in 1886, J. D. van der Plaats, 137·1; B. Brauner in 1905, 137·43; and F. W. Clarke in 1910, 137·363. The International Atomic Weight Commission recommends 137·37 as the best representative value.

1. *The analysis of barium carbonate.*—In 1811, J. J. Berzelius analyzed barium carbonate, and obtained numbers ranging between 134·2 and 143·3 (oxygen 16). W. H. Wollaston, in 1814, obtained 139·2; and A. Salvétat converted the carbonate into sulphate, and obtained 136 for the at. wt. of barium. These results are only of historical interest.

2. *Evaluation of the ratio $BaCl_2$: $BaSO_4$, or $Ba(NO_3)_2$: $BaSO_4$.*—In 1818, J. J. Berzelius found that 100·00 parts of barium chloride yielded 112·175 parts of barium sulphate, which gives 135·6 for the at. wt. of barium. E. Turner, in 1829, obtained 135·4; T. Thomson, in 1831, obtained 136; H. Struve, in 1851, obtained 137·0; J. C. G. de Marignac, 138·5; and T. W. Richards, in 1893, obtained 137·43 ± 0·2. E. Turner, in 1833, obtained 137·0 from the ratio $Ba(NO_3)_2 : BaSO_4$.

3. *Evaluation of the ratio $BaCl_2$: $2AgCl$, or $BaBr_2$: $2AgBr$.*—In 1818, J. J. Berzelius obtained 138·07 parts of silver chloride from 100·00 parts of barium chloride; this gives 136·8 for the at. wt. of barium. T. Thomsen, in 1831, obtained in the same manner 136; E. Turner, in 1829, obtained 137·4; J. C. G. de Marignac, in 1858, obtained 137·1; T. E. Thorpe, in 1908, obtained 137·48; T. W. Richards, in 1893, obtained 137·44 from the ratio $BaCl_2 : 2AgCl$, and 137·43 from the ratio $BaBr_2 : 2AgBr$.

4. *Evaluation of the ratio $BaCl_2$: $2Ag$, or $BaBr_2$: $2Ag$.*—In 1845, T. J. Pelouze measured the amount of barium chloride required for the precipitation of a soln. of a known weight of silver in nitric acid, and obtained for the at. wt. of barium 137·28; J. C. G. de Marignac obtained 137·11 in 1848, and 137·15 in 1858; J. B. A. Dumas, in 1859, obtained 137·00; and T. W. Richards, in 1893, obtained 137·44 for the same ratio, and for the ratio $BaBr_2 : 2Ag$, he obtained 137·43.

A. Sakoschansky[4] discussed the relationship between the at. wt. of strontium and calcium. G. P. Thomson, and A. J. Dempster found that the at. wt. of calcium and strontium are simple in that they are not compounded of sets of isotopic elements. There are no **isotopes**.

F. W. and A. Dupré[5] reported the presence of a fourth member of the alkaline earth family which gave a faint blue spectral line "between the Sr_δ and K_β about twice as far from the former as from the latter, in brightness and sharpness of definition quite equal to the line Sr_β." W. Crookes showed that the blue line is not due to the new element but is a characteristic line belonging to calcium.

§ 6. The Hydrides of the Alkaline Earths

Acetylene prepared from some specimens of calcium carbide, even after being filtered through cotton wool, and passed through water, gave a deposit of calcium oxide in the conducting pipes, a fact which led C. Hoffmeister[1] to assume that a volatile calcium hydride must be present. The fumes of sulphur trioxide, however, will pass through a long train of wash-bottles, without being wholly absorbed; this favours the assumption that fine particles of a solid calcium compound can be carried along with the stream of gas. C. Hoffmeister attempted to isolate the gas by passing a large vol. of acetylene through a number of wash-bottles containing acetone, and then through an ammoniacal copper soln. to remove the acetylene. The colourless gaseous residue burned in air, forming calcium oxide and water, and formed an exceedingly explosive mixture with oxygen. The residual gas was never obtained free from air, and its composition was not determined. C. Winkler ascertained that when the oxides of the alkaline earths are reduced with magnesium, in an atm. of hydrogen, a compound is formed which he regarded as a hydride of the alkaline earth, and symbolized CaH, SrH, or BaH; and he noted that these hydrides are decomposed by contact with water, forming hydrogen gas. Neither C. Hoffmeister's gaseous hydride, nor C. Winkler's hydrides of the type MH, have been substantiated. C. Winkler, however, probably prepared a mixture of the alkaline earth metal M and a hydride of the type MH_2, because the latter have since been made. C. R. Hansen claimed to have obtained evidence of the formation of a calcium hydride, CaH, from his observations on the vap. press. of the normal hydride, CaH_2. The composition of normal **calcium hydride** can be represented by the formula CaH_2, and this is evidenced by the amount of hydride formed from a given weight of calcium, and from the amount of hydrogen evolved when the compound is treated with water. Similarly, the composition of **strontium hydride** agrees with SrH_2, and of **barium hydride** with BaH_2. B. von Lengyel found that metallic calcium slowly absorbs hydrogen at ordinary temp., and rapidly at a dull red heat, forming a white pulverulent hydride.

H. Moissan prepared calcium hydride by heating crystallized calcium, contained in a nickel boat, to dull redness in an atm. of dry hydrogen. G. F. Jaubert, and the Elektrochemische Werke, Bitterfeld, patented the preparation of calcium hydride by passing hydrogen through molten calcium contained in an iron vessel for a few minutes. H. Gautier heated a cadmium-calcium alloy to dull redness in hydrogen, and volatilized the cadmium under reduced press. in hydrogen; a similar process was employed for the corresponding hydrides of strontium and barium. A. Guntz and G. Röderer made strontium hydride by heating an 8 per cent. strontium amalgam in a stream of hydrogen; amalgams with a higher content of strontium are not so suitable for the purpose, since they oxidize so readily. The mercury is distilled by heating in hydrogen to 1000°. A. Guntz prepared barium amalgam in a similar manner. K. Kaiser prepared calcium hydride by passing hydrogen over calcium chloride at 700° until no further evolution of hydrogen chloride occurs; and A. Kiesewalter made it by heating calcium oxide by the arc flame in a stream of hydrogen; if too little hydrogen is used some metallic calcium is formed along with the calcium hydride.

According to F. Ephraim and E. Michel, while the hydrides of the alkali metals are formed slowly, those of the alkaline earth metals are formed rapidly and with incandescence. This is attributed to the greater solubility of the hydride in the metal. The liquid nature of the alkali hydrides at their temp. of formation also contributes to the slowness of the reaction, since the eutectic which is formed protects the metal from the hydrogen. The hydride is a white pulverulent or fused cake with a crystalline fracture. The commercial product is grey, and it was found by G. F. Jaubert to contain 90 per cent. of calcium hydride, and 10 per cent. of oxide and nitride. According to H. Moissan, the **specific gravity** of calcium hydride is 1·7; A. Guntz gives for barium hydride 4·21. According to H. Moissan, calcium hydride does not dissociate when heated in vacuo at 600°, but, according to H. Gautier, **dissociation** is perceptible at 675°. C. R. Hansen found the vap. press. of calcium hydride to be:

	605°	675°	712°	735°	750°	780°	795°
Press. (mm.) . .	28·1	66·3	143·6	269·7	410·0	653·5	854·0

The dissociation press. of strontium hydride was found by H. Gautier to be 100 mm. at 1000°, 300 mm. at 1100°. It is easily decomposed in vacuo at 900°. H. Gautier says barium hydride begins to dissociate at 675°; and A. Guntz found an appreciable volatilization occurs at 1200°, and the vapour is green when viewed through cobalt-blue glass; he also gives 1200° for the **melting point** of barium hydride. According to A. Guntz and H. Basset, the **heat of formation** of calcium hydride is: $Ca+H_2=CaH_2+46{\cdot}20$ Cals.; of strontium hydride, 34·7 Cals.; and of barium hydride, according to A. Guntz, 55·0 Cals. H. Moissan found that a 5 cm. homogeneous compact layer is a non-conductor of electricity.

H. Moissan found that calcium hydride could be heated to the softening point of Bohemian glass in an atm. of **hydrogen** without gain or loss in weight. According to H. Moissan, and B. von Lengyel, calcium hydride can be heated in air on a platinum foil without alteration, but when heated to redness in **air** or **oxygen,** it burns brilliantly, and sufficient heat is developed to fuse the calcium oxide produced. H. Gautier also found that strontium hydride burns slowly in air at a red heat, forming a skin of strontium oxide which protects to some extent the hydride underneath. A. Guntz made similar observations with respect to barium hydride. With oxygen, the reaction is vigorous. According to H. Moissan, calcium hydride is readily decomposed by **water** and dil. acids: $CaH_2+2H_2O=Ca(OH)_2+2H_2$, as indicated in connection with hydrogen. G. F. Jaubert emphasized the use of calcium hydride in the preparation of hydrogen for aeronautical purposes. A kgrm. of the commercial hydride gives a cubic metre of hydrogen. With a little water,

B. von Lengyel found that so much heat is produced that the hydrogen inflames spontaneously. H. Gautier found strontium hydride behaves similarly. According to A. Guntz, the heat of the reaction with water is $BaH_{2\text{solid}}+nH_2O_{\text{liquid}}=Ba(OH)_{2\text{soln.}}+2H_{2\text{gas}}+37.5$ Cals. No solvent for the hydrides of the alkaline earths is known.

The hydrides of the alkaline earths are powerful reducing agents. H. Moissan, and B. von Lengyel noted that calcium hydride is decomposed with incandescence when heated to dull redness with the **halogens.** In the cold, **chlorine** does not act on the hydride, but, when warmed, calcium and hydrogen chlorides are formed; **bromine** and **iodine** behave similarly. H. Gautier found strontium hydride behaved similarly, boiling bromine has no action, while the reaction is vigorous at a red heat. H. Moissan found that hydride is decomposed by **hydrogen chloride,** forming water and barium chloride. Conc. **hydrochloric acid** has but little action in the cold, but if heated a reaction ensues; and a vigorous action occurs with the dil. acid. According to H. Moissan, when a mixture of calcium hydride with **sodium fluoride** or **potassium fluoride** is heated to 500°, hydrogen and the vapour of the alkali metal are formed; **silver fluoride** reacts when triturated with calcium hydride in the cold, producing silver and calcium fluoride; **mercuric fluoride** and **lead fluoride** are reduced at 400°; **sodium chloride** at a red heat is reduced to sodium; molten **potassium iodide** does not react with calcium hydride; but silver iodide reacts vigorously. Molten **potassium chlorate** is reduced with violence; and, generally, **chlorates, bromates,** or **iodates** furnish explosive mixtures; a violent explosion occurs when calcium hydride is rubbed up in a mortar with **potassium perchlorate.** H. Gautier found a vigorous reaction under similar conditions between strontium hydride and chlorates, perchlorates, and bromates; but with iodates the reaction is less vigorous.

B. von Lengyel found that when heated in **sulphur** vapour, calcium hydride is decomposed, forming a dark grey mass; some calcium sulphide is formed; H. Gautier also found strontium hydride forms strontium sulphide under similar conditions. H. Moissan also found that calcium hydride is decomposed when heated with sulphur vapour, but no action was observed with **selenium** vapour at the m.p. of glass. F. M. Perkin and L. Pratt obtained calcium selenide from a mixture of selenium and calcium hydride; they also found **lead sulphide** and **antimony sulphide** react with calcium hydride, producing but little metal, but possibly forming a calcium antimony (or lead) sulphide. H. Gautier also found dichromates and lead or copper oxide are vigorously reduced by strontium hydride. He found **hydrogen sulphide** is decomposed by calcium hydride at a red heat, forming calcium sulphide and hydrogen; and **sulphur dioxide** is reduced to a hydrosulphite by calcium or strontium hydride. Conc. **sulphuric acid** has but little action in the cold, but when heated a reaction ensues; dil. sulphuric acid has a vigorous action.

Calcium hydride was found by H. Moissan not to be affected when heated with **nitrogen** at the m.p. of glass. H. Erdmann and H. van der Smissen observed no evidence of the formation of ammonia when calcium hydride is heated with nitrogen between 500° and 800°. S. Reich and H. O. Serpek said that some ammonia is produced at 500°, but the main reaction results in the formation of calcium nitride. H. Gautier found strontium hydride is partially decomposed by nitrogen at 600°; and A. Guntz found that, at a temp. below redness, barium hydride forms the nitride: $3BaH_2+N_2=Ba_3N_2+3H_2$; and H. Moissan obtained barium amide, $Ba(NH_2)_2$, by heating the hydride with **ammonia.** The **nitrogen oxides** are reduced to ammonia when heated to dull redness with calcium hydride. B. von Lengyel and H. Moissan reported that **nitric acid** behaves like sulphuric acid. Calcium hydride is decomposed when heated with **phosphorus** vapour. F. M. Perkin and L. Pratt said that a mixture of calcium hydride and red phosphorus cannot be ignited by a fuse, but if some calcium be also present, the reaction furnishes red calcium phosphide. H. Moissan observed no change occurred when calcium hydride is heated to the m.p. of glass with **boron** or with **silicon ;** but with silicon C. R. Hansen obtained a silicide ; calcium hydride also reacted with **porcelain** and **glass.** F. M. Perkin and L. Pratt found that calcium hydride reduced **boron trioxide** and also **silica.** When heated to 700°–800° with finely divided **carbon,** H. Moissan obtained some calcium carbide, and M. Mayer and V. Altmayer observed the formation of methane and other products. M. Mayer and V. Altmayer found that **carbon monoxide** does not react with calcium hydride between 300° and 400°, but at a higher temp. some methane is formed: $3CaH_2+3CO=CH_4+2C+H_2+3CaO$; there is also a secondary reaction: $CaH_2+2C=CaC_2+H_2$. According to S. Reich and H. O. Serpek, some formaldehyde is also produced. H. Moissan found that when heated to dull redness, **carbon dioxide** is reduced by calcium hydride, forming carbon, and calcium formate and carbide; and M. Mayer and V. Altmayer obtained some methane: $2CO_2+4CaH_2=CH_4+4CaO+C+2H_2$, as well as calcium formate and oxalate. H. Moissan noted that calcium hydride is not dissolved by, nor does it react with, thoroughly dried *carbon disulphide, carbon tetrachloride, benzene, turpentine, alkyl iodides, alkyl chlorides,* or *ethers ;* but it slowly attacks **ethyl alcohol.** B. von Lengyel said the last reaction is *lebhaft.* S. Reich and H. O. Serpek found mesityl oxide and a cyclic substance, b.p. 226°–236°, is produced in the energetic reaction between calcium hydride and **acetone.** The vapour of **carbon tetrachloride** is decomposed at 400°, forming carbon, hydrogen, and hydrogen chloride ; **pyridine** has no action at the m.p. of glass. Calcium hydride acts as a reducing agent only at high temp., and its use in the hydrogenation of organic substances must be very limited, since when it does react condensation products are formed. F. M. Perkin and L. Pratt found that calcium hydride reduces **cupric oxide, manganese dioxide, ferric oxide, stannic oxide, lead oxide,** and **tungstic oxide ;** but not **zinc oxide.** According to S. Reich and H. O. Serpek, formic acid is produced when a mixture of calcium hydride and **sodium carbonate or hydrocarbonate** is gently heated. The reactions are not usually so violent as when calcium is employed as reducing agent. C. R. Hansen found that calcium hydride is decomposed by **mercury** above 200°. E. Ebler and K. Herrdegen found that calcium hydride reduces **barium sulphate** to a mixture of calcium and barium oxides and sulphides, and hydrogen gas is evolved.

§ 7. The Preparation of the Oxides of Calcium, Strontium, and Barium

The alkaline earths form oxides of the type MO and MO_2. There are also the hydroxides, $M(OH)_2$. Both the dioxides, MO_2, and the hydroxides, $M(OH)_2$, can be prepared with water of crystallization ; and the dioxides, also, with hydrogen peroxide of crystallization. The so-called suboxides are not generally recognized as chemical individuals. The monoxides of barium, strontium, and calcium are respectively called *baryta, strontia,* and *lime.*

A. Guntz and H. Basset [1] tried to make *calcium suboxide*, Ca_2O, by melting calcium with calcium oxide in an indifferent atm., but without success. A. Guntz, however, claimed to have made *barium suboxide*, Ba_2O, by heating a mixture of eq. amounts of barium or magnesium with barium oxide in vacuo at 1100°. The reaction is violent, and the magnesium should not be too finely powdered, nor the baryta too much peroxidized. The product is said to decompose water; to absorb nitrogen at a red heat, forming the nitride, and also to absorb hydrogen under similar conditions, forming the hydride. Barium suboxide dissociates at a high temp., forming barium oxide and barium. A. Guntz said the product is not a mixture of barium and magnesium oxide, because it does not give hydrogen in accord with $2Ba[+2MgO]+4H_2O=2Ba(OH)_2[+2MgO]+2H_2$, but rather in accord with $Ba_2O[+MgO+Mg]+3H_2O=2Ba(OH)_2[+MgO+Mg]+H_2$.

The three oxides, **calcium monoxide,** CaO; **strontium monoxide,** SrO; **barium monoxide,** BaO, are also called *lime*, *strontia*, and *baryta* respectively. Lime is also called *quicklime*—the term "quick" is applied in several European languages to represent the living active nature of lime, especially towards water. They are produced by the oxidation of the metal; traces of the dioxide may be simultaneously produced, and this the more with barium than with calcium. The oxides are produced by the calcination of the carbonates, for instance, with calcium carbonate: $CaCO_3=CaO+CO_2$; but the last traces of the carbon dioxide are expelled with difficulty. The calcium oxide obtained by calcining calcium carbonate has been variously styled *quicklime, burnt lime, caustic lime*—from καυστικός, burnt—*live lime*, etc. This method of preparing calcium oxide is very old, for, under the name lime-burning, it was employed in making mortar, thousands of years ago. It is mentioned in the Pentateuch (*Deut.* **27.** 2). Cato's *De re rustica*, Vitruvius' *De architectura* (**2.** 5), and Pliny's *Historia naturali* (**36.** 55), described the process of manufacturing lime and mortar.

The primitive lime-kilns were rudely constructed of stone blocks, and usually located in a cavity cut in the side of a hill, so that the top was convenient for charging the kiln with limestone. In charging the kiln, large pieces of limestone were formed into a dome-like arch with large open joints; and the kiln was filled with fragments of limestone—the larger pieces of limestone were placed above the arch, and the kiln was topped with fragments of smaller size. Kilns were also charged with alternate layers of limestone and fuel. A wood or other fire was started under the arch, and a bright heat was maintained for three or four days. The kiln was then cooled and the quicklime removed. These temporary intermittent kilns are still in use in districts where the demand is small. In the more permanent shaft-kilns, alternate layers of fuel and limestone are fed in at the top of the kiln and burnt limestone is withdrawn at the bottom, so that the process is continuous—limestone is charged in at the top and removed at the bottom. It will be observed that the air required for the combustion of the fuel is pre-heated by passing through the lime from the burning zone, and at the same time the hot lime is cooled; the products of combustion also heat the limestone on its way to the hot zone. Many kilns are provided with automatic feeding or discharging gear. The carbon dioxide can also be recovered, as in the shaft-kiln illustrated in Fig. 8. The temp. in the different zones are indicated in the diagram. In some of the more recent shaft-kilns, producer gas is led into the shaft near the base, and burnt in the shaft.[2] Commercial limes differ much in composition; they may contain anything from 0 to 40 per cent. of magnesium oxide, and more or less silica, alumina, and iron oxide. The lime should contain no water and less than half per cent. of carbon dioxide. The composition of the lime will be the same as that of the limestone from which it was prepared, less the carbon dioxide and plus impurities derived from the lining of the kiln, fuel ash, etc. For commercial purposes, limes carrying less than 5 per cent. of magnesium oxide can be designated *high-calcium limes*; and those with over 5 per cent., *magnesian limes*. The latter are less plastic or smooth to the trowel in working the mortar, and

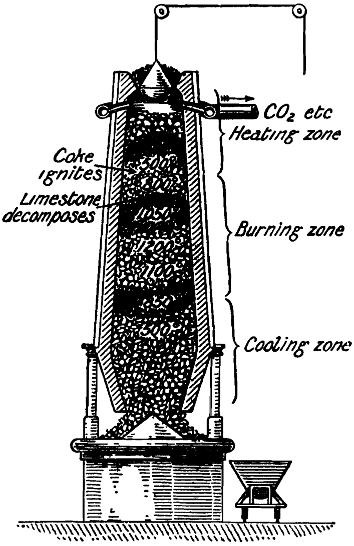

FIG. 8.—Simple Type of Shaft Lime-kiln.

they are disliked by the workmen, who call them "weak," "lean," or "poor" limes in contrast with the high calcium limes which are called "strong," "fat," or "rich" limes. The magnesian limes slake more slowly, and develop less heat than the high calcium limes. Lime with over five per cent. of impurities other than magnesium oxide will also be comparatively slow in slaking, and exhibit the lean or weak qualities. The following represent extremes of the different types :

		Lime.	Silica.	Alumina and ferric oxide.	Magnesia.	Carbon dioxide.
High Ca	Fat	98·4	0·2	0·2	1·0	0·2
		94·3	3·4	1·2	0·3	0·8
	Lean	84·4	5·5	2·0	1·8	—
		81·4	2·4	6·8	1·3	—
High Mg	Lean	90·2	0·1	1·7	6·0	0·3

In his paper embodying *Experiments and observations on terra ponderosa* (*i.e.* barium carbonate), W. Withering stated :

> It is very remarkable that the *terra ponderosa spar* in its native state will not burn to lime. When urged with a stronger fire it melts and unites to the crucible, but does not become caustic.

J. Priestley added his testimony to the fact that *terra ponderosa aërata* gives no fixed air by mere heat ; but when steam is passed over the mineral at a red heat in an earthen tube, "fixed air is produced with the greatest rapidity, and in the same quantity, as when it is dissolved in spirit of salt." Consequently, hypotheses respecting the relation of water to carbon dioxide were made by both W. Withering,[3] and by J. Priestley ; but the hypotheses had to be discarded when T. C. Hope showed that the "fixed air can be expelled from native aërated barytes by heat alone, if sufficiently intense . . . by the assistance of the heat of a smith's forge, the barytic spar can be deprived of its acid, either entirely, or nearly so." H. Abich, and F. C. Schaffgotsch, showed that strontium carbonate does decompose at a high temp. J. T. Conroy found that the decomposition is slow when strontium carbonate is heated by a Bunsen flame, but faster when heated in the blast. According to C. Stiepel and A. Herzfeld, strontium carbonate forms no oxide when heated an hour at 1100° ; but at 1190°, 37 per cent. of oxide is formed ; and at 1250°, decomposition is nearly complete. W. Dittmar found barium carbonate decomposes completely when heated in a blast. According to P. Pott, there is a measurable dissociation of calcium carbonate at 525°, of strontium carbonate at 660°, and of barium carbonate at 1020°. K. Friedrich found that there is an incipient dissociation of calcspar and aragonite at 895°, and the dissociation is complete at 910° ; with strontianite and witherite, incipient dissociation occurs respectively at 1130° and 1100°. According to J. L. Gay Lussac :

> If calcium carbonate be heated to the temp. at which it begins to decompose, the atm. of carbon dioxide which is formed hinders the subsequent development of the gas, for if any more gas is developed it must overcome the press. of the atm. of that gas. Consequently, a higher temp. must be applied, or the atm. of carbon dioxide be removed either by exhaustion or atm. air.

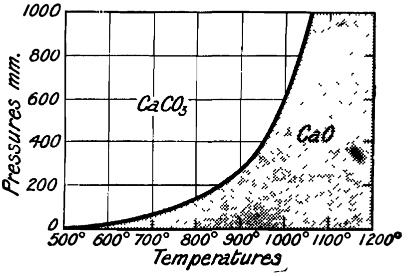

FIG. 9.—Effect of Temperature on the Dissociation Pressure of Calcium Carbonate.

The first measurements of the dissociation press. of calcium carbonate were made by H. Debray, who worked at the m.p. of cadmium and of zinc, and he estimated the dissociation temp., at 760 mm. press., to be 1000°. H. le Chatelier showed that if calcium carbonate be heated in a closed vessel, at different temp., when the system is in equilibrium the state of the system will be represented by a point on the curve, Fig. 9, where the press. in the closed vessel are plotted at different temp. H. le Chatelier's data are plotted in Fig. 9. J. Johnston's values are considered to be more exact; they are here interpolated by the formula: $\log p=-9340T^{-1}+1{\cdot}1 \log T -0{\cdot}0012T+8{\cdot}882$:

	500°	600°	700°	800°	850°	900°	950°	1000°
$CaCO_3$ . .	0·11	2·35	25·3	168	373	773	1490	2710 mm.

H. Riesenfeld gave a more complicated expression in terms of W. Nernst's heat theorem. According to J. Johnston, the **dissociation temperature,** at atm. press., is 898°; H. Riesenfeld gave 908°; D. Zavrieff, 920°; and O. Brill, 825°. H. le Chatelier's value 812° is now considered too low, and 890° is the best representative value of later work. P. Pott's values for strontium carbonate are:

	492°	650°	850°	950°	1050°	1150°	1256°	1263°
$SrCO_3$ . .	9·3	18	50	99	175	320	744	785 mm.

F. Isambert found the dissociation press. of barium carbonate, at 1083°, in a stream of an indifferent gas, is 22 mm. P. Pott further found:

	997°	1017°	1057°	1097°	1137°	1157°	1177°	1197°
$BaCO_3$ . .	0	5	45	120	240	340	450	675 mm.

A. Finkelstein also measured the dissociation press. of barium carbonate and represented his results by $\log (p_1/p_2)-14300(T_1-T_2)/T_1T_2$. P. Pott further found that the dissociation temp. of strontium carbonate at one atm. press. is 1250°; and of barium carbonate, 1200°. The press. curve of strontium carbonate crosses that of barium carbonate at 1160°. O. Brill gives the dissociation temp. of strontium carbonate 1155°; A. Herzfeld and C. Stiepel found it to be approximately 1450°. O. Brill could not determine the temp. exactly because the platinum crucible was so violently attacked. J. A. Hedvall gave 913°–928° for the dissociation temp. of calcium carbonate; 1141° for strontium carbonate; and 1361° (the m.p.) for barium carbonate. The dissociation temp. of calcium carbonate was found to be independent of the size of grain; and the dissociation of strontium carbonate becomes rapid only at about 1255°. K. Friedrich and L. G. Smith give 895° for the temp. at which aragonite or calcite begins to decompose, and 910° for the temp. at which the maximum heat change occurs on the heating curve; and for strontianite and witherite, he obtained a temp. over 1130° when dissociation begins.

There are three phases—CaO, $CaCO_3$, and CO_2; and two components—CaO and CO_2. The system is therefore univariant, meaning that the conc.—that is, the press.—of the gas for each temp. has one fixed definite value called the **dissociation pressure.** The dissociation press. of calcium carbonate is analogous, in many ways, with the vap. press. of a liquid in a closed space. Gaseous molecules of carbon dioxide are continually leaving the dissociating carbonate, and carbon dioxide is continually recombining with calcium oxide. When the speeds of the two reactions are the same, the system is in equilibrium. The carbonate can only dissociate completely into calcium oxide and carbon dioxide if the latter be continuously removed from the reacting system. If the press. at any temp. exceeds the limit indicated by the curve, calcium carbonate will be formed until the press. of the gas attains the fixed value, constant for the given temp.; and, conversely, if the press. be less than that described by the curve, calcium carbonate will dissociate until the required press. is attained. P. Jolibois and P. Bouvier found that the reversal of the dissociation on cooling with most forms of calcium carbonate is never complete except when precipitated calcium carbonate is dissociated by heat in the presence of an excess of calcium oxide. The disturbance is due to secondary changes.

These facts are of interest in that they explain how marble or calcium carbonate can be associated with igneous rocks whose temp., at certain geological epochs, must have exceeded that of the lime-kiln. J. Hutton pointed out in 1798 that the calcium carbonate in the lime-kiln bears only the press. of the atm., which is not sufficient to delay for long the separation of the carbon dioxide from the limestone, whereas in plutonic regions, the enormous press. which existed must have hindered the decomposition, and allowed the calcium carbonate to melt and fuse. J. Hall verified this conclusion by making over 400 experiments on the influence of press. on the melting of calcium carbonate. C. F. Buchholz, A. Petzholdt, L. Pilla, G. Rose, J. Lemberg, A. Becker, A. Wichmann, H. le Chatelier, A. Joannis, H. E. Boeke, F. Rinne, and H. Leitmeier have also experimented on this subject, and shown that if the press. of the gas be great enough, the calcium carbonate may be fused with no appreciable dissociation. On solidification, the mass has a crystalline structure like marble. The melting of barium carbonate under press. has also been investigated by H. le Chatelier, O. Brill, A. Herzfeld and C. Stiepel, A. Finkelstein, H. E. Boeke, and O. Mügge.

It can be assumed that all solids, calcium carbonate and calcium oxide, exert a small vap. press. which is generally too small to come within the range of the instruments at present available for such measurements. This vap. press. is further assumed to be constant at any given temp., like the vap. press. of substances which are accessible to measurement; and is also unaffected by the quantity of solid present.

According to the so-called mass law, the velocity of the dissociation of calcium carbonate will be proportional to the conc. of the carbonate, and equal to the product of the conc. C of the carbonate and the affinity constant k; the velocity of formation of the calcium carbonate will similarly be equal to the product of the conc. of the calcium oxide, C_1, and of the carbon dioxide, C_2, with the affinity constant k' of that reaction. Consequently, if these two velocities are the same, the system will be in equilibrium, and $kC=k'C_1C_2$. The conc., that is, the number of molecules of carbon dioxide per litre, is proportional to the partial press. p of that gas. The conc. C and C_1 are constant, and consequently, at any given temp., the press. p is constant. This means that the dissociation press. of the carbon dioxide is independent of the extent to which the calcium carbonate has dissociated, provided some of the carbonate remains. This same conclusion was obtained in applying the phase rule. The velocity constant k for the decomposition of the carbonates of the alkaline earths in the equation $dC/dt=kC$, was measured by P. Pott, and he found:

	$CaCO_3$			$SrCO_3$		$BaCO_3$	
	770°	846°	890°	1080°	1200°	1195°	1220°
k . .	0·009	0·037	0·042	0·009	0·03	0·00076	0·00076

Hence, the velocity of the reaction with calcium carbonate is greatest and with barium carbonate least—that of strontium carbonate is approximately one-twentieth of that of calcium carbonate, and that of barium carbonate is about half that of strontium carbonate. The velocity constant of calcium carbonate undergoes a five-fold increase per 100° rise of temp. The physical character of the carbonate has some influence on the speed of dissociation, for A. Herzfeld found that limestone is completely decomposed after many hours' heating at 900°, while marble, under similar conditions, suffers very little change, although at 1030° it is completely decomposed.

The burning of limestone at atm. press. should not be effected below 890°, since only at this temp. does the carbon dioxide attain atm. press. when the gas can escape at a sufficient speed. This high temp. is technically expensive, and proposals have been made to burn the lime at a lower temp. and to pass a current of inert gas like air over the heated limestone. A. Herzfeld, for instance, found that in the presence of steam at 700°, calcium carbonate forms calcium hydroxide, while with air alone, a heat of 1000° is required to decarbonate the limestone. H. Rose also found barium carbonate does not decompose at a red heat in dry air, but in moist air or in water vapour decomposition occurs. P. Duhem has showed that the important principle: *When a body is decomposed by heat, it is not the press. of any gas or vapour chosen at random, which can stop its decomposition, but rather* *the gas which arises from the decomposition which alone can act*, was first enunciated by G. Aimé in an important thesis: *De l'influence de la pression sur les actions chimiques* (Paris, 1837). Consequently, in the present case, it is not the total press. but solely the partial press. of the carbon dioxide which must be taken into consideration. An inert gas acts as a vacuum because the press. of the carbon dioxide over the heated material will be the partial press. of the carbon dioxide in the whole gaseous atm. Thus, at 610°, the partial press. will be 46 mm. As the carbon dioxide corresponding to this press. is carried off, the equilibrium is disturbed, and more calcium oxide is formed. This continues until the whole of the carbon dioxide is dissociated.

As T. Bergmann[4] pointed out, workmen reject lime which is too much burned —*dead-burned lime*—as being useless, because it does not fall into powder when slaked. Lime which has been less burned falls into powder at the instant of slaking, and is then in a form suitable for making into mortar. Limestone containing clay is particularly liable to dead-burning, presumably because a more or less inert calcium silicate or alumino-silicate is formed which is not free to take part in slaking—*vide* calcium hydroxide. A. Herzfeld found 8 per cent. of silica suffices for the dead-burning of lime at 1000°, alumina is less active than silica and required a higher temp. to produce dead-burning. A. F. Gehlen, and J. F. W. Nasse found that purified calcium carbonate is not liable to dead-burning. A. Herzfeld, and P. Lebeau observed that calcium oxide which has been fused can be slaked by water, but the action is very slow. C. F. Buchholz, and L. J. Vicat found oyster-shells and chalk are liable to be dead-burnt. H. Rose, and J. N. von Fuchs attributed the so-called dead-burning by the under calcination of limestone to the formation of a **basic carbonate,** but A. Herzfeld obtained no evidence of the existence of such a chemical individual. The subject has been discussed by A. R. Schultaschenko, F. M. Raoult, and A. Finkelstein. Neither O. Brill nor A. Herzfeld could find any evidence of the formation of a basic calcium carbonate on the heating curves; nor is there any satisfactory evidence of the formation of a basic strontium or barium carbonate. The calcium carbonate remaining in underburned lime acts as so much inert matter.

J. P. J. d'Arcet made barium oxide by the action of an alkali lye on a soln. of a barium salt, and calcining the washed product. Strontium and barium oxides can be made by calcining the respective carbonates as indicated below; and also by calcining the nitrates (A. F. de Fourcroy and L. N. Vauquelin,[5] P. J. Robiquet, and A. C. Jaquelain); or the hydroxides (D. Smith). L. N. Vauquelin, and L. J. Thénard prepared baryta by heating barium nitrate until it is completely decomposed; a moderate heat is employed at first, and a very strong heat towards the end of the process. J. J. Berzelius recommended adding a few spoonsful of the nitrate to a crucible heated to bright redness, and heating the contents in the covered crucible until the mass had solidified. More nitrate was added, and the process continued until the crucible was half filled with baryta. If too much nitrate is added at once, the mass boils over. If a platinum crucible is employed, the baryta is difficult to detach from the metal; the platinum is oxidized and contaminates the baryta. If a fireclay crucible be employed, the baryta will be contaminated with silica, alumina, and iron and manganese oxides. As pointed out by G. Brügelmann, and C. F. Rammelsberg, if the calcination is conducted while the nitrate is exposed to air, oxygen and carbon dioxide may be absorbed, forming respectively peroxide and carbonate. F. Kuhlmann found that if the nitrate be calcined in hydrogen gas, barium hydroxide is formed. F. Mohr recommended mixing the nitrate with twice its wt. of heavy spar in order to avoid the frothing and afterwards leached out the baryta with water. W. Artus, and G. C. Wittstein similarly calcined the nitrate with one-half or two-thirds its weight of iron filings.

The technical preparation of barium oxide by the calcination of witherite is difficult, because the barium oxide fuses, and forms an impervious skin on witherite which hinders its subsequent decomposition. A. Scheurer-Kestner[6] mixed the carbonate with chrome iron ore in order to keep the mass more or less porous while decomposition was in progress; he then extracted the barium oxide with water. H. Schulze fused the barium carbonate in an electric furnace arranged so that the carbon dioxide could be readily recovered. J. Priestley, R. Heinz, and O. Lenoir heated the witherite in water vapour to facilitate its decomposition. A. C. Jaquelain heated a mixture of barium and calcium carbonates and carbon in a stream of water vapour; and H. Leplay a mixture of barium and alkali carbonate in steam. A. Leroy and A. Segay heated the barium carbonate to 450° in a stream of hydrogen sulphide, and recovered the latter by passing steam over the resulting barium sulphide. Here again the product is barium hydroxide.

B. Pelletier heated a mixture of witherite with one-tenth its weight of powdered charcoal, in a luted crucible lined with carbon. The baryta so prepared is often mixed with some charcoal or undecomposed carbonate; and, if the charcoal be not free from nitrogen, some barium cyanide is formed. Modifications of this process have been used by G. Lunge, A. Rivière, T. du Motay, and A. Scheurer-Kestner. It is also claimed by R. Schneider that it is an advantage to mix the witherite with some calcium or magnesium carbonate. Several modifications of these processes have been patented. W. Feld heated the witherite by the waste gases from the combustion chamber of a kiln. H. Leplay, and R. Radot heated the witherite with coal gas.

Several processes have been suggested[7] for converting heavy spar, $BaSO_4$, into barium sulphide as a preliminary to its subsequent conversion into oxide, carbonate, or chloride. Many of these processes are also available for the treatment of strontium sulphate or cœlestine. A. Scheurer-Kestner calcined an intimate mixture of pulverized heavy spar with about 17 per cent. of coal-dust in the reducing atm. of a reverberatory furnace or in luted crucibles, and obtained 83 per cent. yield of sulphide, 17 per cent. remained undecomposed. Modifications have been recommended by T. de Brochocky, T. von Dienheim, H. Grüneberg, M. Langsdorf, O. Lenoir, J. Mactear, J. Nicklès, J. von Liebig, A. Rivière, J. Watts, A. Wurtz, etc. L. Marino found that barium sulphate is best reduced by water gas at 600°–625°. The reduction of the sulphates of the alkaline earths by gases and the technical preparations of baryta have been studied by L. Marino and D. Danesi.

A. Frank heated witherite, heavy spar, or barium chloride with the carbide, air excluded: $3BaCO_3+BaC_2=4BaO+5CO$. C. S. Bradley and C. B. Jacobs heated a mixture of barium sulphate and carbon in an electric furnace. The first reaction is represented: $4BaSO_4+4C=BaS+3BaSO_4+4CO$, and the barium sulphide then reacts with the sulphate: $BaS+3BaSO_4=4BaO+4SO_2$; the final product contained 40 per cent. of barium sulphide, and 60 per cent. of oxide. They also heated mol. proportions of barium carbide and hydroxide, acetylene was evolved, and the resulting barium oxide was in a porous condition suitable for peroxidation. E. J. Maumené heated a mixture of barium sulphate with ferric oxide to 1000° or 1200°, whereby an insoluble compound of barium and ferric oxide is produced which is decomposed in an atm. of hydrogen, and the ferric oxide reduced to iron which then reacts: $2Fe+BaO+2BaS+2H_2O=3BaO+2FeS+2H_2$. F. Projahn melted the heavy spar with iron; H. Schulze heated a mixture of barytes with native metal sulphides, *e.g.* $7BaSO_4+2FeS=7BaO+Fe_2O_3+9SO_2$. H. Niewerth heated cœlestine with an eq. of carbon and iron oxide, and extracted the strontia with water. The resulting barium sulphide can be decomposed by hydrolysis with water or steam as recommended by R. Ziomczynsky, F. Konther, A. Rose, etc. E. Terres and K. Bruckner showed that the reaction: $2BaS+2H_2O=Ba(OH)_2+Ba(SH)_2$, is incomplete, a double salt is formed, and the baryta produced always retains some sulphide which is very difficult to remove. The results obtained vary with temp., conc., and many other factors. They finally conclude that processes based on this reaction are not industrial. A. Vogel, and J. P. J. d'Arcet recommended desulphurizing aq. soln. of barium sulphide by treatment with cupric oxide; C. Stahlschmidt, cuprous oxide. E. Asselin, J. Kuczynsky, M. Lalande, A. Müller, A. Rosenstiehl, and C. Stahlschmidt recommended zinc-dust, zinc oxide, hydroxide or zinc white. E. Riegel recommended pyrolusite, but F. Mohr said this method is useless, while H. L. Pattinson showed that when a soln. of barium sulphide is treated with manganese dioxide or Weldon's mud, at 38°, and a stream of air passed through the liquor, two-thirds of the sulphide is transformed into hydroxide, and the remainder into an insoluble thiosulphate, BaS_2O_3. C. F. Claus converted strontium sulphide resulting from the reduction of the sulphate, by treating it with barium hydroxide; E. F. Trachsel and W. Moody treated the sulphide with sodium hydroxide and obtained strontium hydroxide. Electrolytic processes have been patented by H. M. Taquet, A. Brochet and G. Ranson, and W. Pataky, etc.

V. Kohlschütter and J. L. Tüscher[8] made calcium one electrode of an electric arc, and oxidized the vapour by a current of air. They thus obtained a highly dispersed form of the oxide.

§ 8. The Properties of the Oxides of Calcium, Strontium, and Barium

The oxides of calcium, strontium, and barium obtained by calcination at a low temp., are usually white, earthy, porous, and probably amorphous. V. Kohlschütter and J. L. Tüscher obtained calcium oxide in a highly disperse form by vaporizing the metal in an electric arc; suddenly chilling the vapour by a current of cold air; and precipitating the fume by means of a high tension electric field. Several of the methods of preparation above described give crystalline products. If the purified nitrate of calcium, strontium, or barium be heated to the temp. of decomposition, the corresponding oxide is formed in cubic crystals. J. B. Trommsdorff[1] obtained **crystals** of calcium oxide, and G. Brügelmann, cubic crystals of calcium and strontium oxides, by melting and decomposing the dried nitrates by heat applied to the side of the tightly luted crucible. The microscopic needle-like crystals obtained from the nitrate are stated to give chromatic polarization, and these do not therefore belong to the cubic system, rather to the hexagonal system. The product obtained by similarly heating the hydroxide or carbonate was an amorphous powder. According to R. B. Sosman and co-workers, the crystalline form is obtained by heating the porous variety to a high temp., or by crystallization from soln. in molten silicates or fused calcium nitrate. It is the stable form at a high temp. There is a transition or inversion point between 400° and 430°. H. Moissan obtained crystals of calcium and barium oxides in cubes, rectangular parallelopipeds, or in fine needles by fusing the amorphous product in the electric arc furnace. P. Lebeau likewise obtained crystalline masses by heating a mixture of calcium and an alkaline carbonate under similar conditions. A. Levallois and S. Meunier found small distinct cubic crystals of calcium oxide in some parts of a continuous lime-kiln which had been in use 28 months; the crystals had no action on polarized light. Some crystals obtained by H. Moissan by sublimation in the electric furnace did polarize light, and they belonged to the hexagonal system; this makes it appear as if calcium oxide, like barium oxide, is dimorphous. A. Jouve also found some transparent acicular crystals of calcium oxide, formed in a calcium carbide furnace, were probably hexagonal. A. W. Hull, and W. P. Davey found that the **X-radiogram** of calcium oxide corresponds with a face-centred cubic lattice, with the closest approach of the atoms 2·42 A.; and that the arrangement of the atoms is the same in calcium metal, the oxide, and the fluoride, and that the atoms are respectively 2 and 14 per cent. closer in the fluoride and oxide than in the metal. W. Gerlach found that the lattice constants of calcium, strontium, and barium oxides all belong to the sodium chloride type. According to P. Lebeau, an isomorphous mixture of calcium and lithium oxides is obtained by calcining a mixture of the two carbonates, but with strontium and lithium carbonates, or with barium and lithium carbonates, an isomorphous mixture is not obtained and the lithia volatilizes.

The **specific gravity** of amorphous calcium oxide was found by A. Royer and J. B. A. Dumas [2] to be 3·08 (4°); C. J. B. Karsten, 3·16105; P. F. G. Boullay, 3·179; and E. Filhol, 3·180. G. Brügelmann gives 3·251 for the crystalline oxide, and A. Lavallois and S. Meunier, 3·32. The sp. gr. of calcium oxide is the greater the higher the temp. to which it has been calcined. H. G. F. Schröder found 3·13 for the oxide calcined at 1000°; H. Moissan, 3·30 for the oxide calcined at 1500°; and 3·40 for the oxide calcined at the high temp. of the electric arc furnace. H. Davy estimated the sp. gr. of the greyish-white porous strontium oxide to be between 3·0 and 4·0; C. J. B. Karsten gave 3·9321; and E. Filhol, 4·611. G. Brügelmann gave 4·51 for the sp. gr. of amorphous strontium oxide prepared by the calcination of the hydroxide or carbonate; and 4·51 for the crystals obtained by calcining the nitrate. A. F. de Fourcroy gave 4·0 for the sp. gr. of barium oxide; J. Tunnermann, 4·2583; C. J. B. Karsten, 4·7322; L. Playfair and J. P. Joule, 4·907; and E. Filhol, 5·456. G. Brügelmann gave 5·32 for crystallized barium oxide optically uni- or bi-axial, and 5·72 for the cubic crystals. The **hardness** of crystallized calcium oxide is between 3 and 4 on Mohs' scale.

Calcium oxide is a very powerful refractory as shown by its use in the limelight where it resists the intense heat of the oxy-hydrogen blowpipe flame. The less pure forms of lime may fuse under these conditions as observed by E. D. Clarke.[3] In 1802, R. Hare fused both baryta and lime. L. B. G. de Morveau reported the fusion of calcium oxide on charcoal ignited in a stream of oxygen, and H. Davy said that this oxide melts only with the strongest heat of a voltaic battery. H. Moissan found calcium oxide melts easily in the electric arc furnace, and the cold mass is white and crystalline; the **melting point** is near 2540°; C. W. Kanolt gave 2570°; and O. Ruff and P. Schmidt 2570° in an atm. of hydrogen. The last named say the boiling occurs only under reduced press., and they also measured the vap. press. curves. Calcium oxide crystallizes in the hottest part of the flame of the oxy-hydrogen blowpipe. A. A. Read did not detect any change when the oxides of barium, strontium, or calcium are heated to the m.p. of platinum. H. Moissan succeeded in volatilizing calcium oxide in his electric arc furnace. He also melted strontium oxide to a transparent liquid in the same furnace at about 3000°, and showed that a crystalline mass was formed on cooling. H. Abich noted that barium oxide fuses in the strongest heat of the forge; E. D. Clarke found that baryta fuses to a slag in the oxy-hydrogen blowpipe flame; and H. Moissan melted and volatilized the oxide in his electric arc furnace. He found that barium oxide is a molten liquid at 2000°, and is not decomposed at 2500°. W. R. Mott estimated that the **boiling point** of calcium oxide is about 3400°, and those of strontium and barium oxides occur respectively at 3000° and 2000°. O. Ruff and P. Schmidt found 2850° for the b.p. of calcium oxide in an atm. of an indifferent gas at 760 mm. E. Tiede and E. Birnbräuer found lime volatilizes at 1650° and upwards, and that strontia and baryta are more volatile than lime. E. W. Washburn calculated the latent **heat of fusion** of calcium oxide to be 28,000 (±20 per cent.) cals. per mol, or 490(±20 per cent.) cals. per gram. P. N. Laschtschenko's values for the **specific heat** of fused lime point to the existence of a mol. transformation from α-CaO to β-CaO between 405° and 410°, accompanied by an absorption of 5 cals. of heat per gram. The sp. ht. of *chaux fondue* rose from 0·172 at 190° to 0·181 at 375°, and remained stationary at 0·181 at 400°, and it then rose to 0·190 at 415° and to 0·193 at 680°. H. von Wartenberg and G. Witzel found the mol. ht. of calcium oxide at 2552° to be 14·8 cals. W. Nernst and F. Schwers found the mol. ht., C_p, at 89·3° K. to be 3·395, and at 28·2° K., 0·110. G. Gin, and B. Carlson represented the mol. ht. of calcium oxide at θ° between 0° and 3500°, by $11·4+0·001\theta$. Hence,

	0°	1000°	1500°	2000°	2500°	3000°	3500°
Sp. ht.	0·2036	0·2214	0·2303	0·2393	0·2482	0·2571	0·2660
Mol. ht. .	11·4	12·4	12·9	13·4	13·9	14·4	14·9

According to J. Thomsen,[4] the **heat of formation** of calcium oxide from its elements is $Ca_{solid}+O_{gas}=CaO_{solid}+131·3$ Cals.; A. Guntz and H. Basset give

151·9 Cals.; H. Moissan, 145 Cals.; and R. de Forcrand, 151·9. J. Thomsen gave for strontium oxide, (Sr, O), 130·98 Cals.; A. Guntz and G. Röderer, 141·2 Cals.; and R. de Forcrand, 137·60 Cals. J. Thomsen likewise gave for barium oxide, (Ba, O), 130·38 Cals.; A. Guntz, 133·4 Cals.; and R. de Forcrand, 125·86 Cals. See the corresponding hydroxides for the **heat of solution** of these oxides in water. H. Gautier found that the **heat of neutralization** of calcium oxide in hydrochloric acid is the same for the oxide prepared by calcining the carbonate at 1000°, at 1300°, or in the electric arc furnace; and H. Moissan observed no difference in the heat of neutralization of amorphous and crystalline calcium oxide.

R. B. Sosman and co-workers give 1·83 for the **refractive index** of crystalline calcium oxide. Calcium oxide luminesces at a high temp. as shown by the lime-light. According to W. Crookes,[5] calcium oxide emits an orange-yellow **phosphoresence** in cathode rays of a vacuum tube; under similar conditions, strontium oxide gives a deep blue phosphorescence, while barium oxide scarcely phosphoresces at all. On stopping the discharge, calcium oxide gives a residual glow. According to H. Jackson, if calcium oxide which gives a very bright orange glow be heated in the oxy-hydrogen flame, it subsequently gives a blue phosphorescence. Calcium oxide which has been prepared from highly purified calcium carbonate is strongly phosphorescent if in the crystalline condition, but it scarcely glows at all if amorphous. P. Bary studied the fluorescence of these oxides when stimulated by the X-rays, and by Becquerel's rays. L. de Boisbaudran, and F. Schmidt have studied the effect of impurities—particularly manganese and chromium—on the phosphorescence of the alkaline earth oxides. F. Schmidt prepared phosphorescent oxides of the three alkaline earths by mixing them with small quantities of sodium fluoride, chloride, or phosphate, calcium fluoride, magnesium fluoride, lithium phosphate, potassium borate, or potassium hydrophosphate; and then with a soln. of nitrate of bismuth, copper, manganese, or lead. He also measured the spectra of the light. E. L. Nichols and D. T. Wilber found that calcium oxide exhibits a **flame luminescence** in the zone of the hydrogen flame between oxidation and reduction; the phenomenon does not occur with the flame of alcohol, ether, sulphur, or carbon disulphide. A full supply of oxygen in the atm. surrounding the flame is essential. Rapid oxidation and reduction appear to be essential. The effect is not produced by heating in air or hydrogen outside the flame; and the effect is not modified by strong electrostatic fields, thus excluding ionization. Barium and strontium oxides gave a dim flame luminescence.

F. Horton found that the **electric resistance** of a piece of lime at ordinary temp. exceeds 100 megohms, while the resistance in ohms and the **electric conductivity** in mhos at different temp. are:

	763°	930°	1105°	1235°	1370°	1466°
Ohms .	70×10^6	4175×10^3	600×10^3	$104{\cdot}1\times10^3$	2045	91·0
Mhos .	$1{\cdot}38\times10^{-9}$	$2{\cdot}33\times10^{-8}$	$1{\cdot}62\times10^{-7}$	$9{\cdot}33\times10^{-7}$	$4{\cdot}75\times10^{-5}$	$1{\cdot}035\times10^{-3}$

The curve resembles that showing the relation between the emission of electrons and temp. He concludes that only a small fraction of the current is carried by negative electrons. For baryta, subject to the oxidization of the compound to the dioxide at the elevated temp.:

	307°	320°	345°	369°	428°	497°
Ohms .	646×10^3	184×10^3	78400	6892	35·7	14·1
Mhos .	$1{\cdot}00\times10^{-6}$	$3{\cdot}53\times10^{-6}$	$8{\cdot}29\times10^{-6}$	$9{\cdot}43\times10^{-5}$	$1{\cdot}82\times10^{-2}$	$4{\cdot}61\times10^{-2}$

There is evidence of a slight electrolysis during the passage of the current. F. Deininger has studied the emission of ions by heated calcium oxide. According to T. W. Case, the oxides of the alkaline earths are not perceptibly **photo-electric.** H. B Baker showed that heated lime ionizes gases. A. Wehnelt found the relation between absolute temp., T, the number of corpuscles, n, given out by lime (measured by the saturation current) to be $n=aT^{\frac{1}{2}}e^{-b/T}$, where a and b are constants.

The **solubility** of calcium, strontium, and barium oxides in **water** is discussed in connection with the hydroxides; calcium oxide unites with water with great avidity, forming calcium hydroxide—*slaked lime* or *hydrated lime* (*q.v.*). The moistened oxides give an alkaline reaction, and have a caustic alkaline taste; they also corrode organic matter but to a less degree than the caustic alkalies. With calcium oxide and water ranging from 17·962 to 718·67 mols of water to one mol of calcium oxide, S. Chumanoff[6] claimed to have obtained solid phases with 1·0725 to 1·5563 mols of water per mol of calcium oxide; but W. A. Burdakoff showed that this is unlikely unless S. Chumanoff's sample was contaminated with some carbonate. According to W. Eidmann, the three oxides are insoluble in *acetone* and in *methyl acetate*. According to C. Neuberg and B. Rewald, the oxides of calcium, strontium, and barium are soluble in *methyl alcohol*, and the soln. becomes turbid when warmed and clear again on cooling. The soln. does not give the ionic reactions of the metal, but gives colloidal precipitates or soln. The soln. contains 11·2 grms. of strontium oxide or 1·125 grms. of calcium oxide per litre. A similar result was obtained with *ethyl alcohol*. S. Meunier found that one part of barium oxide dissolves in 3·3 parts of molten potassium hydroxide, and the soln. absorbs oxygen from the air. This is explained by the circumstance that when calcium, strontium, and barium oxides are heated in **air** or **oxygen**, the latter gas is absorbed, and peroxides are formed (*q.v.*). According to W. Manchot and W. Kampschulte,[7] **ozone** is completely decomposed when passed through a 30 cm. layer of barium oxide, at ordinary temp., but if cooled with ether and carbon dioxide, the baryta is coloured yellow—*barium ozonate;* calcium oxide behaves similarly, forming *calcium ozonate*—see potassium ozonates. This is particularly the case with barium oxide; and C. F. Rammelsberg's analysis of barium oxide—Ba_3O_4—prepared by calcining the nitrate was affected by an error due to this cause.

According to R. Bunsen and G. Kirchhoff, at the temp. of the electric spark, strontium oxide appears to be reduced by **hydrogen**. For the action of **hydrogen peroxide**, see the corresponding dioxides. J. A. Hedvall and N. von Zweigbergh studied the action of **barium dioxide**. When a piece of calcium oxide is exposed to **air**, it combines with moisture and also carbon dioxide; this is accompanied by a large increase in volume, and the lump crumbles to a powder, which is called *air-slaked lime*. The reaction occurs in two stages: (i) the absorption of water and the formation of calcium hydroxide: $CaO+H_2O=Ca(OH)_2$; and (ii) the development of the water by carbon dioxide, forming calcium carbonate: $Ca(OH)_2+CO_2=H_2O+CaCO_3$. These reactions are slow, and the product at one stage of the process is similar in composition to water-slaked lime, and it is possible to obtain air-slaked lime which has been carbonated to almost any degree. Hence, there is some confusion in literature as to the properties of air-slaked lime.

According to H. Moissan, **fluorine** acts in the cold on calcium oxide liberating oxygen and forming calcium fluoride, at the same time much heat is liberated and the mass glows. V. H. Veley found that dry **chlorine** does not act on calcium oxide below 300°, and at this temp. the oxygen is partially replaced by chlorine. J. J. Berzelius, and H. St. C. Deville and H. Debray also found chlorine transforms heated calcium and barium oxides into the chloride, and **iodine** forms the periodate. In 1814, W. Higgins observed that " dry muriatic acid has no action on dry calcareous earth, whilst these substances readily unite if moisture is present"; and V. H. Veley found that dry **hydrogen chloride** has no action on dried calcium oxide in the cold, but a reaction begins at about 80°. **Ammonium chloride** was found by F. Isambert to have no action on strontium or barium oxide at ordinary temp., but between 180° and 300° an energetic reaction occurs—*vide* ammonia.

H. St. C. Deville and H. Debray found that the oxygen of calcium oxide is displaced by **sulphur** at an elevated temp. J. J. Berzelius made a similar observation with respect to barium oxide. C. Brückner obtained calcium sulphide, polysulphide, and sulphate by heating sulphur with calcium oxide at a red heat. R. E. Hughes found that dry **hydrogen sulphide** has no action on dry calcium oxide in the cold, but when heated, water is evolved and the mass becomes yellow owing to the separation of some sulphur. O. Schumann found **hydrogen sulphide** transforms calcium oxide into a mixture, $4CaS.3CaO$. R. E. Hughes found that the reaction with dry barium oxide and dry hydrogen sulphide is insignificant between 15° and 90°, but if moisture be present, a reaction occurs. V. H. Veley found that **sulphur dioxide** reacts slowly at 300°, and faster at 352°: $CaO+SO_2=CaSO_3$. According to K. Birnbaum and C. Wittich, the dry gas is not absorbed by dry calcium oxide below 400°, but at 418° the gas is rapidly absorbed, and a basic sulphite, $5CaSO_3.CaO$, is formed; and at 500° a mixture of sulphide and sulphate is produced by a reaction which V. H. Veley symbolizes $4CaSO_3=3CaSO_4+CaS$. The absorption with strontium oxide begins at 290°; and at 200° with barium oxide, at 230°, barium sulphate is formed. According to H. B. Baker, thoroughly dried **sulphur trioxide** does not act on dried calcium or barium oxide at ordinary temp. According to J. J. Berzelius, and H. St. C. Deville and H. Debray, when **carbon disulphide** vapour is passed over barium oxide, heated in a tube, the oxide becomes red hot, and a mixture of sulphide and carbonate is formed: $CS_2+3BaO=2BaS+BaCO_3$.

H. Moissan found **boron** reacts with calcium oxide at a high temp., forming calcium borate and a little boride. H. St. C. Deville and H. Debray noted the formation of calcium carbide and carbon monoxide when **carbon** is heated with calcium oxide. E. Tiede and E. Birnbräuer also noted that calcium and strontium oxides form carbides. H. Moissan showed that if the calcium oxide is in excess, a secondary reaction occurs with the **calcium carbide** resulting in the liberation of calcium (*q.v.*): $CaC_2+2CaO=3Ca+2CO$. According to J. Kolb, H. Petzhold, H. Rose, H. Debray, A. R. Schultaschenko, and A. Vogel, dry calcium oxide absorbs no **carbon dioxide** in the cold, but a reaction occurs when the temp. is raised. According to V. H. Veley, the absorption is insignificant at 300°, it is more marked at 350°, and is complete at 420°. K. Birnbaum and M. Mahu found the lowest temp. at which absorption occurs is near 418°. F. M. Raoult found that the rate of absorption of carbon dioxide is largely determined by the thermal history of the calcium oxide; in accord with this, R. B. Sosman and co-workers found that crystalline calcium oxide combines with carbon dioxide very slowly, while the porous variety combines rapidly with the same gas. The reaction has been studied in connection with the dissociation of the carbonate—*vide supra.* J. C. Whetzel studied the effect of exposing quicklime to atm. air, and found a protective layer of carbonate is formed. Calcium oxide reacts with **ethyl alcohol** in a sealed tube between 115° and 120°, forming a mixture of hydroxide and ethoxide: $Ca(OH)_2+(C_2H_5O)_2Ca$. Similar results were obtained by A. Destrem with **propyl alcohol** and **glycerol.** H. Moissan found that **silicon** is oxidized when heated with calcium oxide, and a calcium silicate is formed; H. Moissan and W. Dilthey also found that a silicide is formed: $2CaO+5Si=2CaSi_2+SiO_2$; and W. P. Bradley found that carbon and **silica** in the electric furnace also produce the silicide: $CaO+2SiO_2+5C=CaSi_2+5CO$. Strontium and barium oxides behave similarly. E. Mitscherlich observed that silica, **alumina, chromic oxide,** and **ferric oxide** dissolve in barium oxide at a white heat, forming crystalline compounds soluble in hydrochloric acid. L. Forquignon observed that if **steel** be heated in a bed of quicklime, carbon and silicon are removed from the metal. H. Moissan found that calcium oxide reacts with **titanium** at an elevated temp., forming calcium titanate.

A. Askenasy and F. Grude studied the action of **nitrogen** on a heated mixture of barium oxide and carbon—*vide* nitrides. V. H. Veley found **nitric oxide** is not absorbed by calcium oxide. H. St. C. Deville and H. Debray found that **phosphorus** vapour reacts with calcium oxide, forming the phosphide; J. J. Berzelius made a similar observation with respect to barium oxide. H. Davy observed the reduction of calcium oxide by the vapour of **potassium,** and **sodium,** but J. W. Mallet had his doubts on the matter. L. Gattermann found **magnesium** reduces calcium oxide, but the reduction of calcium oxide is slight; strontia is reduced rather more energetically, and baryta still more so. F. E. Weston and H. R. Ellis found that magnesium partly reduces calcium oxide, and calcium partly reduces magnesium oxide; and **aluminium** reduces lime when heat is supplied. J. W. Mallet found that lime, strontria, and baryta are in part reduced by aluminium at a high temp. and the alkaline earth metal volatilized. E. Dufau found that **chromium** is oxidized by calcium oxide at the temp. of the electric arc, forming a crystalline double oxide: $Cr_2O_3.4CaO$; **manganese, iron, cobalt,** and **nickel** are also oxidized under similar conditions. H. Moissan found calcium oxide reacts with **platinum** at the temp. of the electric arc, and the platinum retains 2·5 to 3 per cent. of calcium; for the action of barium oxide, *vide supra.*

§ 9. The Higher Oxides of Calcium, Strontium, and Barium

In a paper, *Sur l'absorption de l'oxygène par les terres*, A. von Humboldt[1] reported in 1798 that moist earths—baryta, lime, and alumina—are able to decompose atm. air by removing the oxygen and leaving the nitrogen. It was supposed either that the earths unite with the oxygen, or favour the oxidation of the associated water. It had previously been shown by N. T. de Saussure, and J. Ingenhous that soil in contact with atm. air forms carbon dioxide at the expense of the contained oxygen; hence, the former argued that the result obtained by A. von Humboldt was due to the presence of oxidizable organic matter, and was not produced by the purified earths. Meanwhile, J. B. van Mons verified A. von Humboldt's observation, and compiled a number of older records of related phenomena. In 1800, C. L. Berthollet contested the hypothesis that the earths absorb oxygen under the conditions indicated by A. von Humboldt.

In 1810, J. L. Gay Lussac and L. J. Thénard found that potash and soda can form hyperoxides; and, they observed, the rapid absorption of oxygen from air passed over barium oxide heated in a tube to a dull red heat. L. J. Thénard (1811) assumed that a mol of barium oxide absorbs a gram-atom of oxygen, and this assumption was vindicated by the analyses of C. F. Rammelsberg, and J. B. J. D. Boussingault, which corresponded with the formulæ Ba_3O_7 and BaO_2. So that the product of the action is more or less impure barium dioxide, BaO_2. C. F. Rammelsberg, and M. Quesneville obtained this same compound by heating barium nitrate, and J. B. J. D. Boussingault by heating barium hydroxide or barium carbonate to dull redness in a stream of air. The latter also showed that the presence of a little moisture plays an important part in the reaction, for thoroughly dried oxygen or air is not absorbed or, at any rate, the absorption is very slow. It has been suggested that if B. C. Brodie worked with dried oxygen, this explains how he could fix only six parts of oxygen per 100 parts of barium oxide. H. le Chatelier confirmed the observation that dried oxygen is not absorbed by barium oxide; on the other hand, E. Beckmann stated that the presence or absence of moisture is immaterial. F. Kuhlmann also emphasized the fact that the barium oxide should not be sintered or fused, since in that state it absorbs very little oxygen. J. von Liebig and F. Wöhler calcined a mixture of barium oxide with potassium chlorate in a closed crucible and obtained a 50 per cent. conversion of the oxide to dioxide; B. C. Brodie found potassium perchlorate gave no better result. J. A. Wanklyn calcined a mixture of barium oxide with cupric oxide when metallic copper and barium dioxide were formed. The use of barium peroxide for the continuous extraction of oxygen from the air by L. Q. and A. Brin's process (*q.v.*)[2]

attracted some attention before that process was ousted by cheaper methods of extraction. The preparation of a porous form of barium oxide suitable for rapid absorption was the subject of several patents which have been tabulated by R. Heinz. N. Sasaki studied the velocity of formation of the dioxide at 400°–625°, and his results agreed with the assumption that the oxide and dioxide are mutually soluble in one another, and that such a soln. is proved when oxygen reacts with barium oxide. The reaction occurs first at the surface of the solid and afterwards penetrates into the interior so that the mathematical soln. is analogous to that of a problem in the conduction of heat.

When barium dioxide is treated with water, it diffuses itself through the liquid without a rise of temp. and produces a white powder of the hydrated dioxide. L. J. Thénard[3] added hydrogen peroxide to baryta water, and obtained a white crystalline precipitate. An excess of alkali is needed in order to avoid the formation of compounds with hydrogen peroxide of crystallization. B. C. Brodie, and J. Thomsen used an analogous process. H. Geisow added sodium peroxide to a soln. of barium chloride or hydroxide, cooled with ice-water, and washed the precipitate with warm water to remove the sodium chloride and barium oxide until the filtrate begins to decolorize potassium permanganate. G. F. Jaubert employed an analogous process—*vide infra.* The hydrate is also formed by the action of water on barium peroxide. E. Merck treated the anhydrous dioxide with baryta water in order to get hydrated barium dioxide in a form suitable for the preparation of hydrogen peroxide. N. T. de Saussure observed the formation of hydrated barium dioxide by exposing baryta water, at about 5°, for some weeks to air free from carbon dioxide. B. C. Brodie also found that acetyl peroxide in contact with baryta water forms barium acetate and hydrated barium dioxide. H. le Chatelier dehydrated these products by heating them to 700° in a stream of dry oxygen. The analyses of E. Schöne agree with the assumption that the above processes furnish more or less impure **octohydrated barium dioxide,** $BaO_2.8H_2O$; but, said M. Berthelot, it is difficult to decide between $7H_2O$ and $8H_2O$ because of the smallness of the crystals and their proneness to efflorescence. J. von Liebig and F. Wöhler supposed the hydrate to contain 6 mols of water. He also prepared *decahydrated barium dioxide,* $BaO_2.10H_2O$, by the action of a large proportion of water on barium hydroxy-dioxide, $BaO_2.H_2O_2$. E. Schöne believes that M. Berthelot's decahydrate is the result of working with imperfectly dried products, and that no such hydrate exists. E. Schöne prepared **monohydrated barium dioxide,** $BaO_2.H_2O$, by the spontaneous decomposition of barium hydroxy-dioxide. E. H. Riesenfeld and W. Nottebohm found that if the soln. contains more than a mol of barium hydroxide per mol of hydrogen peroxide, the octohydrate is formed; the octohydrate is always formed over 60°; and the anhydrous dioxide cannot be prepared in aq. soln. Soln. containing much hydrogen peroxide give **barium dioxide diperoxyhydrate,** $BaO_2.2H_2O_2$, below 40°; and between 30° and 60°, **barium dioxide peroxyhydrate,** $BaO_2.H_2O_2$.

L. J. Thénard[4] precipitated hydrated strontium dioxide by adding *eau oxygènée* to a soln. of the hydroxide. E. Schöne employed a similar process. R. de Forcrand showed the precipitate is **octohydrated strontium dioxide,** $SrO_2.8H_2O$; and J. Conroy obtained a precipitate with variable proportions of water—8, 10, or $12H_2O$—by adding sodium dioxide to soln. of strontium salts. G. F. Jaubert employed an analogous process to that used for hydrated calcium dioxide—*vide infra.* The hydrate can be dehydrated by heating it to 100° in a stream of air freed from carbon dioxide. B. C. Brodie and J. Conroy did not obtain strontium dioxide by passing a stream of oxygen over heated strontium oxide, or by melting strontium oxide with potassium chlorate. H. Struve, however, did obtain traces of strontium dioxide by heating the monoxide to redness in a stream of air. The presence of ferric oxide hinders the formation of the dioxide. F. Fischer and H. Plötze obtained a maximum yield of 16 per cent. of strontium peroxide by heating strontium oxide at 410° in oxygen at 100 atm. press. G. Röderer made anhydrous **strontium dioxide,** SrO_2, by passing oxygen into a soln. of strontium in dried liquefied ammonia. J. B. Pierce made 85 per cent. SrO_2 by the action of oxygen on strontia under a press. of 105–126 kilogrms. per sq. cm. at 400°–500°. E. H. Riesenfeld and W. Nottebohm obtained the anhydrous dioxide from conc. soln. above 50°, otherwise the octohydrate is formed. They obtained **strontium dioxide diperoxyhydrate,** $SrO_2.2H_2O_2$, by direct preparation from conc. hydrogen peroxides at low temp.

L. J. Thénard precipitated **octohydrated calcium dioxide,** $CaO_2.8H_2O$, by adding a soln. of hydrogen peroxide to an aq. soln. of calcium hydroxide; and L. Mond prepared it by adding hydrogen peroxide to milk of lime. According to R. de Forcrand, if less than two mols of hydrogen dioxide be added to a mol of calcium hydroxide, the precipitate contains some calcium hydroxide; and if three to four mols of hydrogen dioxide be used, the octohydrated dioxide is precipitated. The products are to some extent dependent on the temp., the higher hydrate is not produced above 20°. E. H. Riesenfeld and W. Nottebohm obtained anhydrous calcium dioxide from very conc. soln. near 0°; and above 40°, even from dil. soln. The octohydrate is obtained from dil. soln. at ordinary temp. They also prepared **dihydrated calcium dioxide,** $CaO_2.2H_2O$, from the anhydrous compound. J. Conroy obtained the hydrated dioxide by mixing a soln. of a calcium salt with sodium dioxide. G. F. Jaubert treated equimolecular parts of enneahydrated sodium dioxide and the hydroxide of an alkaline earth with a little water, and the heat of the reaction was neutralized by the heat of soln. of the hydrated sodium dioxide. The resulting sodium hydroxide can be washed from the hydrated dioxide. He also substituted a sulphide of the alkaline earth in place of the hydroxide. The water of hydration can be expelled, as in the case of the hydrated strontium dioxide. By rapidly dehydrating the octohydrate, R. de Forcrand prepared what he regarded as a compound of calcium hydroxide and hydrogen peroxide, $Ca(OH)_2.H_2O_2$, but which may really be dihydrated calcium dioxide, $CaO_2.2H_2O$. In opposition to F. Bergius' statement, B. C. Brodie, F. Fischer and H. Plötze, E. H. Riesenfeld and W. Nottebohm, and J. Conroy did not succeed in making calcium dioxide by passing oxygen over the red-hot oxide, nor by heating the oxide with potassium chlorate. H. Struve, however, obtained a small amount of calcium dioxide by using calcium carbonate free from iron oxide. E. H. Riesenfeld and W. Nottebohm prepared **calcium dioxide diperoxyhydrate,** $CaO_2.2H_2O_2$, by the method used for the compound of strontium. F. Bergius found that a soln. of lime in sodium hydroxide forms calcium peroxide if exposed to oxygen at over 100 atm. press. The low speed of the reaction, $2CaO+O_2=2CaO_2$, prevents equilibrium being attained in a suitable time for experimental work, but if an inert solvent be present, in which both oxide and dioxide are soluble, the experiment can be made.

The anhydrous dioxides are white powders resembling magnesia; the hydrates form pearly scales or else acicular crystals, and lose their water when heated to 100° in a current of air free from carbon dioxide. J. Conroy says the **crystals** of the octohydrates of barium, strontium, and calcium dioxides are isomorphous. J. L. Gay Lussac and L. J. Thénard, and E. Schöne studied the **action of heat** on barium dioxide; they found that it decreases in vol. when strongly heated, that it melts more easily than the monoxide at a red heat, and, giving off bubbles of oxygen, passes into barium oxide. J. B. J. D. Boussingault found that in vacuo, barium dioxide decomposes: $2BaO_2=2BaO+O_2$, at a dull red heat; and under a press. of 7 to 8 cms. it decomposes at 800°. According to J. A. Hedvall and N. von Zweigbergh, there is an arrest in the heating curve of decomposing barium peroxide at 795°, where the vap. press. of the evolved oxygen is one atm. In the presence of catalysts like cupric oxide, the decomposition starts at a lower temp., and extends over a longer range of temp. In the presence of silica, particularly amorphous silica, the reaction, normally endothermic, becomes exothermic, presumably owing to the formation of barium silicate by the great reactivity of barium oxide at the moment of its formation. J. Kendall and F. J. Fuchs found the addition of silica, ceric oxide, chromic trioxide, and ferric oxide accelerate the decomposition; with cupric oxide, the decomposition temp. is lowered from 825° to about 320°. H. le Chatelier has measured the **dissociation pressure** of barium dioxide at different temp. and found:

	525°	555°	650°	670°	720°	735°	750°	775°	785°	790°
Press. .	20	25	65	80	210	260	340	510	620	670 mm.

The hydrate of barium dioxide loses only water when heated below 130°, but when heated still more, it loses oxygen, and the hydroxide remains. E. H. Riesenfeld and W. Nottebohm found that hydrated calcium dioxide is dehydrated at 100°, and there is no appreciable decomposition below 220°; the decomposition is slow up to 275°, and it then becomes rapid. Finely divided calcium dioxide decomposes explosively when rapidly heated to 275°. The dissociation press. exceeds 100 atm. at 255°. F. Bergius gave for the dissociation press.:

	200°	250°	300°	350°	400°
Dissociation press. . .	93·35	101·1	107·2	124·0	151·9 atm.

E. H. Riesenfeld and W. Nottebohm believe that F. Bergius' sample was contaminated with potash.

R. de Forcrand[5] gives for the **heat of formation** of calcium dioxide, $(CaO, O)=5·43$ Cals., and $(Ca, O_2)=150·43$ Cals.; for strontium dioxide, $(SrO, O)=10·875$ Cals., and $(Sr, O_2)=152·10$ Cals.; and for barium dioxide, $(Ba, O_2)=145·71$ Cals. F. Bergius gave $(CaO, O)=1·65$ Cals., E. Riesenfeld and W. Nottebohm gave 3·3 Cals. M. Berthelot gave for barium dioxide, $(BaO, O)=12·10$ Cals. R. de Forcrand gives for the **heat of hydration** of calcium dioxide, $(CaO_2, 8H_2O_{liquid})=15·636$ or $(CaO_2, 8H_2O_{solid})=4·196$ Cals.; and $CaO_2.2H_2O+6H_2O=17·851$ Cals.; and for strontium dioxide, $(SrO_2, 9H_2O_{liquid})=20·481$ Cals. M. Berthelot gave for barium dioxide, $Ba(OH)_2+O=BaO_2+H_2O-5·52$ Cals. with liquid water, and with solid water, 4·00 Cals. He also gave $BaO.10H_2O+O=BaO_2.7H_2O+10·6$ Cals. with liquid water, and 6·4 Cals. with solid water: $BaO_2+H_2O=BaO_2.H_2O+2·8$ Cals. with liquid water, and 1·4 Cals. with solid water: $BaO_2+10H_2O=BaO_2.10H_2O+18·2$ Cals. with liquid water, and 3·8 Cals. with solid water: $BaO_2.H_2O=Ba(OH)_2+O+2·8$ Cals.; $BaO_2.10H_2O=Ba(OH)_2.9H_2O+O+11·8$ Cals. R. de Forcrand gave for $SrO_{solution}+H_2O_{2solution}=26·576$ Cals. M. Berthelot gave $BaO_2+H_2O_{2aq.}=BaO_2.H_2O_2+10·2$ Cals.; $H_2O_2+Ba(OH)_{2aq.}=BaO_{2anhydrous}+Aq.+5·6$ Cals.; $2H_2O_2+Ba(OH)_{2aq.}=BaO_2H_2O_2+Aq.+15·8$ Cals.; $BaO_2.H_2O_2=BaO_2.H_2O+O=14·2$ Cals.

M. Berthelot found that barium dioxide is stable at ordinary temp., and it can be kept many years without suffering any loss of oxygen. Octohydrated calcium dioxide was found by R. de Forcrand to be stable when dry. In vacuo, it loses a little oxygen, but it does not lose all its water in vacuo at ordinary temp. J. L. Gay Lussac and L. J. Thénard,[6] and J. B. J. D. Boussingault found barium dioxide is reduced by heating it in a current of **hydrogen,** and oxygen is evolved: $2BaO_2+2H_2=2Ba(OH)_2+O_2$. E. Schöne said that anhydrous strontium dioxide has a greater affinity for water than has barium dioxide, and strontium has less affinity for oxygen than has barium; he observed a gradual decomposition when it is allowed to stand in contact with **water,** and J. L. Gay Lussac and L. J. Thénard said that the decomposition is comparatively fast with warm water. R. von Foregger and H. Philipp found that dihydrated calcium dioxide dissociates slowly in soln.: $CaO_2.2H_2O \rightleftharpoons Ca(OH)_2.H_2O_2$, possibly the reaction if it really occurs should be symbolized: $CaO_2.8H_2O \rightleftharpoons 6H_2O+Ca(OH)_2.H_2O_2$, and the latter compound then breaks down into calcium hydroxide and free hydrogen peroxide—possibly $Ca(OH)_2.H_2O_2 \rightleftharpoons Ca(OH)_2+H_2O_2$. The decomposition attended by the precipitation of calcium hydroxide is complete after boiling the soln. for 5 hrs. According to L. J. Thénard, hydrated barium dioxide is but slightly soluble in cold water, and the soln. has an alkaline reaction. According to E. Schöne, 100 c.c. of water dissolve

0·168 grm. of the octohydrate, $Ba(OH)_2.8H_2O$; but 100 c.c. of soln. containing 0·3 and 0·6 grm. of octohydrated barium hydroxide dissolve respectively 0·102 and 0·019 grm. of the hydrated dioxide. A sat. aq. soln. of barium dioxide thus gives a precipitate with baryta water. E. H. Riesenfeld and W. Nottebohm found water converts the dioxides of the alkaline earths into the octohydrates. E. Schöne found hydrated barium dioxide to be insoluble in *alcohol* and *ether;* and W. Eidmann found hydrated barium and strontium dioxides to be insoluble in *acetone.* For the action of **hydrogen peroxide,** *vide infra.*

When barium dioxide is treated with dil. **acids,** it forms hydrogen peroxide. S. Tanatar ascertained that acids which react with calcium and barium dioxide with an evolution of less than 3·5 Cals. of heat—*e.g.* phenol—give off oxygen instead of forming hydrogen peroxide; a similar rule was found to apply with salt soln.—*e.g.* aluminium chloride.

A. Baudrimont found **chlorine** reacts with barium dioxide suspended in water, producing ozone-free oxygen; B. C. Brodie found that when barium dioxide is triturated with **iodine** and water, barium iodide and oxygen are formed. When a dry mixture of barium dioxide and iodine is heated, barium periodate is formed. C. Weltzien obtained chlorine, oxygen, and ozone during the action of dry **hydrogen chloride** on heated barium peroxide. Dil. **hydrochloric acid** furnishes a soln. of hydrogen peroxide; while B. C. Brodie found that the conc. acid gives chlorine or a mixture of chlorine and hydrogen peroxide. **Hypochlorites, chlorates,** and **nitrates** do not oxidize either barium or calcium dioxide to the tetroxide.

J. L. Gay Lussac and L. J. Thénard showed that when barium dioxide is heated with **sulphur,** barium sulphide and oxygen are produced. According to B. C. Brodie, when barium dioxide is rubbed up with water and **carbon disulphide,** a yellow liquid is produced which on standing in the cold slowly precipitates barium carbonate, while barium disulphide or, if an excess of barium dioxide is present, barium thiosulphate passes into soln. This reaction is rapid when the mixture is heated. A similar yellow liquid is produced by passing **hydrogen sulphide** into water in which barium dioxide is suspended. F. Wöhler found that a rapid stream of **sulphur dioxide** makes heated barium dioxide white-hot, and a flame is produced. With dil. **sulphuric acid,** hydrogen peroxide is produced, and with a more conc. acid, ozonized oxygen may be found.

A mixture of barium dioxide and **carbon** was found by J. L. Gay Lussac and L. J. Thénard to be decomposed by heat with the evolution of oxygen. D. Korda found that if a piece of barium dioxide and a carbon rod be dipped in molten potassium carbonate, while the free ends are in electrical connection, a current of about one volt is produced and the reaction: $2BaO_2+C=2BaO+CO_2$ occurs. When triturated with organic substances, A. Dupré found an explosion may be produced. F. Wöhler observed that a rapid stream of **carbon monoxide** makes heated barium dioxide white-hot, and a flame appears. B. C. Brodie found a stream of **carbon dioxide** results in the evolution of oxygen and the formation of barium carbonate; H. Struve found the hydrate also forms barium carbonate, and gives off oxygen.

O. Michel and E. Grandmougin found that **ammonia** reacts with heated barium dioxide, with the evolution of nitrogen: $3BaO_2+2NH_3=3Ba(OH)_2+N_2$. L. Santi symbolized the reaction with **ammonium chloride** soln.: $2BaO_2+4NH_4Cl=2BaCl_2+4NH_3+2H_2O+O_2$. According to J. Conroy, hydrated strontium dioxide is readily soluble in soln. of ammonium chloride, and insoluble in aqua ammonia. C. A. L. de Bruyn found that an aq. soln. of **hydroxylamine** reacts with barium dioxide with inflammation. P. Sabatier and J. B. Senderens found **nitrous oxide** reacts with barium dioxide between 500° and 600°, forming nitrogen and barium nitrate. J. L. Gay Lussac and L. J. Thénard observed that when warmed with **phosphorus,** barium dioxide is decomposed and oxygen is evolved; similarly also with **boron** and the **metals.** When an aq. soln. of **sodium carbonate** is digested with barium dioxide, B. C. Brodie observed the formation of a soln. of sodium dioxide and a precipitate of barium carbonate. C. Weltzien treated barium dioxide with aq. soln. of the **alkali sulphates**—lithium, potassium, and sodium—and obtained barium sulphate and a soln. which he believed to contain alkali hydroxide and hydrogen peroxide. H. Kwasnik reported that barium dioxide does not react with soln. of **salts of the alkali and alkaline earths,** but it reacts slowly with **magnesium salts,** giving off oxygen. With **ferric chloride** it reacts: $6BaO_2+4FeCl_3+6H_2O=3O_2+4Fe(OH)_3+6BaCl_2$, and likewise also with **manganic, chromic, and aluminium salts.** There is also a rapid evolution of oxygen with **nickel and cobalt salts** soln.; and a feeble evolution with soln. of **zinc and cadmium salts,** but more quickly than with magnesium salts. The salts of the noble metals are reduced to the metal, but **hydrochloroplatinic acid** furnishes barium chloroplatinate. **Cupric salts** are not reduced and ozonized oxygen is evolved. G. Kassner found **potassium ferricyanide** reacts: $BaO_2+2K_3FeCy_6=O_2+K_6BaFe_2Cy_{12}$, and J. Quincke has shown that the reaction is quantitative.

J. A. Hedvall and N. von Zweigbergh found the rate of decomposition of barium oxide is accelerated by admixture with other **metal oxides,** and the decomposition is exothermic. Compounds were thought to be formed with barium oxide and the oxides of zinc, titanium, aluminium, lead, arsenic, antimony, vanadium, tantalum, chromium, molybdenum, tungsten, uranium, manganese, iron, nickel, and copper. Cuprous oxide and bismuth sesquioxide were oxidized without forming compounds. A catalytic action was observed with cuprous and cupric oxides, and the oxides of magnesium, calcium, cadmium, lanthanum, and cerium, while stannous and stannic oxides, and zirconia were without effect. J. H. Hildebrand, and N. Sasaki found that barium oxide and dioxide are mutually soluble in one another, and that the limits of their mutual solubilities at a given temp. vary with the states of the samples employed.

E. Schöne reported that in the decomposition of barium dioxide by water, the supernatant liquid contains proportionally more barium hydroxide than hydrogen peroxide. This is explained by assuming that a portion of the hydrogen peroxide combines with an eq. quantity of barium dioxide to produce **barium dioxide hydroxyhydrate,** $BaO_2.H_2O_2$. He isolated this compound by two different methods of preparation: first, by direct action on each other of the peroxides of barium and of hydrogen; secondly, by adding a determined quantity of ammonia to a soln. of hydrogen peroxide containing a barium salt. In the first process the reaction is represented by $BaO_2+H_2O_2=BaH_2O_4$. In the second several phases may be distinguished, thus: $BaCl_2+2NH_4OH=2NH_4Cl+Ba(OH)_2$; $Ba(OH)_2+H_2O_2=2H_2O+BaO_2$; $BaO_2+H_2O_2=BaH_2O_4$. The compound, BaH_2O_4, formed microscopic crystals belonging to the monoclinic system. The crystals were usually of a yellow colour, but they could be prepared quite clear and colourless. The latter soon decomposed at room temp., but they are more stable at 0°; they finally break down into barium dioxide, water, and oxygen. The compound is insoluble in the ordinary solvents; acids decompose the colourless compound without giving off any gas, but the yellow product gives off oxygen, and this the more the yellower the product. R. de Forcrand measured the amount of heat evolved when a mol of barium dioxide is treated with *n* mols of hydrogen peroxide:

Mols H_2O_2 . .	0·5	1	2	3	10	12
Heat developed .	3·121	4·350	7·801	8·552	12·261	13·586 Cals.

The breaks in the curve led him to assume that barium hydroxyhydrated-dioxide, $BaO_2.H_2O_2$, or $Ba(O.OH)_2$, is formed as well as another compound richer in hydrogen peroxide. E. Schöne believed that a **strontium dioxide hydroxyhydrate,** $SrO_2.H_2O_2$, exists analogous with the barium compound, but it is so unstable that he was unable to isolate it in a pure state. E. Schöne likewise failed to obtain pure **calcium dioxide hydroxyhydrate,** $CaO_2.H_2O_2$. but he obtained a yellow unstable compound by similar methods to those employed for the barium compound. R. de Forcrand inferred the existence of calcium hydroxy-dioxide, $CaO.2H_2O_2$, or $CaO_2.H_2O_2$, or $Ca(O.OH)_2$, by thermal methods similar to those which he employed with the barium compound. W. Traube and W. Schulze found that calcium dioxide octohydrate is converted by warm hydrogen peroxide into a yellow substance, which, under the most favourable circumstances, may contain 8·7 per cent. of **calcium tetroxide,** CaO_4. The products may be heated to 130° C. without undergoing change. They dissolve in dil. acid with immediate evolution of inactive oxygen which does not liberate bromine or iodine from acidified soln. of potassium bromide or potassium iodide. The corresponding **barium tetroxide** is much less stable. Ultra-violet light hastens the conversion of the hydroperoxide $BaO_2.H_2O_2$ into the tetroxide BaO_4. The tetroxides are not *ozonates*, which, contrary to the opinion of W. Strecker and H. Thienemann, do not contain hydrogen, but an addition compound of oxygen and the dioxide.

It is not clear which of these formulæ

$$Ba<\begin{matrix}O\\ \cdot\\ O\end{matrix}$$

$$Ba<\begin{matrix}O.O\\ O.O\end{matrix}>Ba$$

should be used to represent the composition of barium dioxide ; the second is perhaps preferable because (1) just as the alkaline earth oxides, BaO, readily unite with water, forming soluble hydroxides, $Ba(OH)_2$, so might the corresponding peroxides be expected to form readily soluble hydroperoxides, HO.OBa.O.OH. Barium peroxide unites with hydrogen peroxide to form a compound, $BaO_2.H_2O_2$, but since this compound dissolves in water with difficulty, it is inferred that it is not HO.O.Ba.O.OH, but rather $BaO_2.H_2O_2$, with "hydrogen peroxide of crystallization." (2) An organic derivative—barium ethyl peroxide—is known to have a complex molecule, $C_2H_5O.O.Ba.O.OC_2H_5$, from actual measurements.

§ 10. The Hydroxides of Calcium, Strontium, and Barium

According to B. Pelletier,[1] if calcium oxide is mixed with about half its weight of water, the liquid is at first absorbed by capillary action in the pores of the lime, which remain after the escape of carbon dioxide in the burning. The air contained in the pores is expelled with a hissing noise as the lime combines with the water to form a pulverulent mass of **calcium hydroxide,** $Ca(OH)_2$. The operation is called *slaking lime;* and the product *slaked lime,* or *hydrated lime.* The combination is attended by the evolution of much heat, and the lime is such a bad conductor of heat that there is a considerable rise of temp. This is sometimes sufficient to inflame sulphur, gunpowder, wood, and, according to W. Lenz, straw. The rise of temp. is greater the greater the purity and the quantity of lime employed. The low-grade limes give a temp. of 270°–300°, while with richer limes A. Herzfeld measured a rise of 468°. R. Wagner found that quicklime which has been dropped in oil, and re-calcined, hisses like a red-hot coke when dropped into water. The great amount of heat developed in the slaking of lime is not due to the passage of water from the liquid to the solid state, since the lime is heated to 100° during the slaking with ice, and the escaping steam carries away some fine particles of the solid. A lump of crystallized calcium oxide from a fused cake in water slakes so very slowly that no rise of temp. is perceptible; but A. L. Day, E. S. Shepherd, and F. E. Wright found that the powdered crystals appear to be inert when first placed in water, but in a few minutes hydration occurs with explosive violence. The decrease in the activity of calcium oxide with increasing temp. of ignition is due to shrinkage and a consequent reduction of surface. The denser the calcium oxide, the smaller the surface in proportion to its mass, and the less the reactivity with water. Calcium oxide prepared at a low temp. is loose and porous, and then offers a large surface, and in consequence hydrates rapidly; B. Pelletier, K. Kortum, P. Heinrich, and F. Göbel have noted the emission of light, visible in the dark, when lime is slaked with a little water.

C. J. D. von Grotthus stated that some ammonia is formed during the slaking of lime, but A. Pleischl found no evidence of this. The reaction involves the change from an anhydrous oxide to a hydroxide. J. J. Berzelius' analyses agree closely with that theoretically required for $Ca(OH)_2$; A. L. Lavoisier's and J. L. Gay Lussac's analyses have the water rather low, and in J. Dalton's analysis the water is rather high. L. Reuter showed that the water in ordinary slaked lime is usually 0·5 to 1·5 per cent. higher than corresponds with the formula $Ca(OH)_2$.

Hydrated lime can be obtained in commerce, and it is used for making mortar in place of quicklime. The hydrated lime has other commercial names—*new-process lime, limoid,* etc. If the quicklime is purchased, it is slaked by the consumer before use, and this entails a certain amount of trouble and waste. This question has been discussed by S. T. Brigham, C. Warner, S. V. Peppel, etc. In the preparation of commercial hydrated lime, the quicklime is ground to a fairly uniform small size, it is then mixed with water, and finally sieved or otherwise brought to a uniform fine powder.

The velocity of hydration of the lime (and baryta) was found by H. Rose to vary with its thermal history, and its porosity. (i) The more porous the lime, the more quickly can it be penetrated by water, and the more quickly does slaking occur. Again, (ii) P. Lebeau, A. Herzfeld, H. Moissan and G. Oddo ascertained that lime prepared at 1000° slakes violently when immersed in water, while that calcined at 1300° slakes quietly under the same conditions, and that which has been fused in the electric arc furnace is attacked *très lentement.* V. A. Jacquelain also found the crystals of calcium oxide formed by heating the nitrate at a high temp. slake very slowly. (iii) The presence of magnesium oxide in limestone retards the slaking. As E. de M. Campbell has shown, the hydration of magnesium oxide is very slow compared with that of calcium oxide, so that in the ordinary process of slaking lime, the magnesium oxide acts as so much inert matter.

According to E. Candlot, the presence of calcium chloride accelerates the hydration of calcium oxide; and, according to P. Rohland, the speed of hydration is accelerated by hydrochloric, nitric, acetic, or lactic acid, aluminium, barium, or calcium chloride, sodium acetate, asparagine, and ethyl alcohol; the speed of hydration is retarded by boric acid, potassium or sodium hydroxide, calcium chromate, potassium dichromate, acetaldehyde, glycerol, and cane or grape sugar; and no appreciable effect is produced by aqua ammonia, calcium hydroxide, sodium or potassium chloride, and potassium nitrate or hydrocarbonate. In general, therefore, acids, excepting boric acid, accelerate the hydration of lime; and alkalies retard the action.

T. J. Pelouze obtained calcium hydroxide by precipitation from soln. of calcium salts by potassium or sodium hydroxide; and F. Mohr used a similar process for barium hydroxide. Strontium or barium hydroxide is obtained by the action of moisture on strontia or baryta as shown by J. W. Döbereiner. According to C. F. Bucholz, the hydroxides are obtained by fusing the hydrates, and, according to D. Smith, by heating the hydrates to 100°. M. H. van Laar electolyzed a soln. of barium carbonate in barium nitrate in a cell with barium carbonate in the anode vessel, and found crystalline barium hydroxide was readily formed in the cathode compartment. Several of the technical processes indicated in connection with the preparation of barium or strontium oxide really furnish the hydroxide. This applies to all those processes in which the furnace products are leached with water. These methods have been discussed by R. Heinz.

The hydroxides of calcium, strontium, and barium, obtained by slaking the oxides, are fine white powders; those of barium and strontium, obtained by dehydrating the melted hydrates, are white crystalline masses. F. F. Selivanoff showed that calcium hydroxides prepared in different ways all have the composition: $Ca(OH)_2$, and all adsorb water vapour, which is largely lost by drying in a desiccator over sulphuric acid, or at 60°; but the last traces are retained very tenaciously. The amorphous hydroxide and water behave like two mutually soluble liquids, for when shaken together, soln. of water in the hydroxide and of hydroxide in water are formed. The amorphous hydroxide cannot be transformed into the crystalline form by heating it with water, or by prolonged storage with water; but by heating a supersat. soln. of lime, or by evaporating an aq. soln. of lime under diminished press. at 28°–30°, hexagonal plates or prisms of $Ca(OH)_2$ can be obtained. A. Lamy[2] and R. Phillips prepared small hexagonal prisms of calcium hydroxide by gradually heating a soln. of the hydroxide, the crystals are deposited at about 80°, since the solubility of the hydroxide decreases with rise of temp. J. L. Gay Lussac obtained crystals by allowing a soln. of limewater to evaporate spontaneously in the cold over conc. sulphuric acid or in the presence of quicklime under a bell-jar. According to E. Weinschenk, these crystals had a positive double refraction. A. Riffault and N. M. Chompré passed a current through a cell containing a soln. of calcium nitrate separated by a porous partition from water. The crystals were deposited on the negative electrode which was placed in the compartment containing water. O. Luedecke found hexagonal crystals as a boiler incrustation and as a deposit in a Carré's ice machine. S. Glinka found small six-sided plates of calcium hydroxide in some hydraulic cement; these crystals were probably rhombic with a positive double refraction.

F. F. Selivanoff prepared supersat. soln. by freezing soln. of calcium hydroxide, and they contained 0·260–0·264 grm. CaO per 100 c.c.; he could not prepare a soln. with 0·29 grm. of CaO per 100 c.c., as reported by F. Guthrie. The supersat. soln. are very sensitive to heat, and readily deposit crystals of the hydroxide at ordinary temp. The cryohydrate of lime solidifies, forming transparent ice; when this ice melts, it deposits elongated hexagonal plates, or small rhombic plates of **hemihydrated calcium hydroxide,** $Ca(OH)_2.\frac{1}{2}H_2O$. The hydrate is very unstable, and readily decomposes when slightly heated, forming the amorphous hydroxide. The hemihydrate, and the crystalline hydroxide, are less soluble in water, and dil. sugar soln. than the amorphous hydroxide. The crystalline or amorphous hydroxide, or crystals of the hemihydrate, are without effect on supersat. soln.

Unlike calcium hydroxide, the hydroxides of strontium and barium readily form hydrates. One hydrate of calcium hydroxide, $Ca(OH)_2.\frac{1}{2}H_2O$, has been reported, but this hydroxide is sometimes stated to form no hydrate. There are two hydrated strontium hydroxides with $Sr(OH)_2 : H_2O=1 : 8$, and 1 : 1, and four hydrated barium hydroxides with $Ba(OH)_2 : H_2O=1 : 16$; 1 : 8; 1 : 3; and 1 : 1, although it is not clear if all these are chemical individuals. An increasing at. wt. of the basic metal corresponds with an increasing tendency of the hydroxide to form hydrates. **Octohydrated strontium hydroxide,** $Sr(OH)_2.8H_2O$, or **octohydrated barium hydroxide,** $Ba(OH)_2.8H_2O$, is readily obtained by crystallization from an aq. soln. of the oxide or hydroxide in hot water. According to C. L. Bloxam, the octohydrated strontium hydroxide was obtained by precipitation on adding sodium hydroxide to a soln. of strontium nitrate, just as M. Anfrye and J. P. J. d'Arcet, M. Kirchhoff, and G. Pessina obtained the corresponding barium compound. The precipitate was washed free from alkali by means of ice-cold water, or with alcohol. F. Mohr added the theoretical quantity of powdered barium nitrate to a boiling aq. soln. of sodium hydroxide of sp. gr. 1·1 to 1·5, adding water if necessary, for the complete soln. of the nitrate. The crystals which separate on cooling the filtered soln. can be purified by re-crystallization. E. Beckmann prepared octohydrated barium hydroxide by crystallization from a sat. soln. between 10° and 109°.

The analyses of A. Souchay and E. Lenssen, E. Filhol, C. L. Bloxam, H. M. Noad, J. Thomsen, and D. Smith agreed with the formula $Sr(OH)_2.8H_2O$ for this hydrate; but R. Phillips and M. Berthelot gave analyses in agreement with $Sr(OH)_2.9H_2O$. C. L. Bucholz first analyzed the crystals of hydrated barium hydroxide, and his numbers agree with the formula $Ba(OH)_2.9H_2O$; and this was confirmed by the observations of H. Rose, H. M. Noad, M. Berthelot, R. Phillips, A. Rosenstiehl, and E. Filhol's analyses with $Ba(OH)_2.7H_2O$; but C. L. Bloxam, E. Beckmann, and D. Smith showed that the composition is more in agreement with $Ba(OH)_2.8H_2O$, the value accepted at the present day. The older analyses, said W. Reuling, were made on impure hydroxide, and the water was determined by difference; the presence of aluminium, magnesium, alkalies, and may be barium cyanide, made the amount of barium oxide formed by calcination appear too low. The general formula $M(OH)_2.8H_2O$ is now considered to represent correctly the composition of these two hydrates.

According to C. Neuberg and E. Neimann, when ethyl alcohol and water are added to a methyl alcohol soln. of barium oxide, the octohydrate separates in well-formed needles, which differ from the crystals of the ordinary octohydrate in losing a mol. of water over phosphorus pentoxide.

In vacuo, or in dry air, C. L. Bloxam, and E. Beckmann found the crystals lose seven-eighths of their water, forming what they regarded as **monohydrated barium hydroxide,** $Ba(OH)_2.H_2O$, which, when moistened, again forms the octohydrate with the development of heat. R. de Forcrand prepared the monohydrate by dissolving barium oxide in aq. methyl alcohol, and drying the resulting product, $Ba(OH)_2.2CH_3OH$, in vacuo. J. C. H. Heyer, and H. Lescœur obtained **monohydrated strontium hydroxide** by drying the octohydrate in vacuo; and R. Finkener by heating it to 50°. R. de Forcrand found that by heating octohydrated strontium hydroxide to 45°–50° in a stream of hydrogen, the monohydrate is formed; if the temp. is 95°, the hydroxide $Sr(OH)_2$ appears. Again, 15 hours' exposure of octohydrated barium hydroxide in a stream of hydrogen at 45° gives the monohydrate; while an hour at 95° gives $Ba(OH)_2$. W. Müller-Erzbach's vap. press. measurements at 15°, correspond with the passage of octohydrated strontium hydroxide to *dihydrated strontium hydroxide,* $Sr(OH)_2.2H_2O$, and thence to the monohydrate; but the dihydrate has not yet been isolated. M. Karcz, and A. Herzfeld prepared **monohydrated calcium hydroxide** by dissolving calcium oxide in air-free distilled water, and allowing the soln. to stand some days at 60°; the crystals which separated were dried over potassium hydroxide. The crystals lost part of their water at ordinary temp., and all between 60° and 70°. O. Bauer prepared **trihydrated barium hydroxide,** $Ba(OH)_2.3H_2O$, by gradually raising the temp. of the octohydrate, the molten salt begins to boil at 103°, and at 108·5°, crystals of the trihydrate separate out. In dry air the trihydrate forms the monohydrate. W. Artus claimed to have made crystals of the **hexadecahydrated barium hydroxide,** $Ba(OH)_2.16H_2O$. E. J. Maumené was not right in saying that the water content of the hydrates of barium hydroxide does not follow the law of constant proportion.

The hydroxides of the alkaline earths are all soluble in water, and the soln. form the so-called *lime-water* (*eau de chaux, Kalkwasser*), *strontia-water,* and *baryta-water* respectively. These liquids are clear and colourless; they have an acrid taste; and react alkaline towards vegetable colouring agents, and, according to M. Pettenkofer,[3] this the more strongly the greater the mol. wt. of the base. The aq. soln. rapidly becomes covered with a film of the carbonate on exposure to air. The so-called *milk of lime* and *cream of lime* (*lait de chaux, Kalkmilch*) are not soln. but mixtures of lime-water with different proportions of undissolved calcium hydroxide.

Lime-water is made by stirring an excess of slaked lime with water, and decanting the clear liquid out of contact with the air. Lime made from native carbonate may contain sodium and potassium salts, and in order to eliminate the latter, A. Vogel, and F. Kuhlmann recommend rejecting the first liquid after the residue, and treating the solid with a fresh portion of water.

V. Kohlschütter and G. Walther [4] have studied the rate of hydration of calcium oxide, and the rate of settling of the hydroxide in aq. soln. of various salts—sodium hydroxide, chloride, acetate, and carbonate; potassium chloride, nitrate, and thiocyanate; calcium chloride, and nitrate; ammonia; and ammonium oxalate. Dil. soln. of some salts increase while conc. soln. decrease the velocity of sedimentation; and other salts act in the converse way. The velocity of sedimentation is greater when water is added to quicklime than conversely; there is a difference with lime slaked by water and by lime-water.

When quicklime is slaked: $CaO+H_2O=Ca(OH)_2$, and a very slight excess of water is employed, the product of the reaction, according to P. P. von Weimarn, assumes a colloidal form. V. Kohlschütter and G. Walther showed that it is probable that an intermediate colloidal state is assumed in the production of a soln. of calcium hydroxide in water. B. Kosmann holds that the slaking of lime is an operation involving the step-by-step production of the following (imaginary) compounds: $Ca(OH)_2 \rightarrow HCa(OH)_3 \rightarrow H_3Ca(OH)_5 \rightarrow H_4Ca(OH)_6 \rightarrow H_5Ca(OH)_7 \rightarrow H_6Ca(OH)_8 \rightarrow H_7Ca(OH)_9$. The **setting of mortar** probably consists in the loss of water by the colloid, just as the hardening of gelatinous silica or the drying of plastic clay is due to desiccation of colloidal matter. The drying of colloidal calcium hydroxide is accompanied by a considerable contraction in vol., and it cracks and loses its form. The shrinkage is lessened by the addition of sand, or other inert substance. The particles of sand become coated with a film of lime which adheres very tenaciously. The cohesion of the dried colloid, and its adhesion to the sand, impart mechanical strength to the mortar, and enable it to resist the tensile stresses during its shrinkage.

The slow hardening of mortar is not due to a reaction between lime and the silica of the sand, because no such reaction occurs; although, with the less pure forms of sand—containing felspathic matters, puzzolana, etc.—a reaction may occur. Some of the ancient mortars were made by mixing the slaked lime with puzzolana, and this accounts for the presence of combined silica in many of those which have been analyzed. In general, the essential process involved in the setting of mortar is the dissociation of the colloid. The so-called *sand-lime bricks* are really mortar bricks —made by mixing slaked lime with sand and water, moulding the mixture by press., and hardening the product, either by solar heat, or more usually by superheated steam. There is no satisfactory evidence that the lime and sand react chemically under the conditions of manufacture.

There are at least two secondary changes which may supervene on the primary setting by the desiccation of the colloid. (1) When mortar is exposed to moist air, it gradually forms crystalline calcium carbonate. The crystals are closely interlaced and form a coherent mass. The mortar is thus hardened. The induration of mortar by the formation of carbonate is a secondary process, and is confined to the outer layers of a mass of mortar, because the impervious coating hinders the access of carbon dioxide to the interior. The mortar from old Roman buildings, for instance, after 2000 years' exposure, consists mainly of calcium hydroxide with a superficial layer of carbonate. (2) The crystals of calcium hydroxide which are sometimes found in hardened mortar, are not due to the primary hardening, but owe their formation to the subsequent soln. of the calcium hydroxide in water and its re-deposition in the crystalline form.

Determinations of the **solubility** of calcium hydroxide in *water* have been made by J. Dalton,[5] R. Phillips, L. Wittstein, and many others. As J. Dalton pointed out, the remarkable feature is the decrease in solubility which occurs with rise of temp.—usually the reverse obtains. As a result, R. Phillips showed that a precipitate appears when a sat. soln. is heated, and, added T. Graham, the crystalline deposit "is not diminished sensibly by being allowed to remain in soln. till it becomes cool, or was not re-dissolved on cooling." The composite results of the different observations which have been made with $Ca(OH)_2$ as the solid phase, and expressed in grams of solute per 100 grms. of water, are:

	0°	10°	20°	40°	60°	80°	100°	120°	150°	190°
$Ca(OH)_2$.	0·185	0·176	0·165	0·141	0·116	0·094	0·077	0·041	0·022	0·011
CaO .	0·140	0·133	0·125	0·107	0·088	0·071	0·058	0·031	0·017	0·008

A. Lamy claimed that the solubility of calcium hydroxide depends on the temp. of preparation of the anhydrous oxide. Thus, expressing the results in grams per litre, he reported:

	0°	15°	30°	60°	100°
Lime from nitrate .	0·1362	0·1277	0·1142	0·0844	0·0562
Lime from marble .	0·1381	0·1299	0·1162	0·0868	0·0576
Precipitated hydrate .	0·1430	0·1348	0·1195	0·0885	0·0584

The time required to attain equilibrium between the liquid and solid phases may be different in these cases, and, consequently, A. Lamy may not in all cases have been dealing with sat. soln. This may also explain how the measurements by different workers are not so concordant as might have been anticipated.

The determinations of the solubility of strontium hydroxide in water are not so numerous as is the case with calcium hydroxide. A. Bineau,[6] and C. F. Bucholz made isolated determinations, and C. Scheibler and D. Sidersky measured the results over the range of temp. between 0° and 100·2°. The solubility curve is normal in that the solubility increases with rise of temp. Expressing the results in grams of solute per 100 grms. of soln., when the solid phase is $Sr(OH)_2.8H_2O$:

	0°	10°	20°	30°	40°	50°	60°	80°	100°
$Sr(OH)_2.8H_2O$.	0·90	1·23	1·74	2·57	3·80	5·46	7·77	16·83	47·71
SrO . .	0·35	0·48	0·68	1·00	1·48	2·13	3·03	6·56	18·60

Isolated measurements of the solubility of barium hydroxide in water have been made by H. Davy, R. Osann, and A. Bineau. Determinations from 0° to the m.p. of the octohydrate, $Ba(OH)_2.8H_2O$, 78·65°, have been made by A. Rosenstiehl, where the octohydrate is the solid phase. Expressing the results in grams of the solute per 100 grms. of soln. :

	0°	10°	20°	30°	40°	50°	60°	75°	80°
$Ba(OH)_2.8H_2O$.	1·65	2·42	3·74	5·29	7·60	11·61	17·32	38·85	50·35
BaO . . .	1·48	2·17	3·36	4·75	6·85	10·5	15·8	36·2	47·6

The solubility in water thus increases with increasing mol. wt. of the hydroxide, for 100 parts of water dissolve respectively 0·128, 2·0, and 3·44 parts of calcium, strontium, and barium hydroxides. In this respect, the hydroxides are unlike the sulphates, chlorides, and nitrates, whose solubility increases with decreasing mol. wt. The m.p. of the octohydrate is indicated above. W. A. Tilden suggested that the great difference in the solubility of hydrated barium and strontium hydroxides on the one hand and of calcium hydroxide on the other hand, makes it probable that the former retain their hydrate-water when they pass into soln. H. F. Sill found the solubility of octohydrated barium hydroxide at 25° to be augmented by *pressure* : with a press. of one megabar (*i.e.* 1·02 kgrm. per sq. cm.) the solubility is 8·299 per cent.; with 245 megabars press., 8·840 per cent.; and with 490 megabars press., 9·366 per cent.; he also found the temp. coeff. of the solubility to be 0·288 per cent.

The solubility of calcium hydroxide is greatly reduced in the presence of alkali hydroxides, so much so that L. Wittstein,[7] and T. J. Pelouze stated that calcium hydroxide is not soluble in alkaline lye, and is precipitated from its aq. soln. by the alkali hydroxides. The effect of *potassium hydroxide* or *sodium hydroxide* on the solubility of calcium hydroxide has been measured by A. d'Anselme, at different temp.; when the conc. is expressed in grams of solute per litre, he found :

NaOH. .	0	0·4	1·6	2·66	5·0	8·0	20·0
CaO { 20° .	1·17	0·94	0·57	0·39	0·18	0·11	0·02
CaO { 110° .	0·54	0·35	0·14	0·05	0·01	0·00	0·00

Aqua ammonia acts in a similar manner, but the effect is less pronounced than with the fixed alkalies. E. Maigret measured the simultaneous effect of both sodium hydroxide and chloride on the solubility of calcium hydroxide. F. A. H. Schreinemakers investigated the decrease in the solubility of barium hydroxide produced by increasing proportions of sodium hydroxide; G. Bodländer, the effect of *alkali carbonates* and hydroxides on the solubility of calcium hydroxide.

A. A. Noyes and E. S. Chapin observed that the solubility of calcium hydroxide is augmented in the presence of *ammonium chloride*. Thus, at 25°, the solubility was raised from 0·150 grm. of $Ca(OH)_2$ per 100 c.c. of soln. to 0·442 grm., when 0·447 grm. of ammonium chloride was present. M. Berthelot explained the increased solubility by assuming that a complex salt, $2NH_4Cl.Ca(OH)_2$, that is, $Ca(NH_3)_2Cl_2.2H_2O$, is formed. C. J. B. Karsten found that calcium hydroxide dissolves more copiously in the presence of *sodium chloride* than in water alone; and G. L. Cabot found that (i) the effect is still more marked with *potassium chloride* than with sodium chloride; that (ii) at any assigned temp., the solubility increases with the conc. of the alkali salt up to a certain limiting value corresponding approximately with one-fifth of the conc. of a sat. soln. of the alkali chloride and ubsequently decreasing with increasing conc. of the alkali chloride, becoming, according to G. Kernot and co-workers, less than in water alone; and that (iii) for a given conc. of the alkali salt, the solubility decreases with rise of temp. The raising of the solubility is here conditioned partly by double decomposition, and partly by the formation of a complex calcium salt. W. Herz found the solubility of barium hydroxide to be increased by the *lithium, sodium, potassium,* and *rubidium chlorides.* The effect is greatest with lithium and least with rubidium chloride. C. J. B. Karsten also ascertained that the presence of *sodium nitrate* or *potassium nitrate* also increases the solubility of calcium hydroxide; and that an aq. soln. of calcium hydroxide gives a precipitate with *sodium sulphate* only when the soln. is quite sat. with that salt, while precipitated calcium hydroxide slowly dissolves in an aq. soln. of sodium sulphate at 15° to 19°, and is slowly transformed into dihydrated calcium sulphate, $CaSO_4.2H_2O$—glauberite, $Na_2SO_4.CaSO_4$, is also formed (*q.v.*). I. Herold has investigated the caustification of *potassium sulphate* by calcium hydroxide.

According to C. J. B. Karsten, *calcium chloride* raises the solubility of calcium hydroxide in water; and, according to B. Zahorsky, soln. with less than 10 per cent. of calcium chloride dissolve rather less calcium hydroxide than does water, but when the conc. of the calcium chloride soln. is greater than this, the solubility of calcium hydroxide is augmented because of the formation of what B. Zahorsky regards as *calcium trihydroxychloride,* $3CaO.CaCl_2.15H_2O$, or $3Ca(OH)_2.CaCl_2.12H_2O$, or $Ca_2(OH)_3Cl.6H_2O$; he gives for the number of grams of calcium oxide dissolved in 100 c.c. of soln.:

	0	5	10	15	20	25	30 per cent. CaCl.
20° . . .	0·1374	0·1370	0·1661	0·1993	0·1857*	0·1661*	0·1630*
40° . . .	0·1162	0·1160	0·1419	0·1781	0·2249	0·3020*	0·3684*
60° . . .	0·1026	0·1020	0·1313	0·1706	0·2204	0·2989	0·3664
80° . . .	0·0845	0·0936	0·1328	0·1736	0·2295	0·3261	0·4122
100° . . .	0·0664	0·0906	0·1389	0·1842	0·2325	0·3710	0·4922

The results with water alone are higher than the standard values; and those marked with an asterisk were affected by the separation of any oxychloride from the soln. which lowered the amount of the dissolved calcium chloride. G. Lunge has discussed the part played by calcium chloride in W. Weldon's process for chlorine. F. A. H. Schreinemakers and T. Figee have studied the ternary system $H_2O—CaCl_2—Ca(OH)_2$, and obtained two oxychlorides, $Ca(OH)_2.CaCl_2.H_2O$, and $4Ca(OH)_2.CaCl_2.10H_2O$; F. A. H. Schreinemakers and J. Milikan, the systems $CaCl_2—CaO—H_2O$, and $CaBr_2—CaO—H_2O$; J. Milikan the system with *calcium iodide,* $CaI_2—CaO—H_2O$; and of strontium hydroxide with *strontium chloride,* $SrCl_2—SrO—H_2O$; *strontium bromide,* $SrBr_2—SrO—H_2O$; and *strontium iodide,* $SrI_2—SrO—H_2O$; and F. A. H. Schreinemakers and J. Milikan, the systems with barium oxide and *barium chloride,* $BrCl_2—BaO—H_2O$; *barium bromide,* $BaBr_2—BaO—H_2O$; and *barium iodide,* $BaI_2—BaO—H_2O$—*vide* the corresponding oxy-halides. F. K. Cameron and W. O. Robinson, and H. Bassett and H. S. Taylor have studied the ternary system with *calcium nitrate,* namely, $CaO—Ca(NO_3)_2—H_2O$; C. L. Parsons and C. L. Perkins, the ternary system involving *strontium hydroxide* and *strontium nitrate,* namely, $SrO—Sr(NO_3)_2—H_2O$; C. L. Parsons and H. P. Corson the system with *barium hydroxide* and *barium nitrate,* namely, $BaO—Ba(NO_3)_2—H_2O$; and F. K. Cameron and J. M. Bell, the ternary system with *calcium sulphate,* namely, $CaO—CaSO_4—H_2O$.

The addition of **alcohol** precipitates barium hydroxide from baryta water. E. Beckmann[8] found that barium hydroxide is sparingly soluble in mixtures of alcohol and water. At room temp., 50 per cent. alcohol dissolves 0·43 per cent. of barium hydroxide. W. Rothmund measured the solubility of strontium hydroxide in aq. soln. containing $\frac{1}{2}N$-proportions of the following substances—the given data are expressed in grams per 100 c.c. at 25°—water alone, 1·016; *methyl alcohol,* 0·997; *ethyl alcohol,* 0·905; *propyl alcohol,* 0·861; *tertiary amyl alcohol,* 0·766; *acetone,* 0·842; *ether,* 0·785; *glycol,* 1·121; *mannitol,* 2·429; *urea,* 0·997; *ammonia,* 0·955; *dimethylamine,* 0·713; and *pyridine,* 0·844.

According to W. Eidmann, calcium, strontium, and barium hydroxides are insoluble in *acetone* and in *methyl acetate.* W. Herz and M. Knock found the solubility of barium hydroxide in aq. acetone decreases as the proportion of water becomes less from 4·506 grms. of the solute in water at 25° to 0·018 grm. in water containing 70 per cent. of acetone by vol. They also determined the sp. gr. of the soln. The solubility of calcium hydroxide in *glycerol* has been measured by M. Berthelot, P. Carles, F. K. Cameron and H. E. Patten, W. Herz and M. Knock. The latter found at 25°:

Glycerol	0	7·15	20·44	31·55	40·95	48·7	69·2	per cent.
$Ca(OH)_2$	0·1593	0·3013	0·5522	0·8339	1·486	1·631	3·550	grms. per 100 c.c.
CaO	0·1206	0·2281	0·4180	0·6313	1·125	1·234	2·687	grms. per 100 c.c.

They also measured the sp. gr. of the soln. F. K. Cameron and H. E. Patten found that at 25° the solid phase is always calcium hydroxide, although a complex is probably formed in the soln.; and that the increase in the solubility of calcium hydroxide in aq. soln. of glycerol over that in water, is directly proportional to the conc. of the glycerol. W. Rothmund found a $\frac{1}{2}N$-soln. of glycerol dissolves 1·331 grms. of strontium hydroxide per 100 c.c.

The solubility of calcium hydroxide in aq. soln. of *sugar* has attracted much attention on account of the use of lime in the defecation of sugar. The solubility in a soln. of sugar is much greater than in water. The solubility has been measured by E. M. Péligot, T. J. Pelouze, P. H. Déon, J. Weisberg, etc. The ratio of lime to sugar in the soln. varies almost continuously with the composition of the soln., but M. Berthelot showed that this ratio does not vary proportionally, in consequence of the formation of different compounds in the soln., *e.g.* calcium trisucrate, etc. Whatever compound is formed in the soln. is broken down by water, and F. K. Cameron and H. E. Patten showed that the solid phase in the ternary system, CaO-sugar-H_2O, is one of a series of solid soln. with calcium hydroxide as a limiting or end-member. They also measured the sp. gr. of the soln. F. K. Cameron and H. E. Patten's results at 25°, in grams per 100 grms. of soln., are:

Sugar	0	0·62	4·82	7·50	11·90	17·42	19·86
$Ca(OH)_2$	0·117	0·188	0·730	1·355	3·21	5·38	6·07

H. Claasen has studied the various factors which influence the solubility of calcium hydroxide in soln. of sugar. J. Weisberg showed that the apparent solubility is affected by the condition of the calcium compound employed—*e.g.* whether the oxide, hydroxide, or milk of lime is added to the sugar soln.—the anhydride seems to be the most soluble. The solubility is less as the temp. rises, thus, P. J. H. van Ginneken found at 80°:

Sugar.	0·90	9·90	14·75	19·50	24·60	29·70
$Ca(OH)_2$	0·154	0·249	0·303	0·341	0·723	1·341

grams per 100 grms. of soln. The alleged calcium trisucrate present in the soln. is supposed by E. Boivin and D. Loiseau to be less soluble hot than cold. The lime is precipitated on boiling the soln. With strontium hydroxide, 100 grms. of a soln. containing 10 grms. of sugar were found by C. Scheibler to dissolve 1·21 grms. of strontium oxide at 3°; 1·41 grms. at 15°; 1·87 grms. at 24°; and 3·58 grms. at 40°. The lime is precipitated on boiling the soln. G. J. van Meurs has measured the solubility of calcium, strontium, and barium hydroxides in aq. soln. of *phenol.*

Slaked lime is a white amorphous or colloidal powder. According to H. le Chatelier,[9] crystallized slowly, as in the hydrations of cements, it forms large well-developed crystals which may be recognized by the microscope. As previously indicated, the **crystals** of calcium hydroxide are probably dimorphous—rhombic and trigonal. According to G. Rose, the latter are possibly isomorphous with brucite,

$Mg(OH)_2$. The crystal forms of barium and strontium hydroxides have not been established. According to H. J. Brooke, the crystals of octohydrated strontium hydroxide belong to the tetragonal system with the axial ratio $a : c = 1 : 0·6407$, and this is in agreement with the observations of A. Eppler, and of G. B. von Foullon. The latter also found the crystals of octohydrated barium hydroxide to be monoclinic prisms, with axial ratios $a : b : c = 0·9990 : 1 : 1·2779$, and $\beta = 98° 56'$. These crystals have pseudo-tetragonal symmetry, and were once thought to be isomorphous with the corresponding strontium compound. O. Bauer found the needle-like crystals of trihydrated barium hydroxide are six-sided prisms belonging to the rhombic system, with axial ratios $a : b : c = 0·58905 : 1 : 0·78038$.

A. Lamy[10] found that the **specific gravity** of crystals of calcium hydroxide was 2·239, and when prepared at 60°, 2·236; E. Filhol found 2·078 for calcium hydroxide, 3·625 for strontium hydroxide, and 4·495 for barium hydroxide. The sp. gr. of octohydrated strontium hydroxide was also found by E. Filhol to be 1·911 at 16°; and of the corresponding barium compound, 2·188 at 16°; while A. Eppler gave 1·885 for the former, and 2·080 for the latter. According to J. A. Wanklyn, the sp. gr. of a soln. of 1·344 grms. of calcium oxide in a litre of water is 1·002 at 13°, so that the resulting contraction is eq. to three times the volume of the solute. The sp. gr. of milk of lime has been determined by E. Mategcek, and G. Lunge, and the following is a selection of the results for 15°:

Grms. CaO per litre .	11·7	62·5	126·0	190·0	255·0	321·0
Sp. gr.	1·01	1·05	1·099	1·15	1·20	1·25

F. Kohlrausch found the sp. gr. of an aq. soln. containing 2·3 grms. of $Ba(OH)_2.8H_2O$ in 100 grms. of soln. at 18°, to be 1·0120; and with 4·60 grms. per litre, 1·0252. M. M. Haff has measured the sp. gr. of soln. of barium hydroxide at 8°. C. L. Parsons and H. P. Corson found 1·0512 for the sp. gr. of a sat. aq. soln. with 4·29 grms. of barium hydroxide per 100 grms. of water at 25°, and they measured the sp. gr. of soln. with varying proportions of barium hydroxide and nitrate; and C. L. Parsons and C. L. Perkins measured the sp. gr. of soln. of strontium hydroxide and nitrate. G. A. Carse's data are given in Table I. H. F. Sill found the change in the sp. vol. during the soln. of octohydrated barium hydroxide is 0·0508 c.c. per gram. G. A. Carse measured the **contraction on solution**, that is, the difference in the vol. of soln. of barium and strontium hydroxides, and of the water used in its preparation; and also the **thermal expansion** of the soln. The results are indicated in Table I. The vol., v, of a gram of soln. at $\theta°$ is indicated and the difference between v and the volume v' of the water in a gram of soln. at $\theta°$, namely, $v - v'$, is indicated in the last column of the Table.

TABLE I.—THERMAL EXPANSION OF AQUEOUS SOLUTIONS AND THE CONTRACTION ON SOLUTION OF BARIUM AND STRONTIUM HYDROXIDES.

Strontium hydroxide.					Barium hydroxide.				
Conc.	$\theta°$.	Sp. gr.	v.	$v-v'$.	Conc.	$\theta°$.	Sp. gr.	v.	$v-v'$.

,,	30	0·99600	1·00432	+0·00021	,,	30	0·99611	1·00390	−0·00002

The conc. of the soln. are expressed as grams of hydroxide per 100 grms. of soln. The sp. vol. v of the soln. at $\theta°$, is represented by the formula $v=v_0\{1+a(\theta-15)+b(\theta-15)^2+c(\theta-15)^3\}$, where v_0 denotes the sp. vol. at 15°. The a, b, and c for the two hydroxides are:

	$Sr(OH)_2$			$Ba(OH)_2$		
Conc.	0·3274	0·1216	0·0235	0·8939	0·0821	0·0430
$a\times10^6$	+180	+220	+165	+97	+130	+143
$b\times10^8$	+340	+410	+600	+1200	+980	+630
$c\times10^9$	+50	+380	−12	−180	−210	−28

The coeff. of thermal expansion, a, can be readily calculated for 15°, 20°, 26°, and 30°, since $a=(dv/d\theta)/v$. S. F. Glinka found the **hardness** of crystals of calcium hydroxide to be between 2 and 3. O. Bauer gives 2·5 for the hardness of the crystals of trihydrated strontium hydroxide.

H. Rose found that when calcium hydroxide is heated, no water is lost at 100°, but at 400°, about 30 per cent. of the combined water is given off. All the water can be expelled without the hydroxide melting. H. le Chatelier found the **vapour pressure** of calcium hydroxide at 300° to be 100 mm., and at 450°, 760 mm. Both C. F. Buchholz and D. Smith observed that strontium hydroxide loses its combined water and passes into strontia when it is heated. A. Herzfeld and C. Stiepel found that strontium hydroxide dried in vacuo at 110°, loses 3 per cent. of water after one hour's heating at 590°; 14 per cent. at 650°; and all the combined water is lost at 710°. E. Filhol observed that barium hydroxide melts to an oily-liquid when heated, and C. F. Bucholz and A. F. Gehlen found that if no carbon dioxide be present, barium hydroxide loses no water when calcined to a high temp., but H. Abich found that water could be expelled by heat. W. Dittmar, indeed, observed that in a stream of air, at a bright red-heat, all the water is expelled, and barium monoxide or dioxide is formed. H. Lescœur found the vap. press. of the hydroxide in vacuo at 100° to be extremely small. In further illustration of the increasing affinity of the hydroxide for water with increasing mol. wt., octohydrated strontium hydroxide forms the monohydrate with a slight elevation of temp., octohydrated barium hydroxide forms the trihydrate at 109°, and this in dry air forms the monohydrate. Monohydrated barium hydroxide forms the hydroxide at a dull red heat, while the conversion with monohydrated strontium hydroxide occurs at 100°. J. Johnston found the dissociation press. of the three hydroxides to be:

Diss. press.		0·0229	0·0724	0·196	0·467	1·00 atm.
Temp.	$Ca(OH)_2$	389°	428°	468°	507°	547°
	$Sr(OH)_2$	488°	561°	634°	706°	778°
	$Ba(OH)_2$	670°	749°	829°	910°	998°

The free energy F of the reactions when F is defined by $F=-W+\Sigma_{pv}$, where W stands for the maximum work produced by the change, and Σ_{pv}, for the change in the sum of the pv terms for each part of the system, then for the reaction involving $Ca(OH)_2 \rightarrow CaO$, F is 16,430 cals.; for $Sr(OH)_2 \rightarrow SrO$, 19,700 cals.; and for $Ba(OH)_2 \rightarrow BaO$, 23,360 cals. For the vap. press. of the transition 0–1H_2O, with calcium oxide, H. W. Foote and S. R. Scholes gave 0·8 mm.

According to C. L. Bloxam, C. Heyer, R. Finkener, and W. Müller-Erzbach, the crystals of octohydrated strontium hydroxide lose seven-eighths of their water of crystallization in vacuo, or in dry air, and form the monohydrated hydroxide; and octohydrated barium hydroxide under similar conditions also furnishes the monohydrate. R. de Forcrand found that a week's exposure of octohydrated strontium hydroxide in vacuo furnishes the monohydrate, while a month's exposure furnishes $Sr(OH)_2$; while ten days' exposure of octohydrated barium hydroxide under similar conditions produces the monohydrate, and no more change occurs during many weeks' exposure. C. F. Buchholz found that the crystals of octohydrated strontium hydroxide lose all their water of crystallization when heated, without their melting; D. Smith found the water of crystallization can be expelled at

100°. According to O. Bauer, when octohydrated strontium hydroxide is warmed slightly, it passes without fusion into the monohydrate, and the latter passes into the anhydrous hydroxide below 100°. W. Müller-Erzbach found the vap. press. $Sr(OH)_2.8H_2O \rightarrow Sr(OH)_2.2H_2O$ to be 9·4 mm.; $Sr(OH)_2.2H_2O \rightarrow Sr(OH)_2.H_2O$ to be 3·2 mm.; and $Sr(OH)_2.H_2O \rightarrow Sr(OH)_2$ to be 0 mm. He concluded that hydrates with 8, 7, 2, and $1H_2O$ are formed—but there is no evidence of the existence of the di- or hepta-hydrated hydroxide. H. Lescœur found the vap. press. of the octohydrate to be 5·6 mm. at 20°.

Octohydrated barium hydroxide was found by D. Smith to melt in its water of crystallization at 100°, but this temp. is too high. A. Rosenstiehl gave 78·5° for the **melting point**; O. Bauer, 78°; V. H. Veley, 83° to 85°; and T. W. Richards and J. B. Churchill, 79·9°–80°. D. Smith and C. L. Bloxam found seven mols of water are lost at the m.p., but E. Beckmann found that all is expelled at this temp. W. Müller-Erzbach found the **vapour pressure** of $Ba(OH).8H_2O$ to be 11·4 mm.; $Ba(OH)_2.3$ to $7H_2O$, 2·46 mm.; $Ba(OH)_2.2H_2O$, 1·3 mm.; and $Ba(OH)_2.H_2O$, 0 mm.—all at 15°. He therefore inferred the formation of hydrates with 1, 2, 7, and $8H_2O$. The existence of the di- and hepta-hydrates has not been confirmed, although O. Bauer isolated the tri-hydrate. According to O. Bauer, the octohydrate furnishes crystals of the trihydrate when heated to 108·5° and slowly cooled; the trihydrate passes into the monohydrate at about 100°; and at about 550°, the anhydrous hydroxide is formed. On comparing these results with the behaviour of hydrated strontium hydroxide, and remembering that calcium hydroxide does not form a well-defined stable hydrate, it follows that with increasing at. wt., the three metals of the alkaline earths show an increasing tendency to form hydrated hydroxides. H. Lescœur found the vap. press. of the octo- and mono-hydrates of barium hydroxide, at different temp., to be:

	13·5°	20°	35·5°	58°	70°	74·5°	100°
$Ba(OH)_2.8H_2O$.	4·5	5·5	20·5	84	124	213	530 mm.
$Ba(OH)_2.H_2O$.	<1	1	1	1	1	14	15 mm.

He also found at 100°, the results indicated in Fig. 10. The **molecular heat** was found by W. Nernst and F. Schwers to be 5·09 at −187°, and 0·493 at −251·6°.

O. Bauer found that the **boiling point** of molten octohydrated barium hydroxide is 108·5° when it contains 49·05 per cent. of baryta; at 105°, 52·43 per cent. of baryta; at 107°, 55·35 per cent. of baryta; and at 109°, 61·44 per cent. of baryta, the crystals of the trihydrate then separate. F. Guthrie found the **freezing point** of the cryohydrate of calcium hydroxide to be −0·15° with 1116 mols of water; of strontium hydroxide, −0·1° with 1463 mols of water; and of barium hydroxide, −0·5° with 565 mols of water. W. Nernst and F. Schwers found the **molecular heat**, C_p, of calcium hydroxide to be 5·09 at 86° K., and 0·493 at 21·4° K.

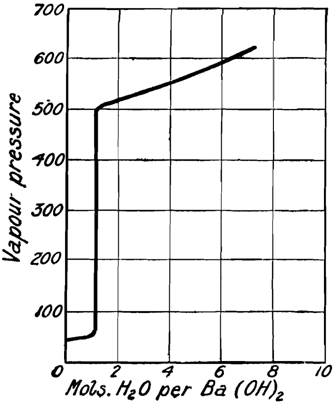

Fig. 10.—Vapour Pressure in the System $Ba(OH)_2$—H_2O.

H. Moissan[11] gave for the **heat of formation** of calcium hydroxide (Ca, O_2, H_2), 229·1 Cals., and for sat. soln. of the same, 232 Cals. J. Thomsen gave for the heat of formation (Ca, O_2, H_2), 146·46 Cals.; for (Ca, O, aq.), 149·46 Cals.; for (Sr, O, H_2O), 148·18 Cals.; for (Sr, O, aq.), 157·78 Cals.; for (Ba, O, H_2O), 148·00 Cals.; and for (Ba, O, aq.), 158·26 Cals. A. Guntz gave for the reaction, $Ba + nH_2O_{liquid} = Ba(OH)_2aq. + H_2 + 92·5$ Cals. at 16°. M. Berthelot gave (CaO, H_2O), 15·1 Cals.; J. Thomsen gave (SrO, H_2O), 17·70 Cals.; (BaO, H_2O), 22·26 Cals.; and M. Berthelot, (BaO, H_2O), 17·6 Cals. J. Johnston found the **free energy** of the reaction;

calcium hydroxide to oxide at 25° is 16·43 Cals.; for strontium hydroxide, 19·7 Cals.; and for barium hydroxide, 23·36 Cals.; J. Thomsen, (CaO, H_2O), 15·54 Cals.; (CaO, aq.), 18·33 Cals; for (SrO, aq.), 29·34 Cals. R. de Forcrand found for the heat of soln. of $Sr(OH)_2.8H_2O$, —14·27 Cals.; for $Sr(OH)_2.H_2O$, 5·26 Cals.; for $Sr(OH)_2$, 10·33 Cals.; for $SrO.0·14H_2O$, 26·10 Cals.; and for SrO, 29·76 Cals. J. Thomsen gave for (BaO, aq.), 34·52 Cals. R. de Forcrand found for the heat of soln. of $Ba(OH)_2.8H_2O$, —14·5 Cals.; for $Ba(OH)_2.H_2O$, 7·06 Cals.; for $Ba(OH)_2$, 11·40 Cals.; and for BaO, 35·64 Cals. J. Thomsen suggested M. Berthelot's oxide still retained some carbon dioxide; and he gave for the **heat of solution** of calcium hydroxide, ($Ca(OH)_2$, aq.), 2·79 Cals. M. Berthelot gave 3·0 Cals. at 15°. J. Thomsen gave ($Sr(OH)_2$, aq.), 11·4 Cals.; ($Ba(OH)_2$, aq.), 18·33 Cals.; ($Sr(OH)_2,8H_2O$), 26·28 Cals.; ($Sr(OH)_28H_2O$, aq.), 14·64 Cals.; and ($Ba(OH)_2 8H_2O$), 27·47 Cals. For the heat of soln. of the octohydrate J. Thomsen gave ($Ba(OH)_28H_2O$, aq.), —15·21 Cals., or 46·0 cals. per gram of solute; and R. de Forcrand, —14·5 Cals., or 48·2 cals. per gram of solute. H. F. Sill found 51·2 cals. for the heat of soln. of octohydrated barium hydroxide at the saturation point.

According to W. Crookes,[12] while barium oxide gives scarcely any **phosphorescence** in the cathode rays, barium hydroxide phosphoresces with a bright orange-yellow glow. The bright glow of lime when heated in the blowpipe flame was mentioned by D. Brewster—*vide* incandescent mantle, Vol. 5. T. Drummond noted that when lime, zirconia, and magnesia cylinders are heated in the oxy-hydrogen blowpipes, the relative intensities were 37, 31, and 16 times the intensity of the light from an argand burner. The **index of refraction** of crystallized calcium oxide is 1·8. E. Duter found that during the electrolysis of baryta water less oxygen is given off than corresponds with the hydrogen—this is attributed to the formation of barium or hydrogen dioxide

The **electrical conductivities** of aq. soln. of calcium, strontium, and barium hydroxides have been measured by S. Arrhenius, F. Kohlrausch, etc. For a soln. containing a mol of hydroxide in *v* litres of water, W. Ostwald's values for the mol. conductivity, μ, at 25°, are:

v . . .	8	16	32	64	128	256	512	1024
μ-$Ca(OH)_2$.	—	—	—	406	426	447	455	—
μ-$Sr(OH)_2$.	—	—	405	419	432	446	451	452
μ-$Ba(OH)_2$.	372	392	410	429	448	461	465	469

These hydroxides are therefore strongly ionized in dil. soln., and this corresponds with their strong basic characteristics. A. A. Noyes has measured the eq. conductivities of soln. of different conc. at different temp. Data for the **transport numbers** of soln. of calcium hydroxide were given by W. Bein, and for strontium and barium hydroxides, by J. F. Daniell.

S. Marsh has studied the electrolysis of soln. of barium hydroxide with an alternating current of varying frequency by means of electrodes of gold, platinum, and nickel. The vol. of gas evolved is greater than in soln. of sulphuric acid. The rate of evolution of gas increases with time, and increasing frequency. With gold and platinum electrodes, the rate of evolution of gas falls off rapidly with time, but for frequencies less than 48, gas is still given off; with nickel electrodes very small quantities of hydrogen are given off with 60 cycles, and with 40 cycles the vol. of gas given off is too small to measure. It is assumed that the electrode is oxidized and subsequently reduced by the hydrogen of the next half-period; and that hydrogen is absorbed and adsorbed by the electrode and oxidized by the oxygen of the next half-period. F. Tiemann argued that because the electrolysis of soln. of barium hydroxide gives no hydrogen dioxide, and because of the formation of the calcium saccharates, it is likely that the hydroxides of the alkaline earths are better formulated $RO.H_2O$, than $R(OH)_2$. P. Pascal found the mol. **coefficient of magnetization** of $Ba(OH)_2.8H_2O$ to be -1569×10^{-7} units.

The hydroxides of the alkaline earths react with acids like strong bases, forming characteristic salts. When calcium hydroxide is exposed to **air**, it absorbs carbon dioxide, and the crystals of the former compound become opaque. According to V. H. Veley,[13] J. Kolb, and H. Debray, **carbon dioxide** is not absorbed to any appreciable extent at ordinary temp. by calcium, strontium, or barium hydroxide if moisture be rigorously excluded. J. C. Whetzel studied the effect of exposure to air on hydrated and quicklime; in both cases a thin layer of protective carbonate is formed. According to N. Tarugi, when a mixture of calcium oxide and water (3 : 1 by weight) is allowed to stand exposed to the air, some calcium peroxide is formed. The action of **carbon dioxide** has been previously discussed; the action of carbon dioxide on soln. of the hydroxides of the alkaline earths is discussed in connection with that gas. Baryta water is a very sensitive reagent for carbon dioxide, since the resulting barium carbonate has a very low solubility. E. Beckmann found that carbon dioxide does not react with barium oxide below 120°, but near 500° the reaction is quantitative. J. J. Berzelius said that when barium hydroxide is heated on charcoal, it fuses with violent effervescence, sinks into the charcoal, and forms a hard mass. D. Walker found that when **carbon disulphide** is agitated with milk of lime, orange crystals of $CaCS_2.2Ca(OH)_2.6H_2O$ are formed; while G. Chancel and F. Parmentier found baryta water at 100° reacts: $CS_2+2Ba(OH)_2=BaCO_3+Ba(SH)_2+CO_2$. C. Bunge studied the action of barium hydroxide on **glass**, and found that glass made from sulphates furnished an insoluble crust containing barium sulphate. By heating calcium hydroxide with **carbon** (anthracite coal dust), H. Vogel obtained results pointing to a reaction: $2Ca(OH)_2+C=2CaO+CO_2+2H_2$; F. Stolba also found hydrogen is evolved when calcium hydroxide is heated with **iron** filings, and if the hydroxide is mixed with carbonate, carbon monoxide, as well as hydrogen, is given off. According to M. Müller, **lead** tubes are attacked by soln. of calcium hydroxide only in the presence of oxygen; carbon dioxide played no part in the reaction. J. K. Weisberg found dry barium hydroxide does not absorb **chlorine**, but in contact with water it takes up a quantity of chlorine, increasing with the proportion of water, until a mol of barium hydroxide has taken up a mol of chlorine. Very little hypochlorite is formed, nearly all the chlorine being in the form of chloride or chlorate: $6BaO+6Cl_2=5BaCl_2+Ba(ClO_3)_2$. The action of chlorine on strontium hydroxide is similar—*vide* bleaching powder (2. 19, 4). For the action of **sulphur**, see the corresponding sulphides. A. Geuther found that at ordinary temp. barium hydroxide is partially decomposed by **phosphoryl chloride**, and when heat is applied, hydrogen chloride is evolved. The reaction is not completed by a prolonged heating on a water-bath. Some barium phosphate is formed. Calcium hydroxide was found by A. Terreil to attack **antimony trisulphide** in the wet way, while barium and strontium hydroxides have no action—*vide supra* for the oxides.

The so-called **soda-lime** is a mixture of calcium and sodium hydroxides made by stirring lime into the molten caustic alkali; and breaking up the cold cake. It is used as an absorbent for moisture, carbon dioxide, etc. It was also employed in admixture with sodium permanganate, and in conjunction with charcoal, in gas masks to absorb the poison gases introduced by the Germans in the Great War. The composition and properties of soda-lime were investigated by A. B. Lamb, R. E. Wilson, and N. K. Chaney.[14] For general toxic gas absorption, 5 per cent. of alkali and 10–13 per cent. of water are recommended; for carbon dioxide absorption, 4–5 per cent. of alkali and 16–19 per cent. of water is best; and for chlorine absorption, 8–9 per cent. alkali is recommended. A mixture of 4 per cent. sodium hydroxide, 4 per cent. kieselguhr, and the remainder lime, with a final water content of 12 per cent., is recommended as an all-round absorbent for industrial gases.

acid; and as a flocculent mass by treating a conc. soln. of the alkaline earth salt with hydrofluoric acid. A. C. Becquerel separated soln. of calcium chloride and ammonium fluoride by a porous membrane, and found crystals of calcium fluoride grew on the calcium chloride side of the membrane. H. Moissan obtained a crystalline precipitate by adding a soln. of the alkaline earth chloride to a boiling soln. of potassium fluoride, and boiling the mixture for half an hour. H. de Sénarmont obtained crystalline calcium fluoride by heating for 60 hrs. under press., at 250°, the gelatinous precipitate with an aq. soln. of sodium bicarbonate almost neutralized with hydrochloric acid; T. Scheerer and E. Drechsel heated the gelatinous mass for 10 hrs. at 250° with hydrochloric acid; they also heated calcium fluosilicate for 10 hrs. with an aq. soln. of calcium chloride: $CaSiF_6+2CaCl_2+2H_2O=3CaF_2+SiO_2+4HCl$; and also by melting non-crystalline calcium fluoride with sodium or potassium chloride, or a mixture of the two salts. F. Röder obtained crystals by melting sodium fluoride with calcium or strontium and sodium chlorides; A. Feldmann melted barium or strontium chloride with calcium fluoride at a red heat: $CaF_2+BaCl_2=CaCl_2+BaF_2$ and the fluoride of barium or strontium remained when the cold mass was lixiviated with water. C. Poulenc fused calcium or strontium chloride with potassium hydrofluoride, and washed the soluble matters from the small cubic crystals of the fluoride of the alkaline earth; he obtained the calcium fluoride in octahedral crystals; but, by heating the amorphous fluoride with a mixture of potassium chloride and hydrofluoride, "beautiful transparent regular octahedra" were obtained. E. Defacqz heated a mixture of manganese fluoride with an excess of alkaline earth halide to at least 800° in a stream of carbon dioxide; the product was washed first with hot water and then with a 2–5 per cent. soln. of hydrochloric or acetic acid to remove soluble salts. If the temp. be below 1000° the crystals are octahedra; if above 1200°, cubes. Barium fluoride has not been obtained in well-defined crystals, but strontium fluoride furnishes octahedral crystals by fusing a mixture of manganese fluoride and strontium iodide. W. Wetzel obtained octahedral crystals of fluorite by allowing calcareous sandstone, or siliceous limestone, to stand for some days in 3 per cent. hydrofluoric acid contained in a vulcanite vessel.

The properties of the alkaline earth fluorides.—These salts furnish **crystals** in octahedra and cubes belonging to the cubic system. A. W. Hull,[3] and W. P. Davey found that the **X-radiograms** of crystals of calcium. strontium, and barium fluoride belong to the face-centred cubic lattice, or the tetrahedral cubic lattice, and that the atoms are 2 per cent. closer than the atoms in the face-centred cubic lattice of the element calcium. W. L. Bragg gave 2·38 A. for the closest approach of the atoms in calcium fluoride; and W. P. Davey, 2·50 A., in strontium fluoride; and 2·69 A. in barium fluoride. W. Gerlach studied the lattice constants of calcium fluoride. The electrostatic potential of the fluorite lattice was studied by A. Landé, and E. Bormann. A. Kenngott obtained 3·183 as a mean for the **specific gravity** of 60 samples of fluorspar—the maximum and minimum values were 3·1988 and 3·1547; and, according to A. Breithaupt, the maximum and minimum values for the ordinary mineral, more or less impure, are 3·01–3·25. E. Madelung and R. Fuchs gave 3·1808 (0°). For strontium fluoride, H. G. F. Schröder gave 4·22, whence W. Biltz gave 29·8 for the mol. vol. H. Bauhans and V. Goldschmidt studied the corrosion figures, the so-called end-figure, and the velocity of dissolution of fluorite in nitric acid.

H. E. Merwin obtained the value 3·180 at 20° for a number of samples of colourless transparent fluorspar; H. G. F. Schröder, 3·150 for the precipitated and calcined calcium fluoride, 4·20–4·24 for strontium fluoride, and 4·828 for barium fluoride; and O. Ruff and W. Plato, 3·16 (20°) for calcium fluoride. C. H. D. Bödeker gives 4·58 for the sp. gr. of barium fluoride. The **hardness** of calcium fluoride on Mohs' scale is 4. W. Voigt[4] gave for the coeff. of **compressibility** of calcium fluoride $1·93\times10^{-6}$ per atm.; the modulus of **extension** or compression along the crystal axis when the distortion is around the axis, is 1473×10^6 grms. per sq. cm.; the same constants for directions equally inclined to this and normal to the third, and equally inclined to all three axes are 1008×10^6 and 910×10^6 respectively E. Madelung and R. Fuchs found for the compressibility, $1{\cdot}22$–$1{\cdot}26\times10^{-6}$ megabars per sq. cm. P. Drude and W. Voigt gave 10,450 kgrms. per sq. mm. for the **elastic modulus ;** 0·221 for the elastic number—ratio of transverse contraction to longtitudinal extension ; and the **torsion modulus** around the crystal axis is 345×10^6 grms. per sq. cm. A. Mallock made some measurements of the elastic constants of fluorspar. K. Försterling studied the relation between the elastic constants and the sp. ht.

The coeff. of **thermal expansion,** according to G. Weidemann,[5] is 0·00001934 at 52° ; and, according to F. Pfaff, 0·0000195. According to H. Fizeau, at 40°, the coeff. of linear expansion, normal to the face of the octohedral cleavage of a crystal of fluorspar, is $\alpha=0{\cdot}00001910$; the same value was obtained for the face of the cube of another crystal ; and $\alpha=0{\cdot}00001915$ for the face cut at an angle of 5° to a face of a cube of another crystal. According to H. Kopp, the coeff. of cubical expansion is 0·000062. F. E. Neumann gives the **specific heat** as 0·2080–0·2084 ; H. V. Regnault, 0·21492, and after calcination, 0·21686 ; H. Kopp, 0·209 ; and J. Joly, 0·21180 for green transparent cubic crystals, and 0·21264 for grey translucent crystalline mass.

The **melting point** of fluorspar, 902°, according to H. Moissan, is too low ; O. Ruff and W. Plato give 1330° ; and E. Beck, 1264°. O. Ruff and W. Plato's value for barium fluoride is 1280°. G. Magnus found there was no change in the sp. gr. of the crystalline mass after it has been melted in a porcelain oven. W. R. Mott gives 1400° for the **boiling point** of barium fluoride. The **heat of formation,** according to A. Guntz : $\mathrm{Ca}+\mathrm{F}_2=108{\cdot}5$ Cals. ; $\mathrm{Sr}_{\mathrm{solid}}+\mathrm{F}_{2\mathrm{gas}}=74{\cdot}3$ Cals. ; and $\mathrm{Ba}_{\mathrm{solid}}+\mathrm{F}_{2\mathrm{gas}}=222{\cdot}6$ Cals. ; $\tfrac{1}{2}\mathrm{CaO}$ (1 eq. in 25 litres) HF (eq. in 2 litres)$=\tfrac{1}{2}\mathrm{CaF}_2$ (solid at 11°)+11·6 Cals. ; similarly, 17·9 Cals. for strontium fluoride ; and 17·40 Cals. for barium fluoride. Again, $\tfrac{1}{2}\mathrm{Ca(OH)}_2+\mathrm{HF}_{\mathrm{gas}}=\tfrac{1}{2}\mathrm{CaF}_{2\mathrm{solid}}+\mathrm{H}_2\mathrm{O}_{\mathrm{solid}}+33{\cdot}3$ Cals. ; similarly, 35·90 Cals. for the strontium salt ; and 35·70 Cals. for the barium salt. According to E. Petersen, $\mathrm{Ca(OH)}_{2\mathrm{aq.}}+2\mathrm{HF}_{\mathrm{aq.}}=36{\cdot}31$ Cals., 35·47 Cals. for the strontium salt, and 32·30 Cals. for the barium salt.

The transparency of fluorite for the infra-red and ultra-violet rays, the low refractive power, and weak colour dispersion makes fluorite useful in correcting the chromatic and spherical aberration errors in lenses for microscopes, small telescopes, and the like. The fluorite for optical purposes should be as clear as glass, and free from cloudiness, inclusions, cleavage cracks, etc. On the other hand, H. Rubens and B. W. Snow[6] found the dispersion in the ultra-red to be very great, so that fluorite lenses are advantageously used in the production of the spectra of the heat rays. H. E. Merwin recommended the **refractive index** of different specimens of the purer varieties of fluorspar as a standard for comparison ; for Na-light, $\mu=1{\cdot}43385$ at 20° when quartz has $\omega=1{\cdot}54425$. A great many determinations of the refractive indices of fluorite for rays of different wave-length have been made. F. Paschen obtained values for wave-lengths λ from $0{\cdot}48607\mu$ to $9{\cdot}4291\mu$ between 17° and 20°.

λ .	9429·1	7071·8	5893·2(D)	3830·6	2946·6	1620·6	486·07
μ .	1·31612	1·36806	1·38721	1·41122	1·41823	1·42592	1·43713

V. Schumann calculated for rays $242{\cdot}883\mu\mu$, 1·47067 ; for $180\mu\mu$, 1·5176 ; $160\mu\mu$, 1·5529 ; $140\mu\mu$, 1·6195 ; $120\mu\mu$, 1·7862 ; $115\mu\mu$, 1·8748 ; $65\mu\mu$, 0·8772. F. J. Micheli, J. Stefan, H. Fizeau, H. Dufet, J. O. Reed. and C. Pulfrich found that the effect of an increase of temp. lowers the value for, say, $\lambda=589{\cdot}3$(Na) by 0·00001215 per 1° at 58·8° to 0·00001652 per 1° at 385°. The refractive index of differently coloured varieties of fluorspar has been determined by C. Hlawatsch, H. Dudenhausen, and F. J. M. Wülfing. H. Dudenhausen's value for Na-light with water-clear fluorspar is 1·43380 ; rose-coloured, 1·43394 ; yellow, 1·43361 ; pale violet, 1·43367 ; green, 1·43381 ; blue, 1·43361 ; greenish-violet, 1·43433 ; intense violet, 1·43389. The dispersion $(\mu_{\mathrm{C}}-\mu_{\mathrm{F}})/(\mu_{\mathrm{D}}-1)$ is 0·0105.

The so-called *normal dispersion* occurs when the refractive index increases as the wave-length decreases at a rate dependent on the nature of the substance ; but substances which exhibit selective absorption do not usually exhibit normal dispersion because the refractive index on the blue side of the absorption band is generally less than the index for the red light on the opposite side of the absorption band. This phenomenon is termed *anomalous dispersion*, although normal dispersion can be regarded as a special case of anomalous dispersion. To evade the implication conveyed by the term "anomalous," A. Schuster proposed to substitute the term *selective dispersion*. In the case of fluorite, the dispersion curve in the visible spectrum is convex towards the wave-length axis, Fig. 11, and eventually becomes concave in the ultra-red region, indicating that an absorption band is being approached. U. Meyer found **Verdet's constant**, ω, at 20°, for rays of wave-length, λ, to be :

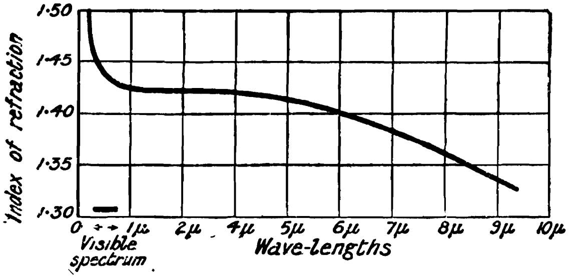

FIG. 11.—Dispersion Curve of Fluorite.

λ	0·2534	0·4358	0·4916	0·6708	0·90	3·00μ
ω	0·05989	0·01717	0·01329	0·00672	0·00367	0·00030

M. Melloni[7] noted that fluorite is more transparent than glass for the infra-red heat rays, and advantage was taken of the fact by P. Desains. G. Magnus showed that a plate 10 mm. thick transmitted 9·1 per cent. of the heat rays with the plate at 150°, and 19·1 per cent. were transmitted by a plate 3·8 mm. thick. Further,

	NaCl	KCl	CaF_2	AgCl	AgBr
Transmission	8·3	54·5	9·1	43·6	48·3 per cent.

H. Rubens also found fluorite to be diathermous for the red heat rays down to a wave-length of 3·3μ, and F. Paschen noticed that with a plate 4 mm. thick, absorption begins at about 7·6μ, and with rays of wave-length 8·2μ the plate has a 9 per cent. absorption, while with a plate 1 cm. thick, H. Rubens and A. Trowbridge obtained a 84·4 per cent. absorption for a wave-length of 8μ ; 16·4 per cent. for 11μ ; and none with 12μ. Fluorite is transparent for the visible spectrum, and, according to W. A. Miller, and E. Mascart, it is also transparent for the ultra-violet. P. Ites[8] observed a maximum in the yellowish-red—about 0·600—in the visible part of the absorption spectrum of fluorite. For a 1·487 mm. thick plate of green fluorite, for light of wave-length λ, the transparency ratio, *i.e.* the ratio of the intensities of the incident and transmitted light d, and the extinction coeff. a,

λ	B	C	0·618μ	D	0·556μ	E	F
μ	1·4317	1·4324	1·4329	1·4335	1·4344	1·4355	1·4374
d	0·641	0·592	0·458	0·623	0·623	0·630	0·604
a	0·0204	0·0246	0·0384	0·0374	0·0219	0·0212	0·0235

In 1677, J. S. Elsholtz showed that fluorite luminesces when warmed ; and G. W. von Leibniz accordingly named the mineral *thermophosphorus*—*vide* the sulphides of the alkaline earths. The violet light emitted during the thermo-luminescence of fluorspar is sometimes sufficiently intense to enable print, at a distance of six inches, to be read. Some colourless specimens exhibit no thermo-luminescence. Most samples decrepitate when heated—the yellow and dark violet varieties usually decrepitate most, and some colourless ones do not decrepitate at all. E. Newbery and H. Lupton found all varieties lose their colour when heated, but the green colour is most difficult to discharge, and those colours induced by exposure to radium are easiest discharged. The coloured varieties of fluorspar, when strongly heated, lose their power of emitting light, but this power is restored after exposure to radium emanation, and a new capacity of emitting a bright green thermo-luminescence at a low temp. is acquired. In 1820, D. Brewster showed that native fluorite phosphoresces when it has been exposed to light; but after it has been heated above 300°, it loses its power of phosphorescing by insolation; and A. E. Becquerel showed this power is restored by exposure to cathode or to Röntgen rays.

According to P. Bary, fluorite phosphoresces when exposed to **X-rays** and to **Becquerel rays**; and, according to A. Wiedemann and G. C. Schmidt, the violet luminescence in **cathode rays** is largely due to the contained manganese. The green glow obtained by exposure to **radium rays** persists for a short time after removing the exciting source. The colour changes produced by radium on colourless fluorspars, or fluorspars which have been decolorized by heat, are very varied. They have been studied by E. Newbery and H. Lupton; different colours may be produced by the α-, β-, and γ-radiations. All fluorspars give a green glow by exposure to the rays from radium; and a violet glow in the cathode rays. The glow continues in each case after the removal of the exciting source. The colour changes are striking—*e.g.* colourless crystals of a fluorspar from Matlock become deep blue after exposure to radium; green crystals deepen in tone; and yellow crystals become blue or purple. They suggest that the colours and thermo-luminescent properties of many minerals have been determined by the presence of radioactive matter either in the water from which they have been deposited, or by radioactive minerals in their immediate neighbourhood. T. J. Pearsall gave a long list of the various colours emitted by different fluorspars at various temp. and times of heating. When the " store " of light is exhausted, he found that the luminescence is restored under the excitation of the electric spark, although the light emitted is never the same as that produced during the first heating. G. C. Kindt noted the broad bands in the spectrum of the thermo-luminescence, and E. Hagenbach, and G. D. Liveing made approximate measurements of the wave-lengths. H. W. Morse photographed the spectra of the thermo-luminescence. P. Schuhknecht found that the fluorescent spectrum with Röntgen or cathode rays extends further into the ultra-violet than that of any other substance. C. Doclter found that colourless fluorspar became rose colour in ultra-violet light.

The theories which have been made as to the cause of the coloration of natural crystals of rock salt apply *mutatis mutandis* to fluorspar. The coloured varieties are decolorized at 300°. Certain fluorites, *e.g.* the *stinking fluorite* from Wölsendorf, emit an alliaceous odour when powdered; the effluvium has oxidizing properties, for, if the pulverization is conducted under water, the liquid blues starch and potassium iodide. C. F. Schafhäutl[9] attributed the coloration of fluorspar to the presence of hypochlorous acid; C. F. Schönbein, and A. Schrötter, to ozone; O. Löw, to a perfluoride; G. Wyrouboff, to two hydrocarbons—one producing a red and the other a blue colour; H. W. Morse, organic matter; and H. Moissan and A. H. Becquerel, to free fluorine. Many of these assumptions are untenable in the light of M. Berthelot's and A. Debierne's observations that decolorized fluorspars had their original colour restored by exposure to radium radiations. B. Blount and J. H. Sequeira do not favour the assumption that the colour is an effect of radioactivity, but believe that the colour is due to organic matter which they extracted in part by chloroform, toluene, or aniline; and determined by combustion analysis. C. S. Garnett found the colour of blue john is due to films of organic matter lying parallel to and in the plane of the faces of the otherwise colourless crystal, and also at the crystal junctions; it was probably deposited on the surfaces of the crystals at intervals during their growth. A very intensely coloured specimen contained 0·27 per cent. of carbon, on distillation gave off inflammable vapours, and a yellowish oil collected in the condenser. The residual fluorite was colourless. The colour of red fluorite is not destroyed by heat, but is readily extracted from the powdered mineral by boiling hydrochloric or nitric acid. The soln. contains rare earths and insignificant quantities of other elements. J. Barnes and W. F. Holroyd claim to have synthesized crystals of fluorspar exhibiting all natural colours; and they conclude that the colour is an optical phenomenon dependent on the crystallization and physical state of the substance. C. Doelter assumed that the colour is due to the presence of colloidal metals or other substances, and that the metals oxidize when heated. A. Debierne found that some dark violet varieties of fluorspar smell of ozone when heated, and also yield a little helium. B. Blount and J. H. Sequeira found argon but no helium in blue john. J. Jakob considered the colour of some minerals is due to the presence of chromogens or groups of colouring atoms; and that of others, by the presence of a finely divided foreign substance.

F. Mohs[10] (1824), F. von Kobell (1830), and D. Brewster (1833) drew attention to the fact that some fluorspars show different colours in transmitted and in reflected light —*e.g.* green is transmitted, and different tints of blue by reflected light. J. F. W. Herschel named the phenomenon epipolar dispersion. The subject was studied by G. G. Stokes, and he recommended the phenomenon be called fluorescence after fluorspar in the same way that opalescence is called after opal. The phosphorescence of fluorspar when heated—thermo-luminescence—has been known for a long time. It was mentioned by J. G. Wallerius[11] in 1747; by M. Sage in 1777; by J. B. L. Romé d'Isle in 1783; and certain varieties were called *chlorophane* by T. von Grotthus in 1794, and *pyrosmargyd* by J. F. L. Hausmann in allusion to this phenomenon. A sample of fluorite from Dorgali (Sardinia) was found by E. Clerici to exhibit thermo-luminescence even under carbon tetrachloride or acetone; it emitted radiations capable of influencing a photographic plate, and of penetrating glass, mica, or gelatine, but not aluminium or black paper. It contained traces of rare earth impurities. J. R. Formhals attributed the thermo-phosphorescence of fluorspar to the oxidation of finely divided arsenic sulphide present in traces in these varieties of fluorspar. A specimen of felspar, which showed no sign of phosphorescence when ignited, exhibited the phenomenon after the addition of a trace of arsenic sulphide. A. Mitscherlich,[12] C. Fabry, J. Rosch, P. Leopold, H. George, C. M. Olmsted, and S. Datta studied the relations between the band spectra of the fluorides of the alkaline earths; and H. Pascal, the X-ray spectrum.

According to W. Hankel,[13] the crystals are electrified by changes of temp., or by exposure to light. The middle of the faces of the cube are negatively and near the edges, more particularly near the corners, are positively electrified. The longer and the more intense the illumination the stronger the effect. The arc light is stronger than sunlight, and the latter is stronger than diffuse daylight. The discharged sparks from two Leyden jars produce the effect, while the light from a vacuum tube is not sufficiently intense to produce the effect. G. C. Schmidt used the limelight for his experiments in this subject. E. Meyer noted the photoelectric effect of different samples of fluorspar. According to J. Curie, the **electrical conductivity** of fluorite is very small, being less than 0·0001 at 20°. J. Curie also found the **dielectric constant** to be 6·80 in agreement with the measurements of M. Romich and J. Nowak, who found 6·70; H. Starke found 6·92; M. von Pirani, 7·36; and W. Schmidt, 6·70. F. Paschen calculated for $\lambda=\infty$, 6·09. W. Voigt and S. Kinoshita found the **diamagnetism** to be $-6·27\times10^{-7}$ mass units and $-20·0\times10^{-7}$ volume units. J. Königsberger gives $-1·130\times10^{-6}$ for the magnetization constant. P. Pascal gave for the mol. coeff. of magnetization of calcium fluoride -281×10^{-7}; strontium fluoride, -272×10^{-7}; and for barium fluoride, 511×10^{-7}.

Calcium fluoride is but very sparingly soluble in water. According to G. Wilson,[14] at 15·6°, 1000 parts of water dissolve 0·37 part of fluorite, but even this number is probably too great, because F. Kohlrausch calculated from the electrical conductivity that at 18° a litre of water dissolves only 0·016 grm. of calcium fluoride. F. Kohlrausch also found the solubility of strontium fluoride to be rather greater, 0·117 grm. at 18°, and of barium fluoride, greater still, 1·630 grms. The eq. conductivity of a c.c. cube of calcium fluoride is $\lambda=0·000037$ reciprocal ohms; strontium fluoride, $\lambda=0·000172$, and barium fluoride, $\lambda=0·001530$ reciprocal ohms. The low solubility of calcium fluoride is utilized in the gravimetric determination of fluorides and fluorine. J. Nicklès found that the solubility of fluorite in water is greater when carbon dioxide is present; H. Rose also showed that the presence of ammonium salts augments the **solubility** of calcium fluoride; and H. Reinsch states that aq. **ammonium carbonate** decomposes calcium fluoride a little, and that the etching of the glass-containing vessel is due to the formation of ammonium fluoride. J. J. Berzelius stated that boiling soln. of **potassium or sodium hydroxide** are without action on calcium fluoride; and that calcium fluoride is easily decomposed by the vapour of **sulphuric acid,** but not by that of **sulphur trioxide.** Cold conc. sulphuric acid with silica-free fluorite, continued J. J. Berzelius, forms a transparent viscid liquid which deposits calcium fluoride when diluted with water; this liquid begins to decompose at 40°: $CaF_2+H_2SO_4=CaSO_4+2HF$. F. Röder said that artificial crystals of fluorite are decomposed by sulphuric acid with difficulty. According to J. J. Berzelius, conc. **hydrochloric and nitric acids** behave like sulphuric acids, but the resulting soln. are less viscid; boiling nitric acid partially decomposes fluorite; boiling hydrochloric acid dissolves it a little, but a precipitate is formed when the acid is neutralized with alkali, or a residue remains when the soln. is evaporated—if the fluorspar contains silica, hydrofluosilicic acid is formed. Aq. **hydrofluoric acid** dissolves a little silica-free fluorite. It is probable that calcium fluoride forms a complex with hydrofluoric acid, because E. Frémy evaporated at a low temp. a soln. of calcium hydroxide in a great excess of hydrofluoric acid, and obtained small crystals of **hexahydrated calcium hydrofluoride,** $CaF_2.2HF.6H_2O$, which are decomposed by boiling water into calcium and hydrogen fluorides. C. Poulenc found that strontium fluoride is completely decomposed by boiling hydrochloric or sulphuric acid, and partially decomposed by nitric acid. According to J. L. Gay Lussac and L. J. Thénard, barium fluoride is readily soluble in hydrochloric, nitric, and hydrofluoric acids. T. Scheerer and E. Drechsel say that if barium fluoride is heated under press. with a few drops of hydrochloric acid to 230°, small crystals of **barium fluorochloride,** $BaClF$; and if nitric acid be used, hexagonal crystals of a double compound, **barium fluoronitrate,** are formed. T. Scheerer and E. Drechsel found that if gypsum remains for a week under **water** in contact with barium fluoride, crystals of barium sulphate and of calcium fluoride are formed. According to E. Paternò and U. Alvisi, a conc. soln. of **oxalic acid** in contact with finely powdered fluorite converts the latter into calcium oxalate; an analogous reaction, but feebler, occurs if **tartaric acid** be employed. According to H. C. Sorby, a soln. of **sodium carbonate** between 100° and 150° transforms fluorite into calcite and sodium fluoride. A. Guntz and H. Basset observed no signs of the formation of calcium subfluoride when calcium fluoride is heated with calcium.

Fluorspar melts when heated before the blowpipe, and, according to J. Smithson, with further heating it develops hydrogen fluoride and calcium oxide; E. Frémy found that at a red heat, **water** vapour acts in a similar manner. C. Poulenc found strontium fluoride to be stable when heated in air to 1000°, but above that temp. it is decomposed into strontia and hydrogen fluoride; at a red heat strontium fluoride is not decomposed by water vapour or **hydrogen sulphide**; but it is decomposed by hydrogen chloride: $2HCl+SrF_2=SrCl_2+2HF$. E. Frémy states that hydrogen has no action on red-hot fluorspar. H. Schulze states that **oxygen** does not attack fluorspar at a red heat, but E. Frémy observed that glass is etched by the issuing gas, and he assumed that an oxyfluoride is formed. H. Schulze showed that in E. Frémy's experiment the fluorspar was heated in a platinum vessel, and that combustible gases which attack the fluoride diffuse through the walls of the vessel. When heated with **carbon disulphide** it forms calcium sulphide and probably carbon tetrafluoride. Dry **chlorine** at a red heat forms calcium fluochloride. E. Defacqz states that when fluorite is fused with **calcium chloride, bromide, or iodide**, double compounds are formed. J. J. Berzelius says that fluospar is not decomposed when fused with **alkali hydroxides or carbonates**, but P. Berthier showed that this is wrong, fluorspar is decomposed when melted with these agents. H. Rose found fluorspar to be completely decomposed when fused with a mixture of silica and sodium carbonate. P. Berthier also examined qualitatively the result of fusing fluorspar with **calcium sulphate**, **calcium sulphide**, **strontium sulphate**, **barium chloride**, **sodium sulphate**, **sodium chloride**, and **borax**. C. Friedel found fluorspar is rapidly decomposed when fused with **aluminium sulphate,** forming calcium sulphate and aluminium fluoride; and W. Briegleb noticed that small crystals of apatite are formed when fluorspar is fused with **sodium phosphate** at a red heat. A. Guntz obtained what he regarded as **sodium barium difluoride,** $NaF.BaF$, by the electrolysis of a molten mixture of sodium and barium fluorides.

E. Paternò, A. Mazzucchelli, and D. Vita have studied the formation of mixed **colloids** of calcium fluorides with calcium phosphate; silver chloride, bromide, iodide, phosphate, or sulphide; cupric sulphide; ferric hydroxide; or silicic acid, and found that these mixtures are stable; on the other hand, mixtures with calcium carbonate or oxalate; silver thiocyanate, chromate, or manganate; zinc, cadmium, or manganese sulphide; lead chromate or sulphate; or barium sulphate form less stable colloids; and calcium fluoride precipitates at once in the presence of arsenious sulphide.

§ 12. Calcium, Strontium, and Barium Chlorides

The Dutch alchemists—Isaac of Holland and either his brother or his son—are supposed to have lived in the fifteenth century,[1] because in their writings they cite a number of authorities prior to that period, but none more recent. They quote Arnold of Villanova with reverence, but they do not mention Paracelsus. Isaac of Holland said that he obtained a salt which he called *sal ammoniacum fixum* by heating together sal ammoniac and lime; this salt could have been no other than calcium chloride. W. Homberg, in his *Observations sur un nouveau phosphore* (1693), noticed by chance that the salt prepared by calcining a mixture of sal ammoniac with twice its weight of lime is phosphorescent when fused, and hence, for a time, calcium chloride was known as *phosphore de Homberg*, or Homberg's phosphorus. Strontium chloride was first described by A. Crawford[2] in 1790; and barium chloride by C. W. Scheele, in his memoir *De magnesia nigra*, in 1774.

Calcium chloride is found in soln. in sea-water, and in many mineral springs, J. F. L. Hausmann[3] found calcium chloride crystals in the anhydrite of Lüneburg, and called it *hydrophylite*—ὕδωρ, water; φίλος, lover—in reference to its hygroscopicity; A. Scacchi also found it mixed with potassium, sodium, and manganese chlorides among the products of the Vesuvian eruption of 1872, and named it *chlorocalcite.* F. Zambonini regarded chlorocalcite as a compound, $KCl.CaCl_2$, but there is no evidence of the homogeneity of the product he analyzed. Calcium chloride also occurs as a constituent of some minerals—*e.g. tachhydrite*, $2MgCl_2.CaCl_2.12H_2O$; *apatite*, $3Ca_3(PO_4)_2.Ca(Cl_2,F_2)$.

Calcium chloride is used as a substitute for salt brine in refrigerating and ice-making plants; in the absorption of moisture from air in cold storage rooms; in the drying of gases in the manufacture of liquid carbon dioxide, ammonia, etc.; for drying air in compressed air power plants; in the manufacture of dry colours or lakes; in the composition of sizing for cotton mill use; as a hot bath in the preparation of canned vegetables and food stuffs; as a liquid in traps for plumbing systems; in the laying of dust in streets; in the seasoning of Portland cement; in the preparation of wall plaster; etc.

The preparation of chlorides of the alkaline earths.—The chlorides of the alkaline earths are formed by the action of chlorine on the metal. According to H. Moissan, in the reaction with calcium the mass becomes incandescent. J. L. Gay Lussac and L. J. Thénard[4] prepared calcium chloride by the action of chlorine on quicklime, which becomes incandescent during the reaction, and oxygen is given off. H. Davy found that oxygen eq. to the chlorine was evolved when the latter gas reacts with barium oxide; and R. Weber, with strontium oxide. M. E. Chevreuil found that calcium oxide also vigorously absorbs gaseous hydrogen chloride, forming calcium chloride and water, without becoming incandescent. With barium and strontium oxides M. E. Chevreuil found the analogous reaction occurs with incandescence. The reaction between hydrogen chloride and calcium oxide is completed at a high temp. W. Heap and E. Newbery passed carbonyl chloride, or a mixture of carbon monoxide and chlorine over a catalyst like animal charcoal, and then over the oxide or salt of a weak acid—carbonate or oxalate—at a suitable temp.

J. B. J. D. Boussingault, and C. Hensgen found that the sulphates of the alkaline earths are very gradually converted into chlorides when heated in a stream of hydrogen chloride. C. Matignon and F. Bourion found barium sulphate or carbonate is converted into chloride when heated in a stream of sulphur chloride vapour, S_2Cl_2, mixed with an excess of chlorine. According to G. P. A. Petzholdt, a mixture of hydrogen chloride and carbon dioxide gives a mixture of calcium chloride and carbonate. Neither calcium oxide nor carbonate, according to G. Gore, is attacked by liquid hydrogen chloride, but precipitated barium or strontium carbonate is converted into the chloride without the evolution of any gas. P. Heinrich found that when hydrochloric acid is dropped on quicklime in the dark, a luminescence appears. Calcium chloride is usually obtained by dissolving calcium carbonate in hydrochloric acid, and evaporating the soln. to crystallization. Crystals of the hexahydrated salt, $CaCl_2.6H_2O$, are formed.

Iceland spar or marble is dissolved in hydrochloric acid, chlorine water is added to oxidize iron and manganese compounds which are then precipitated along with silicic acid by the addition of milk of lime. The filtered soln. is acidified with hydrochloric acid, and evaporated to crystallization. The marble may also be dissolved in nitric acid and heated with an excess of lime. The filtered soln. is acidified and evaporated to crystallization, and recrystallized. Ammonium carbonate is then added to the soln., and the precipitated carbonate washed by decantation, and then dissolved in purified hydrochloric acid. This soln. is evaporated to crystallization.

G. Kirchhoff and R. Bunsen dissolved marble in hydrochloric acid, and precipitated about half the lime with ammonium carbonate, and from the mother liquid the rest of the lime was precipitated by more ammonium carbonate. The first precipitate included most of the impurities in the marble as well as calcium carbonate; the second precipitate was dissolved in nitric acid and evaporated for calcium nitrate, which was dissolved in alcohol. The alcoholic soln. was evaporated, dissolved in water, and treated with ammonium carbonate. The precipitated calcium carbonate was washed and dissolved in hydrochloric acid for calcium chloride. The same process was used for strontium and barium chlorides. J. C. G. de Marignac, and J. B. A. Dumas purified strontium chloride by boiling a conc. soln. of commercial strontium chloride with a little sulphuric acid, and afterwards precipitated the chloride by a stream of hydrogen chloride. L. Barthe and E. Falières, and T. W. Richards and V. Yngve purified strontium chloride; and T. W. Richards, barium chloride by repeated precipitation by adding alcohol to the aq. soln. T. W. Richards purified barium chloride by the following method:

An aq. soln. of the commercial salt was evaporated to dryness with an excess of purified hydrochloric acid so as to decompose the thiosulphates. The hot dil. soln. was treated with an excess of hydrogen sulphide and allowed to stand in a tightly corked stout flask for some time in darkness. The clear liquid was made alkaline with purified barium hydroxide, and after standing some time decanted from the insoluble sulphides; the sulphur was expelled from the filtrate by boiling with hydrochloric acid. The soln. contained traces of calcium, strontium, potassium, sodium, and possibly magnesium. After two crystallizations from water, followed by two precipitations from alcohol, the spectroscope showed no impurity other than a trace of "the ever present sodium." This salt was ignited in a platinum dish at a dull red heat; the aq. soln. in water was acidified with hydrochloric acid and evaporated to crystallization.

If the water be expelled from the crystalline salt by heating the crystals above 200°, a white porous hygroscopic anhydrous mass is obtained. The fused product solidifies to a crystalline mass on cooling. F. P. Dunnington and F. W. Smither obtained $CaCl_2.H_2O$ after heating the hexahydrated salt 12 days at 97°–98°. E. Mitscherlich supposed the dihydrated salt remains when the hexahydrated salt is dehydrated at 200°; but J. Legrand showed that even the ground salt in a boiling sat. soln. has less than $H_2O : CaCl_2 = 2 : 1$. A. Weber says the salt dehydrated at 200° is anhydrous, although R. Bunsen showed that even after the salt has been melted at a white heat, it retains enough water to develop hydrogen when melted with iron. The anhydrous salt so prepared contains oxide or an oxychloride. According to H. C. Dibbits, if calcium hexahydrated chloride be dehydrated below 130°, no trace of hydrogen chloride is evolved, but at a higher temp. some oxychloride is formed. H. Rose showed that if the chloride be heated with ammonium chloride, the partial decomposition is hindered. In order to obtain the anhydrous salt free from oxygen, T. W. Richards found it necessary to expel the water by heating the hydrated salt in a stream of hydrogen chloride, and during cooling to replace gradually the hydrogen chloride by nitrogen. Similar remarks apply to the preparation of the anhydrous chlorides of barium and strontium.

Barium chloride is made by dissolving witherite, native barium carbonate, in hydrochloric acid. Powdered barium sulphate is converted into carbonate by heating it under press. with a soln. of potassium carbonate : $K_2CO_3+BaSO_4=BaCO_3+K_2SO_4$. An early process was to heat a mixture of barium sulphate and calcium chloride : $BaSO_4+CaCl_2=BaCl_2+CaSO_4$, but the reaction is incomplete and the process wasteful. In 1858, F. Kuhlmann proposed to heat a mixture of barytes with carbon, and manganese chloride, obtained as a by-product in the manufacture of chlorine ; but the process was not satisfactory, since the manganese sulphide readily oxidizes reforming barium sulphate. In 1889, J. Kolb modified a process recommended by A. Duflos in 1831, and this process is utilized in the manufacture of barium chloride at the present day. A mixture of barytes, $BaSO_4$, and powdered coke is heated to 1000°–1100° when the barium sulphate is reduced to soluble sulphide : $BaSO_4+4C=4CO+BaS$. The soluble barium sulphide is extracted with water, and calcium chloride added : $BaS+CaCl_2=CaS+BaCl_2$. The decanted soln. is evaporated for barium chloride. The two reactions can be effected in one operation by heating the barytes with the coke and calcium chloride : $BaSO_4+CaCl_2+4C=BaCl_2+CaS+4CO$. Here the barium sulphate is reduced to the sulphide, BaS, which then reacts with the calcium chloride, forming calcium sulphide and barium chloride. The mass is lixiviated with water ; the calcium sulphide remains behind, and barium chloride passes into soln. According to L. Godin, lime precipitates any calcium sulphide from the soln. as calcium oxysulphide. When the soln. is conc. and cooled, barium chloride, $BaCl_2.2H_2O$, separates in colourless rhombic plates.

The barium sulphide can be converted into chloride by treatment with hydrochloric acid : $BaS+2HCl=H_2S+BaCl_2$. The Consortium für elektrochemische Industrie used chlorine for the conversion ; R. Heinz used magnesium chloride ; and J. Waldenberg used ferric chloride. A. Duflos and A. d'Heureuse calcined a mixture of barium sulphate with calcium chloride and charcoal ; E. Asselin used iron in place of charcoal and heated the mixture until the flame of carbon monoxide no longer appeared. The mixture was extracted with water, as before. J. B. Trommsdorff used a similar process. The production of sulphides is avoided in B. Lach's process, where hydrogen chloride is passed over a calcined mixture of barytes and carbon : $BaSO_4+4C+2HCl=BaCl_2+4CO+H_2S$. H. Kunheim decomposed barium carbonate with ammonium chloride ; L. Godin used calcium chloride. F. Muck found that if a soln. of alkaline earth chlorides be mixed with sodium chloride, barium and strontium chlorides crystallize out first. C. S. Bradley and C. B. Jacobs heated the barytes in an electric furnace with insufficient carbon for the reduction ; the unconverted sulphate reacts with the sulphide : $BaS+3BaSO_4=4SO_2+4BaO$. In practice about 40 per cent. of the product remains as sulphide, and about one per cent. as unconverted sulphate. The product can be converted to chloride with hydrochloric acid.

Much of what has been said about barium chloride applies *mutatis mutandis* to the strontium salt. H. W. F. Wackenroder obtained strontium chloride by heating the carbonate with magnesium or calcium chloride, and lixiviating the mass ; and also by the action of calcium chloride on strontium sulphide in an atm. of carbon dioxide—strontium chloride, calcium carbonate, and sulphide are formed. J. Mactear made strontium chloride by reducing celestine with carbon in the presence of calcium chloride.

Calcium chloride is a by-product in several manufacturing processes—*e.g.* the preparation of ammonia or ammonium carbonate ; the production of carbon dioxide from marble ; the preparation of potassium chlorate ; the preparation of sodium carbonate by the Solway process ; the preparation of chlorine by Weldon's process ; etc. Technically, calcium chloride is made from the residue left after the preparation of ammonia—a mixture of calcium chloride and hydroxide—which is treated with hydrochloric acid and evaporated. M. M. T. K. Kaisha made anhydrous alkaline earth chlorides suitable for electrolysis by adding ammonium chloride and the oxide, hydroxide, carbonate or oxychloride of the alkaline earth to a halide salt of a more electropositive metal. I. Namari and Y. Hiraoka used a somewhat similar process. J. H. MacMahon treated the feeder liquor of the ammonia-soda process with barium sulphide, and obtained barium chloride

The properties of the chlorides of the alkaline earths.—The **crystals** of hexahydrated calcium and strontium chlorides belong to the trigonal system. A. Eppler[5] found for the axial ratio of the former: $a:c=1:0·505$, and $\alpha=112° 29'$; and of the latter, $a:c=1:0·5150$, and $\alpha=112° 14'$. G. Wyrouboff gave for the monoclinic prisms of dihydrated barium chloride: $a:b:c=0·6177:1:0·6549$, and $\beta=91° 5'$. For mixed crystals of barium chloride and bromide, *vide infra.* The reported numbers[6] of the **specific gravity** of anhydrous calcium chloride range from C. J. B. Karsten's 2·0401 to L. Playfair and J. P. Joule's 2·480. O. Ruff and W. Plato give 2·26 at 20°. G. Quincke gives 2·219 at 0°; and 2·120 for the molten salt at the melting point. For anhydrous strontium chloride, the numbers range from C. J. B. Karsten's 2·8033 to H. G. F. Schröder's 2·054. G. Quincke's and F. Braun's value for the fused salt at the m.p. are both 2·770; and P. A. Favre and C. A. Valson's, 3·035 at 17·2°. For anhydrous barium chloride, the numbers range from P. Kremer's 3·7 at 17·5°, to P. F. G. Boullay's 4·156. P. A. Favre and C. A. Valson give 3·844 at 16·8°; T. W. Richards, 3·856; and G. Quincke, 3·700, for the molten salt at its m.p. The best representative values at 15° may be taken as: $CaCl_2$, 2·152; $SrCl_2$, 3·052; $BaCl_2$, 3·856; whence W. Biltz gives the respective mol. vol. 51·57, 51·97, and 54·02.

According to J. B. A. Dumas, calcium chloride loses its water and melts at a red heat, in an atm. of hydrogen chloride, and freezes to a crystalline mass. The **melting point** numbers for anhydrous calcium chloride range from W. Ramsay and N. Eumorfopoulos'[7] 710°, to V. Meyer, and W. Riddle's 806·4°; for anhydrous strontium chloride, from T. Carnelley's 829° to W. Plato's 872·3°; and for anhydrous barium chloride, from T. Carnelley's 772° to F. Haber and S. Tolloczko's 965°. There is a **transformation temperature** with barium chloride at 923°–924° when the so-called monoclinic α-$BaCl_2$, melting at 960°, passes into cubic β-$BaCl_2$; H. Gemsky placed the transition temp. at 930°. This change was noted by H. le Chatelier in 1897.

According to E. Kraus, when the chlorides of the alkaline earths are heated to redness in air, a part is transformed into the oxide, so that the aq. soln. of calcined chloride has an alkaline reaction. J. B. Dumas made a similar observation with respect to barium chloride, and T. W. Richards found that a little chlorine is lost. E. Mitscherlich noticed that at a white heat a small quantity of calcium chloride volatilizes without decomposition, and R. Bunsen said that a bead on platinum wire volatilizes 2·717 times as fast as sodium chloride, while T. H. Norton and D. M. Roth found that barium chloride under similar conditions volatilizes 120 times as fast as sodium chloride. G. Bartha found some barium chloride volatilizes at 1000°. When a soln. of strontium or barium chloride is sprayed into a Bunsen's flame, spectroscopic observations by A. Gouy showed that the salt is only partially dissociated, while with calcium chloride, dissociation is complete. L. Rügheimer's determinations show that the mol. wt. of strontium and barium chlorides are normal in boiling bismuth chloride.

H. Kopp's value for the **coefficient of expansion** of calcium chloride is 0·00062. The **specific heat** of anhydrous calcium chloride, according to H. Kopp, is 0·209, and, according to H. V. Regnault, 0·215; for strontium chloride from 13° to 98°, 0·1199; and for barium chloride, from 14° to 98°, 0·08957; or from 16° to 47°, 0·0902.

According to J. Thomsen,[8] the **heat of formation** of the chlorides of the alkaline earths from their elements is ($CaCl_2$, $6H_2O$), 170·23 Cals.; (Sr, Cl_2), 184·55 Cals.; and (Ba, Cl_2), 194·24 Cals. D. Tommasi gives (Ca, Cl_2, $6H_2O$), 191·98 Cals.; (Sr, Cl_2, $6H_2O$), 203·19 Cals.; and (Ba, Cl_2, $2H_2O$), 7·0 Cals.; ($CaCl_2$, aq.), 17·41 Cals.; ($SrCl_2$, aq.), 12·14 Cals.; and ($BaCl_2$, aq.), 2·07 Cals.; (Ca, Cl_2, aq.), 187·64 Cals.; (Sr, Cl_2, aq.), 195·69 Cals.; and (Ba, Cl_2, aq.), 196·32 Cals.; ($CaCl_2$,

$6H_2O$), 21·75 Cals.; ($SrCl_2$, $6H_2O$), 18·64 Cals.; and ($BaCl_2$, $2H_2O$), 7·00 Cals. M. Berthelot gives ($Ca(OH)_2$aq., 2HClaq.), 27·9 Cals.; ($Sr(OH)_2$aq., 2HClaq.), 28·0 Cals.; and ($Ba(OH)_2$aq., 2HClaq.), 27·78 Cals. A. Guntz and G. Röderer give $Sr_{solid}+nHCl_{aq.}=SrCl_{2aq.}+128$ Cals.

According to P. Sabatier, the **heat of solution** of monohydrated calcium chloride, $CaCl_2.H_2O$, is 11·75 Cals., at 21·5°. According to J. Thomsen, the heat of soln. of a mol of $CaCl_2.6H_2O$ in 400 mols of water is —4·34 Cals.; for $SrCl_2.6H_2O$, the corresponding value is —7·51 Cals.; and of $BaCl_2.2H_2O$, —4·93 Cals.; a mol of $BaCl_2.H_2O$ in 400 mols of water, —1·10 Cals. S. U. Pickering gives for the heat of soln. of anhydrous calcium chloride in water, 18·723 Cals.; and in alcohol, 17·555 Cals.; for hexahydrated calcium chloride in water, —4·251 Cals.; and in alcohol, —2·563 Cals. S. U. Pickering gives for the heat of admixture in cals. of 100 grms. of a conc. soln. of calcium chloride in an infinitely large amount of water at 17·91°:

Per cent. $CaCl_2$	1	2	5	10	20	30	40	50	52
Heat in cals.	4·65	10·95	35·1	80·5	215·5	517·5	1277	2915	3328

The heat of soln. of calcium chloride associated with different proportions of water in 400 mols of water, at 18°, is, according to J. Thomsen:

Mols H_2O	0	1·67	2·75	3·49	3·76	6
Heat of soln.	17·80	10·80	6·93	3·75	2·97	—4·34 Cals.

Similarly for strontium chloride:

Mols. H_2O	0	1	2	3	4	5	6
Heat of soln.	11·14	5·88	2·08	—0·39	—2·34	—5·16	—7·5 Cals.

According to C. M. van Deventer and H. J. van de Stadt, the so-called integral heat of soln. of $CaCl_2.6H_2O$ is —7·55 Cals. S. Arrhenius' value for the heat of ionization in $\frac{1}{10}N$-$CaCl_2$ soln. at 35° is —307 Cals. F. R. Pratt, and G. McP. Smith and co-workers have studied the **heats of dilution** of soln. of barium and strontium chlorides alone and mixed with different proportions of the alkali chlorides. The heats of dilution of the mixed soln. bear no simple additive relation, and the results agree with the assumption that compounds of a higher order are formed.

When the anhydrous chlorides are dissolved in water, heat is evolved, and the soln. becomes warmer: *e.g.* $CaCl_2+Aq.=CaCl_{2aq.}+17·4$ Cals.; and with anhydrous barium chloride, 2·1 Cals. On the contrary, when the crystalline hydrates are dissolved in water, heat is absorbed, and the soln. becomes cooler: *e.g.* $CaCl_2.6H_2O+Aq.=CaCl_{2aq.}$, —4·3 Cals.; and with crystalline barium chloride, $BaCl_2.2H_2O$, —4·9 Cals. Thus, the temp. can be reduced from 0° to —42° by a mixture of 2 parts of crystallized calcium chloride, with half its weight of snow or powdered ice; 3 parts of potassium chloride with 2 parts of snow will lower the temp. from 0° to —33°; with 10 parts of snow, from 0° to —11°; 1 part of sodium chloride with 3 parts of snow will lower the temp. from 0° to —17·7°. Hence, the use of such salts as **freezing mixtures.**

The dissolution of a solid is attended by (i) the separation of the mols. from one another against mol. attraction; (ii) the liquefaction of the solid; and (iii) combination of the solute with the solvent. The two former involve an expenditure of energy and exercise a cooling effect, the last alone usually exercises a heating effect; whether the dissolution of a solid will be an endo- or an exo-thermal process is thus determined by the relative magnitudes of these three effects. When liquids are dissolved, (ii) will be zero; and with gases liquefaction will be attended by an evolution of heat. The great evolution of heat which attends the dissolution of anhydrous calcium chloride in water is evidence that the solute is uniting chemically with the solvent.

The **solubility** of calcium chloride in water from —55° to 260° has been determined by P. Kremers,[9] G. J. Mulder, A. B. Poggiale, H. Hammerl, A. Étard, R. Engel, and A. Ditte, H. W. B. Roozeboom's results expressed in grams $CaCl_2$ per 100 grms. of soln. are:

	0°	10°	20°	40°	60°	80°	100°	160°
$CaCl_2$ . . .	37·3	39·4	42·7	53·4	57·8	59·5	61·4	69·0
$SrCl_2$ . . .	30·3	32·3	34·6	39·5	45·0	47·5	50·2	58·5
$BaCl_2$ . . .	24·0	25·0	26·3	28·9	31·3	34·3	37·0	38·9

The solubility of calcium chloride at —55° is 29·8 grms. of $CaCl_2$ per 100 grms. of soln.; and at 260°, 77·6 grms. of $CaCl_2$. The solubility of strontium chloride from —20° to 180° has been determined by G. J. Mulder, A. B. Poggiale, P. Kremers, R. Engel, A. Étard, and W. A. Tilden; at —20°, the solubility is 26·0 per cent. $SrCl_2$; and at 180°, 62·0 per cent. The solubility of barium chloride from 0° to 215° has been determined by G. J. Mulder, J. L. Gay Lussac, P. Kremers, A. Gerardin, R. Engel, and H. Precht and B. Wittzen. A. Étard found that at 215°, the solubility is 43·1 per cent. $BaCl_2$. The solubility curves of these salts would be misleading if plotted from the numbers indicated above, for many of these chlorides give solubility curves with a number of breaks which would thus be smoothed out and accordingly obscured. Care must always be exercised in smoothing data obtained at widely differing temp., because some important phenomena may thus be masked. The breaks correspond with the change in the solubility which attends the transformation of one hydrate into another as the temp. rises. The same remarks apply to formulæ representing the relation between the solubility S and the temp. θ by a continuous function—*e.g.* A. Étard represented the solubility curves of calcium chloride at $\theta°$ between —18° and 6° by $S=32+0{\cdot}2148\theta$; and between 50° and 170° by $S=54{\cdot}5+0{\cdot}0755\theta$. J. L. Gay Lussac represented the solubility curve of barium chloride by $S=30{\cdot}62+0{\cdot}2711\theta$; and A. E. Nordenskjöld by $\log S=1{\cdot}4916+0{\cdot}003413\theta-0{\cdot}0000658\theta^2$.

W. D. Harkins and H. M. Paine measured the solubility of strontium chloride in water, and noted the effect of various additions, and also the sp. gr. of the soln. They found strontium chloride dissolves in water to the extent of 557·6 grms. in 1000 grms. of water, and the soln. has a sp. gr. 1·4015 at 25°/4°. Strontium nitrate increases the solubility to 558·5 grms. with 0·1372 eq., and then decreases it to 551·4 grms. with 3·318 eq. per 1000 grms. of water. Sodium nitrate increases the solubility 584·8 grms. with 3·553 eq., and then decreases it to 542·6 grms. with 3·856 eq. per litre. Nitric acid has very little influence on the solubility, whereas hydrochloric acid strongly depresses the solubility to 42·09 grms. with 9·205 eq. per 1000 grms. The other substances examined all depress the solubility of strontium chloride appreciably, but not to anything like the extent that hydrochloric acid does. The solubility curve for hydrobromic acid lies above that for hydriodic acid, and hydrochloric acid, on account of its common ion effect, gives a curve which lies much below either. Just as hydrochloric acid depresses the solubility more than hydrobromic acid, so potassium chloride is more effective in lowering the solubility than potassium iodide. The curves for sodium nitrate and nitric acid have the same relative positions as potassium iodide and hydriodic acid and potassium chloride and hydrochloric acid. In all these cases, the solubility of strontium chloride is less in the acid than in the corresponding salt soln. W. D. Treadwell found the solubility of dihydrated barium chloride in alcohol and water at 15° to be:

Per cent. alcohol (wt.) . . .	10	20	30	40	60	80	97
$BaCl_2.2H_2O$	31·1	21·9	14·7	10·2	3·5	0·5	0·014

The hydrates of the chlorides of the alkaline earths.—The **solubility** curves of calcium chloride shows the existence of five hydrates: $CaCl_2.H_2O$, $CaCl_2.2H_2O$, $CaCl_2.6H_2O$, and two forms α- and β-$CaCl_2.4H_2O$. H. W. B. Roozeboom's solubility curve is shown in Fig. 12. The eutectic or cryohydric temp. is —55° with a soln. containing one part of $CaCl_2$ in 14·5 parts of water. At this quadruple point, the two solid phases are ice and hexahydrated calcium chloride, the other two phases are the soln. just indicated, and vapour with a scarcely appreciable vapour press. The solubility curve of the hexahydrated salt rises steadily from —55° to 29·2°, when there is a break, corresponding with the passage of the hexahydrated to the β-tetrahydrated salt or to 29·8°, corresponding with the passage to the α-tetrahydrated salt. At the transition point, 29·2°, the two solid phases are $CaCl_2.6H_2O$ and β-$CaCl_2.4H_2O$; liquid phase with one part of $CaCl_2$ per 5·41 parts of water; and vapour at 5·67 mm. press. At the transition point, 29·8°, the two solid phases are $CaCl_2.6H_2O$ and α-$CaCl_2.4H_2O$; soln. with one part of $CaCl_2$ per 6·10 parts of water; and vapour at 6·80 mm. press. The range of stability of β-$CaCl_2.4H_2O$ is from 29·2° to 38·4°, at the latter temp., the two solid phases are β-$CaCl_2.4H_2O$ and $CaCl_2.2H_2O$; the liquid phase has one part of $CaCl_2$ in 4·83 parts of water; and the vapour a press. of 7·88 mm. The range of stability of α-$CaCl_2.4H_2O$ is from 29·8° to 45·3°, at the latter temp., the two solid phases are α-$CaCl_2.4H_2O$ and $CaCl_2.2H_2O$; the liquid phase has one part of $CaCl_2$ to 4·73 parts of water; and the vapour has a press. of 11·77 mm. The range of stability of $CaCl_2.2H_2O$ is either from 38·4° or 45·3° to 175·5°; at the latter temp., the two solid phases are $CaCl_2.2H_2O$ and $CaCl_2.H_2O$; the soln. has one part of $CaCl_2$ per 2·07 parts of water; and the vapour a press. of 842 mm. The range of stability of $CaCl_2.H_2O$ is between 175·5° and about 260°, when the two solid phases are $CaCl_2.H_2O$ and $CaCl_2$; the liquid has a gram of $CaCl_2$ for about 0·18 grm. of water; and the vapour a press. of many atm.

There has been some discussion about the point *H*, Fig. 12, the m.p. of the hexahydrated salt. H. W. B. Roozeboom regards it not as a transition point, but as a maximum on the solubility curve, where the tangent, dT/dS, is parallel to the *S*-axis. On the other hand, H. le Chatelier takes the view that *H* is a definite break or transition point. F. A. Lidbury showed that the m.p. determinations in the system with $CaCl_2$ with between 5·54 and $6{\cdot}44H_2O$ gives a curve with no definite break, but one which has a maximum between 29·918° and 29·920°, corresponding respectively with $CaCl_2+5{\cdot}99H_2O$ and $CaCl_2+6{\cdot}02H_2O$. F. W. Küster, and R. Kremann also regard the point *H* as a turning point or maximum and not a break.

The existence of **hydrated calcium chloride**, $CaCl_2.H_2O$, was suspected after the work of H. Lescœur on the **vapour pressure** of soln. of calcium chloride; and its separation in crystalline needles from soln. of calcium chloride above 175·5° was demonstrated by H. W. B. Roozeboom in 1889. W. Müller-Erzbach obtained it by confining the dihydrated salt over sulphuric acid of the relative vap. press., p/p_0 =0·04, where p is the vap. press. of the acid, and p_0 that of water at the same temp. The speed of conversion is slow, and the salt, $CaCl_2.H_2O$, is formed more quickly by confining the salt in a vessel with a rather higher vap. press. than is required, and subsequently removing the excess in an atm. with the water vapour at a relative press. of about 0·02. The crystals melt at about 260° under press. This temp. is a transition point, $CaCl_2.H_2O \rightleftharpoons CaCl_2+H_2O$. The range of stability of this salt and its solubility are indicated in Fig. 12. **Dihydrated calcium**

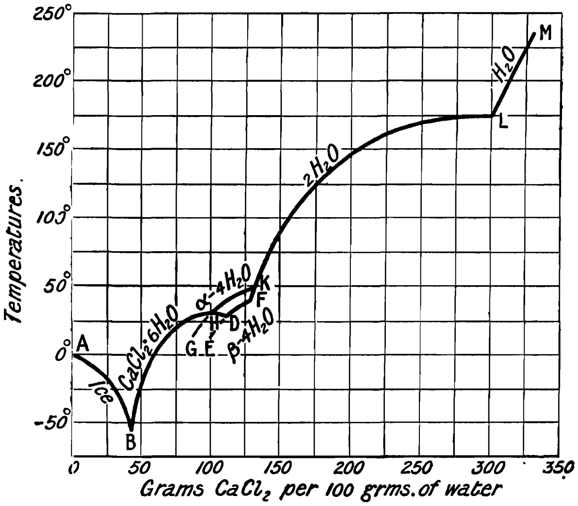

FIG. 12.—Solubility Curve of Calcium Chloride.

chloride, $CaCl_2.2H_2O$, was made by T. Graham by exposing crystals of the hexahydrated salt "in vacuo for 10 days during the heat of summer." He adds that the crystals become opaque and of a talcy lustre, without being disintegrated, and their proportion of water was reduced to $CaCl_2.2H_2O$. A. Ditte obtained crystals of the dihydrated salt by passing a stream of hydrogen chloride over the hexahydrated salt; by passing the same gas into a conc. aq. soln. of calcium chloride, taking precautions to avoid a rise of temp.; and by gradually adding small pieces of fused calcium chloride to a conc. aq. soln. of hydrochloric acid so as to avoid the evolution of gas. The dihydrated salt gradually crystallizes from the soln. in fine transparent very hygroscopic crystals. H. W. B. Roozeboom obtained the salt by evaporating aq. soln. of calcium chloride at about 165°. The range of stability and solubility is indicated in Fig. 12. W. Müller-Erzbach made this salt by confining calcium chloride in an atm. where the relative press. of the water is 0·10 mm., or over hydrating the salt and removing the excess in an atm. with the water vapour at the relative press. 0·05.

H. Hammerl formed **tetrahydrated calcium chloride** by partially melting the hexahydrated salt in its water of crystallization, pouring off the mother liquid, and repeating the process several times. W. Müller-Erzbach made this salt by keeping calcium chloride in an atm. when the relative press. of the water vapour is between 0·13 and 0·18. The salt crystallizes in what appear to be rhombic crystals melting at 45·3°, when it passes into the dihydrated salt. E. Lefebre also obtained transparent plates of the tetrahydrated salt by cooling below 15° a soln. containing 120 parts of $CaCl_2$ per 100 parts of water. H. W. B. Roozeboom showed that two different modifications of the tetrahydrated salt are here in question, and he calls Hammerl's salt α-$CaCl_2.4H_2O$, and E. Lefebre's salt, β-$CaCl_2.4H_2O$. The solubility curves and ranges of stability of the two tetrahydrated salts are indicated in Fig. 12. Soln. represented by the dotted line *DE* are sat. with respect to β-$CaCl_2.4H_2O$, and supersaturated with respect to $CaCl_2.6H_2O$. If the β-salt be heated in the presence of its sat. soln. above 38·4°, *E*, Fig. 12, it forms the stable α-$CaCl_2.4H_2O$. This transformation does not occur spontaneously over 20° except by rubbing or by seeding with the α-salt. According to D. Gernez, if a supersaturated soln. be cooled to 15°, and rubbed cautiously with a glass rod, the tetrahydrated salt crystallizes out, while, with energetic rubbing, the hexahydrated salt crystallizes out. The α-salt of H. Hammerl is the more stable form, and, as is generally the case, the more stable form possesses the smaller solubility. Soln. ranging from *H* to *G*, Fig. 12, are sat. with the α-salt, and supersaturated with the hexahydrated salt. At 45·3°, *K*, Fig. 12, α-$CaCl_2.4H_2O$ passes into the dihydrated salt.

Hexagonal crystals of **hexahydrated calcium chloride**, $CaCl_2.6H_2O$, are obtained from aq. soln. of calcium chloride below 29·2°; and W Müller-Erzbach obtained it by confining calcium chloride in an atm. where the relative vap. press. is between 0·34 and 0·192. The published values for the specific gravity range from the 1·612 (10°) of H. Kopp,[10] to the 1·701 (17·1°) of P. A. Favre and C. A. Valson. J. Dewar gives 1·7187 at —188°, and 1·6775 at 17°; the coeff. of thermal expansion between these temp. is therefore 0·0001191. H. Kopp says the crystals expand from 1 to 1·007 when heated from 0° to 20°; and from 0° to 29°, 1·020; and in melting at 29°, the volume increases to 1·118, corresponding with a 9·6 per cent. expansion. The latent heat of fusion, according to G. G. Person, is 40·70; and, according to S. U. Pickering, 11·417 Cals.; the sp. ht., according to S. Pagliani, 0·345, and the heat of soln. —4·3 Cals., but after soln., further dilution was shown by A. Ditte to raise the temp. by the evolution of heat. J. Milikan studied the ternary system, $CaCl_2$—HCl—H_2O, at 30°, and found a soln. with 44·50 per cent. of calcium chloride and 3·3 per cent. of HCl is in equilibrium with the hexa- and tetra-hydrates; and soln. with 28·48 per cent. of calcium chloride and 21·40 per cent. of HCl is in equilibrium with the tetra- and di-hydrates.

The hydrates of strontium and barium chlorides have not been so closely examined as those of calcium. Strontium forms the hydrates, $SrCl_2.2H_2O$ and $SrCl_2.6H_2O$. P. Kremers[11] showed that although the latter crystallizes from soln. at ordinary temp., **dihydrated strontium chloride**, $SrCl_2.2H_2O$, separates out when the temp. is high—between 90° and 100°, according to A. Étard; and above 61·5°, according to T. W. Richards and J. B. Churchill. A. Ditte, and H. Lescœur made the same compound by leading hydrogen chloride into a sat. soln. of the hexahydrated salt; by treating the solid hexahydrated salt with conc. hydrochloric acid; or by adding the anhydrous chloride to conc. hydrochloric acid—the soln. becomes warm and the dihydrated salt crystallizes out on cooling in water clear plates which becomes anhydrous when heated. According to O. Lehmann, the crystals of dihydrated strontium chloride which separate from hot soln. of barium and strontium chlorides are somorphous, but the (cold) crystals of the strontium salt form ordinary crystals when they are squeezed or scratched.

The long six-sided crystals of **hexahydrated strontium chloride**, $SrCl_2.6H_2O$, belonging to the trigonal system are isomorphous with those of $CaCl_2.6H_2O$, and, according to A. Eppler, have the axial ratio $a:c=1:0·5150$, and $\alpha=112° 14'$. The crystals of hexahydrated strontium chloride have a sp. gr. 1·933 (17°), according to P. A. Favre and C. A. Valson; 1·964 (16·7°), according to F. W. Clarke; and 1·921, according to H. J. Buignet. They melt, according to W. A. Tilden, at 112°, and pass into the dihydrated salt above 61·5°, as indicated previously. J. Milikan studied the system, $SrCl_2$—HCl—H_2O, at 25°, and found the solid phases, $SrCl_2.6H_2O$ and $SrCl_2.2H_2O$, coexist in equilibrium with soln. containing 2·11 per cent. of strontium chloride and 27·14 per cent. of HCl.

H. Lescœur deduced the existence of **hydrated barium chloride**, $BaCl_2.H_2O$, from the constancy of the vap. press. curves of the system containing $BaCl_2$, and up to one eq. of water; and J. Thomsen inferred the existence of the same compound from the fact that the thermal value of the reaction, $BaCl_2+H_2O$, is not half so great as for the reaction, $BaCl_2+2H_2O$. H. Lescœur claims to have made the monohydrate by saturating the aq. soln. with hydrogen chloride, and by heating the dihydrated salt between 60° and 65°. Colourless plates of the monohydrate are also said to be formed when the dihydrate is agitated with methyl alcohol, and the filtered soln. allowed to crystallize. Monoclinic prismatic crystals of **dihydrated barium chloride**, $BaCl_2.2H_2O$, are formed when barium chloride crystallizes from aq. soln. The transition point for the passage: $BaCl_2.2H_2O \rightleftharpoons BaCl_2.H_2O+H_2O$, has not yet been observed, although probably one does exist at an elevated temp. F. A. H. Schreinemakers and J. Milikan studied the ternary system, $BaCl_2$—HCl—H_2O, at 30°. According to G. Wyrouboff, the axial ratio for the crystals of dihydrated barium chloride is $a:b:c=0·6177:1:0·6549$, $\beta=91° 5'$. O. Mügge measured these ratios. The crystals of dihydrated barium chloride are not isomorphous with those of dihydrated barium bromide, or dihydrated barium iodide, although the two latter salts crystallize isomorphously from aq. soln. of the chloride, and, consequently, these forms are unstable under ordinary conditions. The crystals of dihydrated barium chloride have a sp. gr. 3·054 (3·9°), according to J. P. Joule and L. Playfair; 3·054 (15·5°), P. A. Favre and C. A. Valson; 3·097, according to T. W. Richards; and 3·090 (18°), according to O. Brill and C. de B. Evans. The crystals lose their water when heated to 121°, without melting. F. A. Gooch and F. M. McClenahan find that it makes no difference to the product whether dihydrated barium chloride be heated in air or in hydrogen chloride below 100°, and at this temp. dehydration is complete. E. Jänecke also found similar remarks apply when the dehydration is conducted under press. T. W. Richards plotted the total loss of water which occurred when dihydrated barium chloride was heated at 30° for different periods of time and found the curve

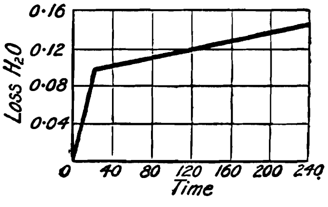

FIG. 13.—Velocity Curve of the Dehydration of $BaCl_2.2H_2O$.

presented a sharp angle "exactly at the point corresponding with $BaCl_2.H_2O$," as illustrated in Fig. 13. F. A. Gooch and F. M. McClenahan explain the fact that the water can be expelled without the loss of chlorine by assuming the constitutional formula:

$$\overset{H}{\underset{H}{}}{>}O{=}Cl{-}Ba{-}Cl{=}O{<}\overset{H}{\underset{H}{}}$$

Contrast this with the phenomena attending the dehydration of the hydrated magnesium and aluminium chlorides. E. H. Davis claimed to have made monohydrated barium chloride, $BaCl_2.H_2O$, but this has not been confirmed.

The **specific gravities** of aq. soln. of calcium chloride have been determined by J. B. Richter,[12] P. Kremers, G. T. Gerlach, J. G. McGregor, and S. U. Pickering. The relation between the percentage composition of the soln. at 17·925° and the sp. gr. is (water alone 0·99869):

Per cent. of salt .	0·1	1·0	5·0	10·0	20·0	30·0
Sp. gr. $CaCl_2$.	0·99954	1·00703	1·04089	1·08467	1·17910	1·28271
,, $SrCl_2$.	—	1·0092	1 0458	1·0951	1·2061	—
,, $BaCl_2$.	—	—	1·0453	1·0929	1·1989	1·3220

Soln. with 40 to 50 per cent. calcium chloride have the respective sp. gr. 1·39489 and 1·50676. The values for barium and strontium chlorides at 16° are by G. T. Gerlach. P. Kremers and F. Kohlrausch, G. T. Gerlach, H. Schiff, D. I. Mendeléeff have also measured the sp. gr. of soln. of strontium and barium chlorides. According to R. Engel, a soln. sat. with calcium chloride at 0° has a sp. gr. of 1·367; strontium chloride, 1·334; and barium chloride, 1·25. T. Poleck has also measured the contraction which occurs on dissolving calcium chloride in water. According to G. T. Gerlach, the sp. gr. of a soln. of strontium chloride at 15° rises from 1·0453 for a 5 per cent. soln. to 1·3633 for a 33 per cent. soln.; and the sp. gr. of a soln. of barium chloride rises from 1·0092 for a one per cent. soln. to 1·2702 for a 25 per cent. soln. N. A. Tschernay gives for the volume, v, of a soln. at $\theta°$, barium chloride, $BaCl_2+50H_2O$, $v=1+0{\cdot}0_32393\theta+0{\cdot}0_52456\theta^2$; $BaCl_2+100H_2O$, $v=1+0{\cdot}0_31345\theta+0{\cdot}0_53537\theta^2$; strontium chloride, $SrCl_2+50H_2O$, $v=1+0{\cdot}0_32204\theta+0{\cdot}0_52542\theta^2$; calcium chloride, $CaCl_2+50H_2O$, $v=1+0{\cdot}0_31925\theta+0{\cdot}0_52647\theta^2$; $CaCl_2+100H_2O$, $v=1+0{\cdot}0_31085\theta+0{\cdot}0_53613\theta^2$.

The lowering of the temp. of maximum density of water by calcium chloride was found by L. C. de Coppet to be proportional to the conc.: soln. with $M=0{\cdot}0431$, 0·0744, and 0·1500 mol of $CaCl_2$ per litre lowered the temp. of maximum density of water respectively to 3·208°, 2·645°, and 1·234°, where $dT=0{\cdot}776°$, 1·337°, and 2·748° respectively, so that the mol. lowering of the temp. of maximum density, dT/M, is respectively 17·97°, 18·00°, and 18·31°. Similar results were obtained with barium chloride; with soln. containing 0·0002 and 0·1995 gram-mol. of $BaCl_2$ per litre, the temp. of maximum density is respectively +3·982° and —0·843°, and the mol. lowering of the temp. of maximum density is 24·1°.

According to J. Drecker,[13] the coeff. of **compressibility** of 5·8 per cent. soln. of calcium chloride is $39{\cdot}7\times10^{-6}$; for 17·8 per cent. soln. $31{\cdot}3\times10^{-6}$; and for 40·9 per cent. soln. $21{\cdot}7\times10^{-6}$. V. Schumann, and L. Grassi also made observations with soln. of calcium chloride. V. Schumann gave for 1·24, 17·7, and 27·26 per cent. soln. of strontium chloride between 16° and 19°, $45{\cdot}4\times10^{-6}$, $37{\cdot}2\times10^{-6}$, and $32{\cdot}3\times10^{-6}$ respectively. V. Schumann gave for the compressibility coeff. of 2·11, 10·84, and 20·16 per cent. soln. of barium chloride, respectively $44{\cdot}7\times10^{-6}$, $41{\cdot}1\times10^{-6}$, and $36{\cdot}0\times10^{-6}$, between 19° and 20°. P. G. Tait, and O. Schmidt also calculated values for soln. of barium chloride. According to E. Jänecke, by compression, dihydrated barium chloride can be melted at 100°, and it is then converted into the anhydrous chloride. G. Wertheim measured the **velocity of sound** in soln. of calcium chloride. According to G. Timberg, the **surface tension** of soln. of calcium chloride of sp. gr. 1·4007 is 9·581 mgrms. at 6·73°; and for soln. of sp. gr. 1·4007 it is 9·581 mgrms. at 6·73°. For soln. of strontium chloride of sp. gr. 1·3357, 8·800 mgrms. at 6·2°, and for soln. of sp. gr. 1·2994, 7·049 mgrms. at 70°. J. Wagner's value[14] for the **viscosities** of N-, $\frac{1}{2}N$-, $\frac{1}{4}N$-, and $\frac{1}{8}N$-soln. of calcium chloride at 25°, are respectively 1·1342, 1·0631, 1·0310, and 1·0202, when the value for water is unity; for strontium chloride, 1·1411, 1·0674, 1·0338, and 1·0141; and for barium chloride, 1·1228, 1·0572, 1·0253, and 1·0128 respectively. G. Quincke's values for σ for molten calcium, strontium, and barium chlorides are respectively 98·7, 111·1, and 150·5 dynes per cm.; and for a^2 respectively 9·49, 8·18, and 8·29 sq. mm. According to J. D. R. Scheffer,[15] the **diffusion coefficient** of calcium chloride changes very little with conc. and for soln. containing 0·047 and 1·22 mols per litre at 9°, k is respectively 0·68 and 0·72; similarly, for soln. with 0·028 and 0·201 mol of barium chloride per litre at 8°, k is respectively 0·65 and 0·66. F. E. Bartell and O. E. Madison studied the **osmosis** of soln. of barium chloride through animal membranes.

The **thermal expansion** of soln. of calcium chloride has been measured by G. J. W. Bremer, N. A. Tschernay, and J. Drecker.[16] According to N. A. Tschernay, the vol. v of soln. in 50 mols of water at $\theta°$ between 0° and 60° is $v=1+0{\cdot}0001925\theta+0{\cdot}000002647\theta^2$; for strontium chloride, $v=1+0{\cdot}0002204\theta+0{\cdot}000002542\theta^2$; and for barium chloride, $v=1+0{\cdot}0002393\theta+0{\cdot}000002456\theta^2$. With soln. containing between 4 and 31 parts of $CaCl_2$ per 100 parts of water, the coeff. of expansion ranges from 0·0001126 to 0·0003425. G. Bender's value for the coeff. of cubical expansion of a soln. with 9·5 per cent. of barium chloride is 0·00025818; for a 24·7 per cent. soln., 0·0003613. The comparatively large coeff. of thermal expansion for soln. of calcium chloride has led to the selection of these soln. for use in thermostats.

According to G. Jäger,[17] the **heat conductivity** of soln. of calcium, strontium, and barium chlorides decreases regularly—respectively 309×10^{-5}, 216×10^{-5}, 176×10^{-5}—for each per cent. increase in conc. The relative conductivities (water 100) of 15 and 30 per cent. soln. of calcium chloride are respectively 95·4 and 90·7; of a 25 per cent. soln. of strontium chloride, 94·6; and of 21 per cent. soln. of barium chloride, 96·3. C. H. Lees found a decrease of about 20 per cent. on the thermal conductivity of solid and molten hexahydrated calcium chloride.

The **specific heat,** C, of soln. of calcium chloride, according to J. Drecker,[18] with soln. containing p per cent. of the salt, is $S=1{\cdot}022-0{\cdot}01603p+0{\cdot}00016p^2$. According to J. C. G. de Marignac, soln. with a mol of the salt in n eq. of water have the sp. ht.:

Eq. H_2O . . .	10	25	50	100	200
Sp. ht. $CaCl_2$ . .	0·6176	0·7538	0·8510	0·9714	0·9550
Mol. ht. $CaCl_2$ . .	179·6	422·8	860	1753	3544
Sp. ht. $SrCl_2$ . .	—	—	0·8165	0·8950	0·9424
Mol. ht. $SrCl_2$ . .	—	—	864	1753	3542
Sp. ht. $BaCl_2$ . .	—	—	0·7799	0·8751	0·9319
Mol. ht. $BaCl_2$ . .	—	—	864	1757	3549

Anhydrous calcium chloride has long been used for drying gases; thus P. L. Dulong and J. J. Berzelius[19] about 1820, and O. L. Erdmann and R. F. Marchand about 1842, employed it for drying the gases in their work on the at. wt. of oxygen. They seem to have assumed that it removes a relatively large proportion of water in the gas, although J. B. A. Dumas in 1842, and M. Pettenkofer in 1862, mentioned as well known that calcium chloride will not dry a gas so completely as sulphuric acid. The relative efficiency of many desiccating agents has been indicated in connection with the drying of hydrogen gas (*q.v.*). According to W. Müller-Erzbach, calcium chloride has almost the same attractive force as sodium hydroxide for water, but smaller than potassium hydroxide, sulphuric acid, or phosphorus pentoxide. Calcium chloride deliquesces rapidly in air. G. J. Mulder found that 100 parts of calcium chloride in air sat. with moisture at 16° to 20°, absorbed 712 parts of water, and strontium chloride, 354 parts of water in 56 days. R. Brandes made observations on this subject. According to H. W. Hake, the hygroscopicity of calcium chloride at a definite temp. has a definite maximum. W. Busnikoff has compared the speeds of absorption of moisture from air by sulphuric acid and calcium chloride.

H. Lescœur[20] has measured the **vapour pressures** of the different hydrates of calcium chloride. According to H. Lescœur, the vap. press. of

	35·5°	65°	78°	100°	129°
$CaCl_2.2H_2O$.	4	13	24	60	175 mm.
$CaCl_2 4H_2O$.	8·5	32	57	132	decomposed

By gradually removing water from the system calcium chloride and water at a constant temp., say 100°, the vapour gradually falls until the system contains a single hydrate, $CaCl_2.4H_2O$, the vap. press. then remains constant at 132 mm., until the system contains the hydrate, $CaCl_2.2H_2O$, with a lower vap. press., when the vap. press. of the system abruptly falls to 66 mm. and then remains constant until the system contains the hydrate with a still lower vap. press., $CaCl_2.H_2O$, whose vap. press. is very small. A system with two hydrates has three phases and two components, and has therefore one degree of freedom, so that the vap. press. at a constant temp. is independent of the amount of hydrate present. W. Müller-Erzbach, and H. W. B. Roozeboom have measured the vap. press. of the different hydrates in the presence of their sat. soln. If p denotes the vap. press. of the hydrate, p_0 that of pure water at the same temp., p/p_0 represents the relative vap. press. of the sat. soln., which, according to H. W. B. Roozeboom, have the values:

$CaCl_2.6H_2O$	α-$CaCl_2.4H_2O$	β-$CaCl_2.4H_2O$	$CaCl_2.2H_2O$	$CaCl_2.H_2O$
0·380 (10°)	0·273 (20°)	0·205 (20°)	0·155 (40°)	0·160 (160°)
0·323 (20°)	0·218 (29·8°)	0·188 (29·2°)	0·178 (10°)	0·121 (180°)
0·210 (30·2°)	0·207 (35°)	0·173 (35°)	0·187 (125°)	0·115 (205°)

At 25°, the vap. press. at the transition α-$4H_2O \rightarrow 6H_2O$ is 6·3 mm., according to W. Müller-Erzbach; and 5·1 mm., according to H. W. B. Roozeboom. A. Wüllner, G. Tammann, R. Emden, C. Dieterici, and W. Biltz have measured the vap. press. of more dil. soln. of calcium chloride. According to R. Emden, the relative vap. press., in agreement with L. von Babo's rule, is independent of temp.—*e.g.* at 19·64°, p_0=17·09 mm., p=16·0 mm., or p/p_0=0·936; at 50·04°, p_0=92·19 mm., p=85·9 mm., or p/p_0=0·931; and at 96·94°, p_0=679·15 mm., p=633·35 mm., or p/p_0=0·932. G. Tammann did not find his results in agreement with L. von Babo's rule. R. Emden did not find the lowering of the vap. press., in agreement with A. Wüllner's rule, to be proportional with the conc. If C denotes the number of grams of $CaCl_2$ and C', the number of grams of $CaCl_26H_2O$ in 100 grms. of water:

C	$\frac{1}{C}\cdot\frac{p_0-p}{p_0}$	C'	$\frac{1}{C'}\cdot\frac{p_0-p}{p_0}$
12·55	5·44	28·22	2·42
19·99	5·86	48·96	2·39
20·22	6·06	49·64	2·47

Analogous results were obtained by C. Dieterici, and W. Biltz. G. R. Paranjpe, and E. M. Baker and V. H. Waite measured the vap. press. and b.p. of aq. soln. of calcium chloride; and W. Pieper of aq. and alcoholic soln. of calcium and barium chlorides.

The vap. press. of soln. of strontium chloride have been measured by G. Tammann, and W. Biltz; and of the hydrates by H. Lescœur, P. C. F. Frowein, and J. L. Andreæ. The vap. press. of $SrCl_2.6H_2O$ given by J. L. Andreæ are:

	19·7°	25·6°	29·9°	34·1°	37·5°
$SrCl_2.6H_2O$.	5·61	8·72	11·84	15·83	19·86 mm.

The vap. press. of the hexahydrated strontium chloride is therefore greater than for the corresponding calcium salt, and if the barium salt be ever prepared, it is probable that its vap. press. will be still greater. From the fact that the vap. press. of systems $SrCl_2$+0 to $2H_2O$, and $SrCl_2$+2 to $6H_2O$, have a constant vap. press., it is inferred that only the hydrated salts, $SrCl_2.2H_2O$ and $SrCl_2.6H_2O$, exist. J. B. Hannay found the curve representing the velocity at which hexahydrated strontium chloride lost water at 100° showed a break only with the formation of $SrCl_2.2H_2O$; but when dehydrated over sulphuric acid at 10°, there was a break with $SrCl_2.3H_2O$. G. P. Baxter and J. E. Lansing measured the vap. press. of hydrated strontium chloride, and represented their results at T° K. by $\log p=15\cdot081-6731/(T+152)$. At 25°, for the transition 2–6H_2O, P. C. F. Frowein gave 7·5 mm.; J. L. Andreæ, 8·5 mm.; and G. P. Baxter, 8·37 mm. A. W. C. Menzies also measured the dissociation press. of hexahydrated strontium chloride.

H. Lescœur's measurements of the vap. press. of solid barium chloride at 100°:

	$2H_2O$	$1\cdot90H_2O$	$1\cdot20H_2O$	$0\cdot94H_2O$	$0\cdot18H_2O$
$BaCl_2+$	620	626	615	272	270 mm.

correspond with the possible existence of $BaCl_2.2H_2O$ and $BaCl_2.H_2O$; and his values at 10°, $BaCl_2+2H_2O$, 2·7 mm.; $+2\cdot25H_2O$, 7·5 mm.; $+2\cdot40H_2O$, 7·5 mm.; $+2\cdot51H_2O$, 7·4 mm., indicate the possible existence of a still higher hydrated salt; and because barium chloride acts as a nucleus for seeding supersat. soln. of $CaCl_2.6H_2O$, he believes that *hexahydrated barium chloride*, $BaCl_2.6H_2O$, isomorphous with the calcium salt, really exists. The first argument is not sound, because at a constant temp. the vap. press. of the mixture, $BaCl_2.2H_2O+nH_2O$, will be a constant. There are present 3 phases and 2 components, and the system has accordingly only one degree of freedom—the temp. The vap. press., p, of dihydrated barium chloride at different temp., determined by P. C. F. Frowein, are 2·97 mm. at 18·25°; 7·125 mm. at 28·83°; 13·478 mm. at 37·30°; and 21·117 mm. at 43·45°. According to W. Müller-Erzbach, the relative vap. press. of $BaCl_2.2H_2O$ at 17·5° is 0·21; and of $BaCl_2.H_2O$ at 16·7°, 0·10. For the transition, 0–1H_2O, at 25°, H. W. Foote and S. R. Scholes gave 2·5 mm.; W. Müller-Erzbach, 2·4 mm.; A. H. Pareau, 2·9 mm.; and H. Schottky, 1·1 mm.; while for the transition, 1–2H_2O, H. W. Foote and S. R. Scholes gave 4·8 mm.; P. C. F. Frowein, 5·2 mm.; H. Lescœur, 6·9 mm.; W. Müller-Erzbach, 4·9 mm.; J. R. Partington, 5·6 mm.; and R. E. Wilson, 5·8 mm. G. Tammann found the transition temp., 0–6H_2O, is 29·7° at atm. press., and 60·22° at 3030 kgrms. per sq. cm.; or, at a press. p kgrms. per sq. cm., the transition temp. θ is $\theta=29\cdot7+0\cdot01163p-0\cdot0_66p^2$. He also found for $SrCl_2.6H_2O \rightarrow SrCl_2.4H_2O$ the transition temp. 62·6° at one atm. press., and 75·08° at a press. of 2820 kgrms. per sq. cm. A. W. C. Menzies measured the dissociation press. of dihydrated barium chloride. According to G. Tammann, the lowerings of the vap. press. of $\frac{1}{2}N$-, N-, and $2N$-soln. of barium chloride are respectively 16·4 mm., 36·7 mm., and 77·6 mm. He further found that the effects of variations of temp. and conc. are not in accord respectively with L. von Babo's and A. Wüllner's rules.

According to F. Rüdorff,[21] the **boiling point** of a sat. soln. of calcium chloride is 180°; for a sat. soln. of strontium chloride, P. Kremers gives 114°; G. J. Mulder, 118·8°; and J. Legrand, 117·45°; and for a sat. soln. of barium chloride, P. Kremers gives 106°; J. L. Gay Lussac, 105·48°; J. Legrand, 104·2°; and G. J. Mulder, 104·1°. H. Hammerl found that the rise in the b.p. over that of water for soln. containing p per cent. of anhydrous calcium chloride is $0\cdot0519p+0\cdot011163p^2$. A. Schlamp has measured the b.p. of dil. soln. G. T. Gerlach gave for conc. soln. with over 6 grms. of $CaCl_2$ per 100 grms. of water:

Grms. $CaCl_2$.	0·585	2·405	6·0	11·5	25·0	101	222	305
B.p. . .	100·091°	100·302°	101°	102°	105°	130°	160°	178°

The rise in the b.p. of the first-named soln. corresponds with the factor $i=3\cdot32$, for the second soln. $i=2\cdot58$, and the value of i steadily increases to $i=2\cdot93$ for a soln. with 10·87 grms. $CaCl_2$ per 100 grms. of water which boils at 101·49°. S. Skinner has measured the b.p. of alcoholic soln. of calcium chloride. G. T. Gerlach gives the b.p. of strontium chloride containing 20 grms. of $SrCl_2.6H_2O$ per 100 grms. of water as 101°; 40 grms., 102°; 60 grms., 103°; rising to 117° with 819 grms. of $SrCl_2.6H_2O$ per 100 grms. of water. G. T. Gerlach, and L. Kahlenberg also measured the b.p. of soln. of barium chloride. According to G. T. Gerlach, soln. with 1·5 and 17·6 grms. $BaCl_2.2H_2O$ per 100 grms. of water boil respectively at 101° and 104·5°. J. Sakurai, and G. Harker studied the temp. of the steam arising from boiling soln. of calcium chloride.

The **freezing points** of soln. of calcium chloride have been measured from many points of view by L. C. de Coppet,[22] H. W. B. Roozeboom, S. U. Pickering, S. Arrhenius, H. C. Jones and V. J. Chambers, A. Ponsot, E. H. Loomis, etc. S. U. Pickering found that the mol. depression of the f.p. of soln. of calcium chloride rises steadily with soln. containing less than 0·4 per cent. of calcium; there is then a break in the curve, and also a second break when the soln. has 2·4 per cent. of the salt. The lowering of the f.p. of soln. with 0·0100 mol per litre is 0·0513°; 0·1004 mol, 0·4823°; 0·5021 mol, 2·605°; 2·0 mols, 17·867°. The f.p. of soln. of strontium and barium chlorides have likewise been measured by S. Arrhenius, E. H. Loomis, H. C. Jones and F. H. Getman, H. C. Jones and V. J. Chambers, F. Rüdorff, and by L. C. de Coppet. With all three chlorides of the alkaline earths, the mol. lowering of the f.p. increases with increasing conc.

The cryohydric or **eutectic temperature** with water and calcium chloride, $CaCl_2.6H_2O$, is —55°, according to H. W. B. Roozeboom,[23] with soln. containing one part of calcium chloride in 14·5 of water. According to F. Guthrie, the cryohydric temp. of strontium chloride is —17° to —18°. L. C. de Coppet gives —18·7°. According to F. Guthrie, also, the cryohydric temp. of barium chloride is —8° with soln. containing 23·2 per cent. of $BaCl_2.2H_2O$; L. C. de Coppet gives —7·85° with soln. containing 25·1 parts of $BaCl_2$ per 100 parts of water; F. Rüdorff gives —8·7°. The cryohydric point is the lowest temp. which can be obtained by mixing ice and the salt in question, consequently hexahydrated calcium chloride is far more suited than dihydrated barium chloride for making a freezing mixture. H. Hammerl obtained the data indicated in Table II, for hexahydrated calcium chloride used as a freezing mixture.

TABLE II.—CALCIUM CHLORIDE AND SNOW AS A FREEZING MIXTURE.

Kilograms of snow at 10° mixed with a kilogram of $CaCl_2.6H_2O$.	Heat absorbed in Cals. per kilogram.	Temp. when all snow is melted.
0 35	522	0°
0·45	592	—14·1°
0·53	667	—28·7°
0·64	736	—45·5°
0·66	748	—49·5°
0·70	779	—54·9°
0·74	811	—48·2°
0·81	871	—40·3°
0·91	909	—36·5°
1·19	1160	—22·7°
1·39	1319	—18·3°
1·64	1518	—14·7°
2·46	2169	— 9·0°
4·92	4136	— 4·0°

Although H. Lescœur[24] supposed that the introduction of hydrogen chloride into an aq. soln. of calcium chloride will not precipitate the salt, both R. Engel and A. Ditte have shown that the solubility of calcium chloride is depressed in the presence of *hydrochloric acid*, as in the analogous case of sodium chloride; thus, expressing quantities in grams per 100 c.c. of soln., at 0°:

HCl . .	0	3·32	5·83	10·66	15·84	23·15	34·62
$CaCl_2$.	51·45	46·45	42·80	36·77	29·84	20·12	11·29
Sp. gr. .	1·367	1·344	1·326	1·310	1·283	1·250	1·238

Similarly with strontium chloride and hydrochloric acid at 0° :

HCl .	0	2·22	4·65	8·49	10·35	13·58	19·23
$SrCl_2$.	49·9	35·5	30·0	21·56	17·44	11·09	3·37
Sp. gr. .	1·334	1·304	1·269	1·220	1·201	1·167	1·133

In 1843, C. J. B. Karsten, and also S. Schlesinger, found that the solubility of barium chloride in hydrochloric acid is less than in water ; that barium chloride is scarcely soluble at all in conc. hydrochloric acid ; and the salt is precipitated from sat. aq. soln. by hydrochloric acid. R. Engel showed that with barium chloride and hydrochloric acid at 0°, as in the two preceding tables :

HCl .	0	1·51	4·58	6·13	7·55	10·81	16·92
$BaCl_2$.	24·07	20·14	12·76	9·37	6·33	2·64	0·28
Sp. gr. .	1·250	1·210	1·143	1·118	1·099	1·079	1·088

According to F. W. Mar, less than one part of barium chloride is soluble in 20,000 parts of conc. hydrochloric acid, and in 120,000 parts of hydrochloric acid containing one-sixth of its vol. of *ether*. The solubility of these salts is also lowered by the presence of alkali chloride ; thus G. J. Mulder found 100 grms. of water dissolve 63·5 grms. $CaCl_2$ in the presence of 4·9 grms. of KCl at 7° ; 59·5 grms. $CaCl_2$ with 4·6 grms. NaCl at 7° ; 57·6 grms. of $CaCl_2$ with 2·4 grms. NaCl at 4° ; and, according to F. Rüdorff, 72·6 grms. of $CaCl_2$ with 16 grms. NaCl at 15°. H. W. Foote found 100 grms. of a sat. soln. contains 13·83 grms. of barium chloride and 18·97 grms. of potassium chloride at 25° ; and there is no sign of the formation of a double salt. H. Precht and B. Wittjen, and F. Rüdorff have measured the effect of sodium chloride, and found that at 20°, a soln. containing 25 per cent. of NaCl dissolves 2·9 per cent. of $BaCl_2$; and at 100°, 22·2 per cent. of NaCl and 11·8 per cent. of $BaCl_2$. H. W. Foote and H. S. Bristol found that barium chloride unites with mercuric chloride, forming a series of double salts. C. J. B. Karsten, and S. Schlesinger found that *nitric acid* precipitates barium nitrate from a sat. aq. soln. of barium chloride, and hydrochloric acid precipitates barium chloride from a sat. aq. soln. of the nitrate. A. Étard found the effect of barium nitrate on the solubility of barium chloride, C. J. B. Karsten showed that the addition of either salt to a sat. soln. of the other does not precipitate either salt, and, accordingly, P. N. Evans assumed that a double salt is formed. C. J. B. Karsten also showed that no salt is precipitated when soln. of barium chloride and *potassium nitrate*, sat. at 7·5°, are mixed ; and that *sodium nitrate* dissolves readily in sat. soln. of barium chloride with the precipitation of barium nitrate ; while barium chloride dissolves but slowly in a conc. soln. of sodium nitrate and becomes covered with crystals of barium nitrate. R. W. Pearson found that *acetic acid*, *ammonium acetate*, and *ammonium chloride* dissolve barium chloride with greater difficulty than dil. hydrochloric acid ; 5 to 5·5 vols. of dil. *aqueous ammonia* dissolve as much barium chloride as 4 vols. of water. According to C. J. B. Karsten, pieces of *ammonium chloride* dissolve in aq. soln. of barium chloride, while barium chloride separates out ; barium chloride dissolves in a sat. soln. of ammonium chloride, and later the salt separates out again. F. Rüdorff found that a sat. soln. of both salts, formed by warming and cooling at 20°, contains 33·8 parts of NH_4Cl and 11·6 of $BaCl_2$ per 100 parts of water—the composition is not altered by adding either salt. Calcium chloride is readily soluble in ethyl, propyl, isobutyl, and amyl alcohols. From E. Bödtker's measurements [25] the solubility of calcium chloride in *ethyl alcohol* increases as the conc. of the alcohol increases, but, as A. Gerardin has shown, the converse obtains with strontium chloride—for, at 18°, 100 grms. of 6 per cent. ethyl alcohol dissolve 49·81 grms. of strontium chloride, while 100 grms. of 91 per cent. alcohol dissolve 3·2 grms. ; the same conclusion follows from H. Schiff's and P. Rohland's measurements with barium chloride—for, at 15°, 100 grms. of 10 per cent. ethyl alcohol dissolve 31·1 grms. of $BaCl_2.2H_2O$; and 100 grms. of 97 per cent. alcohol dissolve 31·1 grms. of $BaCl_2.2H_2O$; and 100 grms. of 97 per cent.

alcohol dissolve 0·014 grm. of $BaCl_2.2H_2O$. According to C. A. L. de Bruyn, 100 grms. of absolute ethyl alcohol at 6° dissolve 3·8 grms. of $SrCl_2.6H_2O$; and 100 grms. of absolute *methyl alcohol* at 6°, 63·3 grms. of $SrCl_2.6H_2O$; or 7·3 grms. of $BaCl_2.2H_2O$; and at 15·5°, 2·18 grms. of $BaCl_2$. According to A. Schlamp, 100 grms. of *propyl alcohol* dissolve 10·75 grms. of $CaCl_2$. According to P. Rohland, one part of $BaCl_2.2H_2O$ dissolves in 78 parts of methyl alcohol of sp. gr. 0·790 (15°) at room temp.; in 7000 parts of ethyl alcohol of sp. gr. 0·8035 (15°); and in 100,000 parts of propyl alcohol of sp. gr. 0·8085 (15°). According to R. Fresenius, one part of barium chloride dissolves 7500 parts of absolute alcohol (99·3 volumes per cent.) at 14°, and in 4800 parts of the boiling alcohol; and one part of strontium chloride dissolves in 111·6 and 262 parts of the same alcohol at 14° and at the b.p. respectively.

According to T. Graham, anhydrous calcium chloride unites with ethyl alcohol, forming a compound $CaCl_2.3C_2H_5OH$ with *alcohol of crystallization*. P. Einbrodt objected to the evidence of chemical union, but R. Kane obtained a complex with methyl alcohol, $CaCl_2.4CH_3OH$, which is analogous to A. Chodnew's view of the composition of T. Graham's compound, viz. $CaCl_2.4C_2H_5OH$. J. B. Heindl prepared a series of compounds with ethyl, isobutyl, and amyl alcohols with the general formula $CaCl_2.3ROH$—where R represents the radicles C_2H_5, C_4H_9, or C_5H_{11}. E. Linnemann also made a compound with isopropyl alcohol. B. Völlmer measured the electrical conductivity of soln. of calcium chloride in ethyl alcohol, A. Schlamp in propyl alcohol. J. Wölfer determined the effect of calcium chloride on the b.p. of alcohol. The results show that calcium chloride in ethyl alcohol is partly ionized. According to L. Cailletet, calcium chloride is insoluble in *liquid carbon dioxide*. W. Eidmann found calcium and strontium chlorides to be soluble in *acetone;* and barium chloride insoluble. A. Lieben found a series of double compounds are formed with the *fatty acids—e.g.* with butyric acid, $CaCl_2.2C_4H_8O_2.2H_2O$; $CaCl_2.Ca(C_4H_7O_2)_2.4C_4H_8O_2$; and $CaCl_2.C_4H_8O_2$. P. B. Davis and co-workers measured the conductivity of soln. of barium chloride in *formamide*. According to A. Köhler, 100 grms. of a sat. soln. contain 42·84 grms. of *sugar* and 25·25 grms. of calcium chloride; and, according to C. A. L. de Bruyn, 100 parts by weight of *glycerol* dissolve 10 parts of barium chloride at 15·5°. L. Kahlenberg and F. C. Krauskopf say that calcium and strontium chlorides are very slightly soluble, and that barium chloride is insoluble in dehydrated *pyridine*, while calcium and strontium chlorides are soluble in pyridine with over 3 volumes per cent. of water, and barium chloride is insoluble in pyridine with 5 per cent. of water and slightly soluble in pyridine with 7 per cent. of water.

The crystals of dihydrated barium chloride have a positive double refraction. A. des Cloizeaux [26] gives the **indices of refraction** for the red rays, $\alpha=1·628$; $\beta=1·64$; $\gamma=1·657$; and for the yellow rays, $\alpha=1·635$; $\beta=1·646$; $\gamma=1·660$. The index of refraction of soln. of calcium chloride has been measured by V. S. M. van der Willigen, H. C. Jones and F. H. Getman, J. H. Gladstone, and G. J. W. Bremer. The following is a selection from G. J. W. Bremer's results for the *D*-line:

TABLE III.—REFRACTION CONSTANTS OF SOLUTIONS OF CALCIUM CHLORIDE.

Per cent. $CaCl_2$.	Temp.	μ	Sp. gr., D.	$\frac{\mu-\mu_0}{p}$	$\frac{\mu^2-1}{(\mu^2+2)D}$
7·0110	20°	1·35089	1·05389	0·002525	0·20464
10·9749	17°	1·35897	1·09053	0·002357	0·20344
13·0884	16°	1·36631	1·11139	0·002529	0·20176
19 6565	13°	1·38230	1·17210	0·002544	0·19912

This is in agreement with the view that the difference $\mu-\mu_0$ is proportional to the conc.; and the Lorenz and Lorentz's formula summarizes the effects very well. P. Barbier and L. Roux have measured the dispersion of soln. of calcium chloride.

A. G. Hankel and H. Lindenberg[27] found the crystals of dihydrated barium chloride to be electrified on warming. H. Jahn gives the mol. **electromagnetic rotation** of the plane of polarization of soln. of calcium chloride, 9·39 (water unity); strontium chloride, 9·71; and barium chloride, 10·094. P. Bary found the salts to fluoresce in the **Röntgen rays** and **Becquerel rays.** Molten calcium chloride is a fairly good conductor of electricity.

During the electrolysis of fused calcium chloride, there appears at the cathode a red pleochroic crystalline product which has a composition approximating **calcium subchloride,** CaCl. A. Guntz and H. Basset[28] did not make calcium subchloride by melting calcium with calcium chloride in a neutral atm., contrary statements are said to be based on a product containing a mixture of calcium hydride, CaH_2, and chloride. F. Haber and S. Tolloczko claim to have obtained an almost theoretical yield of barium subchloride, BaCl, by the electrolysis of solid barium chloride in an atm. of nitrogen at 600°, and the failure to obtain metallic barium by the electrolysis of fused barium chloride is attributed to the formation of this product. A. Guntz also claims to have made this compound by heating in an iron boat a mixture of barium and barium chloride to 850° in vacuo. Barium subchloride is said to be a brown crystalline substance which develops hydrogen when treated with water. It is difficult to obtain this compound in a pure state, because, says A. Guntz, if the attempt be made to volatilize the excess of barium, the **barium subchloride** decomposes at 1000° into $BaCl_2$ and barium. F. Haber and S. Tolloczko calculated the heat of formation of BaCl to be 115·8 Cals.

W. Hampe[29] found a similar remark applies to fused chlorides of strontium and barium, and K. Arndt has investigated the electrical conductivity of the fused salts. According to K. Arndt and A. Gessler, the eq. conductivity at 900° of calcium chloride with 36·2 gram-eq. per litre is λ=64·1; 34·0 gram-eq. of strontium chloride per litre, λ=58·2; and 30·5 gram-eq. of barium chloride per litre, λ=56·1. According to K. Arndt and K. Willner, the decomposition potential of fused calcium chloride at 800° is 3·24 volts; strontium chloride, 3·40 volts; and over 3·3 volts barium chloride. The electrolysis of soln. of calcium chloride gives hydrogen and calcium hydroxide at the cathode, and chlorine, oxygen, hypochlorite, and chlorate at the anode. The mechanism of the chemical reactions[30] involved is analogous with that which occurs during the electrolysis of the alkali chloride (*q.v.*).

The **electrical conductivities** of soln. of calcium chloride have been measured by J. G. MacGregor,[31] H. C. Jones and F. H. Getman, S. Arrhenius, and C. Heim. F. Kohlrausch has measured the eq conductivity, λ, at 18°. H. C. Jones and co-workers gave for the mol. conductivity, μ, and the percentage degree of ionization, α, of soln. with a mol of the salt in v litres of water:

	v	2	8	32	128	512	2048
$CaCl_2$	$\mu_{0°}$	80·5	95·3	106·4	117·8	124·0	131·4
	$\mu_{65°}$	—	318·7	378·5	418·9	452·5	474·8
	$\alpha_{0°}$	61·2	72·5	80·9	89·6	94·3	100·0
	$\alpha_{65°}$	—	67·1	79·7	88·2	95·3	100·0
$SrCl_2$	$\mu_{0°}$	81·36	92·97	106·3	118·5	125·0	133·9
	$\mu_{65°}$	—	324·4	377·5	424·6	453·9	476·5
	$\alpha_{0°}$	60·8	69·5	79·4	88·5	93·4	100·0
	$\alpha_{65°}$	—	66·6	77·5	87·2	93·2	97·8
$BaCl_2$	$\mu_{0°}$	86·62	99·06	—	—	126·5	132·7
	$\mu_{65°}$	259·8	322·3	375·3	421·5	453·8	478·0
	$\alpha_{0°}$	65·3	74·6	—	—	95·3	100·0

The same subject has been considered by G. Kümmell, and J. Drucker. The temp. coeff. of the conductivities of the chlorides of the alkaline earths have been studied by H. C. Jones and A. P. West, H. C. Jones, and A. C. MacGregory and F. Kohlrausch. C. Heim detected no abrupt change in the electrical conductivity of conc. soln. of calcium chloride in their passage to the supersaturated state. According to J. Trötsch, a 25 per cent. soln. of calcium chloride is the best conductor, and has the smallest temp. coeff.; he considers this phenomenon is not explained satisfactorily by assuming the formation of hydrates. O. Gropp studied the effect of temp. on the conductivity of liquid and frozen soln. of calcium chloride; G. Dickhaus, the effect of temp. on the conductivity of aq. soln. of barium and calcium chlorides. S. Lussana has studied the effect of press. on the conductivity of soln. of barium chloride; and E. MacKay measured the conductivity of mixed soln. of barium and sodium chlorides. G. N. Lewis and G. A. Linhart measured the **degree of ionization** of soln. of barium chloride; and G. N. Lewis and M. Randall, the activity coeff. of the ions. According to S. Arrhenius, the **heat of ionization** of barium chloride at 35° in $\frac{1}{10}N$-soln. is —307 cals. S. von Lasczynsky and S. von Gorsky found a soln. of calcium chloride in pyridine is a non-conductor. J. C. Ghosh measured the conductivity of soln. of barium chloride in mixtures of pyridine and water; and A. Schlamp, of calcium chloride in a number of non-aqueous solvents. A. B. Bryan measured the conductivity of planes charged with calcium and barium chlorides.

The **transport numbers** of the anion Cl′ with soln. of the alkaline earth chlorides have been determined by W. Hittorf, A. Weiske, W. Bein, B. D. Steele, etc.[32] The transport number with calcium chloride rises from 0·553 for 0·01N-soln. to 0·715 for 2N-soln.; from 0·625 for 0·5N-soln. to 0·715 for 2N-soln. of strontium chloride; and from 0·576 for 0·5N-soln. to 0·633 for 2N-soln. of barium chloride. The increase in the transport number with increasing conc. has led to the assumption that complex ions $BaCl_3'$ and $BaCl_4''$ are formed. A. Heydweiller found the **dielectric constant** of anhydrous barium chloride to be 3·11, and of the dihydrate 4·14, for λ=478 cms. The value for the contained water in the hydrated salt is 6·36, showing that the water is profoundly modified.

The chemical properties of the chlorides of the alkaline earths.—K. Kaiser[33] found that **hydrogen** converts calcium chloride at 700° into calcium hydride. According to H. Schulze, when chlorides of the alkaline earths are calcined in **oxygen** gas they are transformed into the oxides and chlorine, and, even in air, there is evidence of the same reaction as shown by E. Kraus, J. C. G. de Marignac, J. B. A. Dumas, and T. W. Richards. With barium chloride, the oxidation proceeds less readily than with the calcium salt. H. Schulze also showed that if the chloride be heated with chlorate, it is oxidized and chlorine gas is liberated. According to H. Kunheim, when calcined in a stream of **water vapour,** calcium chloride is less easily decomposed than magnesium chloride, and more easily than barium chloride, and, according to T. J. Pelouze, the reaction is incomplete, presumably $CaCl_2 + 2H_2O \rightleftharpoons Ca(OH)_2 + 2HCl$. E. Solvay says the reaction is accelerated when china clay or silica is present. C. Göpner says that **hydrogen chloride** transforms calcium oxide into a stone-like mass containing 40 per cent. $CaCl_2$ and 60 per cent. $Ca(OH)_2$. G. P. A. Petzholdt found that when strongly heated with **carbon dioxide,** the chloride of the alkaline earth is partly decomposed, and, according to F. Haber and S. Tolloczko, the thermal value of the reaction: $2CaCl_2 + 2CO_2 + O_2 = 2CaCO_3 + 2Cl_2 + 3{\cdot}1$ Cals.; and with barium chloride, 23·7 Cals. Calcium chloride which contains some oxide, absorbs carbon dioxide, a fact which O. L. Erdmann and H. Hess found requires attention when carbon dioxide is being dried by calcium chloride.

Calcium chloride, said H. Moissan, is attacked in the cold by **fluorine**, and chlorine is disengaged. J. Post, and A. Gorgeu say that an oxychloride is formed by the action of moist **chlorine** on red-hot calcium chloride, and that the oxychloride is impure because it is partly decomposed by the water. W. L. Goodwin showed that chlorine dissolves more copiously in soln. of calcium or strontium chloride than in water, and although no chlorohydrate separates out on cooling, it is supposed that the soln. contains *calcium or strontium polychloride.* A. Potilitzin and M. Berthelot found that **bromine** partially converts calcium, strontium, or barium chloride into the bromide, in a sealed tube at 400°. A 40 per cent. soln. of strontium chloride dissolves three times as much bromine or nine times as much iodine as water, and the bromine is expelled by passing a current of air through the diluted soln. The reactions are exothermal. There is only a very slight substitution of the chlorine by the bromine or iodine, and hence, adds M. Berthelot, strontium chlorobromide or chloroiodide must be formed. Similar remarks apply to the barium salt: $BaCl_2+4Br_2=BaBr_6+2BrCl+16\cdot4$ Cals.; but A. Potilitzin objects to this hypothesis. According to W. T. O. Casselmann, **phosphorus oxychloride**, $POCl_3$, at 100°, transforms barium chloride into a jelly. V. Merz and W. Weith found that if potassium iodide be melted with barium chloride, in air, iodine is evolved.

According to L. Smith, molten calcium chloride dissolves **calcium oxide**, but, says K. Arndt, no oxychloride is formed. At 800°, 5·4 per cent. CaO is dissolved; at 850°, 5·6 per cent.; and at 900°, 7·3 per cent. The solubility is not appreciably affected by the addition of calcium fluoride. The cooling curve shows that a solid soln. not a compound is formed. K. Arndt found similar results with strontium chloride and oxide; a soln. sat. at 910° contains 34·4 mols of SrO to 1000 of $SrCl_2$; with barium chloride and oxide, a eutectic is formed melting at about 870°, and containing 111 mols of $BaCl_2$ to 473 mols of BaO. B. Zahorsky studied the solubilities of lime in soln. of calcium chloride—*vide* calcium hydroxide. P. Berthier studied qualitatively the product obtained by fusing calcium sulphide and chloride, or barium sulphide and chloride; J. W. Döbereiner, mixtures of strontium chloride and sulphate; and P. Berthier, barium chloride and sulphate. According to H. Caron, when an alloy of sodium with lead, bismuth, antimony, or zinc is heated with strontium chloride, an alloy of sodium and strontium is formed. A. Rosensthiel says that calcium chloride, at a high temp., undergoes double decomposition with **barium hydroxide or sulphide**; C. J. B. Karsten, with **barium carbonate**; G. Lunge, with **calcium sulphide**; and G. Borsche and F. Brünjes, with **magnesium carbonate** in an atm. of carbon dioxide: $MgCO_3+CaCl_2=MgCl_2+CaCO_3$. A soln. of **potassium dichromate** was found by M. Prud'homme and E. Binder to precipitate normal barium chromate from a soln. of barium chloride: $K_2Cr_2O_7+BaCl_2=BaCrO_4+2KCl+CrO_3$. F. Ullik also noted that on evaporating a soln. of a little **strontium sulphate** in calcium chloride, a little strontium chloride is formed which can be extracted from the residue by alcohol. According to H. A. von Vogel, acetic, phosphoric, and boric acids displace a part of the chlorine from calcium chloride; the same observation was made by E. L. Salkowsky with respect to the action of nitrous anhydride. H. Schulz says that **nitric acid** partially converts a soln. of the alkaline earth into nitrate. M. Prud'homme and E. Binder found that **carbonic acid** at a low temp. and under press. decomposes soln. of the chloride of the alkaline earth, forming hydrochloric acid and calcium carbonate. The vapour of *sulphuric anhydride*, says H. Rose, does not act on anhydrous barium chloride; but, according to S. U. Pickering, **sulphuric acid** or a soluble sulphate gives a turbidity in a soln. containing 0·0000012 grm. of barium chloride per c.c. A soln. of **potassium carbonate** also converts a soln. of barium chloride into carbonate, a reaction studied by J. Bevad, who found that the speed of precipitation is greater the more conc. the soln. of the chloride, and is greatest with the barium salt and slowest with the calcium salt. M. M. P. Muir has studied the conditions of equilibrium between soln. of calcium chloride and the alkali carbonates. J. Piccard studied the action of aq. **phosphoric acid** on soln. of calcium chloride, and found that the product behaves like a mixture of normal calcium phosphate and hydrochloric acid, and that hydrogen chloride is given off when evaporated. The repeated soln. and evaporation at 100° of equi-molar parts of phosphoric acid and calcium chloride gives a residue of calcium hydrophosphate, $CaHPO_4$, with the evolution of hydrogen chloride; if more calcium chloride be employed, the excess remains unchanged; and with double the proportion of phosphoric acid, calcium dihydrophosphate, $Ca(H_2PO_4)_2$, is produced. C. J. B. Karsten noted that **sodium hydroxide** dissolves in soln. of calcium chloride without the separation of calcium hydroxide; and that soln. of sodium chloride dissolve more calcium hydroxide than water does. S. Chumanoff, and W. A. Burdakoff studied the effect of mixing soln. of **potassium hydroxide** of different conc. with aq. soln. of calcium chloride, and when the soln.

are mixed in the converse way. A. Tixier proposed to heat various **silicates** with calcium chloride to form chlorine, or if water vapour be present hydrogen chloride. The alkali chlorides and undecomposed chloride can be dissolved out by water; and the residual lime and the aluminium silicate decomposed by hydrochloric acid. The aluminium and calcium chlorides are evaporated to dryness, heated to 300°, and the residual alumina washed with water. The chlorides of the alkaline earths are but incompletely reduced when heated with **magnesium**.

J. J. Berzelius [34] noted in 1824 that anhydrous calcium chloride absorbs **ammonia** gas and at the same time swells up, cracks, splits in all directions, and at last falls to a white powder; according to H. Rose, with the vitreous salt, the initial absorption is rapid, and slows down towards the end; he also found the product of the action occupies 20 times the original volume of the solid. M. Faraday noted that the absorbed ammonia is expelled on heating, and the chloride remains chemically unchanged; and he added that vitreous barium and strontium chlorides slowly change in ammonia gas after many days' exposure—about 2 grms. of strontium chloride absorbed about 16·4 c.c. of the gas in a fortnight, and "a slight efflorescent appearance was seen on the broken edge." T. Weyl showed that the absorption by barium chloride is greater under press., and that the absorbed ammonia is rapidly lost on exposure to air. A. Joannis condensed liquid ammonia at —30° on still warm freshly prepared vitreous barium chloride in a tube provided with a stop-cock. When the action was complete, the stop-cock was opened and the tube warmed to 0°. The excess of ammonia escaped. The composition of the residue corresponded with **barium tetrammino-chloride**, $BaCl_2.4NH_3$. The vap. press. at 0° is 541 mm.; and at 28·4°, 1850 mm. The press. remained constant until all the ammonia had escaped, showing that a lower ammino-compound was not formed at this temp. H. Rose regarded the product formed by strontium chloride and ammonia to be **strontium octammino-chloride**, $SrCl_2.8NH_3$; and with the calcium salt, **calcium octammino-chloride**, $CaCl_2.8NH_3$. According to F. Isambert, the dissociation press. of calcium octammino-chloride at 0° is 120 mm., and at 46·2°, 1551 mm. C. Antoine represented the vap. press., p mm., of calcium ammino-chloride by $\log p=2·1361+0·023\theta$. The compound inflames spontaneously in chlorine gas, forming nitrogen chloride; it dissolves in water with the evolution of ammonia. F. Isambert inferred the existence of **calcium tetrammino-chloride**, $CaCl_2.4NH_3$, and of **calcium diammino-chloride**, $CaCl_2.2NH_3$, from the arrests in the press. curves of the dissociating octammino-salt, and from the heat developed per mol of ammonia when the product is dissolved in water—for $CaCl_2.2NH_3$, 14·03 Cals.; for $CaCl_2.4NH_3$, 12·16 Cals.; and for $CaCl_2.8NH_3$, 12·16 Cals. per mol of ammonia. R. O. E. Davis and co-workers measured the vap. press. of ammoniacal soln. of calcium chloride. L. Crismer [35] obtained impure compounds of calcium chloride with *hydroxylamine*, and G. N. Antonoff a series of compounds with $CaCl_2 : NH_2OH : H_2O$ as 2 : 1 : 5; 2 : 3 : 6; 1 : 2 : 0; 1 : 2 : 1; 1 : 2 : 2; 2 : 5 : 4; and $CaCl_2.3NH_2OH.HCl$. G. N. Antonoff also made $2SrCl_2.5NH_2OH.2H_2O$; and $2SrCl_2.9NH_2OH.3HCl.H_2O$. L. Crismer and G. N. Antonoff also made $BaCl_2.NH_2OH.2H_2O$.

F. A. H. Schreinemakers and W. C. de Baat [36] have studied the quaternary system, $NH_4Cl—CuCl_2—BaCl_2—H_2O$; $NaCl—CuCl_2—BaCl_2—H_2O$; and $KCl—CuCl_2—BaCl_2—H_2O$, in addition to the corresponding ternary system, with the alkali or ammonium chloride, cupric chloride, and water; and the ternary systems, $CuCl_2—BaCl_2—H_2O$ and $BaCl_2—KCl—H_2O$. In neither of the two latter is there any sign of a double salt.

The basic chlorides of the alkaline earths.—Calcium oxychlorides have been reported by J. B. Trommsdorff, C. F. Buchholz, and C. L. Berthollet [37] (*vide supra*). H. Rose made calcium oxychloride by boiling calcium hydroxide (0·4 part) with calcium chloride (15 parts) and water (5 parts), and filtering the hot soln. Needle-like crystals of **calcium oxychloride**, $3CaO.CaCl_2.15$ or $15H_2O$, separated in a few hours; they were dried between filter paper in an atm. free from carbon dioxide. G. André used 100 grms. each of hexahydrated calcium chloride and water, and 10–15 grms. of powdered calcium chloride. B. Zahorsky made this salt by treating hydrochloric acid with an excess of lime. The formula for the calcium salt has given rise to some discussion:—A. Ditte, and G. André gave $16H_2O$; T. Beesley, $14H_2O$; H. Rose (1854) later gave $2CaO.CaCl_2.H_2O$. B. Zahorsky gave $15H_2O$; and H. Grimshaw, $3CaO.CaCl_2.15H_2O$, or $CaCl.O.Ca(OH)+7H_2O$. F. A. H. Schreinemakers and co-workers have studied the ternary system, $CaO—CaCl_2—H_2O$, at different temp., and found at 10° the results indicated in Fig. 14. The solubility curve is *abcde*, where *ab* refers to $Ca(OH)_2$ soln. in equilibrium with $Ca(OH)_2$ as solid phase; *bc*, to $CaCl_2.3CaO.16H_2O$ as solid phase; *cd*, to $CaCl_2.CaO.2H_2O$ as solid phase; and *de*, to $CaCl_2.6H_2O$ as solid phase. Similar solid phases were obtained at 25°, but at 50° the solid phases in equilibrium with the soln. are $CaCl_2.CaO.5(\text{or } 4)H_2O$, $CaCl_2.CaO.2H_2O$, $CaCl_2.2H_2O$, and $Ca(OH)_2$. G. André made crystalline plates of **strontium oxychloride**, $SrO.SrCl_2.9H_2O$, in a similar manner to the process employed for the calcium oxychlorides. G. André also reported $SrO.SrCl_2$ with 12, 14, and $15H_2O$. J. Milikan's study of the ternary system $SrO—SrCl_2—H_2O$ at 40° gave as solid phases $Sr(OH)_2.8H_2O$; $SrCl_2.SrO.9H_2O$; and $SrCl_2.6H_2O$. In Fig. 15, the curve *ab* refers to soln. in equilibrium with $Sr(OH)_2.8H_2O$; *bc*, with $SrCl_2.SrO.9H_2O$; and *cd*, with $SrCl_2.4H_2O$ at 25°, the zone of stability of the oxychloride becomes very small, and at 0° disappears. E. Tassily, and G. André also made crystalline plates of **barium oxychloride**, $BaO.BaCl_2.5H_2O$, in a similar way by dissolving barium oxide in a conc. soln. of barium chloride. E. Beckmann reported the formation of an oxychloride, $Ba(OH)Cl.2H_2O$ or $BaCl_2.Ba(OH)_2.4H_2O$, by the action of baryta on a soln. of barium chloride in conc. hydrochloric acid. This was confirmed by F. A. H. Schreinemakers whose study of the ternary system, $BaO—BaCl_2—H_2O$, at 40°, gave a result obtained later by J. Milikan for the strontium oxychloride, but the solid phases were $Ba(OH)_2.8H_2O$; $BaCl_2.BaO.5H_2O$; and $BaCl_2.2H_2O$.

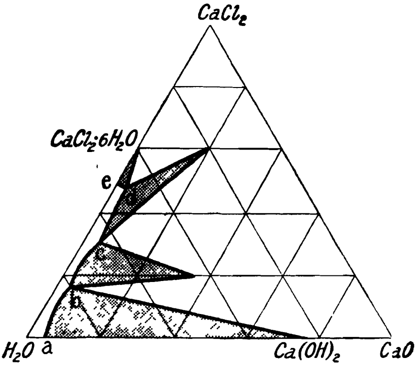

FIG. 14.—Ternary System, $CaO-CaCl_2—H_2O$, at 10°.

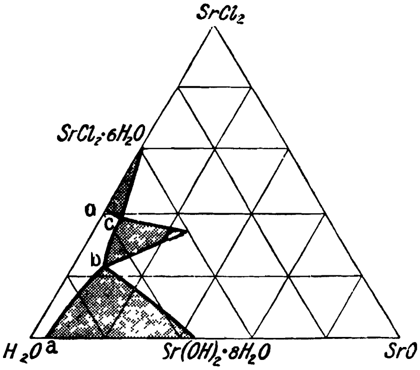

FIG. 15.—Ternary System, $SrO—SrCl_2—H_2O$, at 25°.

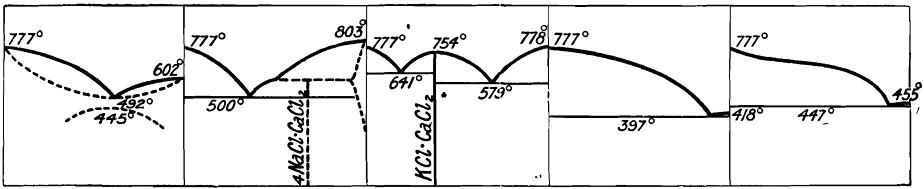
The heat of formation of G. André's ($CaCl_2.3CaO$, $16H_2O_{\text{liquid}}$) was 92·006 Cals.; with the $16H_2O_{\text{solid}}$, 69·126 Cals.; (SrO, $SrCl_2.9H_2O_{\text{liquid}}$), 24·44 Cals.; or with the $9H_2O_{\text{solid}}$, 18·01 Cals. E. Tassily gives ($BaCl_2$, BaO, $5H_2O_{\text{solid}}$), 39·2 Cals., or with $5H_2O_{\text{liquid}}$, 32·2 Cals. The heat of soln. of a mol of $SrO.SrCl_2.9H_2O$ in a dil. soln. of two mols of HCl at 22° is 8·36 Cals.; with a mol of $BaO.BaCl_2.5H_2O$ under similar conditions, 18·5 Cals. The crystals of the calcium salt lose the eq. of $14H_2O$ in vacuo; the barium salt loses $4H_2O$ at 120°. Water or alcohol decomposes the oxychlorides, so also do aq. soln. of ammonium and the alkali chlorides. Glycerol readily dissolves the calcium salt. Carbon dioxide forms the carbonate, but, according to E. Beckmann, at ordinary temp. carbon dioxide scarcely attacks the barium salt, which has been partially dehydrated at 120°, but at a red heat it is rapidly decomposed. According to P. A. Bolley, dry chlorine forms hypochlorite.

Complex salts.—E. Defacqz[38] prepared **barium fluorochloride**, $BaF_2.BaCl_2$, by heating 10 parts of manganese fluoride and 40 parts of barium chloride for 2 hrs. at 1000°; and purifying the product by repeated extraction with cold water, and finally with alcohol at 95°. The colourless crystalline plates have a sp. gr. 4·51 at 18°. The salt is insoluble in, and undecomposed by, boiling alcohol, very slowly decomposed by cold water, but much more readily attacked by the boiling solvent, being thereby converted into the chloride and fluoride of barium; dil. acetic, hydrochloric, or nitric acid effects a similar decomposition; it is soluble in conc. hydrochloric or nitric acids, whilst hot sulphuric acid decomposes it into barium sulphate, hydrofluoric, and hydrochloric acids. It is not changed by fusion with manganese chloride, but converted into barium fluoride on fusion with barium chloride. **Strontium fluorochloride**, $SrF_2.SrCl_2$, sp.gr. 4·18, and **calcium fluorochloride**, $CaF_2.CaCl_2$, sp.gr. 3·07, were prepared in a similar way. They resemble the barium salt, but are more readily dissociated by water. O. Ruff and W. Plato found mixtures of barium fluoride and chloride have a eutectic at about 860° and 86 molar per cent. of barium chloride; and mixtures of calcium fluoride and chloride, a eutectic at about 660°, and 78 molar per cent. of calcium chloride; there is also a break in the curve at about 750° and 50 molar per cent. of calcium chloride—$CaCl_2.CaF_2$.

W. Plato found that the f.p. curve of calcium fluoride with calcium chloride gave a minimum at 644°, and 80 mols per cent. of calcium chloride; and a break in the curve at 737°, corresponded with the formation of calcium fluorochloride, $CaF_2.CaCl_2$; with strontium chloride and fluoride there are two eutectics at 751° and 945° with respectively 36 and 89 mols per cent. of strontium fluoride, the intermediate maximum at 955° corresponds with the formation of strontium fluorochloride, $SrF_2.SrCl_2$; and with barium chloride and fluoride the two eutectics are at 942° and 845° corresponding respectively with 30 and 80 mols per cent. of barium chloride, the intermediate maximum at 1005° represents the m.p. of barium fluorochloride, $BaF_2.BaCl_2$.

C. Sandonnini[39] showed that lithium and calcium chlorides furnish a continuous series of mixed crystals with a sharp minimum temp., Fig. 16, at 492° and 36·4 molar per cent. of calcium chloride. Mixtures with 10–60 molar per cent. of calcium chloride show an evolution of heat after solidification. This corresponds with a breaking up of the solid soln. very near the temp. of crystallization. Simple eutectics are obtained with lithium chloride and strontium or barium chloride—in the former case at 492° and 48 molar per cent. of $SrCl_2$; and in the latter case at 510° and 33 molar per cent. of $BaCl_2$. O. Menge found that mixtures of molten calcium chloride with sodium, potassium, cuprous, or silver chloride are miscible in all proportions. E. Vortisch, and H. Gemsky found that the f.p. curve of binary mixtures of sodium and barium chlorides has one typical V-eutectic at 506° for 39 molar per cent. of barium chloride. H. le Chatelier noted the break in the curve corresponding with the transformation of α- to β-$BaCl_2$. With mixtures of sodium and strontium chloride; and with sodium and calcium chlorides, F. E. E. Lamplough, and K. Scholich obtained a V-eutectic at 506° with 53 molar



FIGS. 16 to 20.—Freezing-point Curves of Binary Mixtures of Calcium Chloride with Lithium, Sodium, Potassium, Cuprous, and Silver Chloride.

per cent. of calcium chloride. For the last case, O. Menge obtained a break corresponding with *sodium hexachlorocalciate*, $4NaCl.CaCl_2$, Fig. 17, but this has not been confirmed by other observers. C. Sandonnini measured the sp. gr. and electrical conductivities of the fused mixtures, and obtained no evidence of the formation of a compound.

O. Menge obtained a maximum with mixtures of potassium and calcium chlorides corresponding with **potassium calcium trichloride**, $KCl.CaCl_2$, or $KCaCl_3$, m.p. 754°, with two eutectics at 641° and 597° corresponding respectively with 19 and 65 molar per cent. of potassium chloride, Fig. 18. W. Moldenhauer and J. Andersen determined the m.p. of mixtures of the two chlorides. The existence of the double salt was confirmed by K. Scholich. C. Sandonnini measured the sp. gr. and electrical conductivities of the fused mixtures, and obtained evidence of the formation of a compound. Evidence of the formation of complexes of the chlorides of the alkalies and alkaline earths was obtained from a study of the heats of dilution of mixed soln. by G. McP. Smith and co-workers. With strontium and potassium chlorides, K. Scholich obtained long rhombic prisms of **potassium strontium tetrachloride**, $2KCl.SrCl_2$, m.p. 597°; and what are probably monoclinic prisms of **potassium strontium pentachloride**, $KCl.2SrCl_2$, m.p. 638°. H. Gemsky obtained the m.p. diagram, Fig. 21, for mixtures of barium and potassium chloride; there are two eutectic temp., E_1 and E_2 respectively, at 672°–680° and 652°–660°. The maximum between the eutectics corresponds with the formation of **potassium barium tetrachloride**, $BaCl_2.2KCl$, or potassium tetrachlorobariate, K_2BaCl_4. O. Ruff and W. Plato obtained a similar result. The corresponding curve with barium and sodium chlorides is of the simple V-type with a eutectic at 654° and 39 mol per cent. of barium chloride. The area FGE_3EE_2, Fig. 22, represents the range of existence of the double salt K_2BaCl_4; the area AHC, the region of mixed crystals. The eutectic lines are represented E_2E, E_1E, and E_3E. The dotted curve AHC represents the breaking down of the mixed crystals into their components.

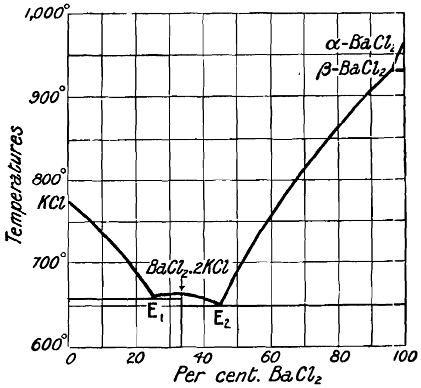


FIG. 21.—Melting-point Curve of Binary Mixtures, $BaCl_2$—KCl.

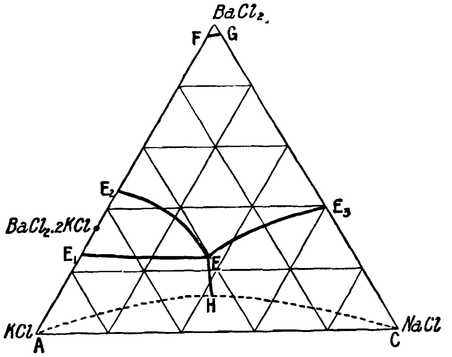

FIG. 22.—Ternary System, $BaCl_2$—KCl—$NaCl$.

G. S. Jamieson obtained slender prisms of dihydrated **cæsium calcium chloride**, $2CsCl.CaCl_2$, from soln. containing 1–4 mols of each component per litre. E. H. Ducloux used the formation of the salt as a microchemical test for calcium. Similarly, with soln. containing 2 mols of cæsium chloride to one of strontium chloride, hydrated **cæsium strontium chloride**, $5CsCl.2SrCl_2.8H_2O$, was obtained; but with soln. containing $CsCl : SrCl_2 = 3 : 1$, only cæsium chloride appeared, and with 1 : 1 only strontium chloride.

E. Chauvenet, P. Job, and G. Urbain's analysis of the thermal effect on mixing soln. indicated the formation in soln. of **cupric calcium decachloride**, $2CuCl_2.3CaCl_2$, and **cupric calcium tetrachloride**, $CuCl_2.CaCl_2$. O. Menge found that with mixtures of calcium and silver chlorides there is a eutectic at 452° with 95 per cent. of silver chloride, Fig. 19; and with mixtures of calcium and cuprous chloride, a eutectic at 386° with 91 per cent. of cuprous chloride, Fig. 20. A. C. Becquerel prepared what he regarded as **barium cupric chloride,** by allowing soln. of barium chloride and cupric nitrate to diffuse slowly one into the other. F. A. H. Schreinemakers and W. C. de Baat obtained no complex salts in their study of the quaternary systems, $H_2O—NH_4Cl—BaCl_2—CuCl_2$; $H_2O—NaCl—BaCl_2—CuCl_2$; and $H_2O—KCl—BaCl_2—CuCl_2$. There is some evidence of the formation of complex salts **calcium, strontium, and barium silver chlorides** in soln. G. S. Forbes measured the solubility of silver chloride in soln. of calcium, strontium, and barium chlorides, at 25°, and found that when conc. are expressed in gram-eq. per 1000 grms. of water, the following values of $K_m=[Ag]/[MCl]^m$, where M is a gram-eq. of the metal, and m is a small whole number:

$[Ag]\times10^3$	0·289	0·900	2·802	5·823
$[\frac{1}{2}CaCl_2]$	1·748	2·741	4·033	5·005
$K_2\times10^4$	0·95	1·20	1·72	2·32
$K_3\times10^4$	0·54	0·44	0·427	0·464

$[Ag]\times10^3$	0·033	0·236	1·252	12·04
$[\frac{1}{2}SrCl_2]$	0·550	1·572	2·992	5·775
$K_2\times10^4$	1·10	0·95	1·40	3·61
$K_3\times10^4$	2·00	0·61	0·47	0·62

$[Ag]\times10^3$	0·186	0·339	1·274	2·366
$[\frac{1}{2}BaCl_2]$	1·248	1·610	2·676	3·260
$K_2\times10^4$	1·20	1·31	1·78	2·20
$K_3\times10^4$	0·96	0·81	0·67	0·67

Data were also obtained for hydrogen, sodium, potassium, and ammonium chlorides. The increase in solubility was explained by assuming that complex anions, $AgCl_3''$, $AgCl_4'''$, and possibly $AgCl_5''''$, are formed which are stable throughout considerable ranges of conc. No evidence of the complex anion $AgCl_2'$ was obtained.

A. Guntz prepared what he regarded as **barium sodium dichloride,** BaCl.NaCl, by the electrolysis of a molten mixture of sodium and barium chlorides; and by heating in a covered iron crucible, two gram-atoms of sodium with a mol of barium chloride. The product is a greyish-white mass which develops hydrogen when treated with water, and when heated to 700°, loses its sodium and leaves a residue of barium chloride.

According to T. Liebisch and E. Korreng, the fusion curve of the binary system with barium and calcium chlorides has a eutectic at 600° and 40 molar per cent. of barium chloride; there is a break in the curve at 631° corresponding with the formation of **calcium barium tetrachloride**, or *calcium tetrachlorobariate*, $CaCl_2.BaCl_2$, crystallizing at 631°. O. Ruff and W. Plato obtained a simple V-eutectic with mixtures of barium and calcium chloride at about 590° and 64 molar per cent. of calcium chloride. The binary system with calcium and strontium chlorides has a U-shaped minimum at 658° and 33 molar per cent. of strontium chloride; similarly also with strontium and barium chlorides at 847° and 30 molar per cent. of barium chloride. C. Sandonnini, W. Schäfer, and O. Ruff and W. Plato obtained confirmatory results.

T. Liebisch and E. Vortisch studied the ternary system, $BaCl_2—SrCl_2—NaCl$; H. Gemsky, E. Vortisch, and E. Jänecke, $BaCl_2—KCl—NaCl$—*vide* Fig. 22; K. Scholich, $SrCl_2—KCl—NaCl$, and $CaCl_2—KCl—NaCl$; and W. Schäfer, $BaCl_2—SrCl_2—CaCl_2$. In the last case there is evidence of the ternary compound **calcium strontium barium hexachloride,** $CaCl_2.SrCl_2.BaCl_2$, crystallizing at about 500°.

§ 13. Calcium, Strontium, and Barium Bromides

According to A. J. Balard (1826),[1] calcium bromide is formed when bromine acts on red-hot calcium oxide or carbonate, and a little is formed when the bromine acts on heated calcium chloride. C. Löwig made it by the action of hydrobromic acid on calcium oxide; C. Wendler, by the action of bromine on calcium sulphite; C. Klein, by the action of 200 parts of bromine, 16 parts of phosphorus, and 75 parts of calcium oxide; O. Henry, by the action of bromine on lime in the presence of metallic iron, or of ferrous bromide on the hydroxide or carbonate; J. S. Stas and G. Macdonald made it by mixing bromine with ammoniacal milk of lime, or ammonium bromide with calcium carbonate; and A. Faust, by the action of sulphur bromide on milk of lime: $SBr_6+4CaO=3CaBr_2+CaSO_4$. According to M. Henner and J. Hohenhauser, if bromine is allowed to act on an aq. soln. with an excess of the hydroxide of the alkaline earth, a mixture of the bromide and bromate is formed. The latter can be separated by crystallization, or by adding 90 per cent. alcohol. The alcohol can be distilled from the filtrate, and the bromide obtained; the bromate can be converted into bromide by calcination with charcoal, and leaching the product with water. The corresponding salts of barium and strontium are prepared in a similar manner. The hexahydrated bromides separate from aq. soln.—the barium dihydrated salt is formed as in the case of the corresponding chloride. The anhydrous salts are obtained by heating the hydrated salt, or by the calcination of the bromate. A. J. Balard prepared barium bromide by the action of hydrobromic acid on barium hydroxide or carbonate; C. Löwig, on barium sulphide. T. W. Richards in his work on the at. wt. of barium prepared barium bromide by the action of purified hydrobromic acid on the carbonate; by the decomposition of barium bromate; by the action of bromine on the hydroxide prepared by the action of potassium oxide on the nitrate, and by the ignition of the nitrate. The chief difficulty was to obtain the barium salt free from strontium and calcium.

Barium hydroxide was prepared by treating purified barium nitrate with purified potassium hydroxide, and recrystallizing several times from hot water. In order to remove potassium salts, the hydroxide was precipitated from its aq. soln. by purified alcohol, and the precipitate washed with alcohol by suction. The barium hydroxide was boiled in a platinum vessel for some time to remove the alcohol, and sat. with bromine in a Bohemian glass flask. The large amount of bromide filtered off from the bromate was half crystallized out by boiling down the mother liquor in a platinum dish, treating with alcohol, and cooling. The mother liquor from these crystals contained most of the strontium. The solid was dissolved, boiled down, treated with alcohol, and cooled ; and the new crystals were washed four times with alcohol. After repeating this round of operations once again, the mother liquor showed no trace of strontium. The pure crystals yielded a faintly brownish mass upon fusion, and this in turn left a brownish precipitate upon soln. The clear filtered liquid was boiled down and treated with alcohol just as described above. The crystals were again fused, and again subjected to the same succession of operations. For the last time the crystals were raised to a dull heat by means of a spirit lamp, and the residue was dissolved in the purest water in a platinum dish, allowed to stand exposed to the air until neutral, filtered, recrystallized twice more, and washed with the purest alcohol.

Similar remarks apply to the preparation of strontium bromide free from barium and calcium in T. W. Richards' work on the at. wt. of strontium.

A soln. of 500 grms. of strontium nitrate in 2 litres of water was treated four times in succession with a cubic centimetre of dil. sulphuric acid, and in each case, after standing 4 days, the clear liquid was decanted. The liquid was evaporated to a small bulk, filtered from the precipitated sulphate, and twice recrystallized. Each lot of crystals was washed three times with alcohol by suction. The nitrate was treated with ammonium carbonate, and the washed precipitate of strontium carbonate was treated with purified hydrobromic acid. The strontium bromide was evaporated in a platinum dish. This was slightly attacked, bromine having been set free by a little occluded strontium nitrate in the carbonate. After evaporation to dryness the bromide was fused at a bright red heat in platinum. The alkaline soln. of the fused cake was treated with hydrogen sulphide, filtered, acidified with hydrobromic acid, warmed, filtered from the platinum sulphide, boiled to free it from sulphuretted hydrogen, again filtered, and crystallized twice from water.

The properties of the bromides of the alkaline earths.—Hexahydrated calcium bromide forms silky needle-like crystals, likewise also the corresponding strontium salt which, according to O. Mügge,[2] belong to the hexagonal system. The latter also stated that the crystals of dihydrated barium bromide are monoclinic prismatic crystals with axial ratios $a:b:c=1·4494:1:1·1656$, and $\beta=113° 29\frac{1}{2}'$, and isomorphous with the corresponding chloride, $BaCl_2.2H_2O$. J. Herbette studied mixed crystals of barium chloride and bromide. There are the monoclinic crystals resembling the chloride, studied by G. Wyrouboff, and O. Mügge: $a:b:c=0·1676:1:0·6548$, and $\beta=88° 55'$; the monoclinic crystals resembling the bromide studied by O. Mügge, and H. Dufet: $a:b:c=1·44943:1:1·6559$, and $\beta=66° 30'$; and another form studied by J. Herbette: $a:b:c=1·17104:1:1·6240$, and $\beta=89° 50'$. T. W. Richards and V. Yngve found evidence of the existence of dihydrated strontium bromide, and they gave 88·62° for the transition temp., $SrBr_2.6H_2O \rightarrow SrBr_2.2H_2O+4H_2O$. O. Mügge said that crystals of pentahydrated strontium bromide, $SrBr_2.5H_2O$, resemble those of hexahydrated barium iodide, and have the axial ratio $a:c=1:0·515$. The **specific gravity** of anhydrous calcium bromide is 3·32 (11°), according to C. H. D. Bödeker[3]; and 3·4 (20°), according to O. Ruff and W. Plato, for anhydrous strontium bromide. C. H. D. Bödeker gives 3·962 (12°); T. W. Richards, 4·216 (24°); and P. A. Favre and C. A. Valson, 3·985 (20·5°); and for anhydrous barium bromide, H. Schiff gave 4·23 and T. W. Richards 4·781 (24°). The best representative values for the sp. gr. of calcium, strontium, and barium bromides are given by W. Biltz as 3·956, 4·549, and 5·150 respectively, and the mol. vol. 74·29, 75·07, and 75·96 respectively. For hexahydrated strontium bromide, P. A. Favre and C. A. Valson give 2·358 (18°); and for dihydrated barium bromide, H. Schiff gives 3·690; H. G. F. Schröder, 3·710; F. W. Clark, 3·679 (24·3°); and J. W. Retgers, 3·827 (20°).

The reported numbers for the **melting point** of calcium bromide vary from W. Ramsay and N. Eumorfopoulos' 485°,[4] which is very much too low, to O. Ruff and W. Plato's 760°. G. Kellner gave 730°, and T. Carnelley, 676°–680°. For the m.p. of strontium bromide there is W. Ramsay and N. Eumorfopoulos' very low value 498°; G. Kellner's 643°; and T. Carnelley's 630°. For barium bromide, W. Ramsay and N. Eumorfopoulos gave the very low value 728°; O. Ruff and W. Plato, 880°; T. Carnelley, 812° ± 3°; and G. Kellner, 847°. E. Lubarsky's value for the m.p. of hexahydrated calcium bromide is 38·2°; and C. O. Curtmann's for trihydrated calcium bromide, 80°–81°.

According to J. Thomsen,[5] the **heat of formation** (Ca, Br_2) is 141·25 Cals.; (Sr, Br_2), 157·7 Cals.; and (Ba, Br_2), 169·46 Cals. M. Berthelot's values are: ($Ca, Br_{2liquid}$), 151·6 Cals.; (Sr, Br_2), 168 Cals.; and (Ba, Br_2), 172·4 Cals. J. Thomsen also gives ($Ca, Br_2, 6H_2O$), 166·85 Cals.; ($Sr, Br_2, 6H_2O$), 181·01 Cals.; and ($Ba, Br_2, 2H_2O$), 178·57 Cals.; ($CaBr_2$,aq.), 24·51 Cals.; ($SrBr_2$,aq.), 16·11 Cals.; and ($BaBr_2$,aq.), 4·98 Cals.; (Ca, Br_2,aq.), 165·76 Cals.; (Sr, Br_2,aq.), 173·81 Cals.; and (Ba, Br_2,aq.), 174·44 Cals.; ($CaBr_2, 6H_2O$), 26·60 Cals.; ($SrBr_2, 6H_2O$), 23·31 Cals.; and ($BaBr_2, 2H_2O$), 9·11 Cals.

The **heat of solution** of $CaBr_2.6H_2O$, 400 mols of water is, —1·09 Cals.; for $SrBr_2.6H_2O$, —7·2 Cals.; and for $BaBr_2.2H_2O$, —4·13 Cals. S. U. Pickering gives the heat of soln. of $CaBr_2$ in water, 23·293 Cals., and in alcohol, 2·1471 Cals. J. Thomsen also gives for the heat of soln. of strontium bromide associated with different amounts of water, $SrBr_2+nH_2O$, in 400 mols of water at 18°, n=0, 16·11 Cals.; n=1, 9·96 Cals.; n=2, 6·16 Cals.; n=3, 3·06 Cals.; n=4, —0·04 Cals.; n=5, —3·20 Cals.; and n=6, —7·20 Cals.

P. Kremers' values for the **solubility** of the bromides of the alkaline earths[6] in grams of MCl_2 per 100 grms. of soln. are:

	0°	10°	20°	25°	40°	60°	80°	100°
$CaBr_2$ . .	55·5	57·0	58·8	60·5	68·1	73·5	74·7	75·7 (105°)
$SrBr_2$ . .	46·0	48·3	50·6	51·7	55·2	60·0	64·5	69·0
$BaBr_2$ . .	49·5	50·2	51·0	52·1	53·2	55·1	57·4	60·0

A. Étard gives for calcium bromide at 22°, the solubility 50·5; at —7°, 52·6; and for barium bromide at —20°, A. Étard gives 45·6; and at 145°, 60·5; at 160°, 59·4; and at 175°, 60·3. A. Étard's values for calcium bromide are considered to be less accurate than those of P. Kremers; the solubility curve travels in a straight line to 50°; there are two breaks in the curve between 50° and 70°, which A. Étard attributes to the formation of two hydrates; and from 70° to 170°, the curve again travels in a straight line. The values for strontium bromide are averaged from those of P. Kremers and A. Étard. W. D. Harkins measured the solubility of strontium bromide in water and in soln. of strontium nitrate at 25°. They found that strontium bromide dissolves in water to the extent of 1066·2 grms. per 1000 grms. of water at 25°, and the soln. has a sp. gr. 1·7002 at 25°/4°. The following values have been obtained for the solubility of strontium bromide in grams per 1000 grms. of water in soln. of the following mol. conc. of strontium nitrate, and the soln. have the appended sp. gr.:

Solubility $SrBr_2$	1066·2	1066·95	1067·42	1068·54	1068·9	1069·17	1073·97
Conc. $Sr(NO_3)_2$	0·0000	0·0360	0·07216	0·14568	0·3066	0·61124	1·8610
Sp. gr. 25°/4°	1·7002	—	1·70325	1·72844	1·73766	1·74866	1·77368

A. Étard's values for barium bromide are rather lower than those of P. Kremers. A. Étard found a maximum between 104° and 160°, and since the heat of soln. does not here change its sign, it is assumed that the maximum—if not a mal-observation—has the same character as that with hexahydrated calcium chloride at 29·9°. A. Étard found the solubility of barium bromide is reduced by salts of barium or soluble bromides. Aq. soln. of calcium and strontium bromides, at ordinary temp., furnish crystals of the hexahydrated salts; barium bromide forms **dihydrated barium bromide**. J. L. Kreider[7] heated dihydrated barium bromide at different temp. for half an hour in a stream of dry air, and also in a current of hydrogen bromide, and the loss of hydrogen bromide and of water was determined in each case. There was no appreciable difference in the results by the two sets of experiments, and he infers that the two mols of water are similarly associated in the mol., and he gives the graphic formula :

$$\overset{H}{\underset{H}{}}{>}O{=}Br{-}Ba{-}Br{=}O{<}\overset{H}{\underset{H}{}}$$

which may be compared with those for magnesium and hexahydrated aluminium bromides.

According to C. O. Curtmann, when hexahydrated calcium bromide is dehydrated, **trihydrated calcium bromide**, $CaBr_2.3H_2O$, is formed which melts between 80° and 81° ; and at 180° is said to form $CaBr_2.2{\cdot}5H_2O$, which is probably not a true compound. If freshly dehydrated calcium bromide be dissolved in absolute alcohol, the soln. becomes hot, and, after filtering off the calcium oxide, X. Roques found the syrupy liquid furnished rhombic plates of $CaBr_2.3H_2O$. which are very deliquescent ; and which, if hot soln. are used, may contain a little ethyl bromide, C_2H_5Br. The **specific gravities** of soln. of calcium bromide have been determined by D. I. Mendeléeff, and G. T. Gerlach. P. Kremer's observations at 19·5° furnish :

Per cent. salt . .	5	10	20	30	40	50	55
Sp. gr. $CaBr_2$ . .	1·044	1·089	1·194	1·315	1·461	1·641	—
Sp. gr. $SrBr_2$ . .	1·046	1·094	1·204	1·332	1·492	1·694	—
Sp. gr. $BaBr_2$ . .	1·045	1·092	1·201	1·329	1·485	1·685	1·800

H. C. Jones and F. H. Getman also determined the sp. gr. of soln. of calcium bromide at 25° (water at 4° unity). The sp. gr. of the sat. soln. of calcium bromide at 20° is 1·82 ; of strontium bromide, 1·70 (20°) ; and of barium bromide, 1·71 (20°). P. Kremers also measured the changes in volume of soln. of these salts ; and L. C. de Coppet, the effect of calcium and barium bromides on the temp. of maximum density—the lowering of the temp. is proportional to the conc. for the temp. with 0·0403 and 0·1631 mols of the salt per litre are respectively 2·969° and —0·304° ; and $d\theta/dM$=25·14 and 26·28 respectively.

The **lowering of the vapour pressures** of soln. of calcium, strontium, and barium bromide were determined by G. Tammann,[8] and W. Biltz. The quotient $(p_0-p)/C$ rises with increasing conc. and falls with rise of temp. H. Lescœur's value for the vap. press. of hexahydrated strontium bromide at 20° is 9·1 mm. W. Pieper measured the vap. press. of aq. and alcoholic soln. of calcium bromide. H. C. Jones and V. J. Chambers [9] measured the **lowering of the freezing point** of soln. of calcium chloride, and they found for calcium bromide :

Gram-mols/litre, *C* . . .	0·04355	0·08710	0·13065	0·17422	0·2613	0·5226
Lowering f.p., *dt*. . .	0·228°	0·445°	0·664°	0·904°	1·368°	2·049°
dt/C	5·24	5·11	5·07	5·18	5·23	5·64

Hence the mol. lowering first decreases continuously with increasing conc. to 0·13065 mol per litre, and in more conc. soln., as with the lowering of the vap. press., increases more rapidly than would occur if ionization alone were in question. The halides of the alkaline earths all show a similar behaviour, and W. Biltz has shown that the phenomenon is more pronounced in passing from barium to strontium and to calcium, and from chlorides to bromides to iodides.

The **refraction equivalents** of 42·36 to 43·50 per cent. soln. of calcium bromide for the *A*-line were found by J. H. Gladstone[10] to be in accord with the $(n-1)/D$ formula. H. C. Jones and F. H. Getman also determined the index of refraction of soln. of calcium bromide. The **index of refraction** rises from 1·34106 to 1·42339 for soln. with 0·542 to 3·011 mols per litre when the sp. gr. rises from 1·07535 to 1·48093. P. Barbier and L. Roux have measured the dispersion of these soln. According to H. Jahn, the mol. **electromagnetic rotation** of the plane of polarization of soln. of calcium bromide is 17·605 (water unity) ; strontium bromide, 18·163 ; barium bromide, 18·54. C. Sheard and C. S. Morris found the **emission spectrum** of calcium bromide had a band between 5500 and 4850.

According to W. Hampe,[11] molten strontium bromide is a good conductor of electricity. H. C. Jones and V. J. Chambers found the deductions from the mol. **electrical conductivity** of soln. of the bromides of the alkaline earths agreed with the conclusions obtained with the lowering of the f.p. of soln. of the bromides of the alkaline earths. H. C. Jones and co-workers' values for the mol. conductivity, μ, and the percentage **degree of ionization**, α, of soln. with a mol of the salt in v litres, are :

	v . .	2	8	32	128	512	2048
$CaBr_2$	$\mu_{0°}$.	85·95	97·74	108·2	117·3	122·9	126·8
	$\mu_{65°}$.	262·05	339·40	391·68	431·83	458·67	487·30
	$\alpha_{0°}$.	67·7	77·1	85·3	92·5	96·9	100·0

$BaBr_2$	$\mu_{0°}$.	91·81	103·4	114·4	123·6	131·8	134·2
	$\mu_{65°}$.	—	340·1	392·8	439·2	467·6	484·6
	$\alpha_{0°}$.	68·4	77·1	85·3	92·1	98·2	100·0
	$\alpha_{65°}$.	—	68·4	79·0	83·3	94·0	97·4

H. C. Jones and A. P. West have measured the temp. coeff. of the conductivities of soln. of these salts ; H. C. Jones and H. P. Bassett also investigated the formation of hydrates in conc. soln. from the conductivities, the lowering of the f.p., and the sp. gr. of those soln. G. Dickhaus measured the effect of temp. on the conductivity of soln. of calcium bromide. A. Heydweiller found the **dielectric constant** of dihydrated barium bromide to be 4·25 for λ=478 cms.

Anhydrous calcium bromide is soluble in **alcohol,** and X. Roques [12] found the soln. furnishes rhombic hygroscopic crystals of the compound, $CaBr_2.3C_2H_5OH$. H. Fonzes-Diacon found that 64·5 grms. of anhydrous strontium chloride dissolve in 100 grms. of absolute alcohol, and the soln., at 0°, has the sp. gr. 1·210. Rhombic prismatic crystals of a compound, $SrBr_2.2\frac{1}{2}C_2H_5OH$, are formed by slow evaporation. According to O. Henry, and R. Piria, barium bromide is soluble in absolute alcohol, and P. Rohland found at room temp. one part of dihydrated barium bromide is dissolved by 36 parts of methyl alcohol, 207 parts of ethyl alcohol, and 652 parts of propyl alcohol, while 100 parts of 50, 93·5, and 100 per cent. methyl alcohol at 15° dissolve respectively 4, 27·3 and 45 9 parts of barium chloride, and at 22·5°, 100 parts of absolute methyl alcohol dissolve 56·1 parts of $BaCl_2$. At 15°, 100 parts of 97 per cent. ethyl alcohol dissolve 0·48 part of $BaBr_2.2H_2O$, while at 22·5°, 100 parts of 100 and 87 per cent. ethyl alcohol dissolve respectively 3 and 6 parts of $BaBr_2$. According to W. Eidmann, barium bromide is soluble in *acetone.*

Calcium bromide rapidly deliquesces on exposure to air ; and C. Löwig [13] showed that when melted, calcium bromide loses some bromine ; and that with conc. *sulphuric acid* it develops first hydrogen bromide, and then bromine and sulphur dioxide. According to C. Löwig, hexahydrated strontium bromide effloresces in air, and, according to T. W. Richards, it loses five-sixths of its water of crystallization over sulphuric acid, and the water is restored on exposure to air. Strontium bromide loses its water of crystallization when heated to a low temp., and, when melted, C. F. Rammelsberg found that the salt loses all its water of crystallization. If carbon dioxide and air is passed through an aq. soln. of barium bromide what is considered to be a complete reaction occurs: $BaBr_2+CO_2+O=BaCO_3+Br_2$. H. Schulze found that when barium bromide is heated red hot in *oxygen* gas, some barium oxide is formed, but E. Beckmann says it is indifferent to oxygen and carbon dioxide at a red heat. A. Potilitzin found that bromine is partially displaced by *chlorine* at 100°.

If anhydrous calcium bromide be warmed with *bromine*, in equi-mol proportions, J. Meyer obtained a red liquid which on cooling gave a crystalline mush, which at ordinary temp. loses bromine until calcium bromide remains. Similar remarks apply to strontium and barium bromides. It is supposed an unstable **calcium polybromide**—possibly $CaBr_4$—is formed, a conclusion confirmed by the lowering of the f.p. of soln. of calcium bromide and bromine. Evidence has likewise been obtained of the existence of **strontium polybromide**, but the solid has not been isolated. M. Berthelot also found a soln. of 400 grms. of hexahydrated strontium chloride in a litre of water dissolves 92 grms. of bromine developing 0·5 cal. per 80 grms. of bromine. The soln. is not altered by dilution, but it loses bromine in a stream of air. M. Berthelot also found evidence of the formation of **barium polybromide :** $BaBr_2+2Br_{2gas}=BaBr_6+20·8$ Cals., but J. Meyer found no signs of the depression of the f.p. of soln. of barium or strontium bromide by the addition of bromine.

C. F. Rammelsberg found that anhydrous calcium bromide absorbs ammonia gas, forming a voluminous unstable white powder, heat is developed at the same time. The composition approximates to **calcium hexammino-bromide,** $CaBr_2.6NH_3$. This salt forms a clear soln. with water which deposits calcium carbonate on exposure to air. C. F. Rammelsberg said that anhydrous strontium bromide under similar conditions forms **strontium hemiammino-bromide**, $SrBr_2.\frac{1}{2}NH_3$. A. Joannis made **barium octammino-bromide**, $BaBr_2.8NH_3$, by condensing ammonia in a tube with recently fused barium bromide, at —30°, and then allowing the excess of ammonia to escape at 0°. The vap. press. of the product remains constant for many hours. Barium bromide reacts with liquid ammonia and potassium: $BaBr_2+2KNH_3=2KBr+Ba(NH_2)_2+H_2$.

C. Löwig[14] reported the formation of fine needle-like crystals of **calcium oxybromide** by boiling a soln. of calcium bromide with milk of lime. E. Tassily obtained a basic calcium bromide, or calcium oxybromide, $3CaO.CaBr_2.16H_2O$, by digesting on hot plates 100 grms. of calcium bromide in 75 c.c. of water, with 3 grms. of calcium oxide. The hot soln. is filtered, and needle-like crystals of the salt in question separate out; they can be washed by a soln. of calcium bromide. F. A. H. Schreinemakers and J. Milikan obtained besides E. Tassily's oxybromide, a second one, $3CaBr_2.4CaO.16H_2O$. In the isothermal lines of Fig. 23 for the ternary system, $CaBr_2$—CaO—H_2O, at 25°, the sat. soln is in equilibrium with the solid phase, $Ca(OH)_2$ along *ab*; with $CaBr_2.3CaO.16H_2O$ along *bc*; with $3CaBr_2.4CaO.16H_2O$ along *cd*; and with $CaBr_2.6H_2O$ along *de*. The salt is decomposed by water with the separation of calcium hydroxide; it is also decomposed by carbon dioxide, alcohol, and acids. The heat of formation is given as $CaBr_2+3CaO+16H_2O_{solid}=76·45$ Cals., and the heat of soln. in 6 mols hydrogen bromide in a dil. soln. at 20° is 63·55 Cals. If this salt be dehydrated at 120° in a stream of dry air freed from carbon dioxide, $3CaO.CaBr_2.3H_2O$ is formed. The heat of formation is given as $CaBr_2+3CaO+3H_2O_{solid}=62·3$ Cals., and the heat of soln. in 6 mols of a dil. soln. of hydrogen bromide is 95·7 Cals. E. Tassily also obtained non-hygroscopic crystals of **strontium oxybromide**, $SrO.SrBr_2.9H_2O$, with the heat of formation $SrO+SrBr_2+9H_2O_{solid}=41·95$ Cals., and a heat of soln. of 38·3 Cals. in two mols of hydrogen bromide in dil. soln. at 20°. J. Milikan obtained E. Tassily's strontium oxybromide, and its range of stability is indicated in Fig. 24, where the composition of the sat. soln. in equilibrium with the solid phase $SrO.9H_2O$ is indicated by the isothermal line *ab*; with $SrBr_2.SrO.9H_2O$ by

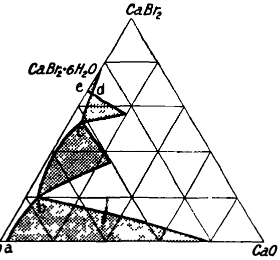

FIG. 23.—Ternary System, $CaBr_2$—CaO—H_2O, at 25°.

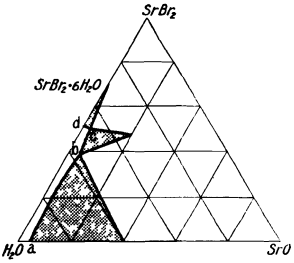

FIG. 24.—Ternary System, $SrBr_2$—SrO—H_2O, at 25°.

bc; and with $SrBr_2.6H_2O$ by *cd*. If the oxybromide, $SrBr_2.SrO.9H_2O$, be dehydrated at 120° in a stream of dry air free from carbon dioxide, $SrO.SrBr_2.3H_2O$ is formed. The heat of formation is $SrBr_2+SrO+3H_2O=32\cdot7$ Cals., and the heat of soln. at 13° is 38·3 Cals. in a dil. soln. with 2 mols of hydrogen bromide. E. Beckmann made an impure **barium oxybromide**, $BaO.BaBr_2.7\cdot54H_2O$, by dissolving 3 grms. of $BaO.9H_2O$ and 10 grms. of $BaBr_2.2H_2O$ in 30 grms. of water, and adding 120 grms. of alcohol. He also made $BaO.BaBr_2.5H_2O$, or $Ba(OH)Br_{aq.}$ by a method analogous to that employed for the corresponding chloride. E. Tassily made the same compound and found the heat of formation, $BaBr_2+BaO+5H_2O_{solid}=34\cdot2$ Cals.; and the heat of soln. at 20° in a dil. soln. of 2 mols of hydrogen bromide, 19·5 Cals. E. Tassily's oxybromide was obtained by J. Milikan and F. A. H. Schreinemakers in their study of the ternary system, $BaBr_2$—BaO—H_2O, at 25°. The composition of the sat. soln. in equilibrium with the solid phase $BaO.9H_2O$ is represented by the line *ab*, Fig. 25; with $BaBr_2.BaO.9H_2O$ by *bc*; and with $BaBr_2.2H_2O$ by *cd*. By dehydrating the oxybromide product at 120° in a stream of air free from carbon dioxide, E. Tassily made $BaO.BaBr_2.2H_2O$; E. Beckmann considers the compound contains $3H_2O$. E. Tassily calculated the heat of formation $BaO+BaBr_2+2H_2O_{solid}=24\cdot1$ Cals.; and the heat of soln. at 13° in a dil. soln. of 2 mols of hydrogen bromide, 33·8 Cals.

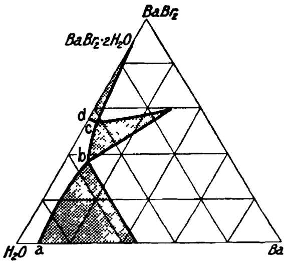

FIG. 25.—Ternary System, $BaBr_2$—BaO—H_2O, at 25°.

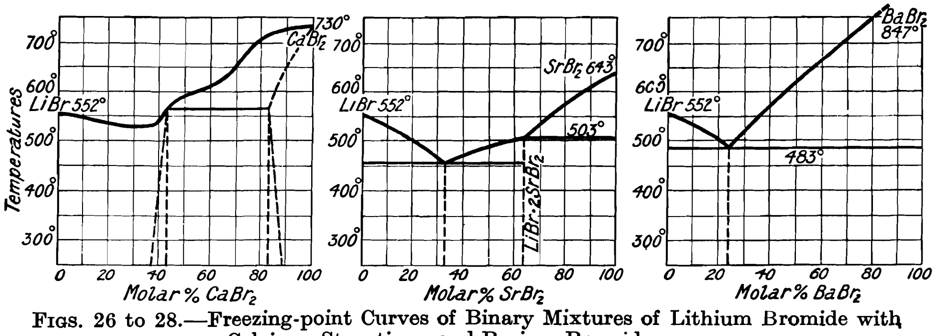
E. Defacqz[15] prepared **barium fluorobromide**, $BaF_2.BaBr_2$, of sp. gr. 4·96, at 18° like the fluorochloride, *q.v.*, but the former salt is more readily decomposed by water. He also prepared crystalline **strontium fluorobromide**, $SrF_2.SrBr_2$, sp. gr. 4·06; and **calcium fluorobromide**, $CaF_2.CaBr_2$, sp. gr. 3·15; the two latter are more readily decomposed by water than the barium salt. According to O. Ruff and W. Plato, mixtures of barium fluoride and bromide give a eutectic at about 800° with 90 molar per cent. of barium bromide; calcium fluoride and bromide, at 660°, and 82 molar per cent. of calcium bromide; calcium chloride and bromide, a depression in the curve reaching a minimum at about 740° and about 60 molar per cent. of calcium bromide; and barium chloride and bromide at about 870° with 90 molar per cent. of barium bromide. According to J. Herbette, barium chloride and bromide form mixed crystals containing large proportions of the chloride, the crystals resemble those of the chloride, and M. Berthelot supposed that **barium chlorobromide** was formed: $BaBr_2+BaCl_2=BaCl_2.BaBr_2+3$ Cals., in the cold.



FIGS. 26 to 28.—Freezing-point Curves of Binary Mixtures of Lithium Bromide with Calcium, Strontium, and Barium Bromides.

Lithium bromide forms solid soln. of limited conc. with calcium bromide; G. Kellner's results are shown in Fig. 26; with strontium bromide, the double salt **lithium strontium pentabromide**, $LiBr.2SrBr_2$, is formed, decomposing at 503°,

Fig. 27 ; and with barium bromide, the f.p. curve is a simple eutectic, Fig. 28. No solid soln. are formed in the two last cases. Sodium and calcium bromide solidify to form two series of solid soln. with a eutectic at 513°, and on further cooling a reaction occurs at 469°, and **sodium calcium pentabromide,** $NaBr.2CaBr_2$, is formed, Fig. 29. Sodium bromide forms simple eutectiferous systems with both strontium bromide, Fig. 30, and barium bromide, Fig. 31, the eutectic temp. being 486° and 600° respectively. Potassium bromide forms double salts with all the alkaline earths without forming solid soln. With calcium bromide, the compound **potassium calcium tribromide,** $KBr.CaBr_2$, is represented by a maximum at 637°, the adjacent eutectic temp. are 544° and 563°, Fig. 32. With strontium bromide, there are two flat maxima, Fig. 33; the one at 559°, corresponds with **potassium strontium tetrabromide,** $2KBr.SrBr_2$, and the other at 574°, corresponds with **potassium strontium pentabromide,** $KBr.2SrBr_2$; the three eutectics are respectively 556°, 534°, and 562°. With barium bromide, one flat maximum, Fig. 34, at 634°, corresponds with **potassium barium tetrabromide,** $2KBr.BaBr_2$. The adjacent eutectic temp. are 632° and 612°.

§ 14. Calcium, Strontium, and Barium Iodides

When hydrogen iodide acts on barium oxide the mass becomes incandescent, and barium iodide is formed. In 1814, J. L. Gay Lussac[1] prepared calcium iodide by evaporating a soln. of calcium oxide in hydriodic acid with the exclusion of air. H. Moissan led a stream of hydrogen iodide into a vessel containing fragments of the purer forms of marble, and after standing 24 hrs. to ensure the neutralization of the acid and the precipitation of the iron, he filtered and evaporated the soln. G. P. Baxter and F. N. Brink prepared calcium iodide of a high degree of purity.

A soln. of marble in nitric acid was heated with an excess of lime to precipitate iron and manganese compounds. The filtered soln. was acidified, and evaporated to crystallization, and the product recrystallizes three times. Calcium carbonate was precipitated by the addition of ammonium carbonate, and the precipitate thoroughly washed by decantation. The carbonate was dissolved in purified hydriodic acid, and the iodide crystallized from the soln. In order to remove any mother liquid included in the crystals, the salts were fused; if the fusion be conducted in a stream of nitrogen the soln. of the product in water is strongly basic; this is but partially prevented by mixing the calcium iodide before fusion with ammonium iodide, and keeping the temp. below the sublimation point of the ammonium iodide until practically all the water is expelled; the salt is then heated to fusion long enough to drive off all the ammonium salt. The product is still slightly alkaline.

Strontium and barium iodides were prepared in a similar manner. O. Henry, O. Hesse, and R. Rother made it by the joint action of iodine,iron, calcium carbonate, and water as in the process for alkali iodides; Lies-Bodart and M. Jobin, by the action of iodine and water on calcium sulphide; J. von Liebig, by the action of iodine and phosphorus on milk of lime; C. Wendler, and R. Wagner, by the action of iodine on calcium sulphite: $BaSO_3+Ba(OH)_2+I_2=BaI_2+BaSO_4+H_2O$; J. B. Berthemot, by the double decomposition of lead iodide and calcium carbonate; and H. Croft made the barium salt by treating baryta water with iodine and filtering off the very soluble iodate formed at the same time. S. Kern reduced the iodate with hydrogen sulphide, and evaporated the soln. to dryness. The evaporation of the aq. soln. furnish hydrated salts, which are dehydrated to form the anhydrous salts by heating them in a current of hydrogen iodide, as recommended by E. Tassily for ignition in nitrogen or air, is attended by some decomposition of the iodide.

According to O. Mügge,[2] **dihydrated barium iodide,** $BaI_2.2H_2O$, crystallizes in monoclinic prisms isomorphous with dihydrated barium bromide, and with axial ratios $a:b:c=1·4580:1:1·1528$, and $\beta=112°\ 58'$. E. Beckmann says heptahydrated barium iodide crystallizes in prisms. O. Mügge found **hexahydrated barium iodide,** $BaI_2.6H_2O$, crystallizes in hexagonal prisms isomorphous with hexahydrated strontium chloride, and with axial ratio $a:c=1:0·538$. The crystals are doubly refracting. The **specific gravity** of anhydrous calcium iodide by O. Ruff and W. Plato[3] is 4·9 at 20°; G. P. Baxter and F. N. Brink give 3·956 at 25° (water at 4° unity); for anhydrous strontium iodide, C. H. D. Bödeker gives 4·415 at 10°; G. P. Baxter and F. N. Brink, 4·549 at 25° (water at 4° unity); and for anhydrous barium iodide, E. Filhol gives 4·917, G. P. Baxter and F. N. Brink 5·150 at 25° (water at 4° unity). F. W. Clarke gives the sp. gr. of heptahydrated barium iodide, 3·67 (20°).

The reported numbers for the **melting point** of anhydrous calcium iodide vary from W. Ramsay and N. Eumorfopoulos' 575°,[4] to O. Ruff and W. Plato's 740°; for the hexahydrated salt, $CaI_2.6H_2O$, E. Lubarsky gives 42°. J. L. Gay Lussac noted in 1814 that strontium iodide melts at a red heat; W. Ramsay and N. Eumorfopoulos' value for the m.p. of anhydrous strontium iodide is 402°; and T. Carnelley's, 507°. For barium iodide, W. Ramsay and N. Eumorfopoulos give 539°, and O. Ruff and W. Plato, 740°. The b.p. of calcium iodide is between 718° and 719°. It is possible that the discordant data here given arise from the use of impure or imperfectly dehydrated salts. J. L. Gay Lussac noted that in melting calcium iodide in air, there is a partial decomposition, iodine is liberated and calcium oxide is formed; and that in the absence of air strontium iodide can be melted without decomposition, but in the presence of air the iodide is partially decomposed. The hydrated forms of barium iodide readily melt in their water of crystallization. O. Mügge said that hexahydrated barium iodide melts in its water of crystallization at 25·7°. When anhydrous barium iodide is melted, much of the salt is decomposed: $2BaI_2+O_2\rightleftharpoons 2BaO+2I_2$.

J. Thomsen's values for the **heats of formation** are: (Ca, I_2), 107·65 Cals.; M. Berthelot's values (Ca, I_2), 118·6 Cals.; (Sr, I_2), *circa* 134 Cals.; and E. Tassily[5] gives (Sr, I_{2gas}), 123·1 Cals.; (Sr, I_{2solid}), 112·3 Cals., and (Ba, I_{2gas}), 13·7 Cals., or (Ba, I_{2solid}), 2·9 Cals. E. Tassily gives $Ca+I_2+8H_2O_{liquid}=CaI_2.8H_2O+133·7$ Cals. and for the formation (Sr, I_{2solid}, $7H_2O_{liquid}$), 147·3 Cals. J. Thomsen's value for (CaI_2, aq.) is 27·69 Cals.; and for (Ca, I_2, aq.), 135·34 Cals.; (Sr, I_2, aq.), 143·39 Cals.; (Ba, I_2, aq.), 144·02 Cals.; and for (Ba, I_2, $7H_2O$), 151·37 Cals. S. U. Pickering's value for the **heat of solution** of anhydrous calcium iodide in water is 15·973 Cals., and in alcohol, 19·833 Cals. J. Thomsen's value for the heat of soln. of $BaI_2+7·17H_2O$ in 500 mols of water is —6·85 Cals. E. Tassily's value for the heat of soln. of $CaI_2.8H_2O$ is 1·735 Cals, of anhydrous strontium iodide at 12°, 20·5 Cals., and of $SrI_2.7H_2O$ at 15°, —4·47 Cals.; and for anhydrous barium iodide, at 16°, 10·3 Cals. The heat of soln. of the three anhydrous barium halides increase in passing from the chloride to the iodide: $BaCl_2$, 2·07 Cals.; $BaBr_2$, 4·98 Cals.; and BaI_2, 10·3 Cals.

Anhydrous calcium, strontium, and barium iodides deliquesce in moist air. Calcium iodide forms **hexahydrated calcium iodide,** $CaI_2.6H_2O$. According to H. Croft, **hexahydrated strontium iodide,** SrI_2 $6H_2O$, crystallizes in six-sided plates; E. Tassily says the sat. soln. at 70° gives $SrI_2.7H_2O$. According to A. Étard, the transition temp.: $SrI_2.6H_2O\rightleftharpoons SrI_2.2H_2O+4H_2O$, is near 90°; and for $BaI_2.6H_2O\rightleftharpoons BaI_2.2H_2O+4H_2O$ it is nearly 35°. According to P. Kremers' solubility data, there is also a transition point with calcium iodide between 40° and 43°. **Hexahydrated barium iodide,** $BaI_2.6H_2O$, as well as salts with 1, 2, and $7H_2O$, have been reported. The stability of the higher hydrates thus appear to be greater with the iodides than with the bromides, and with the bromides than with the chlorides. The equilibrium conditions and transformation points of the different hydrates on the iodides of the alkaline earths have not been investigated closely. There are some differences in the views of different workers on the composition of the hydrates of the iodides of the alkaline earths and more particularly of barium iodide, owing to its great solubility and deliquescence. Thus H. Croft, J. Thomsen, and E. Beckmann give for ordinary crystalline iodide, $BaI_2.7H_2O$, while H. Lescœur gives $BaI_2.6H_2O$. E. Beckmann says hydrated barium iodide, $BaI_2.H_2O$, is stable over 125°, and begins to dehydrate at 150°; and G. Werther obtained barium di- or tri-hydrated iodide by evaporating soln. of the salt nearly to dryness.

The solubilities of calcium, strontium, and barium iodides have been measured by P. Kremers,[6] and A. Étard; the results represented in grams of MI_2 per 100 grms. of soln. are:

	0°	10°	20°	40°	60°	80°	100°
CaI_2 . . .	64·6	66·0	67·6	70·8	74·0	78·0	81·0
SrI_2 . . .	62·3	—	64·0	65·7	68·5	73·0	79·3
BaI_2 . . .	63·0	65·0	67·0	69·8	71·2	72·3	73·1

According to A. Étard, the solubility of strontium iodide at 120° is 80·7; at 140°, 82·5; and at 175°, 75·6; and the solid phase below 90° is $SrI_2.6H_2O$, and above 90°, $SrI_2.2H_2O$. The solubilities of a mol of strontium chloride, bromide, and iodide are as 2·79 : 3·54 : 4·81 at 0°. Similarly for barium iodide, the solubility at —20° is 59·0; at 120°, 73·8; and at 140°, 74·6; the solid phase below 35° is $BaI_2.6H_2O$, and above that temp. $BaI_2.2H_2O$. A. Étard also found that the solubilities of barium and strontium iodides were depressed in the presence of one another.

The **specific gravities** of soln. with different amounts of the iodides of the alkaline earths in 100 grms. of water at 19·5°, are, according to G. T. Gerlach :[7]

Grms. of salt	5	10	20	40	60	65
Sp. gr. CaI_2	1·044	1·090	1·198	1·477	1·910	—
„ SrI_2	1·045	1·091	1·200	1·491	1·955	2·150
„ BaI_2	1·045	1·091	1·201	1·495	1·970	—

H. C. Jones and F. H. Getman have also measured the sp. gr. of soln. of these salts. P. Kremers has studied the change in the vol. of soln. of the iodides of the alkaline earths with temp. L. C. de Coppet finds the **temperature of maximum density** of water is lowered to 2·980° and 0·872° respectively by the addition of 0·0384 and 0·1166 mol of CaI_2 per litre ; and to 2·827° and 1·152° respectively by the addition of 0·0395 and 0·0962 mol of BaI_2 per litre. The mol. lowering dT/M is a constant in both cases.

C. Dieterici[8] has measured the **vapour pressures** of soln. of calcium iodide at 0°, H. C. Jones and F. H. Getman found the mol. **lowering of the freezing point** of soln. of calcium iodide dT/M showed a minimum with a 0·32N-soln., and rose to 19·23 with a 6·24N-soln. Similar results were observed with soln. of calcium chloride and bromide. Strontium and barium iodide soln. behave similarly. H. C. Jones and F. H. Getman also measured the **index of refraction** of soln. at 25°, and found it to rise from μ=1·01468 to 1·693 respectively with soln. containing 0·078 and 3·120 mols of calcium iodide per litre. C. Sheard and C. S. Morris[9] measured the emission spectrum of calcium iodide and found that there are continuous spectral regions or bands between 6075 and 5845 ; 5615 and 5528 ; 5180 and 5100 ; 4830 and 4787 ; 4507 and 4465 ; and 4438 and 4360, and these corresponded closely with bands from mercuric and zinc iodides.

The **electrical conductivities** of soln. of calcium iodide have also been measured by H. C. Jones and F. H. Getman,[10] and they find the results agree with a rise in the percentage ionizations from 26·0 to 80·0 respectively for soln. with a mol per 0·32 and 12·82 litres of solvent at 0°, when the mol. conductivity μ_∞=135·7. H. C. Jones and B. P. Caldwell measured the conductivities of strontium iodide soln. at 25°, and also of mixtures of strontium and cadmium iodide. The conductivity of the mixture in aq. soln. is less than in the corresponding soln. of strontium iodide ; and they assume that both salts form complex ions corresponding with strontium polyiodide, SrI_4''. R. G. van Name and W G. Brown have studied this subject. W. Hittorf gave data for the **transport numbers** of the ions of calcium iodide. H. C. Jones and C. F. Lindsay have also measured the electrical conductivities of soln. of strontium iodide in water methyl, ethyl, and propyl alcohols, and noted a continuous decrease in the conductivity and in the temp. coeff. of the conductivity in passing through the series from water to propyl alcohol ; and they therefore conclude that the association of the salt with the solvent decreases in the same series. With methyl alcohol and water mixtures containing a mol of strontium iodide in 32 litres of the soln., the conductivity falls to a minimum value with about 50 per cent. alcohol at 0°, or 75 per cent. alcohol at 25°. For example :

Per cent. alcohol	0	25	50	75	100
μ at 0°	113·1	63 06	50·19	55·53	75·82
μ at 25°	205·3	131·3	103·8	98·09	101·4

The iodides of the alkaline earths are easily soluble in *ethyl alcohol.* As with water, the solubilities of the halides of the alkaline earths in alcohol decrease in passing from the chlorides to the iodides. According to A. Étard,[11] 100 grms. of a sat. soln. of strontium iodide contains 2·6 grms. SrI_2 at —20° ; 3·1 grms. at 4° ; 4·3 grms. at 39° ; and 4·7 grms. at 82°. P. Rohland found that 100 grms. of 97 per cent. alcohol dissolve 1·07 grm. of $BaI_2.2H_2O$ at 15°, and that one part of $BaI_2.2H_2O$ dissolves at room temp. in 22 parts of methyl, 93 parts of ethyl, and 307 parts of propyl alcohol. W. Eidmann says that calcium and barium iodides are soluble in *acetone.*

The iodides of the alkaline earths can be preserved unchanged in air free from carbon dioxide. J. L. Gay Lussac[12] mentions that barium iodide becomes brown when exposed to the air, and that barium carbonate is formed. E. Beckmann observed that soln. of this salt behaved in a similar manner, and that the brown colour which soln. of barium iodide acquire when exposed to sunlight, disappears in darkness, while in an atm. of hydrogen the brown colour persists. M. Berthelot found that when barium iodide is heated in an atm. of oxygen, it is completely converted to barium oxide; and E. Beckmann that in a stream of air at 170° all the iodine is driven off, while in a stream of carbon dioxide or hydrogen no change occurs. S. Kern found that molten barium iodide is reduced to barium by sodium, and if mercury is present, barium amalgam is formed. Fuming hydrochloric acid, said F. Gramp, converts barium iodide into barium chloride and hydriodic acid, not free iodine. F. Isambert gave evidence of the formation of **calcium hexammino-iodide**, $CaI_2.6NH_3$, by the action of *ammonia* on calcium iodide; and W. Biltz has shown that the temp. of decomposition of this salt and those of the corresponding **strontium hexammino-iodide**, $[Sr(NH_3)_6]I_2$, and **barium hexammino-iodide**, $[Ba(NH_3)_6]I_2$, at a press. $p=50$ mm., are respectively 369°, 335°, and 298°. The corresponding heats of formation, Q, calculated from $\log p=-Q\,4{\cdot}57T+1{\cdot}75 \log T-aT+3{\cdot}3$, are respectively 13·63, 13·40, and 10·80 Cals. C. F. Rammelsberg states that soln. of barium iodide readily absorb sulphur dioxide; F. Ephraim and I. Kornblum prepared an orange-red **barium tetrasulphoniodide**, $BaI_2.4SO_2$, and a yellowish-red **barium disulphoniodide**, $BaI_2.2SO_2$; they also made red **strontium tetrasulphoniodide**, $SrI_2.4SO_2$; **strontium disulphoniodide**, $SrI_2.2SO_2$; and **calcium tetrasulphoniodide**, $CaI_2.4SO_2$.

J. J. Berzelius[13] noted that iodine dissolves more copiously in soln. of calcium iodide than in water, and that when evaporated over potassium hydroxide dark grey crystals with a metallic lustre are obtained. The solubility of iodine in water is 0·0142 per cent., and J. Meyer found that 100 c.c. of 10 per cent. soln. of the halides of the alkaline earths dissolve the following amounts of iodine:

	Chloride.	Bromide.	Iodide.
Barium . . .	0·067	0·231	6·541 grms.
Strontium . .	0·066	0·270	6·616 ,,
Calcium . . .	0·078	0·274	8·062 ,,

The f.p. of the soln. of iodine in these halide soln. is not appreciably depressed, possibly because of the formation of periodides, *e.g.* CaI_4. Indeed, while an aq. soln. of 8·062 grms. iodine in 10 per cent. calcium iodide exhibits a slightly greater lowering of the f.p. than calcium iodide alone, less conc. soln. exhibit a rather smaller depression of the f.p. than calcium iodide alone, due, it is suggested, to the smaller degree of ionization exhibited by the polyiodide than by the normal iodide. A. Mosnier claimed to have obtained crystals of $CaI_3.15H_2O$ by the spontaneous decomposition of the double iodide of lead and calcium in contact with its sat. soln. Similar remarks apply to $SrI_3.15H_2O$. J. Meyer supposes **calcium polyiodide**, CaI_4, to be formed as a hygroscopic mass when the necessary proportions of iodine and calcium iodide are mixed, and heated to 70°–80°; when melted and cooled, needle-like crystals can be separated from the mass—these reflect light with a green metallic lustre; no iodine vapours are given off at 100°; a reddish-brown soln. is produced with water, and carbon disulphide or chloroform extracts from the aq. soln. two gram-atoms of iodine per mol of calcium iodide. The f.p. curve for mixtures of calcium iodide and iodine was found by F. Olivari to give no distinct maximum, but it has an almost horizontal branch with a eutectic on the iodine side. The polyiodide, if formed at all, must therefore be greatly dissociated under these conditions. If calcium iodide be melted with a large proportion of iodine, the product dissolves in a little water, but iodine separates when this soln. is diluted; the product is assumed to contain higher periodides than CaI_4—possibly CaI_{10}—because with heating there is a low iodine tension. There is also evidence of the formation of poly-chloroiodides and poly-bromoiodides. Similar remarks apply to **barium and strontium polyiodides**, but the polyiodides of calcium are more stable than those of strontium, or barium. R. G. van Name and W. G. Brown have studied the formation of strontium polyiodide. A. A. Jakowkin assumed that the soln. of iodine in barium iodide soln. corresponded with the formation of barium polyiodide, BaI_9. C. K. Tinkler obtained some evidence of the existence of barium polyiodide from the identity of the absorption spectra of soln. of barium iodide and iodine with the spectra of analogous soln. of cadmium, sodium, potassium, magnesium, zinc, and aluminium. Barium iodide forms crystalline double salts with the iodides of zinc, cadmium, mercury, antimony, tin, and lead; *e.g.* A. Mosnier[14] prepared **lead calcium iodide,** $2PbI_2.CaI_2.7H_2O$; **lead strontium iodide,** $2PbI_2.SrI_2.7H_2O$; and **lead barium iodide,** $2PbI_2.BaI_2.7H_2O$. C. F. Rammelsberg also reported the formation of complex compounds by heating barium peroxide with iodine—*e.g.* $BaI_2.2BaO_2$ and $BaI_2.Ba_3O_4$. R. F. Weinland and F. Schlegelmilch prepared compounds of calcium chloride with *iodine trichloride,* $CaCl_2.2ICl_3.8H_2O$, in golden-yellow deliquescent needle-like crystals by the action of iodine on a soln. of anhydrous calcium chloride in hydrochloric acid. Likewise also $SrCl_3.2ICl_3.8H_2O$ was prepared.

E. Tassily[15] claims to have made **calcium oxyiodide,** $3CaO.CaI_2.16H_2O$, needle-like crystals, similar to the corresponding oxybromide; and he calculates the heat of formation to be $CaI_2+3CaO+16H_2O_{solid}=79{\cdot}9$ Cals.; and the heat of soln. in dil. hydriodic acid with six mols of HI, at 20°, to be 53·4 Cals. J. Milikan's study of the ternary system, CaI_2—CaO—H_2O, at 25°, gave the isothermal line *ab,* Fig. 35, for soln. in equilibrium with the solid phase, $Ca(OH)_2$; *bc,* with $CaI_2.3CaO.16H_2O$; and *cd,* with $CaI_2.6H_2O$. The crystals of the oxyiodide are less hygroscopic than the iodide, CaI_2. When kept in vacuo over sulphuric acid, crystals of $3CaO.CaI_2.3H_2O$ are formed: (CaI_23CaO, $3H_2O_{solid}$), 64·7 Cals.; the heat of soln. under the same conditions as the preceding compound, 96·7 Cals. E. Tassily made **strontium oxyiodide,** $5SrO.2SrI_2.30H_2O$, in a similar manner. J. Milikan's study of the ternary system, SrI_2—SrO—H_2O, at 25°, gave the isothermal line *ab,* Fig. 36, for soln. in equilibrium with $SrO.9H_2O$; *bc,* with $SrI_2.2SrO.9H_2O$; and *cd* with $SrI_2.6H_2O$. Needle-like prismatic crystals of **barium oxyiodide,** $BaI_2.BaO.9H_2O$, were likewise formed: (BaI_2, BaO, $9H_2O_{solid}$), 41·64; and the heat of soln. in dil. hydriodic acid with 2 mols of HI at 20° is 11·76 Cals. E. Beckmann prepared barium oxyiodide, $Ba(OH)I.2H_2O$, analogous with the oxychloride. J. Milikan's study of the ternary system, BaI_2—BaO—H_2O, at 25°, gave the isothermal line *ab,* Fig. 37, for soln. in equilibrium with $BaO.9H_2O$; *bc* with $BaI_2.BaO.9H_2O$; and *cd* with $BaI_2.2H_2O$. According to E. Beckmann, at 120°, the crystals lose a mol of water. E. Tassily dried the preceding salt in vacuo over sulphuric acid, and obtained crystals of $BaO.BaI_2.2H_2O$, with a heat of soln. of 33 Cals. in dil. hydriodic acid with two mols of HI at 20°; and a heat of formation, ($BaO.BaI_2.2H_2O_{solid}$), 29·9 Cals. The individuality of all these oxy-salts is by no means established.

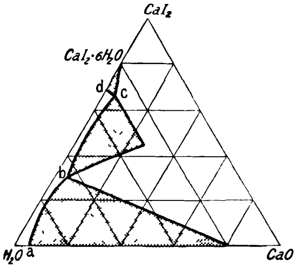

FIG. 35.—Ternary System, CaI_2—CaO—H_2O, at 25°.

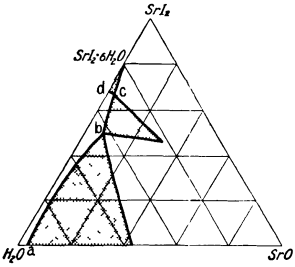

FIG. 36.—Ternary System, SrI_2—SrO—H_2O, at 25°.

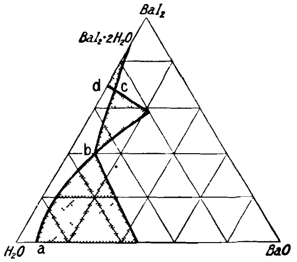

FIG. 37.—Ternary System, BaI_2—BaO—H_2O, at 25°.

E. Defacqz[16] prepared **barium fluoroiodide**, $BaF_2.BaI_2$, of sp. gr. 5·21, 118°, by a similar process to that employed for the fluorochloride, *q.v.*, but the former salt is more readily decomposed by water. He also made **strontium fluoroiodide**, $SrF_2.SrI_2$, sp. gr. 4·5; and **calcium fluoroiodide**, $CaF_2.CaI_2$. The latter is very deliquescent. O. Ruff and W. Plato found the f.p. curve of mixtures of barium fluoride and iodide has a eutectic at about 660° with about 92 molar per cent. of barium iodide; and with calcium fluoride and iodide, a eutectic at about 625° with about 82 molar per cent. of calcium iodide. Mixtures of barium chloride and iodide give a eutectic at about 700° with about 91 molar per cent. of barium iodide; and mixtures of calcium chloride and iodide, a eutectic at 550° with 49 molar per cent. of calcium iodide.

§ 15. Calcium, Strontium, and Barium Sulphides

According to W. P. Jorissen and J. H. Wieten,[1] an impure form of calcium sulphide is supposed to have played a part in the old Bacchanalia—*vide* hydrogen sulphide. V. Casciorolo's *lapis solaris* or Bologna stone was an impure barium sulphide, and in 1700, F. Hoffmann obtained a product with similar properties by the calcination of a German mineral, presumably gypsum. A. S. Marggraf likewise obtained a luminescent product by calcining gypsum. In 1675, C. A. Baldwin (Latin, Balduinus) found that a like phenomenon was presented by the residue obtained when calcium nitrate is calcined, and the product came to be known as *Baldwin's phosphorus*. In 1730, W. Homberg heated a mixture of *sel armoniak* with twice its weight of *chaux vive*, and obtained a phosphorescent substance which he regarded as a *nouveau phosphore*, and which came to be called *Homberg's phosphorus*. In 1768, J. Canton made a similar substance by calcining a mixture of oyster shells and sulphur, and the impure calcium sulphide so prepared came to be called *Canton's phosphorus*.

The mixture of calcium sulphide and calcium sulphate, investigated by L. N. Vauquelin, was obtained by calcining a mixture of sulphur and lime : $4CaO+4S=3CaS+CaSO_4$, came to be called *hepar sulphuris calcarem*. T. von Grotthus, G. F. Wach, G. Osann, J. P. Dessaignes described modifications of J. Canton's process ; and they prepared phosphori with other bases—tin, cadmium, zinc, arsenic, antimony, barium, strontium, etc. F. Förster, T. P. de Sagan, W. F. McCorty, and F. Pfeiffer, A. Verneuil, etc., have also discussed the preparation of these phosphori. Quite a number of compounds of calcium and sulphur, with and without oxygen, have been reported. Similar remarks apply to compounds of sulphur with barium and strontium. The calcium sulphides, hydrosulphides, and oxysulphides have an important economical bearing because the soln. prepared by boiling together lime, sulphur, water, etc., is extensively employed as an insecticide for scab on animals, and for soft-bodied scale insects on fruit trees. Calcium sulphide is a by-product in the Leblanc's soda process, and is treated for the recovery of sulphur—*vide* alkali sulphides. W. Flight and N. S. Maskelyne reported the occurrence of calcium sulphide in an aerolite found at Busti (India).

R. Bunsen and A. Matthiessen,[2] and B. von Lengyel obtained calcium sulphide by the direct union of the elements. J. J. Berzelius prepared **calcium monosulphide**, CaS, by passing hydrogen sulphide over red-hot calcium oxide or hydroxide free from carbon dioxide and water. The reactions are symbolized : $CaO+H_2S=H_2O+CaS$; or $Ca(OH)_2+H_2S=CaS+2H_2O$. V. H. Veley prepared the sulphide by these processes, and in the case of calcium hydroxide, the temp. of the solid was maintained at 60° during the action of the gas. He noted that the excess of hydrogen sulphide was retained by the calcium sulphide with considerable pertinacity, possibly owing to the soln. of calcium oxide in the water, and the formation of calcium hydrosulphide, or by the union of hydrogen and calcium sulphides : $CaS+H_2S=Ca(HS)_2$. V. H. Veley also observed that thoroughly dried calcium oxide is unaltered by dried hydrogen sulphide, as is also the case with dried calcium oxide and carbon dioxide. The former case, however, is the more remarkable, in that it would appear more *a priori* probable that the elimination of an infinitesimally small proportion of water would cause the reaction to proceed to its final completion. Neither J. J. Berzelius nor L. N. Vauquelin succeeded in preparing a polysulphide in the dry way. P. Sabatier passed hydrogen sulphide for an hour over red-hot calcium carbonate, and cooled the resulting calcium sulphide in a stream of hydrogen. A. Forster heated a mixture of sulphur and calcium oxide to redness in a stream of hydrogen: $4CaO+4S=3CaS+CaSO_4$; and $3CaS+CaSO_4+4H_2=4CaS+4H_2O$. E. H. Riesenfeld and H. Feld purified calcium monosulphide by first dissolving the sulphide in an aq. soln. of hydrogen sulphide, and removing the hydrogen sulphide from the soln. of calcium hydrosulphide by suction. If air be not excluded, the soln. of hydrosulphide will be yellow owing to the formation of polysulphides, etc. Hence, all operations should be conducted in an atm. of hydrogen sulphide. E. Becquerel emphasized the fact that if air be not excluded the sulphide will be partially oxidized to sulphate.

P. Berthier prepared an impure form of calcium sulphide by heating calcium sulphate, or a mixture of calcium sulphate with one-third its weight of charcoal, in a graphite crucible to a white heat; and A. Mourlot heated the mixture of calcium sulphate and carbon in an electric arc furnace for a few minutes. The molten calcium sulphide so formed crystallized on cooling. F. Sestini, and A. Violi reduced calcium sulphate to sulphide by heating it with sulphur. C. Stammer reduced calcium sulphate by heating it in a stream of carbon monoxide; and B. Unger, L. Marino, and E. H. Riesenfeld, in a stream of hydrogen or water gas. O. Schumann so obtained an 85–86 per cent. yield. H. A. Pagenstecher (1819) first employed hydrogen for reducing barium sulphate. E. Divers and T. Shimidzu converted calcium hydrosulphide, $Ca(SH)_2.2H_2O$, into the sulphide, by heating it in a stream of hydrogen sulphide first at 65° and finally at 100°; the product was contaminated with a little hydrosulphide. A. P. Dubrunfaut, and A. Scheurer-Kestner heated to redness equi-mol. parts of calcium carbonate and sodium sulphide: $Na_2S+CaCO_3=Na_2CO_3+CaS$. According to T. J. Pelouze, sodium or potassium monosulphide precipitates calcium hydroxide from soln. of calcium salts, and the alkali hydrosulphide is formed. E. Schöne prepared calcium sulphide by heating calcium carbonate in a stream of carbon dioxide sat. with the vapour of carbon disulphide; the yield of calcium sulphide is almost quantitative. J. J. Berzelius first used this process for making barium sulphide.

P. Berthier, A. Mourlot, A. Violi, E. Schöne, and O. Schumann prepared **strontium monosulphide**, SrS, by the process they employed for calcium sulphide. O. Schumann obtained a 66–67 per cent. yield by passing hydrogen sulphide over heated strontium oxide. J. R. Mourelo recommended cooling the product in a stream of hydrogen. G. Kessler, and S. Kern heated strontium thiosulphate: $2SrS_2O_3=SrS+SrSO_4+S+SO_2$, the mass was extracted with water, and the soln. evaporated on a water-bath. J. J. Berzelius, V. H. Veley, O. Schumann, J. Violi, E. Schöne, P. Berthier, and A. Mourlot prepared **barium monosulphide**, BaS, by processes similar to those which they employed for preparing calcium monosulphide. The reaction is utilized in preparing barium salts from heavy spar. The product of the reduction by P. Berthier's process, is extracted with water, and the resulting soln. of barium sulphide is treated with the required acid.

J. von Liebig, for example, mixed heavy spar with about 20 per cent. of charcoal or soot from bituminous coal, and by means of a paste made from starch, moulded the whole into rods. The rods were dried and heated red hot in a furnace, while suitably protected from oxidation. Crucibles or saggars can be used, and E. F. Anthon has described a special furnace for the purpose. C. F. Buchholz recommended the addition of about 16 per cent. of sodium chloride to the mixture of heavy spar and charcoal so as to facilitate the decomposition of the heavy spar. A. Duflos recommended sodium sulphate. In any case the furnace product is dissolved when digested with boiling water, and filtered from the undecomposed heavy spar, charcoal, iron sulphide, etc.

The reduction of the barium sulphate to sulphide by means of carbon has been studied by H. Grüneberg, C. F. Buchholz, H. Langsdorf, J. Kuczynsky, F. J. Otto, M. Rivière, A. Scheurer-Kestner, H. Rose, O. Lenoir, A. Rosenstiehl, etc.

The crude barytes is crushed and mixed with the proper proportions of pulverized coal —say one part of coal and four parts of bartyes. The mixture is roasted for about 4 hrs.

in a rotating reduction furnace, and barium sulphate is thereby converted to sulphide. The black ash containing 70 per cent. of sulphide is extracted with water. The resulting soln. of barium sulphide is the starting-point for the preparation of many other commercial salts. For example, with salt cake it forms the so-called *blanc fixe* or precipitated barium sulphate; with soda-ash it forms barium carbonate; with calcium chloride it forms barium chloride; with Chile saltpetre it forms barium nitrate; etc. Strontium sulphide is made in a similar manner. L. Marino claims that water gas is a better reducing agent than çoal. E. H. Riesenfeld has studied the reduction of the sulphates of the alkaline earths by carbon and by methane with the idea of extracting the sulphur industrially.

The purified sulphides of the alkaline earths are white amorphous powders or masses. The impurities found in native limestone or gypsum are present, and these impart a yellowish or a reddish tinge to the sulphide. The sulphides are then phosphorescent, for they are luminescent in darkness; the pure sulphides are not luminescent—*vide infra.* A. Mourlot's products were masses containing **crystals** of cubes and octohedra belonging to the cubic system. According to W. P. Davey,[3] **X-radiograms** of the crystals of calcium and barium sulphides show a simple cubic lattice. The side of the elementary cube is 5·64 A. with calcium sulphide, and 6·40 A. with barium sulphide; the closest approach of the atoms on calcium sulphide is 2·82 A. and 3·20 A., with barium sulphide. According to A. Mourlot, at 15°, the **specific gravity** of amorphous calcium sulphide is 2·25, and when crystalline, 2·80; amorphous strontium sulphide, 3·35, and crystalline, 3·70; and amorphous barium sulphide, 4·18, and crystalline, 4·30.

The **heat of formation** of calcium sulphide, according to P. Sabatier, is (Ca, S) =92·0 Cals.; of strontium sulphide, (Sr, S)=99·2 Cals.; and of barium sulphide, (Ba, S)=102·5 Cals. J. Thomsen gave (Ca, S, aq.)=110·23 Cals. (Sr, S, aq.) =104·68 Cals.; and (Ba, S, aq.)=107·67 or x—40·84 Cals., where x represents the heat of formation of the sulphide. M. Berthelot gave $Ca(OH)_2+H_2S_{aq.}=78$ Cals. P. Sabatier gave for $CaO+H_2S_{gas}=CaS+H_2O_{gas}+13·6$ Cals.; and for the corresponding reaction with strontia, 21·6 Cals.; and with baryta, 22·1 Cals. P. Sabatier gave for the **heat of solution** for calcium monosulphide, 6·3 Cals.; for strontium monosulphide, 6·8 Cals.; and for barium monosulphide, 7·3 Cals. He gave for the reaction $CaS+2HCl_{aq.}$, 26·3 Cals.; $SrS+2HCl_{aq.}$, 21·6 Cals.; for $BaS+2HCl_{aq.}$, 27·2 Cals.; he also gave for the oxidation, $CaS+O=CaO+S_{solid}$, 40·0 Cals., and with gaseous sulphur, 37·40 Cals.; for the corresponding reaction with strontium sulphide the numbers are respectively 33·6 and 31·0 Cals.; and with barium sulphide, respectively 31·5 and 28·9 Cals. Again, for the heat of oxidation of calcium sulphide to sulphate: $CaS+2O_2=CaSO_4+227·0$ Cals.; strontium sulphide, 230·60 Cals.; and barium sulphide, 236·50 Cals. B. Vaillant found the **electrical conductivity** of calcium sulphide rapidly increases with temp.

The action of water on the sulphides of the alkaline earths.—According to E. H. Riesenfeld and H. Feld,[4] a litre of water at 20° dissolves 0·2120 grm. of calcium monosulphide, and the solubility is greatly augmented if hydrogen sulphide be present when the monosulphide passes into hydrosulphide—*q.v.* According to A. Mourlot, when crystalline calcium monosulphide is heated with air-free **water**, it is rapidly converted into a mixture of calcium hydroxide and hydrosulphide, and hydrogen sulphide is evolved. E. Terres and K. Brückner found that the same remarks apply to strontium sulphide, but when barium sulphide is extracted with water at all temp. up to 100°, **barium hydroxyhydrosulphide**, $Ba(SH)(OH).5H_2O$, is formed. This is fairly stable, and under no circumstances can barium hydroxide be separated from the soln. by crystallization. When strontium sulphide is treated with boiling water, the soln. deposits crystals of strontium hydroxide on cooling. These facts explain many failures to manufacture barium hydroxide from barium sulphide. Crystalline calcium sulphide is peculiar in that it is more readily attacked by water than the amorphous sulphide. As a rule, the amorphous form of a compound is the more susceptible to attack by chemical agents. C. Lauth found that when calcium or barium sulphide is heated to redness in a current of steam, hydrogen sulphide and the corresponding oxide are formed. According to O. Schumann, calcium sulphide also furnished a little calcium sulphate, and he found strontium sulphide is oxidized to the sulphate by water vapour. H. V. Regnault said that steam reacts with red-hot barium sulphide forming barium sulphate and hydrogen. The reaction was also studied by O. Lenoir. E. H. Riesenfeld showed that an excess of steam favours the desulphurization of calcium sulphide by the reaction $CaS+H_2O=CaO+H_2S$; but, partly in consequence of the dissociation of the hydrogen sulphide, and partly in consequence of its reaction with water vapour, as shown by M. Randall and F. R. von Bichowsky, the sulphur was obtained in the form of sulphur dioxide, or elementary sulphur. The latter predominated when an excess of steam was used. When amorphous calcium sulphide is boiled with an excess of water, frequently renewed, H. Rose found that calcium or barium sulphide is slowly converted into a soln. of hydrosulphide, and a residue of the hydroxide mixed with a little undecomposed sulphide, *e.g.* $2BaS+2H_2O\rightleftharpoons Ba(OH)_2+Ba(SH)_2$, and, added T. J. Pelouze, some hydrogen sulphide is simultaneously evolved. According to A. Béchamp, calcium monosulphide is but slightly soluble in water, the solubility is augmented by raising the temp., and J. Kolb found that:

	10°	18°	40°	60°	90°
Grm. CaS . . .	0·15	0·23	0·30	0·48	0·33 per litre

F. Stolle's numbers are not consistent with J. Kolb's, and they are indicated below. A prolonged contact results in what appears to be increased solubility. H. Rose believed it to be very doubtful if calcium sulphide can exist in aq. soln. According to P. de Clermont and J. Frommel, the reaction is more vigorous the higher the temp.; and, according to R. Rickmann, the presence of calcium chloride facilitates the decomposition of calcium sulphide by water. The sulphide is really hydrolyzed by water: $2CaS+2H_2O\rightleftharpoons Ca(OH)_2+Ca(SH)_2$; or, expressed ionically: $S''+H_2O\rightleftharpoons SH'+OH'$. It might, therefore, be anticipated that the solubility of calcium sulphide in water will be diminished by soluble hydroxides, as was found to be the case with sodium and calcium hydroxides. Thus, a soln. of *calcium hydroxide*, limewater at 14°, dissolves the same quantity of calcium sulphide as water alone, and at 60° it dissolves 0·18 grm. of calcium sulphide. Milk of lime at 60° was found to dissolve 0·55 grm. of calcium sulphide. Again, water at 10°, containing the eq. of 4 to 102 grms. of *sodium hydroxide* per litre dissolves only traces of calcium sulphide; at 40° to 60°, or at the b.p., considerable amounts of sodium sulphide are formed, and this the more the greater the conc. of the soln. J. Kolb also found that the solubility of calcium sulphide in water between 10° and 60° appears to be slightly diminished by *sodium chloride*, and increased by *sodium sulphate*. W. Gossage stated that calcium sulphide is not decomposed by an aq. soln. of *sodium carbonate*, but, added J. Kolb, the carbonate is decomposed if it be in conc. soln., if the action be long continued and if the soln. be warmed; if sodium or calcium hydroxide are also present, the action between calcium sulphide and sodium carbonate is retarded. F. Stolle has measured the solubility of calcium sulphide in soln. of *sugar*, at different conc.—selecting the extreme limits employed by him, the amounts in grams of calcium sulphide dissolved by a litre of water, and of a soln. containing 55 per cent. of sugar are:

	30°	40°	50°	60°	70°	80°	90°
Water alone . . .	1·982	2·123	1·235	1·390	1·696	2·032	2·496
55 per cent. sugar soln. .	2·509	2·226	2·340	2·882	2·766	2·972	3·616

C. L. Berthollet found a soln. of strontium sulphide in boiling water gives crystals of octohydrated strontium hydroxide on cooling, and, according to H. Rose, the mother liquid contains the hydrosulphide; while if strontium sulphide is treated with a small proportion of water, strontium hydrosulphide passes into soln., and if the residue is again extracted with water, strontium hydroxide is mainly dissolved. Anhydrous barium sulphide prepared at a temp. below red heat has not been described. H. Rose, and E. Schöne found an aq. soln. of barium mono- or polysulphide when evaporated in vacuo furnishes thin, white, colourless plates of **hexahydrated barium sulphide**, $BaS.6H_2O$, or possibly **pentahydrated barium hydroxyhydrosulphide**, $Ba(OH)(SH).5H_2O$; if the crystals are contaminated with the mother liquid, they have a yellow tinge; and, according to H. Rose, they are coloured yellow by exposure to air. E. Schöne found that at 100° the water of crystallization and some hydrogen sulphide is given off, and above 350°, hydrogen sulphide and sulphur are evolved, and the residue is a mixture of barium sulphide and sulphate with a little sulphite. When the crystals are extracted with a little water, H. Rose found that barium hydrosulphide passes into soln. and the hydroxide remains; and when boiled with a large proportion of water, E. Schöne found that the crystals gradually pass into soln., giving a clear liquid which when treated with acids gives off hydrogen sulphide without the decomposition of sulphur. When the crystals are boiled with alcohol, some hydrogen sulphide is given off, but the sulphide does not dissolve. According to W. Eidmann, calcium sulphide is soluble in *methylal.* For the **monohydrated barium sulphide**, $BaS.H_2O$, see barium hydroxyhydrosulphide.

The chemical properties of the sulphides of the alkaline earths.—When a sulphide of the alkaline earths is exposed to **air**, it is decomposed by the action of water and carbon dioxide, and the compound smells of hydrogen sulphide, for this gas is continuously evolved. At the same time, the mass acquires a pale yellow colour owing to the formation of what H. Rose regarded as oxysulphides. According to B. Unger, moist calcium sulphide is readily oxidized by the oxygen of the air, forming calcium thiosulphate. According to A. Mourlot, crystalline calcium monosulphide is not reduced by **hydrogen**, but when heated in **oxygen**, it is quantitatively oxidized to the sulphate, but no sulphur dioxide is formed. Similar results were obtained with strontium and barium sulphides. The sulphides of the alkaline earths were found by A. Mailfert to form sulphates when exposed to **ozone.** A. Mourlot found that **fluorine** reacted with the cold sulphides of the alkaline earths, heating the mass red hot and forming the corresponding fluoride as well as sulphur fluoride; **chlorine** reacts with barium sulphide in a similar manner at a suitable temp.; and **bromine** and **iodine** react with greater difficulty. The **hydrogen halides** decompose the cold sulphide with a slight rise of temp. The sulphides give off hydrogen sulphide when treated with **dilute acids.** When heated with **sulphur,** polysulphides are formed—*vide infra.* H. Feigel studied the action of a benzene soln. of **sulphur chloride** on the dry sulphides of the alkaline earths, and obtained a yellow product; and in the action of sulphur chloride in benzene soln. on calcium sulphide, he obtained a yellow precipitate of a phenyl sulphide. Dil. **sulphuric acid** furnishes hydrogen sulphide; but A. Mourlot found that fuming sulphuric acid decomposes the sulphide with the separation of sulphur.

According to P. Berthier, dil. **nitric acid, or aqua regia,** gives off hydrogen sulphide, but V. H. Veley found that the sulphide becomes red hot, owing to the vigour of the reaction, if conc. nitric acid is dropped on the compound, and A. Mourlot found that with the conc. acid, an evolution of nitrous fumes and separation of sulphur occurs; with **phosphorus pentoxide,** sulphur dioxide is formed and the mass becomes red hot; with **phosphorus trichloride**, PCl_3, or **phosphoryl chloride**, $POCl_3$, a sulphide of the alkaline earth is completely decomposed, and phosphorus sulphide is formed; A. Baudrimont obtained similar results with phosphorus pentachloride, PCl_5; and A. Mourlot found that with **arsenic trichloride**, $AsCl_3$, arsenic sulphide is formed. According to A. Mourlot, when the sulphide is heated in the electric arc furnace with **carbon**, the corresponding carbide is formed. According to E. Schöne, **carbon dioxide** decomposes heated barium sulphide, forming the carbonate, and if the carbon dioxide is dry, free sulphur is sublimed, but if moisture be present, O. Lenoir found that hydrogen sulphide is formed, and this same gas is evolved when moist air is passed over the heated sulphide. If carbon dioxide be passed through an aq. soln. of the sulphide, barium hydrosulphide is formed as an intermediate product. According to B. Unger, if carbon dioxide be passed slowly over red-hot calcium sulphide some carbon monoxide is produced. E. H. Riesenfeld has shown that the equilibrium, $CaS+H_2O+CO_2 \rightleftharpoons CaCO_3+H_2S$, cannot be utilized for the desulphurization of calcium sulphide, because the temp. at which the action is sufficiently rapid, favours the re-formation of calcium sulphide. According to J. Kolb, dried calcium monosulphide is not altered by dry carbon dioxide.

According to P. Berthier, when equi-molar parts of barium sulphide and **sodium carbonate** are fused together, a pale brown opaque mass is obtained which, when treated with water, furnishes a soln. of sodium sulphide and an insoluble residue of barium carbonate. J. W. Kynaston found that when calcium sulphide is heated with **sodium hydroxide**, sodium sulphide and calcium oxide are formed. Aq. soln. of barium sulphide with the **metal hydroxides** give barium hydroxide and the metal sulphide which is often united with the barium sulphide. A. Rosenstiehl found this is the case with calcium, manganous, ferric, and ferrous hydroxides, while with zinc hydroxide, the metal sulphide does not unite with the barium sulphide. Oxidizing agents like **lead dioxide, potassium chlorate**, and **potassium nitrate** react vigorously when heated with the sulphides of the alkaline earths—according to P. Berthier, there is an " imperfect " detonation with the mixture of barium sulphide and potassium chlorate, and a " perfect " one with potassium nitrate. A. Mourlot found that **chromyl chloride**, CrO_2Cl_2, reacts vigorously with the sulphides of the alkaline earths. F. Mohr found **ferric oxide** and **manganese dioxide** do not act on boiling soln. of barium sulphide, but when evaporated with the latter, some barium sulphide is formed.

According to A. Brochet and G. Ranson, when a conc. soln. of barium sulphide is electrolyzed at 60°–65°, sulphur, barium hydroxide, and hydrogen are formed. The sulphur forms polysulphides with the barium sulphide, and these are reduced by the hydrogen to sulphide and hydrogen sulphide. In dil. soln. sulphur, sulphite, thiosulphate, and sulphate are formed, and as these oxidized products are insoluble they are deposited on the anode. Platinum, iron, nickel, carbon, or lead may be used as anode. Copper behaves as a soluble anode. The addition of sodium chloride has no effect on the general course of the electrolysis, but if iron or nickel be used as electrodes, they behave like soluble anodes. Increase of cathodic current density has little effect. The primary action when barium sulphide soln. is electrolyzed with the electrodes separated by a diaphragm is the same as when no diaphragm is used; sulphur and polysulphides are formed at the anode, and the cathode chamber contains barium hydroxide, hydrogen being evolved at the cathode. The barium hydroxide diffuses into the anode compartment, but as it has no action on the soluble polysulphides it may be recovered, since it separates on cooling the soln. The electrolysis of barium sulphide soln. offers a convenient method for the manufacture of barium hydroxide.

The photo-luminescence of the sulphides of the alkaline earths.—The photo-luminescence or phosphorescent action which occurs when the so-called Bolognian and Canton's phosphori have been exposed to sunlight or the electric light, has attracted much attention. The duration and intensity of the phosphorescence is determined by a number of factors—nature and amount of impurity; the temp.; the intensity and duration of the light stimulus; etc., so that apparently discrepant statements of the duration of the phosphorescence have been reported. Thus, J. P. Dessaignes[5] found Canton's phosphorus will shine for 10 hrs. after being exposed to sunlight for 10 secs., and T. von Grotthus found it to shine for five days; while F. M. Zanottus found that 1–2 secs.' illumination suffices to make Bolognian phosphorus luminesce for about 30 mins. L. J. M. Daguerre found that Bolognian phosphorus will shine for 48 hrs. after it has been insolated; P. Heinrich said 1 hr.; G. Osann, 4 mins.; and J. P. Dessaignes, 80 secs. J. P. Dessaignes and P. Heinrich found that a momentary illumination lasting 10 secs. produces as bright and lasting a phosphorescence as a long-continued insolation.

Instruments called *phosphorescopes* have been designed by E. Becquerel, W. Crookes, E. Wiedemann, C. de Watteville, and P. Lenard for measuring the duration of short-lived phosphorescences. J. R. Mourelo showed that with calcium, strontium, barium, and zinc sulphides the effect is more intense and of longer duration when stimulated by diffused light; bright sunlight shortens the duration and lessens the intensity of the phosphorescence. Diffused light also increased the sensibility of the substance to light stimuli, and this sensibility may be augmented by repeated exposure, and J. R. Mourelo developed the sensibility of a specimen of strontium sulphide to such a degree that the light of a candle sufficed to excite the phosphorescence. Again, if the phosphorescence of the strontium sulphide be of sufficient intensity, it can excite the phosphorescence of another sample of the sulphide, but to a less degree. This phenomenon has been termed *auto-excitation.* In illustration, when a flask of phosphorescent sulphide is exposed to light, only the outside layers are directly stimulated by light, but yet the mass is phosphorescent in zones of decreasing intensity towards the centre of the flask. The phosphori retain their peculiar properties so long as they are not chemically changed, and therefore those which are liable to oxidize and change when exposed to air must be preserved in sealed tubes. According to D. Gernez, alkaline earth sulphides lose their property of phosphorescing when exposed for a long time, but heating the substance in a current of dry hydrogen acts as a restorative—probably by reducing the sulphates. F. M. Zanottus stated that Bolognian stone phosphoresces in vacuo.

F. M. Zanottus experimented on the effect of coloured light on the phosphorescent substance. He inquired whether the phosphorescent light is the same as the exciting light; he stated that the luminosity is whiter or redder than the exciting light, and that the colour of the phosphorescence is the same whether it is excited by exposure to red or blue light. He thought the phenomenon was due to a kind of internal combustion of the stone. J. Herbert experimented on the same subject in 1763; and in 1771, J. B. Beccaria proved that *light which is absorbed is alone capable of exciting phosphorescence.* In 1775, B. Wilson ascertained that the most refrangible rays, near the violet end of the spectrum, are the most active, while the least refrangible rays, near the red end of the spectrum, may even quench the phosphorescence excited by the other rays. In 1777, L. Euler expressed the opinion that the smallest particles of the phosphorescent body have a definite period of oscillation, and that light of the same vibration frequency can set these particles vibrating so as to enable them to emit light. The action of light of various colours was also studied by W. L. Krafft (1777), M. de Magallan (1777), A. A. Scherer (1795), G. Osann (1825), T. von Grotthus (1815), C. L. Morozzo (1786), J. W. Ritter (1803), and P. Heinrich (1820), etc. E. Becquerel ascertained that the property possessed by light of rendering certain bodies luminous in the dark appears to reside, if not entirely, at least to a great extent, in the violet rays, whilst the red rays are completely devoid of this property. T. J. Seebeck, J. B. Biot, and F. J. Arago showed that the invisible ultra-red rays render a phosphorescent body luminous, or visible, whilst when plunged in the visible red, yellow, or green rays, the same body is not rendered luminous, and the luminescence previously excited by the invisible rays is quenched. E. Becquerel and E. Wiedemann concluded, as J. B. Beccaria had done previously, that those rays which are absorbed by a body can alone produce phosphorescence; rays which are not absorbed do not induce the phenomenon.

E. Becquerel, E. Lommel, W. de W. Abney, and P. Lenard have studied the *spectrum* of the phosphorescent light. In general, the spectrum consists of one or more continuous bands having maxima at different wave-lengths determined by the nature of the phosphorescent substance. Thus, there are three maxima with calcium sulphide which phosphoresces with a blue light—the first in the yellow with $\lambda=0{\cdot}584$; the second in the green with $\lambda=0{\cdot}517$; and the third in the blue with $\lambda=0{\cdot}462$. The position of the maxima are determined by the impurities in the sulphide; and P. Lenard stated that the wave-length in vacuo of such a maximum determined by a given impurity is proportional to the dielectric k of the containing medium. If $k=\mu^2$ be true, then the wave-length in the substance corresponding to such a maximum is always the same.

The *colour* of the phosphorescent light is less refrangible than the incident light, thus Bolognian phosphorus excited by blue or violet light, shines with a yellowish-red light, and Canton's phosphorus under similar conditions shines with a yellow or rose-coloured light. The light which is capable of exciting a green phosphorescent band consists of one or more bands in the spectrum. All wave-lengths corresponding with a maximum exciting power are shorter than those of the maximum of the phosphorescent bands which they excite, but the band of the exciting light may overlap that containing the phosphorescent light. In general, therefore, *the incident light is of shorter wave-length and greater frequency than that of the excited light.* This is in accord with G. G. Stokes' law, cited in connection with the fluorescence of the halogens. The intensity of the phosphorescence increases up to a maximum with a rise of *temperature,* but it is of shorter duration. E. Dreher found that the phosphorescence endures longer at —15° than at 20°, and it vanishes at 40°. F. P. le Roux, and R. Pictet and M. Altschul found that illuminated calcium sulphide does not phosphoresce if cooled down to —100°, but as the temp. rises, the phosphorescence appears. J. Canton, T. von Grotthus, and G. Osann stated that Canton's phosphorus, which has ceased to shine at a certain temp., will phosphoresce again, even months afterwards, when its temp. is raised—*e.g.* by boiling water—but it afterwards requires renewed exposure to make it shine again.

L. Vanino and E. Zumbusch found that the luminosity is augmented by covering the phosphori with hot water, benzene, amyl alcohol, glycerol, acids, anhydrides, bases, and salt soln. Uninsolated calcium and strontium phosphori become luminous by this treatment—*thermo-luminescence.* Hot sulphuric acid causes calcium phosphori to emit a blue light; strontium phosphori, a green light; and barium phosphori, an orange-yellow light—there is simultaneously an evolution of hydrogen sulphide. The phosphorescence is also augmented by treating the stones with water along with a reagent which develops heat by contact with water. Bolognian phosphorus insolated at —31°, was found by T. von Grotthus to shine at 10° longer, and with greater intensity, than when exposed to light at 31°; G. Osann found that freshly prepared and warm phosphori acquire little or no luminosity by exposure to light, it is only when cool that they are susceptible; and E. Becquerel found that Canton's phosphorus insolated at 100°–200° exhibits but little phosphorescence, and the effect of temp. on the colour of phosphorescent strontium sulphide is:

–20°	20°	40°	70°	100°	200°
Pale violet	Violet-blue	Pale blue	Green	Yellow	Pale orange

The change is not always so marked as this. It will be observed that with a rise of temp. the colour moves towards the less refrangible red end of the spectrum. J. Dewar found that the phosphorescence of the alkaline earth sulphides ceases at a temp. of —0°, but they are yet capable of absorbing light energy, so that when the sulphide is insolated at —80°, it phosphoresces when warmed up to ordinary temp. If the light stimulation be at a still lower temp., the intensity of the resulting phosphorescence is increased. M. Curie studied the action of the red and infra-red rays on phosphorescent substances. P. Lenard and V. Klatt showed that the phosphorescent glow is decreased by *pressure,* and the colour is at the same time altered. C. Gutton found that the luminescence is perceptibly increased in a *magnetic field.*

The method of preparation, and the nature of the raw materials has an important influence on the phenomenon. The sulphides of a high degree of purity do not exhibit the phenomenon, while E. Becquerel showed that the sulphides produced from different specimens of native calcium carbonate, furnished an orange, yellow, green, or violet phosphorescence. The phenomenon seems to be dependent on the presence of some foreign substance. In 1791, J. Marchetti attributed the phosphorescence of Bolognian stone to the presence of a little *hepar sulphures,* and in 1909, L. Vanino and E. Zumbusch stated that the phosphorescence of Bolognian stone is mainly dependent on the presence of a small proportion—say, 0·5 to 2·5 per cent.—of a polysulphide. They prepared a good phosphorescing sample of Canton's phosphorus by heating calcium oxide with sulphur at 1200°. The quality of the sulphur was found to be immaterial, but the quality of the lime is of vital importance. It was found that preparations from calcium hydroxide or carbonate are of good quality. Barium and strontium oxides are rather fusible to be used alone, and they are mixed with the carbonates; the thiosulphates were found by L. Vanino and J. Gans to give good results. The total amount of sulphur in Canton's phosphorus may vary from 12 to 30 per cent., but if the sulphur content is slightly greater than this, the luminosity is impaired. Whenever polysulphides could not be detected, the phosphori were but feebly luminescent, and the addition of a small proportion of sulphur to feebly luminescent phosphori, free from polysulphides, enhanced the phosphorescence to a marked degree. The phosphorescence also depends on the texture of the product. The hard, stony varieties of the monosulphide phosphoresce feebly or not at all. The addition of metal oxides improves the photo-luminescence. According to E. Tiede and A. Schleede, pure fused alkaline earth sulphides are phosphorescent.

P. Breteau prepared phosphorescent calcium sulphide by heating a mixture of calcium carbonate with 15 times its weight of sulphur in a crucible at a dull red heat for an hour. The cold mass was ground to a paste with alcohol, and sufficient alcoholic soln. of basic bismuth nitrate was added to introduce one part of bismuth to 10,000 parts of the sulphide. The mixture was dried in air, and slowly cooled. The product has a violet phosphorescence. The *phosphorogen*—γεννάω, I produce—bismuth can be replaced by molybdenum, vanadium, or tungsten.

The presence of traces of foreign metal sulphides—copper, lead, bismuth, thorium, and thallium—modifies the colour and intensity of the luminescence. According to L. Vanino and E. Zumbusch, it is astonishing what a small proportion of these metals is required—often one millionth part of copper, manganese, bismuth, etc., is effective. H. Jackson found that in some cases the amount of impurity is too small to be detected by ordinary chemical tests. Different phosphorescent colours are produced by using different metals. For example:

Rb	Al	Mn	Na	Li	Zn	Bi
Crimson	Red	Yellow	Yellowish-green	Green	Bluish-green	Blue

P. Lenard and V. Klatt found that a certain proportion of the impurity corresponds with a maximum effect of phosphorescence, the effect being diminished if the amount of impurity is increased or diminished.

The effect of additions of traces of the *exciters*, bismuth, manganese, lead, antimony, cadmium, mercury, tin, copper, platinum, uranium, zinc, and molybdenum, was studied by A. Verneuil, E. Becquerel, L. Bruninghaus, J. R. Mourelo, J. de Kowalsky and C. Garnier, L. E. O. de Visser, O. Prager, P. Wäntig, L. Vanino and J. Gans, etc. The presence of cobalt, nickel, iron, or silver seems to diminish appreciably the phosphorescence. According to E. Becquerel, the presence of some alkali appears to be necessary—lithium and sodium salts produce a greenish light; and rubidium salts give a fiery-red luminescence; while potassium salts produce but little effect. L. Vanino and E. Zumbusch observed that sodium sulphate (m.p. 880°) and lithium carbonate (m.p. 660°) have a greater effect than potassium sulphate (m.p. 1074°) in increasing the phosphorescence, and that generally salts of a low m.p. have more influence than those of a high m.p. Too much of any of these salts does not favour the phosphorescence. The presence of 2 per cent. of lithium carbonate gives a bright luminescence, while 12 per cent. is less luminous. It was also found that a salt of silver, gold, or platinum, ultramarine, arsenic sulphide, or Thénard's blue has very little influence on the phosphorescence. Reducing agents like starch prevent the phosphorescence if present in large quantities, but smaller amounts favour the luminosity; *e.g.* 4 per cent. of starch or cane sugar has a good influence, but this is not the case with lamp-black. P. Lenard showed that phosphorescent sulphides contain three components: (i) a compound of, say, zinc, calcium, strontium, or barium with sulphur; (ii) a heavy metal—bismuth, manganese, nickel, copper, uranium, thallium, platinum, etc.—which is present in minute proportions as a readily soluble salt; and (iii) a flux—an alkali salt, fluorspar, etc. The heavy metal exists in the form of a solid soln. in the sulphide of the alkaline earth or zinc. P. Wäntig produced phosphorescent sulphides with constantly increasing proportions of the heavy metal, and found 800° to be the most advantageous temp. of calcination; it is assumed that a sat. solid soln. of the heavy metal is formed. At higher temp. some of the heavy metal is volatilized.

Robert Boyle, J. Canton, and the early observers assumed that material light is actually absorbed by the phosphorescent body. The general idea is that light or some associated form of energy is held by the substance in the form of a strain, and during the recovery from the strain, light is emitted. One set of hypotheses—A. Debierne, E. Wiedemann and G. C. Schmidt, E. L. Nichols and E. Merritt, etc.—assumes that under the influence of light a substance A is converted into a new substance B, which is reconverted to A when the stimulus is removed, and luminescence is the energy evolved as a result of the transformation of B to A. Another group of hypotheses—L. E. O. de Visser, G. T. Beilby, etc.—explained the necessary presence of minute traces of impurities by assuming a solid soln. is formed, and that the solute is ionized in the act of soln.; the ions are still further split into electron-like particles by exposure to light. When the stimulus is removed, the latter reunite to form ions, and the phosphorescence is produced in the act of combination. In the electron theories of J. Stark, P. Lenard, H. S. Allen, etc., it is assumed that under the influence of light electrons are emitted from certain centres, and not uniformly from the whole area of the alkaline-earth sulphide exposed to light. The areas from which the electrons have been liberated acquire a positive charge of electricity, while the electrons themselves become attached to the sulphur atoms. Phosphorescence occurs when the electrons return from the sulphur atoms to their original centres, and in the consequent neutralization of the charges.

It is assumed by P. Lenard that the *centres of emission* with the calcium-copper sulphide is a complex $Ca_xCu_yS_z$; and the calcium sulphide forms a closed-chain molecule, with the added metal forming a kind of side chain:

$$\ldots\text{—Ca—}\underset{\underset{\text{Cu}}{\cdot\cdot}}{\text{S}}\text{—Ca—}\ldots$$

$$\ldots\text{—Ca—}\underset{\underset{\text{Cu Cu}}{\cdot\cdot}}{\text{S}}\text{—Ca—}\ldots$$

A complex ray of light splits off an electron, which after the lapse of a certain interval of time returns to its former position. The oscillations of the *liberated electron* induce sympathetic vibrations in another electron—the *emission electron*. The two kinds of electrons have been compared with "two electric vibration circuits such as are employed in wireless telegraphy, one of which excites the other to a sympathetic vibration by means of resonance." The emission electron sends off light rays when its period of vibration coincides with that of the liberated electron. The period of vibration of the latter becomes less and less until it is finally smaller than that of the first; otherwise expressed, the wave-length of the exciting light is shorter than that of the excited light—Stokes' law. When the insolated sulphide is cooled to the temp. of liquid air, no phosphorescence occurs, because it is assumed that the electrons split off do not return, and the energy is in a measure stored up. If the temp. is allowed to rise, the sulphide becomes feebly phosphorescent, because the electrons slowly return to their original centres corresponding with a quiet uniform emission of light. If the insolated sulphide be heated by a Bunsen flame, the phosphorescent light is brilliant, because the electrons return with great rapidity; when the original state is restored, the sulphide loses its capacity to phosphoresce until it is re-illuminated.

W. P. Jorissen and W. E. Ringer compared the phosphorescence of calcium and barium sulphides with that of Sidot's blende. T. J. Seebeck, T. von Grotthus, and P. Heinrich noted that Canton's phosphorus becomes luminous when placed in a glass tube over which an electric discharge is passed. J. P. Dessaignes found that the phosphorescence produced by exposure to the light of an electric discharge has the same colour and duration as when produced by ordinary light, and, according to T. von Grotthus, the phosphorescence excited by the electric light is brighter than that excited by ordinary light. T. J. Pearsall, A. C. Becquerel, J. B. Biot and E. Becquerel, J. W. Draper, C. Matteucci, K. Kortum, J. Trowbridge and J. E. Burbank, and H. Dufour, studied the effects of electricity on phosphorescent minerals; H. E. Armstrong and T. M. Lowry, the relation between the phosphorescence of calcium-bismuth sulphide mixture and its radio-activity. H. Becquerel studied the effect of **radium radiations**; J. Lepinay, and E. A. Bichat, the effect of **N-rays**; A. W. Hofmann, J. Precht, and P. Bary, the effect of **X-rays** and **Becquerel's rays**; E. Becquerel, H. Jackson, E. Goldstein, and P. Lenard, E. Wiedemann and G. C. Schmidt, the effect of **cathode rays**, on the phosphorescent sulphides of the alkaline earths. E. L. Nichols and D. T. Wilber found that purified calcium sulphide, like calcium oxide, exhibits **flame luminescence**. P. Vaillant found the **photoelectrical conductivity** of a thin plate of calcium sulphide exposed to light increases up to a maximum and then rapidly diminishes. In darkness the decrease is continuous, and is immeasurably small after five days. The results are not due to changes of temp. B. Gudden and R. Pohl studied the photoelectric conductivity and phosphorescence of calcium sulphide.

The hydrosulphides of the alkaline earths.—J. J. Berzelius[6] prepared aq. soln. of hydrated **calcium hydrosulphide,** $Ca(SH)_2.6H_2O$, by passing hydrogen sulphide into water in which calcium hydroxide or sulphide is suspended so long as the gas is absorbed. A relatively large proportion of water must be used in order that all the calcium hydroxide or sulphide can be converted into the soluble hydrosulphide; if the proportion of water is too small, some calcium sulphide remains undissolved. E. H. Riesenfeld and H. Feld found for the solubility, S, of calcium hydrosulphide —grams per 100 c.c.—in water in the presence of hydrogen sulphide at the partial press., p,

	p	100	200	300	400	500	600	700	760 mm.
S	0°	26·61	29·45	30·09	30·67	31·17	31·66	32·08	32·41
	20°	24·87	26·15	27·35	28·10	28·76	29·43	30·09	30·42
	40°	21·97	24·24	25·20	25·94	26·61	27·35	28·04	28·44

Calcium sulphide of a high degree of purity can be made by extracting the crude material with aq. hydrogen sulphide under press. and in the absence of air, and precipitating the calcium sulphide by removing the hydrogen sulphide from the soln. at a low press.

Water is needed for the production of hydrosulphide; however long the gas may be passed over calcium hydroxide, the monosulphide is formed with but a trace of hydrosulphide in consequence of the small amount of water set free from the hydroxide—the reaction is incomplete. Conc. soln. of calcium chloride and potassium hydrosulphide give a slimy precipitate with the evolution of hydrogen sulphide, whereas dil. soln. give no precipitate because of the formation of the soluble calcium hydrosulphide. For an analogous reason, T. Graham showed that moistened calcium hydroxide absorbs the gas very much more slowly than if it is mixed with sodium sulphide, because, in the latter case, calcium sulphate and sodium hydrosulphide are formed, and the latter, unlike calcium hydrosulphide, can exist when only a little water is present. The soln. prepared by T. J. Pelouze contained only 7 per cent. of hydrosulphide—any calcium hydroxide in excess of this remains undissolved without passing into the monosulphide; but he obtained more conc. soln. of the hydrosulphide by using calcium sulphide, or a soln. of the so-called sugar-lime in place of the hydroxide. According to A. Béchamp, if hydrogen sulphide be passed into water in which calcium carbonate is suspended, an alkaline liquid is obtained containing calcium hydrosulphide and hydrocarbonate, and free hydrogen sulphide. The reaction is reversible, for E. Divers and T. Shimidzu showed that carbon dioxide decomposes the hydrosulphide; and a mixture of carbon dioxide and hydrogen sulphide may be sent through lime-water without causing a precipitate, because soluble calcium hydrosulphide is formed. This is a case where lime-water would fail to detect carbon dioxide by the generally recognized test for that gas. R. Böttger's and L. T. Wright's directions for making calcium hydrosulphide in which hydrogen sulphide is passed into milk of lime until the mass acquires a bluish-grey colour, is founded on a misapprehension, because the production of this colour is due to the formation of ferrous sulphide, and this occurs as soon as any soluble sulphide is present. E. Divers and T. Shimidzu's directions for preparing crystals of calcium hydrosulphide are:

> Hydrogen sulphide is passed into a paste-like mass made by mixing calcium oxide gradually with four parts of water. When the lime has all dissolved, fresh lime is gradually added about four times until the point of sat. is reached. The current of gas is then stopped, and the liquid left in the tube to clarify, very carefully sealed up, at the ordinary, or a slightly warm, temp., in order that most of the crystals which may have formed in the cold shall redissolve. After decantation, the clear soln. is again kept in ice, when it crystallizes, and the more abundantly the better it has been sat. at a low temp. The calcium hydrosulphide thus obtained is separated from its mother-liquor by draining, and blowing a current of hydrogen sulphide through the mass of crystals, the tube being all the while immersed in snow. The crystals cannot be removed from an atm. of hydrogen sulphide without undergoing change, and admit therefore of no further drying, except by a momentary swinging of the tube to expel adhering liquid centrifugally.

The operations required several days. V. H. Veley obtained good results with this process. H. Rose obtained a soln. of calcium hydrosulphide by boiling calcium monosulphide repeatedly with water and filtering off the calcium hydroxide. Calcium hydrosulphide is found in the drainings from soda-waste heaps. C. Kraushaar leached with cold water the interior of a heap of soda-waste, and obtained a soln. containing 3 per cent. of the sulphur in the alkali-waste, and of this, 90 per cent. was in the form of hydrosulphide of calcium and sodium. It has also been proposed to make a soln. of calcium hydrosulphide on an industrial scale by treating a mixture of alkali-waste and water with hydrogen sulphide. C. Kraushaar also recommended acting on the calcium sulphide with water under press. According to H. von Miller and C. Opl, if the soln. be evaporated, hydrogen sulphide is expelled, and crystals of calcium hydroxide are formed, since during the evaporation the salt hydrolyzes: $Ca(SH)_2+2H_2O \rightleftharpoons Ca(OH)_2+2H_2S$. On account of this reversal of the reaction, E. Divers and T. Shimidzu recommend drying in a stream of hydrogen sulphide the crystals of calcium hydrosulphide obtained by cooling the sat. soln. to 0°.

J. J. Berzelius, and H. Rose prepared a soln. of **strontium hydrosulphide**, $Sr(SH)_2$, by the same process as they employed for the calcium salt. J. J. Berzelius described the preparation of crystals of hydrated **barium hydrosulphide**, $Ba(SH)_2.4H_2O$, by saturating an aq. soln. of the oxide with hydrogen sulphide, adding alcohol to the soln., filtering off the sulphur and oxidized products, and cooling the soln. to —10°, when colourless four-sided prisms are produced; the soln. may also be crystallized by evaporating it in vacuo, when white opaque prisms are produced; H. Rose concentrated a soln. of barium sulphide by evaporation in a retort, and obtained on cooling the liquid a crystalline mass of the hydrosulphide. V. H. Veley employed a modification of the process used by E. Divers and T. Shimidzu for calcium hydrosulphide and found the crystals had the composition $Ba(SH)_2.4H_2O$. The barium salt is far more stable than the corresponding calcium compound. E. Schöne's crystals of tetrabarium heptasulphide, $Ba_4S_7.25H_2O$—*vide infra*—are possibly impure barium hydrosulphide.

The hydrosulphides of the alkaline earths form colourless prismatic crystals; those of the hydrated calcium salt melt with a slight rise of temp. in their water of crystallization, and, according to E. Divers and T. Shimidzu, a little decomposition occurs even in an atm. of hydrogen sulphide. V. H. Veley found the crystals of the hydrated barium salt when heated in an atm. of hydrogen in a sealed capillary tube, showed no signs of liquefaction in their water of crystallization, but were simply dehydrated, as previously recorded by J. J. Berzelius. E. Schöne found the crystals of barium hydrosulphide did not give off hydrogen sulphide below 230°, but V. H. Veley found no decomposition at 18°; there is a very slight decomposition at 50°, with the evolution of hydrogen sulphide and water; and as the temp. rises, the decomposition proceeds more quickly. When barium hydrosulphide is dehydrated, its stability is much increased, the hydrogen sulphide is retained with great persistence. The hydrogen sulphide is completely eliminated only at a red heat, forming barium monosulphide. According to J. Thomsen, the heats of formation are: $(Ca,S_2,H_2,aq.)=115·36$ Cals.; $(Sr,S_2,H_2,aq.)=123·68$ Cals.; and $(Ba,S_2,H_2,aq.)=124·16$ Cals. According to E. Divers and T. Shimidzu, calcium hydrosulphide is readily soluble in water. The aq. colourless soln. is corrosive and has a bitter taste; it reacts alkaline. With calcium hydrosulphide at ordinary temp., one-fourth of its weight of water appears more than sufficient to hold it in soln.; and 4 or 5 drops of water in 10 c.c. of a sat. soln. prevents its crystallization when cooled in ice. This phenomenon is characteristic of salts with a large amount of water of crystallization, at a temp. near their m.p. A soln. nearly sat., even when warm, loses scarcely any water in a stream of dry hydrogen sulphide. The sp. gr. of an aq. soln. containing 32 per cent. of $Ca(SH)_2$ was 1·225 at 23°, and a soln. with 37 per cent. of $Ca(SH)_2$ was 1·210 at 23·5°. J. J. Berzelius showed that when the aq. soln. of calcium hydrosulphide is evaporated in an atm. of hydrogen, hydrogen sulphide is evolved, and acicular crystals are deposited; and when the evaporation is nearly completed, the mass swells up, hydrogen sulphide is rapidly evolved, and calcium monosulphide remains. When the soln. is evaporated in a retort, H. Rose found that hydrogen sulphide is evolved, and calcium sulphate, and later calcium oxysulphide, $4CaO.CaS_4.18H_2O$, is deposited. When the aq. soln. of the calcium salt is boiled, it gives off hydrogen sulphide and forms a soln. of the pentasulphide. P. V. Robiquet and M. E. Chevreul found that when a soln. of barium sulphide is oxidized, the sulphite is formed before the sulphate. J. J. Berzelius noted that the crystals of hydrated barium hydrosulphide effloresce in air and form barium sulphite and thiosulphate. E. Divers and T. Shimidzu say that the crystals of hydrated calcium hydrosulphide are readily soluble in alcohol, H. Rose that hydrated barium hydrosulphide is insoluble in alcohol. T. J. Pelouze ascertained that calcium hydroxide does not convert the hydrosulphide into the monosulphide. The aq. soln. of barium hydrosulphide dissolves sulphur with the evolution of hydrogen sulphide and the formation of polysulphides—*vide infra;* a soln. of manganous sulphate or chloride gives a precipitate of manganese sulphide when added to a soln. of barium hydrosulphide, hydrogen sulphide is at the same time evolved; and iodine forms barium iodide, hydriodic acid, and sulphur. A soln. of the calcium salt gives a precipitate with carbon dioxide, and with salts of zinc. Soln. containing calcium hydrosulphide have been used as a delapidary.

The polysulphides of the alkaline earths.—According to G. Calcagni, 100 c.c. of a cold sat. soln. of calcium hydroxide dissolves 0·1116 grm. of sulphur, or 32·3 parts of sulphur for 40 parts of calcium. This proportion corresponds with the formation of calcium monosulphide. Similarly, a cold sat. soln. of barium hydroxide dissolves 2·6 grms. of sulphur; and the conc. of the soln. furnishes acicular crystals of the tetrasulphide, BaS_4. All the soln. respond to reactions for sulphides, polysulphides, thiosulphates, and sulphites. No disulphide has been obtained. Barium tri-, tetra-, and penta-sulphides, and $Ba_4S_7.25H_2O$, have been reported; and strontium and calcium tetra-, and penta-sulphides, but not the trisulphides. L. N. Vauquelin[7] calcined a mixture of eight parts of barium oxide with six parts of sulphur, and extracted the product with water; barium sulphate remained behind, and a soln. of **barium trisulphide**, BaS_3, was supposed to remain in soln.: $4BaO+10S=3BaS_3+BaSO_4$. E. Schöne prepared barium trisulphide by melting together an intimate mixture of barium monosulphide with half its weight of sulphur, and distilling off the excess of the latter at a temp. not exceeding 360°. According to the latter, the yellowish-green mass when crushed forms a yellow powder, which melts at 400° to a black liquid and at the same time loses sulphur ; sulphur is expelled at a red heat until barium monosulphide remains ; in moist air the powder smells of hydrogen sulphide, and, according to J. L. Gay Lussac, the gas is formed when steam is passed over the red-hot sulphide. According to E. Schöne, barium trisulphide dissolves when repeatedly boiled with much water and forms an alkaline liquid which is dark red when hot, and yellowish-red when cold. The soln. gives off no hydrogen sulphide when treated with manganese sulphate ; but it changes rapidly on exposure to air, and barium carbonate and thiosulphate separate out. When the soln. is evaporated in vacuo, it furnishes first a crop of white or pale yellow plates of hexahydrated barium sulphide, $BaS.6H_2O$; second a crop of pale orange-red monoclinic prisms of tetrabarium heptasulphide, $Ba_4S_7.25H_2O$—possibly $3(BaS.6H_2O)(BaS_4H_2O).6H_2O$, or impure hydrosulphide.

The crystals of tetrabarium heptasulphide are yellow by transmitted light, and pale red by reflected light. When exposed to air, a yellowish-white crust of barium thiosulphate appears on the crystals ; barium thiosulphate is also formed if air be excluded, possibly by interaction with the water of crystallization. Part of the water of crystallization is expelled at ordinary temp., part at 100° ; and at 230°, barium thiosulphate or a decomposition product and hydrogen sulphide are formed. Decomposition into the monosulphide and hydrosulphide is not complete at 280° to 300°. The aq. soln. form barium thiosulphate on exposure to air ; it develops hydrogen sulphide when treated with acids, but not with manganous sulphate, and sulphur is at the same time deposited.

According to E. Schöne, if an aq soln. of a mol of calcium sulphide be boiled with three gram-atoms of sulphur, a soln. of **calcium tetrasulphide**, CaS_4, is formed. If less than this amount of sulphur be employed, the excess of calcium monosulphide is hydrolyzed, forming calcium hydroxide and hydrosulphide, and crystals of an oxysulphide, $4CaO.CaS_4.18H_2O$, are formed by the union of the hydroxide with the tetrasulphide. E. Divers and T. Shimidzu doubt the existence of calcium tetrasulphide (*vide infra*). E. Schöne prepared crystals of **hexahydrated strontium tetrasulphide**, $SrS_4.6H_2O$, by evaporating at 16° in vacuo a soln. prepared like that containing calcium tetrasulphide, and cooling the red syrupy liquid below 8°. The syrup crystallizes to radiating masses of red crystals which melt at 25°. The crystals are very deliquescent, and at 100° form **dihydrated strontium tetrasulphide**, $SrS_4.2H_2O$. The latter compound is formed by evaporating the aq. soln. of strontium tetrasulphide at 20°–25° in vacuo. The resulting crystal aggregates are pale yellow, and readily deliquesce, forming a dark yellow syrupy liquid which on exposure to air forms an oxysulphide, $SrO.SrS_4.12H_2O$. E. Schöne prepared **hydrated barium tetrasulphide**, $BaSr_4.1$ or $2H_2O$, by boiling a mixture of four parts of sulphur with seven of barium sulphide, and allowing the filtered soln. to crystallize out of contact with air ; the same salt is obtained as indicated above as the final crop in the crystallization of a soln. of barium trisulphide. The red crystals so obtained are frequently mixed with acicular crystals of barium thiosulphate and other barium polysulphides. The product is purified by dissolving it in air-free water and evaporating the soln. in vacuo. H. Rose prepared what he regarded as a soln. of barium polysulphide by dissolving sulphur in a hot soln. of the hydrosulphide. According to V. H. Veley, sulphur dissolves with effervescence in a warm sat. soln. of barium hydrosulphide, forming a dark red liquid which furnishes red crystals with the composition $2BaS_3.7H_2O$, and which are probably $BaS_4.2H_2O$ slightly dehydrated. E. Schöne's analysis corresponds more nearly with imperfectly dried $BaSO_4.H_2O$.

According to E. Schöne, the rhombic crystals of barium tetrasulphide are strongly dichroïc. When freshly prepared, the colour is red, and this becomes paler on standing, finally passing to orange-red. The colour in transmitted light is yellow, in reflected light, red. The powdered crystals are yellow. The sp. gr. is 2·988 (20°). The crystals oxidize in air more slowly than the other barium sulphides. At 105°, in vacuo, sulphur is given off, and the colour darkens; at 200°, the crystals lose water and hydrogen sulphide; at 300°, the pseudomorphs after the tetrasulphide consist of a mixture of trisulphide and barium sulphate: $8(BaS_4.H_2O)=BaSO_4+7BaS_3+4H_2O+4H_2S+6S$; and at a higher temp. the trisulphide loses sulphur to form the monosulphide. A dil. aq. soln. is orange yellow. At 15°, 100 parts of water dissolve 41·3 parts of the tetrasulphide, and the red soln. has an alkaline reaction; the soln. becomes dark brown when heated. The sulphide may be crystallized unchanged from its aq. soln. The soln. when exposed to air smells of hydrogen sulphide, and it gradually becomes turbid owing to the separation of barium carbonate and thiosulphate. The sulphide is insoluble in alcohol and in carbon disulphide; alcohol precipitates orange-yellow crystals from the aq. soln. According to V. H. Veley, the aq. soln. dissolves sulphur and gives off hydrogen sulphide, with the precipitation of sulphur, when treated with hydrochloric acid, but not with manganese sulphate.

According to H. Rose, hydrogen sulphide is given off when a soln. of calcium hydrosulphide is boiled, but when sulphur is present, the evolution of gas is augmented. E. Divers and T. Shimidzu noted that the temp. falls 2°–3° when powdered sulphur dissolves in a soln. of calcium hydrosulphide at ordinary temp.; and that conc. soln. of calcium hydrosulphide react with sulphur almost as vigorously as hydrochloric acid acts on marble. If sulphur be dissolved in a soln. of calcium hydrosulphide heated on a water-bath, until a further addition of sulphur produces no effervescence, and sinks to the bottom, the hydrosulphide is almost completely decomposed, and **calcium pentasulphide**, CaS_5, is formed—all the calcium which is not present as hydrosulphide is pentasulphide. The hot soln. takes up a little more sulphur than corresponds with the pentasulphide, but the excess is deposited as the soln. cools, and it then takes up no more sulphur if boiled with that element. The reaction is reversible, for hydrogen sulphide decomposes the yellow soln. of calcium pentasulphide with the copious precipitation of sulphur, and a colourless soln. of calcium hydrosulphide is formed. It is assumed that hydrogen pentasulphide is formed as an unstable intermediate product in both cases: $CaS_5+2H_2S=Ca(SH)_2+H_2S_5$; and $Ca(SH)_2+8S=CaS_5+H_2S_5$. The preparation of impure calcium pentasulphide by boiling milk of lime with sulphur is described below.

J. J. Berzelius was unable to prepare a polysulphide by fusing calcium monosulphide with sulphur; but when calcium monosulphide or hydroxide and water is boiled for a long time with sulphur, a soln. of calcium pentasulphide is formed. If the hydroxide be employed, some thiosulphate is formed, and if the hydroxide be in excess, an oxysulphide is formed. When the conc. reddish-brown or dil. yellowish-brown liquid is evaporated in vacuo, an amorphous yellow mass is obtained, which is soluble in water and alcohol, and when heated in vacuo loses sulphur, forming the monosulphide. E. Schöne was unable to crystallize the pentasulphide by the conc. of its aq. soln. since it readily decomposes into calcium monosulphide and hydroxide, and free sulphur. J. J. Berzelius and E. Schöne obtained similar results in their attempt to obtain crystals of **strontium pentasulphide**, SrS_5, from the aq. soln. prepared as in the case of the calcium pentasulphide. As indicated above, H. Rose prepared a soln. of barium pentasulphide by boiling a soln. of barium sulphide or hydrosulphide with sulphur; and J. J. Berzelius and E. Schöne, in their attempt to isolate **barium pentasulphide**, BaS_5, obtained similar results to those which attended the attempt to crystallize calcium and strontium pentasulphides from the aq. soln. Barium pentasulphide has not been isolated. L. Guitteau boiled two parts of barium hydroxide with one of sulphur and 25 parts of water, and obtained a black liquid which became orange-red when cold. The soln. decomposed slowly depositing needles of the thiosulphate, and evolving hydrogen sulphide. On evaporation a crystalline crust of barium tetrasulphide mixed with the thiosulphate and sulphur was obtained and the mother-liquor contained Ba : S in the at. proportions 1 : 5. This shows that barium pentasulphide is unstable and probably decomposes in aq. soln.: $2BaS_5+3H_2O=BaS_4+BaS_2O_3+3H_2S+S$.

The ready decomposition of the pentasulphides of the alkaline earths led E. Divers and T. Shimidzu to suggest that the soln. really contains an unstable hydroxy-derivative of hydrogen pentasulphide, H_2S_5, namely $HO.Ca.HS_5$; and in support of this they show that the only known solid polysulphides of the alkaline earths—namely, the tetrasulphides—all contain water. The action of water is then symbolized: $CaOH(HS_5)+H_2O=Ca(OH)_2+H_2S_5(=4S+H_2S)$; and of hydrogen sulphide: $CaOH(HS_5)+2H_2S=Ca(SH)_2+H_2O+H_2S_5(=4S+H_2S)$. When soln. of calcium pentasulphide are boiled out of contact with air, E. Schöne found that only small quantities of thiosulphate are formed; but if the soln. be boiled down until solid matter—sulphur and lime—is deposited and the hydrogen sulphide has escaped, much thiosulphate is produced. According to E. Divers and T. Shimidzu, the result is rather due to the interaction of lime and sulphur than to hydrolysis: $CaS_5+3H_2O=CaS_2O_3+3H_2S$, suggested by E. Schöne; the action of air on calcium pentasulphide gives thiosulphate and sulphur, and the former believe that the reaction should not be symbolized; $2CaS_5+3O_2=2CaS_2O_3+6S$. They argue that hydrogen sulphide is first liberated by the pentasulphide, and if this gas be removed as rapidly as it is formed, the soln. undergoes no marked oxidation; but if this gas remains in contact with the liquid, it is oxidized, and the products of the oxidation react with the pentasulphide to form thiosulphate and sulphur. The reaction is analogous to the oxidation of calcium hydrosulphide into thiosulphate, except that additional lime is needed in order that no sulphur may be deposited. Air does not directly oxidize either calcium hydrosulphide or pentasulphide.

The oxysulphides of the alkaline earths.—J. J. Berzelius showed that the decomposition of an aq. soln. of calcium hydrosulphide furnishes, presumably hydrated, calcium sulphide; T. J. Pelouze obtained calcium hydroxide. E. Divers and T. Shimidzu reported that calcium hydrosulphide is converted into the hydroxyhydrosulphide in conc. soln., hydroxide in weak ones, and mixtures, or possibly compounds of the two, when the soln. are of medium strength, while the hydroxyhydrosulphide itself becomes hydroxide by the action of water. These decompositions proceed only when the hydrogen sulphide produced can escape or become dil., and are much more rapid and complete in hot soln. than in cold soln. Crystals of hydrated **calcium hydroxyhydrosulphide,** $Ca(SH)(OH).3H_2O$, have been isolated by E. Divers and T. Shimidzu; and since the composition of the hydrated hydrosulphide is $Ca(SH)_2.6H_2O$, they give the graphic formulæ:

$$Ca{<}\begin{array}{l}SH.3H_2O\\SH.3H_2O\end{array}$$

Calcium hydrosulphide.

$$Ca{<}\begin{array}{l}SH.3H_2O\\OH\end{array}$$

Calcium hydroxyhydrosulphide.

This mixed salt is formed from the hydrosulphide by reaction with water: $Ca(SH)_2+H_2O=Ca(SH)(OH)+H_2S$, or with calcium hydroxide: $Ca(SH)_2+Ca(OH)_2=2Ca(SH)(OH)$. It is also formed by the union of calcium sulphide with water, as occurs in the interior of heaps of alkali-waste; and by the action of hydrogen sulphide on calcium hydroxide in the purification of coal-gas. Calcium hydroxyhydrosulphide is conveniently made by passing a stream of hydrogen through a conc. aq. soln. of the hydrosulphide, when colourless four-sided prisms, or minute acicular crystals of the desired salt separate from the liquid. When the crystals of calcium hydrosulphide deliquesce at ordinary temp., hydrogen sulphide is simultaneously evolved; consequently, deliquescence is accompanied by a loss of weight—the deliquescence of normal ammonium carbonate is also accompanied by a loss of weight owing to the loss of water and ammonia: $(NH_4)_2CO_3.H_2O=NH_3+H_2O+(NH_4)HCO_3$. The crystals of calcium hydroxyhydrosulphide gradually decompose and become opaque, when exposed to air, hydrogen sulphide is slowly evolved, oxygen is absorbed and the crystals become yellow; the salt also takes up carbon dioxide from the air, but not very freely at first.

C. Neuberg and E. Neimann treated a soln. of barium oxide in methyl alcohol with an alcohol soln. of potassium hydrosulphide and obtained a gelatinous precipitate of hydrated barium monosulphide, $BaS.H_2O$, possibly barium hydroxyhydrosulphide, $Ba(SH)OH$, which dissolves slowly in methyl alcohol. Hexahydrated barium sulphide, $BaS.6H_2O$, is very probably pentahydrated **barium hydroxyhydrosulphide,** $Ba(SH)(OH).5H_2O$. Its preparation and properties have been previously described. Both the calcium and barium hydroxyhydrosulphides are crystalline, and have a relatively large proportion of water of crystallization; they dissolve readily in water, but the soln. is soon decomposed into hydroxide which is precipitated, and hydrosulphide which remains in soln. This shows how improbable it is that the hydrosulphides can without decomposition lose their water of crystallization by heat; anhydrous barium sulphide has not been prepared in the wet-way at a temp. below redness. Calcium hydroxyhydrosulphide is insoluble in, and is not affected by, a moderately conc. soln. of the hydrosulphide; it is insoluble in alcohol, but is slowly decomposed by that liquid, as by water, and hydrosulphide passes into soln. From the readiness with which calcium hydroxyhydrosulphide is converted into the hydroxide, the preparations of the former are apt to be more or less mixed with the latter. Hydrogen sulphide converts the hydroxyhydrosulphide into hydrosulphide; and, according to V. H. Veley, calcium hydroxyhydrosulphide absorbs carbon disulphide. forming unstable basic calcium thiocarbonates which are slowly decomposed by hydrogen sulphide, and rapidly by carbon dioxide.

T. J. Pelouze,[8] and A. W. Hofmann were unable to obtain any evidence of combination when a mixture of calcium oxide and sulphide is heated to redness; nor was the former able to find any satisfactory evidence of the presence of an oxysulphide in the alkali-waste of Leblanc's soda process. E. Kopp is of the opinion that calcium hydroxide and sulphide do combine to form an oxysulphide. J. K. Haywood, and R. W. Thatcher found that the lime-sulphur soln. prepared by boiling milk of lime and sulphur contains two main constituents, calcium pentasulphide and thiosulphate, with small amounts of sulphite or sulphate produced by the oxidation of the soln. When freshly slaked lime and sulphur—with or without sodium chloride—are boiled with an excess of water in open vessels, they dissolve in the proportion $CaO : S = 1 : 1{\cdot}94$ if lime is in excess, and $1 : 2{\cdot}24$ if sulphur is in excess. The solubility of lime as calcium hydroxide in water in the proportions used accounts for most of the difference in these ratios, so that the proportion of lime united with sulphur is probably the same whichever component be in excess. Allowing for the excess of lime in soln., therefore, the ratio may be regarded as $1 : 2{\cdot}24$. After a time, however, the excess of lime may unite with some of the calcium pentasulphide, for the soln. frequently deposits yellow or red crystals of calcium oxysulphide—*vide infra*—which O. B. Winter represents as $2CaO.CaS_3.11H_2O$. The ratio $CaO : S = 1 : 2{\cdot}286$ corresponds with the reaction $3Ca(OH)_2 + 12S = CaS_2O_3 + 2CaS_5 + 3H_2O$. Although the ratio $CaO : S$ approximates to $1 : 2{\cdot}24$, the ratio of the sulphur present as CaS_5 to that present as CaS_2O_3 was found to vary from $1 : 4{\cdot}19$ to $1 : 27{\cdot}78$. Hence, some secondary reaction must take place—*e.g.* $CaS_2O_3 + Ca(OH)_2 + 4S = CaS_5 + CaSO_4 + H_2O$; $2CaS_2O_3 + 3Ca(SH)_2 = 2CaS_5 + 3Ca(OH)_2$; etc., and R. W. Thatcher believes the first of these equations represents the most probable reaction.

C. W. Folkard exposed calcium hydroxide to hydrogen sulphide so long as there was any gain in weight. and obtained a grey powder which he regarded as a compound: $4Ca(OH)_2.3H_2S$. When this product was treated with coal-gas, hydrogen sulphide was given off, and at 100° water was eliminated leaving behind a greyish-green substance which he regarded as a compound: $2Ca(OH)_2.2Ca(SH)OH$. When gently heated, this product loses a mol of water and forms a yellowish-white substance, $2Ca(OH)_2.CaS.Ca(SH)OH$; and at a red heat, out of contact with air, it loses two mols of water, producing $2CaO.CaS.Ca(SH)OH$, which, when ignited in air, burns like tinder, producing calcium sulphate. W. Foster also prepared some oxygenated sulphides of calcium.

V. H. Veley studied the action of hydrogen sulphide on calcium hydroxide, and found that both by the dry and the wet method the calcium oxide is converted respectively into calcium sulphide and hydrosulphide; and he concludes that "the mol. combinations described by C. W. Folkard are in all probability mixtures of calcium sulphide with unaltered oxide." In addition to E. Divers and T. Shimidzu's hydroxyhydrosulphide two other oxysulphides, or more probably hydroxyhydrosulphides, have been reported, and in the absence of definite or precise information as to their composition, they are conveniently called Herschel's crystals and Buchner's crystals after their respective discoverers. Their limits of existence in the ternary system, CaO—S—H_2O, or even their individuality, have not been established.

J. F. W. Herschel boiled two parts of calcium hydroxide with one of sulphur and 20 of water for an hour, and allowed the filtrate to cool in a closed vessel out of contact with air. A piece of calcium hydroxide was placed in the liquid, and the crystals of oxysulphide which were deposited on the lime, were washed with cold water, and dried in vacuo over sulphuric acid. According to E. Schöne, if the mother liquid is boiled with calcium hydroxide, another crop of crystals of the oxysulphide are deposited on a piece of calcium hydroxide provided the soln. contained calcium thiosulphate. A. Geuther has also described the preparation of this substance, and he objected to the washing of the crystals with water, which has a decomposing action; he preferred to dry them by press. between filter paper. According to J. F. W. Herschel, and A. Geuther, the crystals are orange-yellow, dichroïc, transparent, four- or six-sided prisms with di- or tri-hedral summits. According to A. Geuther, the so-called *Herschel's crystals* have the composition of a hydrated **calcium tetrahydroxytrisulphide**, $Ca_3(OH)_4S_3.8(or\ 9)H_2O$; or $CaS_3.2CaO.10$ or $11H_2O$, or $CaS_3.2Ca(OH)_2.8$ or $9H_2O$; E. Schöne's analysis $CaS_4.3CaO.12H_2O$, or $CaS_4.3Ca(OH)_2.9H_2O$, is vitiated by the fact that he decomposed the crystals before analysis, by washing them with water. The crystals were partially analyzed by H. Rose, and J. F .W. Herschel. The crystals gradually effloresce at a summer's temp. over sulphuric acid; but they are stable when kept in a sealed tube. They give off water and hydrogen sulphide when heated to 100°, and sulphur sublimes at a higher temp., the residue is white, and is very slightly soluble in water with an alkaline reaction. Both J. F. W. Herschel and E. Schöne reported that water extracts calcium polysulphides—CaS_n—and leaves a residue of calcium hydroxide. According to A. Geuther, the aq. extract contains insignificant quantities of sulphuric acid, and no thiosulphate; and, according to E. Schöne, it gives off no hydrogen sulphide when treated with manganese sulphate; and no sulphur dioxide when treated with a hydrochloric acid soln. of arsenic trioxide. J. F. W. Herschel and E. Schöne observed that the crystals are not changed by alcohol; and they dissolve in hydrochloric acid with the evolution of hydrogen sulphide. A. Geuther said that with dil. hydrochloric acid, the crystals become brownish-yellow, and sulphur is separated; while with conc. acid, hydrogen trisulphide, H_2S_3, is formed with but a slight evolution of hydrogen sulphide.

J. A. Buchner, and C. F. Buchholz and R. Brandes obtained orange-yellow monoclinic prismatic crystals, the so-called *Buchner's crystals*, by treating *hepar sulphuris calcarem* with insufficient hydrochloric or acetic acid for complete soln., and allowing the liquid to stand while protected from air. E. Schöne prepared them by digesting calcium tetrasulphide with calcium hydroxide and hydrosulphide; and also by boiling two parts of calcium tetrasulphide with one of sulphur and 20 of water for half an hour, and allowing the unfiltered liquid to stand while protected from the air. H. Rose also obtained what appeared to be similar crystals among the products obtained by allowing a soln. of calcium hydrosulphide to stand slightly exposed to air. The composition of Buchner's crystals has not been definitely established; H. Rose deduced the formula $CaS_5.5CaO.20H_2O$ from his analysis; E. Schöne, $CaS_4.4CaO.18H_2O$; and A. Geuther, $CaS_3.3CaO.14$ or $15H_2O$. The latter agrees with the formula $CaS_3.3Ca(OH)_2.11$ or $12H_2O$, or hydrated **calcium hexahydroxyltrisulphide**, $Ca_4(OH)_6.S_3.11$ or $12H_2O$. The crystals when protected from air become paler and finally white. At 100°, they lose about three-fourths of the water, and half the hydrogen sulphide. The action of water, manganese sulphate, acids, and alcohol on Buchner's crystals is the same as with Herschel's crystals. J. L. Gay Lussac, on the contrary, stated that they are soluble in alcohol.

E. Schöne reported the formation of hydrated **strontium dihydroxytetrasulphide**, $Sr(OH)_2S_4.11H_2O$, or $SrO.SrS_4.12H_2O$, by slightly exposing to the air an aq. or alcoholic soln. of strontium tetrasulphide. The ruby-red, transparent crystals decompose when heated in a glass tube giving off water, hydrogen sulphide, and sulphur, and leaving a residual mixture of strontium monosulphide, sulphate, and a little sulphite. Water gives a yellow soln. with an alkaline reaction, from which strontium hydroxide soon separates; the aq. soln. gives hydrogen sulphide and sulphur when treated with hydrochloric acid. Barium chloride gives no signs of a sulphate, nor arsenious chloride any signs of a thiosulphate. It is insoluble in alcohol, ether, and carbon disulphide. A. Geuther expressed the opinion that Schöne's oxysulphate is a mixture of a polysulphide and a thiosulphate. H. Rose extracted barium sulphide with water five times and analyzed the residue; the analyses have been represented by formulæ showing $x\text{BaS}+y\text{BaO}+z\text{H}_2\text{O}$, but there is nothing to justify the assumption that any of the products are chemical individuals.

P. Berthier[9] heated a mixture of gypsum with twice its weight of cupric sulphate in a carbon crucible, and obtained a leaden grey sulphide sprinkled with granules of copper. Acetic acid dissolved out of the lime, with the evolution of hydrogen sulphide. Similar results were obtained with barium sulphate. There is no evidence here of the formation of *calcium copper sulphide* or of *barium copper sulphide*. P. Berthier treated a mixture of barium and potassium sulphates in a similar way, but there is little to show that the reddish mass so obtained is really *potassium barium sulphide*.

§ 16. The Sulphates of the Alkaline Earths

The native form of dihydrated calcium sulphate, $CaSO_4, 2H_2O$, called **gypsum,** occurs as a fine-grained or compact mass which is normally white, but may be coloured grey, brown, or red owing to admixtures of clay, carbonaceous matter, ferric oxide, etc. An earthy or sandy variety is sometimes called gypsum dirt, or *gypsite.* The pure white massive varieties are known as **alabaster,** and have been used for making statuary, vases, and other objects for internal decoration. The same term is also applied to the white and banded stalagmite or onyx marble varieties of calcite; and this is generally considered to have been the alabaster of the ancients. The so-called *lapis specularis*, referred to by Pliny, was possibly crystalline gypsum mixed with mica. The colourless, water-clear or transparent, crystalline variety is known as **selenite**; and in the eighteenth century it was sometimes called *glacies mariæ*, or *Marienglas*. Some fibrous varieties of gypsum are called *satin spar*. The anhydrous form of calcium sulphate is known as **anhydrite**, $CaSO_4$, and also as *muriacite*, or *karstenite*. This variety is usually found massive, and is sometimes found associated with gypsum and rock-salt; it also occurs in coloured—brown or blue—crystals. Gypsum is soft enough to be scratched by the finger-nail; anhydrite is slightly harder.

The mineral *gypsum* is of considerable commercial importance as a source of plaster of Paris, so named because it was obtained by burning the gypsum from the quarries of Montmarte, Pantin, Belleville, Sannois, and Enghein in the Tertiary deposits of the Paris basin. The deposits in Nottinghamshire, Derbyshire, Leicestershire, Staffordshire, and Gloucestershire, are all associated with the keuper marls. The gypsum industry of Germany is developed in the southern part of the Hartz Mountain district, in Thuringia near Possench and Krolpa, and at various towns on the Rhine near the mouth of the Neckar. Deposits occur in Switzerland, Sweden, Italy, Cyprus, Sicily, India, Queensland, Canada, and in Ohio, Virginia, Iowa, Arkansas, Colorado, Nevada, Michigan, etc. Numerous reports have been made on these various deposits.[1] Crystals of gypsum have been found in the residues obtained by the evaporation of natural waters holding calcium sulphate in soln.—*e.g.* in boiler scale, etc.[2]

Anhydrite associated with gypsum occurs in the salt mines near Hall (Tyrol), Bex (Switzerland), Sulz (Würtemberg), Himmelsberg (Ilfeld), Bleiberg (Carintha), Lüneberg (Hanover), Lauterberg (Harz), Hapnik (Hungary), Ischl (Austria), Aussee (Styria), Berchtesgaden (Bavaria), at Rienthal (Alps), Stassfurt, Lockport (N.Y.), Windsor (Nova Scotia), Hillsboro (New Brunswick), etc. Celestine occurs in the Bristol basin, in Gloucester and Somerset, Westphalia, Thuringia, Pshov (Silesia), Dornberg (near Jena), Sicily, Bex (Switzerland), Montmarte, Beaumont, and Meudon (France), Conil (Spain). Deposits occur in numerous localities in the United States, at Strontian Island (Lake Erie). Barytes occurs at Dufton (Westmorland), Liskeard (Cornwall), Egremont (Cumberland), Breidden Hills (Shropshire), Wetherton and Newhaven (Derbyshire), Nutfield (Surrey), Felsöbanya and Kremmitz (Hungary), Freiberg, Marienberg, and Clausthal (Germany), Roya and Raure (Austria), Connecticut North Carolina, Tennessee, Virginia, Missouri, etc., Prizibran and Mies (Bohemia).

In connection with the alkali halides, it was shown that during the evaporation of sea-water, gypsum or anhydrite is deposited before the more soluble salt; and the common and intimate association of gypsum or anhydrite with rock-salt points clearly to the marine origin of most of the gypsum beds.[3] Gypsum also occurs as irregular masses in limestone. It is then supposed to have resulted directly from the action of sulphuric acid on the limestone, when the sulphuric acid is derived from the oxidation of pyrites or other sulphides by the joint action of air and water. Small quantities of gypsum found in some volcanic districts are supposed to have been formed by the action of sulphuric acid vapours on the lime of volcanic tuffa and other rocks.

About three centuries before our era, Theophrastus, in his Περὶ Λίθων, described very clearly the occurrence and some of the properties of the mineral gypsum and alabaster. The name of the mineral is derived from γύψος, a term applied to what is equivalent to burnt gypsum. Attempts have been made to derive the term alabaster from Greek words; another connects the word with the town Alabastron in Egypt, where ornaments were made from gypsum in early times. Theophrastus stated that it was employed as a cement and for casing the outsides of buildings; for making internal ornaments and statues; as a colour for painters; and for "fulling" cloth. He said:

> Gypsum is prepared for use by burning certain stones. It is then reduced to powder, and well mixed with water by stirring with wooden instruments. The mixing cannot be done by hand because of the heat which is developed. This mixture is prepared immediately

before it is used, for in a very short time after moistening it dries and becomes hard, and not in a condition to be used. The gypsum which has been used can be re-burnt and made fit for use.

In the first century, Pliny, in his *Historia naturalis*, described this mineral, and stated that it has a close relationship with lime—*cognata calci res gypsum est.* The opinion was based rather on its properties as a cement, which is prepared like lime by the calcination of the native stone.

The earliest plaster casts are said to have been made by Lysistratus of Sicyon, brother of the sculptor Lysippus. He first made a cast in plaster from the object, and then made a second one in wax. According to A. Rees,[4] the walls of the temple of Fortuna Seia were made of compact gypsum which, though without windows, was sufficiently illuminated by light transmitted through the semi-pellucid walls; the old Arabian monastery of Arsoffa Emu is also said to have been constructed of gypsum; at Florence, the gypsum of Volterra was made into vases in which lamps were placed, and thus diffused a soft light over the room; and a church at Florence was illuminated by large slabs of alabaster in place of panes of glass. The light transmitted through plates of gypsum seems to have reminded the ancients of light from the moon—hence selenite, from σελήνη, the moon.

G. Agricola, in his *De natura fossilium* (Basil, 1546), supposed gypsum to consist of lime because the former can be converted into the latter. J. H. Pott, in his *Lithogeognosia* (Potsdam, 1746), said that many chemists regarded true gypsum as a compound of lime and sulphuric acid, and they called it *gypsum arte factum*, but he considered the two were different. In the eighteenth century, the white substance obtained by the action of sulphuric acid on chalk was called *selenite*. B. Allen[5] prepared this mineral by the action of sulphuric acid on chalk. The chemists of this period regarded gypsum and artificially prepared calcium sulphate as two different substances. In 1747, P. J. Macquer showed that gypsum contained sulphuric acid, but the mineral was still considered to be different from the calcium sulphate, because calcination converted the former into a substance which reacted with water, forming a kind of mortar, while the latter remained unaffected by fire. In 1750, A. S. Marggraf showed that when gypsum is heated with charcoal, a gas with the pungent smell characteristic of burning sulphur is given off, and he hence inferred that it is a component of sulphuric acid and lime. He explained the formation of gypsum in nature by the gradual deposition of the crystals from calcareous waters; time, said he, brings about marvellous results which cannot be reproduced in our laboratories. In 1768, A. L. Lavoisier confirmed Marggraf's analysis, and showed that the hardening of gypsum is a result of its re-combining with the water of crystallization from which it had been deprived by heat. He said:

> If the water of hydration removed from gypsum by fire be returned to it, the water is taken up with avidity, and a sudden and irregular crystallization occurs so that the small crystals which are formed become confused with one another, and a very hard mass results.

A. L. Lavoisier stated that in his opinion these results leave *rien à désirer sur l'explication de ce phénomène*. Analyses were also made by R. Chenevix and others.

The recognition of the mineral **celestine** or *celestite* as the native form of strontium sulphate, and of **heavy spar** as the native form of barium sulphate, has been described at the beginning of this chapter. For a long time, the minerals barytes and celestine were confused, and the difference in the crystalline forms was regarded as a puzzling exception to R. J. Haüy's law of the constancy of the angles of the crystals of a given substance. L. N. Vauquelin, however, demonstrated that the minerals belong to two different species, since the one (barytes) imparts a green colour to the flame, while the other (celestine) gives a crimson flame. Heavy spar, also called *barytes*, and *barite*, occurs in fine crystals and granular or fibrous masses. It is a very common mineral in metalliferous veins—*e.g.* lead, silver, cobalt, etc.—both with the veinstone and on the wall. That in the Derbyshire lead mines occurs in aggregates of white, opaque crystals, where it is called *cawk*. The aggregates of tabular crystals are known as *crested barytes*, or *cockscomb barytes*. The mineral celestine occurs in tabular crystals, and in granular or fibrous masses. The colour of both forms is usually white or creamy, and in some cases the mineral has red or brown ferruginous stains. Many forms of celestine have a blue tinge—hence the name, from *cœlestinus*, blue. Analyses of barytes were made by T. Gruner and R. Brandes, etc. There has been some discussion as to the existence of true barium strontium sulphates—*barytocelestines*. Are the barytocelestines mixtures of barytes with strontium sulphate, or of celestine with some barium sulphate ? The evidence is indecisive ; the barytocelestines with analyses corresponding with *strontium barium sulphates*, $BaSO_4.2SrSO_4$ and $BaSO_4.3SrSO_4$, reported from Ontario, are probably mixtures.

The preparation of the sulphates of the alkaline earths.—According to K. W. G. Kastner, when sulphuric acid is poured upon calcium oxide, the whole becomes red hot if relatively large quantities of material are used ; and P. Heinrich said that chemi-luminescence occurs if sulphuric acid is dropped on calcium oxide in a darkened room. **Dihydrated calcium sulphate** is precipitated when dil. sulphuric acid, or a soln. of an alkali sulphate, is added to a soln. of a calcium salt. The same salt is also formed by the action of dil. sulphuric acid on powdered calcium oxide, hydroxide, or carbonate. As emphasized by J. J. Berzelius, the solid is very liable to form clots in which the interior is protected from the action of the acid by an impervious skin of the sulphate. A. Lacroix[6] obtained crystals of gypsum by the action of sulphuric acid on powdered fluorspar at 12° for some months. P. P. von Weimarn obtained a **colloidal calcium sulphate** by precipitating the salt in alcoholic soln. **Hemihydrated calcium sulphate,** $CaSO_4.\frac{1}{2}H_2O$, or $2CaSO_4.H_2O$, was obtained by N. A. E. Millon, by the dehydration of the dihydrate at 110°.

The partially dehydrated gypsum forms the hemihydrate, $CaSO_4.\frac{1}{2}H_2O$, and this is virtually the composition of the commercial *plaster of Paris, Stuckgips*, or *plâtre*. This product is not hygroscopic, but it generally holds up to 1·5 per cent. of adsorbed moisture and a total 6 to 8 per cent. of water. The adsorbed moisture can be removed by a stream of dry air. The term *stucco* is almost a synonym for plaster of Paris ; if there is a difference, plaster of Paris is whiter and more finely ground than stucco. C. Cloez found some samples of plaster of Paris contained considerable proportions of soluble anhydrite, and they contained less than 6 per cent. of combined water. Plaster of Paris with over 7·5 per cent. of moisture probably contains unconverted gypsum. P. Berthier's analyses, confirmed by those of E. Landrin and others, showed that commercial plaster of Paris contains 4 to 8 per cent. of water.

F. Hoppe-Seyler obtained needle-like crystals of hemihydrated calcium sulphate by heating to 140°–160° the dihydrate with water in a sealed tube. H. le Chatelier prepared the hemihydrate by heating a sat. soln. of calcium sulphate in a sealed tube at 130°–150° ; but special precautions are needed to remove water rapidly before it cools much below 130°, or rehydration sets in ; H. le Chatelier, therefore, transferred the hot crystals into absolute alcohol and dried them at 100°. A simple method of making the hemihydrate was devised by J. H. van't Hoff and E. F. Armstrong, who heated between 40° and 50°, for 18 hrs., 20 grms. of precipitated gypsum with 50 c.c. of conc. nitric acid (sp. gr. 1·4), and obtained well-defined minute needles. J. F. W. Johnston reported the formation of transparent prismatic crystals of the hemihydrate in a marine boiler working under a press. of two atm. H. Rose thought that he had prepared crystals of *monohydrated calcium sulphate*, $CaSO_4.H_2O$, by boiling gypsum for a short time with a half-sat. soln. of sodium chloride, but he probably obtained crystals of the hemihydrate which practically re-hydrated on cooling, and which were also contaminated with some sodium chloride. According to R. Grengg, the formation of the hemihydrate by heating gypsum appears to involve the intermediate formation of soluble anhydride, which then absorbs water.

H. Rose found that sulphuric anhydride, SO_3, reacts with calcium oxide at a temp. approaching redness, but not at ordinary temp. The product is **anhydrous calcium sulphate**. Calcium hydroxide does react with sulphuric trioxide at ordinary temp. C. M. Marx showed that hot or cold calcspar, limestone or chalk, does not react with the vapour of sulphur trioxide, and only a superficial film of sulphate is formed with the vapour of sulphuric acid. The anhydrous sulphate is obtained by heating one of the hydrates above the temp. of dehydration. J. H. van't Hoff, W. Hinrichsen, and F. Weigert obtained a soluble form of anhydrite by heating the hemihydrate to 100° with an excess of water, or by dehydrating precipitated calcium sulphate in vacuo between 60° and 90°. A. Lacroix obtained what appeared to be a triclinic form of anhydrite by keeping gypsum at 125° for a long time; if the temp. be kept at bright redness ordinary anhydrite is formed, and E. Mitscherlich obtained crystals of anhydrite by heating precipitated calcium sulphate in a pottery oven, where the cooling is slow. N. S. Manross obtained crystals of anhydrite by fusing potassium sulphate with four times its weight of calcium chloride, and extracting the more soluble product with water. F. Hoppe-Seyler obtained anhydrite by heating gypsum with a sat. soln. of sodium or calcium chloride in a sealed tube at 125°–130°; L. Bourgeois, from a sat. soln. of calcium sulphate in nitric acid sp.gr. 1·381, diluted with one-third its vol. of water; and R. T. Simmler, by melting hydrated gypsum with sodium chloride in the presence of silica.

F. Posepny found anhydrite is formed from gypsum in soln. of calcium or magnesium chloride. H. Rose and F. Hoppe-Seyler said that while gypsum loses water at a temp. as low as 100°, gypsum is always the form which separates from soln. of sodium chloride. J. Roth objected to this statement, because he obtained deposits of anhydrite from sodium chloride soln. at ordinary temp. G. Spezia obtained a separation of anhydrite from a sat. soln. of sodium chloride at 500 atm. press. in spite of the fact that gypsum occupies a less vol. than anhydrite, and water resulting from the decomposition. H. Vater evaporated soln. of gypsum sat. with respect to sodium or magnesium chloride, and obtained crystals of gypsum while natural anhydrite remained unchanged in these soln. It is unlikely that H. Vater realized equilibrium conditions in his experiments. R. Fassbender found gypsum to be the stable phase in equilibrium with cold sat. soln. of sodium chloride at ordinary temp., but at higher temp. anhydrite is the stable phase. R. Brauns obtained natural anhydrite at ordinary temp. with gypsum in contact with sat. soln. of calcium or magnesium chloride. H. Struve and K. Haushofer found natural anhydrite to be the stable phase in the presence of conc. sulphuric acid. The general conclusion from the work of J. H. van't Hoff is that gypsum and natural anhydrite are the only forms of calcium sulphate which are stable in the presence of any soln., and the conditions under which one or other form is stable depend on the temp. and nature of the soln. with which it is in contact. For an aq. soln. of calcium sulphate, this temp. is about 66°; for a sat. soln. of sodium bromate, 50°; for a sat. soln. of sodium chloride, 30°; and for a sat. soln. of magnesium chloride, 11°. So long as it was assumed that the change of gypsum to anhydrite requires a temp. exceeding 150°, there appeared no satisfactory explanation of the presence of anhydrite in natural deposits. The geological evidence is in agreement with the work of J. H. van't Hoff in showing that anhydrite has been deposited from soln. containing sodium chloride and other soluble salts, all of which depressed the inversion temp.

As in the case of calcium oxide, K. W. G. Kastner found strontia can be made red hot when it is treated with conc. sulphuric acid; J. S. E. Julia-Fontenelle and G. A. Quesneville did not get so high a temp. when smaller quantities were used. Anhydrous **strontium sulphate**, $SrSO_4$, is precipitated by treating a soln. of a strontium salt with sulphuric acid or a soluble sulphate. The precipitate with dil. soln. is a crystalline powder, but with conc. soln., it is flocculent and amorphous, and later assumes a crystalline form. M. M. P. Muir and C. Slater studied the effect of conc. on the reaction between sulphuric acid and strontium chloride. By working with alcoholic soln., P. P. von Weimarn obtained **colloidal strontium sulphate.** O. Schumann oxidized heated strontium sulphide to sulphate by the action of steam. A. B. de Schulten prepared crystals of artificial celestine by adding a soln. of 5 grms.

sulphuric acid in 3 litres of water in a soln. of 28 grms. of strontium chloride in 3 litres of water, and allowing the mixture to stand for a couple of weeks. L. Bourgeois prepared artificial celestine by repeatedly heating to 150° and cooling a mixture of precipitated strontium sulphate with an excess of hydrochloric acid (1 : 2); N. S. Manross, by melting potassium sulphate with an excess of strontium chloride; H. Struve, by evaporating a conc. sulphuric acid soln. of precipitated strontium sulphate; and A. Gorgeu, by fusion with alkali chlorides.

According to A. A. B. Bussy, the vapour of anhydrous sulphuric acid is absorbed by heated baryta, and the mass becomes incandescent; similarly, F. Kuhlmann found that when baryta is brought in contact with anhydrous sulphuric acid, fused at 26°, it becomes incandescent; and M. Barry found the baryta becomes red hot when mixed with conc. sulphuric acid containing a little more or a little less than one mol of acid to one of water; and F. Kuhlmann added that sulphuric acid of sp. gr. 1·848 does not combine with baryta at ordinary temp., but if the solid, moistened with the acid, be touched at any point with a hot iron, or a wet glass rod, combination commences at that point, and is propagated throughout the mass; combination also ensues on exposure to moist air. If the same acid be mixed with a little water and cooled, it unites with baryta with incandescence; but if the acid be mixed with more water, the phenomenon does not occur. When the acid is mixed with water, no reaction occurs if the baryta has been previously mixed with alcohol or ether.

Sulphuric acid and soluble sulphates precipitate **barium sulphate,** $BaSO_4$, from aq. soln. of its salts. Sulphuric acid also transforms insoluble barium salts wholly or partially into the sulphate A protective film of sulphate is formed when witherite is treated with sulphuric acid, but, according to T. J. Pelouze, dil. sulphuric acid mixed with 4 per cent. of hydrochloric acid, rapidly converts witherite into the sulphate. The purification of native barium sulphate has been discussed by C. Coffignier, J. Ramsden, etc. Barium sulphate was formerly made by treating a soln. of barium chloride with sodium sulphate or sulphuric acid, but it is now made by treating barium sulphide with salt-cakes. The latter process furnishes a denser product than the former, and gives sodium sulphide as a valuable by-product. Barium sulphate is also a by-product in the manufacture of hydrogen peroxide from barium dioxide and sulphuric acid. P. A. Mackay obtained barium and strontium sulphates in a finely divided form by grinding the native mineral, dissolving it in sulphuric acid containing free sulphur trioxide and pouring the soln. into water to precipitate the dissolved sulphates. C. H. Hall studied the electro-precipitation of colloidal barium sulphate.

The structure of precipitated barium sulphate has been studied by P. P. von Weimarn, and S. Odèn—*vide* **3.** 23, 8. According to G. Buchner, **colloidal barium sulphate** is obtained by mixing equal mol. proportions of a 40 per cent. soln. of barium acetate and a 60 per cent. soln. of aluminium acetate. Y. Kato obtained it by adding a dil. alcoholic soln. of sulphuric acid to a dil. alcoholic soln. of barium acetate. E. Feilmann heated a mixed aq. soln. of casein and sodium sulphate with an aq. soln. of barium chloride. N. G. Chatterji and N. R. Dhar observed no peptization of barium sulphate with glycerol and alkali hydroxide.

According to R. Pictet, a mixture of sulphuric acid with an alcoholic soln. of barium chloride is quite clear at —85°; but as the temp. rises to —70°, the liquid suddenly becomes turbid, showing that no reaction occurs at the lower temp. L. Joulin showed that a slight excess of sulphuric acid is needed for the complete precipitation of barium from soln. of its salts, and conversely a slight excess of barium salt soln. is needed for the complete precipitation of sulphuric acid; soln. containing an equal number of mols of sodium sulphate and barium chloride, at a dilution of 1 : 5000, are completely precipitated in four days, but in 24 hrs. $\frac{1}{27}$th part still remained unchanged. According to E. Schöne, when barium sulphide is oxidized by fuming nitric acid to barium sulphate, the filtered soln. contains both a little barium and a little sulphuric acid. W. Spring compressed an intimate mixture of one part of dry barium carbonate with three parts of dry sodium sulphate, at 6000 atm., and found 59·16 per cent. of the carbonate was converted to sulphate; by re-grinding the mass, another compression gave a 73·3 per cent. conversion. Equilibrium was obtained when 80 per cent. was converted.

In 1829, E. Turner[7] pointed out that barium sulphate has a tendency to carry down other salts during its precipitation:

> The adhesion of potassium sulphate to the precipitate ensues even in a dil. soln.; and it is not prevented by the presence of other salts, such as potassium nitrate, ammonium chloride, or ammonium nitrate. The quantity of adhering salt is variable, depending apparently as well on the relative quantity of the two salts, and the strength of the soln., as on the manner and extent of edulcoration. I have known it to increase the weight of the barium sulphate by 1 per cent.

A large number of observers have placed similar facts on record. Salts of the alkalies, alkaline earths, silica, magnesium, cobalt, copper, iron, and aluminium compounds may be carried down with the precipitate. There are difficulties also due to the solubility of barium sulphate in the presence in the soln. of certain other compounds.

Crystalline barium sulphate can be made by evaporating a conc. sulphuric acid soln. of the precipitated salt; T. Scheerer and E. Drechsel evaporated a soln. of barium sulphate in metaphosphoric acid; and they fused barium fluoride with calcium sulphate in the presence of potassium or sodium chloride, and extracted the cold mass with water; H. de Sénarmont[8] heated precipitated barium sulphate with dil. hydrochloric acid, or sodium bicarbonate to 250° for 60 hrs., and C. M. Manross fused 12 grms. of potassium sulphate with 50 grms. of barium chloride; A. Macé obtained crystals of barium sulphate by double decomposition between barium nitrate and ferrous sulphate; and C. E. Guignet, by double decomposition between sodium sulphate and barium chloride.

§ 17. The Dehydration and Rehydration of Gypsum. Plaster of Paris

C. Pape [1] found that crystals of gypsum effloresce at 100°, and J. W. Gunning showed that the dihydrate loses water when dried in a steam-bath. According to F. Knapp, gypsum loses the whole of its water below 100°; and, according to W. A. Shenstone and J. T. Cundall, gypsum can be dehydrated by heating it to 70° in dry air; and 3 per cent. of water was lost by heating hydrated calcium sulphate at 40° for 144 hrs. The dehydration of gypsum has been also studied by N. A. E. Millon, G. and E. Plessy, H. Precht and K. Kraut, etc. A. Payen noted that gypsum begins to lose its water when heated to 115°, and it then loses water more quickly the higher the temp. W. A. Davis confirmed an observation of W. A. Shenstone and J. T. Cundall that there is a distinct initial period of inertness during the dehydration of gypsum. H. How found tabular gypsum dehydrated more readily than the fibrous variety. J. B. Hannay found a break in the dehydration curve corresponding with $CaSO_4.1\frac{1}{2}H_2O$, but none with $CaSO_4.\frac{1}{2}H_2O$; on the other hand, H. le Chatelier determined the time rate of rise of temp., *i.e.* the heating curve, Fig. 38, of powdered gypsum. The temp. rose steadily up to 128°, when there was a long interval during which the temp. remained stationary; a second steady rise occurred between 128° and 163°, when a second but shorter break occurred: this was followed by another continuous rise. There was a continuous loss of weight on heating gypsum to 155°, until 15·6 per cent. had been lost, when the residue retained a constant weight corresponding with $CaSO_4.\frac{1}{2}H_2O$; similarly, the loss at 194° was continuous until the anhydrous sulphate was formed, when the weight remained stationary.

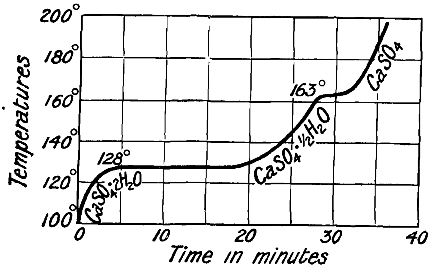

FIG. 38.—Heating Curve of Gypsum.

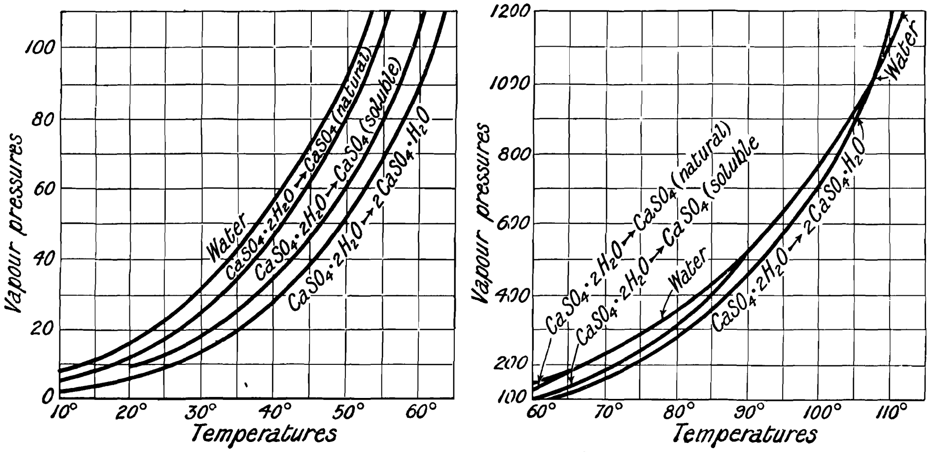
The following is a selection from the **vapour pressure** measurements of J. H. van't Hoff and E. F. Armstrong[2] for the system $CaSO_4.2H_2O—CaSO_4.\frac{1}{2}H_2O—H_2O_{vapour}$ at different temp.:

	0°	10°	20°	40°	60°	80°	100°	110°
Vap. press. . .	1·17	2·78	6·24	26 3	91·4	272·4	710·8	1104 mm.

where the corresponding values for the vap. press. of water are:

Vap. press. . .	4·57	9·14	17·4	54 9	149	355	760	1075 mm

The observed results are in close agreement with the formula: $\log p=\log p^{n}+1·493-567·7/(\theta+273)$, where p denotes the vap. press. of the system at θ°, and p_w that of water at the same temp. They are plotted in Figs. 39 and 40 on different scales—the latter shows diagrammatically the transition points; otherwise expressed, when gypsum is heated with water under press., above 107°, the hemihydrate will be formed, and when the latter is heated with water below 107°, gypsum will be formed. The transition temp. is lowered in the presence of aq. soln. having a lower vap. press. than water—*e.g.* a sat. soln. of sodium chloride converts gypsum into the hemihydrate above 77°, the temp. at which the vap. press. of the system: $CaSO_4.2H_2O—CaSO_4.\frac{1}{2}H_2O$, becomes equal to the vap. press. of the sat. soln. In the presence of a 20 per cent. soln. the transition temp. is 93·3°; and in the presence of a 3·5 per cent. soln. (sea-water), 105°. Again, in the presence of solid hexahydrated calcium chloride, the transformation temp. is 17°; in a 13 per cent. soln. of calcium chloride, it is a little above 100°; and in a sat. soln. of magnesium chloride, 11°. The effect of soln. of sodium or calcium chloride on the dehydration of gypsum was also investigated by F. Hoppe-Seyler, and G. Rose; and of soln. of sodium sulphate by



FIGS. 39 and 40.—Vapour Pressure Curves of the Hydrates of Calcium Sulphate.

H. Rose. W. A. Davis and E. F. Armstrong have indicated that there is a possibility that these measurements really refer to the system : Hemihydrate⇌soluble anhydrite. Two determinations by H. Lescœur are not in close agreement with these values. The transformation temp. for gypsum→hemihydrate is 107° at a press. of 970 mm., and at 758·8 mm. press., 101·45°.

A. Potilitzin found that if gypsum be converted into anhydrous sulphate below 200°, it sets with water, and he calls this α-anhydrite in contrast with the dead-burned form which he calls β-anhydrite. He represents the di- and hemi-hydrates and the α- and β-forms of anhydrite by the formulæ :

$\mathrm{Ca}{<}\begin{matrix}\mathrm{O}\\\mathrm{O}\end{matrix}{>}\mathrm{S(OH)_4}$

Dihydrate.

$\mathrm{O}{<}\begin{matrix}\mathrm{SO_3.CaOH}\\\mathrm{SO_3.CaOH}\end{matrix}$

Hemihydrate.

$\mathrm{O}{<}\begin{matrix}\mathrm{SO_3.Ca}\\\mathrm{SO_3.Ca}\end{matrix}{>}\mathrm{O}$

α-Anhydrite.

$\mathrm{O}{<}\begin{matrix}\mathrm{SO_3Ca.O.SO_3Ca}\\\mathrm{SO_3Ca.O.SO_3Ca}\end{matrix}{>}\mathrm{O}$

β-Anhydrite.

The dihydrate is thus regarded as the calcium salt of orthosulphuric acid, $S(OH)_6$; and the hemihydrate as the calcium salt of parasulphuric acid, $SO(OH)_4$. Again, β-anhydrite is considered to be a polymerized form of α-anhydrite. K. Zulkowsky and P. Rohland regard the dihydrate as a calcium salt of orthosulphuric acid, H_6SO_6 or $S(OH)_6$. J. H. van't Hoff, W. Hinrichsen, and F. Weigert showed that under special circumstances, gypsum in the presence of water is converted into anhydrous calcium sulphate, which, unlike natural anhydrite, is fairly soluble in water, and sets in water even more rapidly than the hemihydrate. This **soluble anhydrite** is produced when precipitated gypsum is heated in vacuo over conc. sulphuric acid between 60° and 90° ; or when gypsum, regenerated from plaster of Paris, is heated at 100°. It was assumed that gypsum is converted directly into soluble anhydrite, and not through the hemihydrate as an intermediary, because the vap. press. of gypsum in equilibrium with soluble anhydrite is greater than gypsum in equilibrium with the hemihydrate. Vap. press. measurements show that the transformation temp. of gypsum into soluble anhydrite, in contact with water, is lower than the transformation temp. of gypsum into hemihydrate, being 93° in the former case and 107° in the latter. The production of the hemihydrate in E. F. Armstrong's experiments in preference to soluble anhydrite is explained by assuming that it is due to the suspension of the transformation : gypsum→soluble anhydrite. In the absence of a lag—*Verzögerung*—J. H. van't Hoff believed that the change of gypsum into soluble or natural anhydrite should precede the change into the hemihydrate. W. A. Davis takes the opposite view—*vide infra*. The vap. press. of the system $CaSO_4.2H_2O—CaSO_{4\text{soluble anhydrite}}—H_2O_{\text{vapour}}$ was found to be :

	15°	20°	40°	50°	60°	70°	80°	85°
Vap. press. . .	7	10·7	34	61·5	108	185	314	407 mm.

and the results represented by $\log p=\log p_w+3341{\cdot}5T^{-1}+25{\cdot}905 \log T-75{\cdot}198$. The transformation temp. is given as 90°–93°. The data are plotted on different scales in Figs. 39 and 40.

J. H. van't Hoff further assumes that a second variety of gypsum which gives rise to natural anhydrite should occur at an even lower temp., but is normally prevented from appearing ; and it is estimated that the transformation temp. of gypsum into natural non-setting anhydrite is as low as 63·5° when in contact with water. He also gives for the system $CaSO_4.2H_2O—CaSO_{4\text{natural anhydrite}}—H_2O_{\text{vapour}}$

	0°	5°	10°	20°	30°	40°	50°	60°
Vap. press. . .	2·62	3·93	5·79	12·2	·24	45·4	82·5	143 mm.

and the transformation temp. is given as 63·5°–66°. They are plotted on different scales in Figs. 39 and 40.

TABLE IV.—TRANSFORMATION TEMPERATURES OF GYPSUM.

The conversion temp. of gypsum into	In the presence of		Press of water.
	Water.	Sat. soln. NaCl.	
Natural anhydrite . . .	63·5°	36°	17·5 mm.
Soluble anhydrite . . .	93°	62°	588·0 mm.
Hemihydrate	107°	76°	791·0 mm.

These results are summarized in Table IV. This classical work of J. H. van't Hoff wants revision in the light of W. A. Davis' work: *The nature of the changes involved in the production and setting of plaster of Paris.*

W. A. Davis has shown that when monoclinic gypsum is heated, it is very probably converted into a second rhombic form of gypsum; and that before monoclinic gypsum is dehydrated, it first changes into the rhombic form. This is evidenced (i) by the inflection in the dehydration curve of gypsum, which shows that the loss of water does not begin immediately the material is heated, but there is a distinct period of induction. W. A. Shenstone and J. T. Cundall first showed the initial reluctance of gypsum to give up water, and attributed the phenomenon to the presence of "molecular aggregates of great stability, and it is only after the gradual breaking up of these that the dissociation can take place." (ii) The change which occurs in the optical properties when gypsum is heated. At ordinary temp., the optic axes of gypsum lie in the plane of symmetry of the crystal, but on heating to a temp. slightly above 100°, and before dehydration begins, the optic axes revolve so as to take up a position at right angles to this plane. A. Lacroix has shown that when a plate of gypsum is heated, long needles appear within the crystal, and they are elongated in the direction of the vertical axes of the gypsum, and give a rigidly longitudinal extinction. (iii) All the products of the dehydration of gypsum—hemihydrate, soluble anhydrite, and ordinary anhydrite—have rhombic symmetry. (iv) No period of induction has been observed in the transformation of the rhombic hemihydrate to rhombic soluble anhydrite.

W. A. Davis has also shown that just as the dehydration of monoclinic gypsum is preceded by a change into a rhombic form, so when the hemihydrate is rehydrated, it is first converted into the rhombic form and subsequently into ordinary monoclinic gypsum. The changes are strictly reversible:

$$\underset{\text{Monoclinic}}{\alpha\text{-CaSO}_4.2\text{H}_2\text{O}} \rightleftharpoons \underset{\text{Rhombic}}{\beta\text{-CaSO}_4.2\text{H}_2\text{O}} \rightleftharpoons \underset{\text{Rhombic}}{\text{CaSO}_4.\tfrac{1}{2}\text{H}_2\text{O}} + 1\tfrac{1}{2}\text{H}_2\text{O}$$

W. A. Davis inferred that the setting of plaster of Paris is not simply a regeneration of gypsum by the rehydration of the hemihydrate, for if the setting is observed under the polarizing microscope, "not a single gypsum crystal can at first be detected in the set mass; the cake of set material, during the first quarter of an hour after it has hardened to a coherent mass, which is only slightly indented by the finger-nail, is made up of crystals showing a straight extinction only, and therefore probably orthorhombic. The first product of the setting of the half-hydrate (or soluble anhydrite) is, indeed, the same orthorhombic dihydrate as is produced in the first stage of the dehydration of gypsum. Gypsum crystals subsequently make their appearance within the set mass owing to the fact that the orthorhombic form of the dihydrate is labile at the ordinary temp., and undergoes change, more or less rapidly—during the course of several hours or several days, the time varying greatly—into the more stable form gypsum."

When gypsum plaster is ground, the heat developed is sufficient to liberate all the water, forming soluble anhydrite; if ground under such circumstances that the water is not permitted to escape, W. E. Emley showed that the product is as plastic as lime putty—*palstic gypsum plaster.*

The continuity of the dehydration curves obtained by heating gypsum in a stream of dry air between 98° and 130°, whereby soluble anhydrite is formed, appears at first sight to favour J. H. van't Hoff's assumption that soluble anhydrite is formed directly from gypsum, but W A. Davis also showed that (i) the hemihydrate is likewise converted into soluble anhydrite after 4 hrs.' heating at 98° ; (ii) gypsum heated in an open crucible at 98° is converted into the hemihydrate, and that the latter remained unchanged after 18 hrs.' heating under the same conditions. This agrees with W. A. Shenstone and J. T. Cundall's experiment where gypsum was completely dehydrated at 70° in a stream of dry air, but formed only the hemihydrate at 100° in ordinary undried air. Hence it was inferred that in the formation of soluble anhydrite by heating gypsum, the hemihydrate is formed as an intermediate product.

W. A. Davis also found that although the hemihydrate does not lose water in an open vessel at 98°, it gives soluble anhydrite when heated for 9 hrs. in a toluene bath at 107°–108°, and gypsum, under similar conditions, gives the same product in about the same time. At 129°, the loss of water is completed in half the time, and soluble anhydrite is formed. C. Cloez also showed that gypsum can be entirely converted into soluble anhydrite at 145° in 4 hrs. Hence, at a temp. below 100°, the vap. press. of the system gypsum–hemihydrate is sufficiently great to allow gypsum to pass to the hemihydrate, but only above 100° does the press. become sufficient for the hemihydrate to form soluble anhydrite. E. F. Armstrong stated that the vap. press. of the system gypsum–hemihydrate is equal to one atm. at 101·45°, but he has also stated that, owing to lack of knowledge concerning the crystallographic characters of the hemihydrate and soluble anhydrite, what was regarded as the hemihydrate was probably soluble anhydrite ; and the transition point really refers to the change from the hemihydrate to soluble anhydrite.

The change of the hemihydrate to soluble anhydrite and water vapour is reversible. Soluble anhydrite was shown by C. Cloez to be very hygroscopic and to take up 8 per cent. of its weight of moisture from the air. W. A. Davis showed that the excess above the 6·62 per cent. required for the formation of the hemihydrate is mechanically retained, as is evident by (i) the variability in the amount which depends on the humidity of the air, (ii) no gypsum can be detected among the products of the action, and (iii) if dry air be passed over the product at ordinary temp., the excess of water is removed, and the actual absorption compounds with that theoretically required for the formation of the hemihydrate ; while the gypsum shows no sign of a loss of weight under similar conditions. The original hemihydrate can be quantitatively regenerated from a known weight of hemihydrate which has been converted into soluble anhydrite at 100°, by exposing it to humid air, followed by treatment with a current of dry air so as to remove the excess or adsorbed moisture. The raising of the amount of absorbed moisture above the limit required for the hemihydrate owing to adsorption plus chemical combination misled C. Cloez into stating that *cette limite ne correspond à aucun hydrate défini*, and hence believing that no definite hydrate is formed.

W. A. Davis has shown that gypsum loses water to form the hemihydrate when heated to 98° in an open crucible. J. C. G. de Marignac observed no change when gypsum is heated with boiling water : nor could E. F. Armstrong transform gypsum into the hemihydrate by heating it with water at 100° for a couple of hours. W. A. Davis treated 4 grms. of the hemihydrate with 500 c.c. of water at 100°, and found nearly all dissolved ; on heating this soln. minute crystals separated out—these crystals gave an oblique extinction of 52·5°, and the twin forms characteristic of gypsum ; when these crystals were heated under boiling water for 3 hrs., they had the characteristics of rhombic crystals—not a single crystal of gypsum remained. The crystals had the composition $CaSO_4.\frac{1}{2}H_2O$. Unlike the ordinary hemihydrate, that prepared by the prolonged action of boiling water on gypsum sets very slowly, and is not very coherent after standing a couple of hours ; it thus resembles that prepared by H. le Chatelier by heating gypsum with water at 130°–

150°, and which he said sets *moins rapide et moins complète qu'avec la plâtre.* W. A. Davis regarded the slow-setting hemihydrate as a dimorphous variety, which is distinct from the quick-setting hemihydrates obtained (i) by the partial dehydration of gypsum at 100°; (ii) by the adsorption of water vapour by soluble anhydrite; and (iii) by the action of nitric acid on gypsum. These varieties of the hemihydrate bear the same relation to one another as do the natural and soluble forms of anhydrite. W. A. Davis infers that calcium sulphate is dimorphous not only when anhydrous, but also when hydrated, for both the di- and hemihydrates exist in two different forms. His summary of the relationship with isodimorphous calcium chromate is indicated in Table V. The dimorphism of calcium chromate has been observed only in the case of the dihydrate; and it is remarkable that the monohydrate is the most stable hydrate of calcium chromate, while a monohydrated calcium sulphate does not exist.

TABLE V.—COMPARISON OF CALCIUM SULPHATE AND CHROMATE (W. A. DAVIS).

	$CaSO_4$	$CaCrO_4$
Dihydrate	α-form : monoclinic gypsum β-form : rhombic (labile)	α-form : monoclinic (labile). β-form : rhombic.
Monohydrate	Not known	Rhombic.
Hemihydrate	α-form : rhombic (slow setting) β-form : rhombic (quick setting)	One form only is known.
Anhydrous	α-form : rhombic (native anhydrite) β-form : rhombic (soluble anhydrite)	α-form only is known.

Anhydrous, hemihydrated, and dihydrated calcium sulphate are therefore all dimorphous. As a rule, the hydrated sulphates of the bivalent metals are also dimorphous—*e.g.* $MnSO_4.4H_2O$; $MnSO_4.7H_2O$; $FeSO_4.4H_2O$; $FeSO_4.7H_2O$; $MgSO_4.7H_2O$; $ZnSO_4.6H_2O$; $ZnSO_4.7H_2O$; $NiSO_4.6H_2O$; $NiSO_4.7H_2O$; $CuSO_4.7H_2O$; and $CuSO_4.5H_2O$—and the dimorphism generally extends to the different hydrates of the same sulphates as in the case of the manganese, nickel, zinc, and ferrous sulphates; and in nearly all cases two forms crystallize in different systems, generally rhombic and monoclinic.

The cause of the setting of plaster of Paris is mainly that indicated by A. L. Lavoisier in 1768; and, nearly 120 years later, further details were established and described by H. le Chatelier in his *Recherches expérimentales sur la constitution des mortiers hydrauliques* (Paris, 1887). Minor details have since been elucidated by J. H. van't Hoff and co-workers, W. A. Davis, etc.

The predominant constituent in normal plaster of Paris is hemihydrated calcium sulphate, $2CaSO_4.H_2O$, or $CaSO_4.\frac{1}{2}H_2O$. J. C. G. de Marignac showed that when plaster of Paris is stirred with water, it gives a more conc. soln. of calcium sulphate than can be prepared from powdered gypsum. F. Knapp, E. Landrin and H. le Chatelier assumed that such a soln. is formed when plaster of Paris is mixed with a small proportion of water. If a large proportion be employed, the hemihydrate is readily hydrated and a loose coherent mass of isolated prismatic crystals is formed, but, continued H. le Chatelier, with a small proportion of water, the particles of the plaster are in close contact, and minute crystals of gypsum separate from the supersaturated soln. More plaster is dissolved and more crystals of gypsum are formed, the final result—the set plaster—is a confused mass of interlocking lath-shaped prismatic crystals. In favour of this explanation, H. le Chatelier showed that anhydrous sodium sulphate readily forms a soln. supersaturated with respect to the decahydrate, $Na_2SO_4.10H_2O$, and it too sets when moistened with water; the hardening of zinc oxide in contact with a soln. of zinc chloride is likewise preceded by the formation of a supersaturated soln. from which crystals of zinc oxychloride separate. F. Knapp also showed that the setting of plaster of Paris is an alternating process of dissolution and crystallization. If the hemihydrated calcium sulphate be hydrated without a solvent being present no setting occurs. For example, gypsum dehydrated at 150°, takes up water from 80 per cent. alcohol, and forms a non-setting mush, since the resulting dihydrated calcium sulphate does not dissolve. The mass hardens if one-third to one-fourth part of water is present. E. Landrin stated that the strongly heated anhydrous sulphate will set if it be mixed with a little calcium sulphate and moistened with water.

C. Cloez believes that the same soluble anhydrite is always present in plaster of Paris, and that this constituent, not the hemihydrate, is the important constituent. He said that the hemihydrate *ne se formait pas pendant la cuisson du plâtre*, and it plays no part in the setting of plaster. The formation of the supersaturated soln. of the soluble anhydrite and its subsequent crystallization in a mass of interlocking bundles of radiating prisms of gypsum, produces set plaster. C. Cloez is probably wrong, and H. le Chatelier right, in assuming that the hemihydrate is the essential constituent of plaster of Paris; although it may be conceded that if the boiling or baking of plaster is a little overdone, some soluble anhydrite may be present; and if a little underdone, some unconverted gypsum remains with the hemihydrate. According to P. Rohland, the setting of plaster of Paris is not solely due to the anastomosing of the crystals of the dihydrate, but a colloidal soln. with water is formed, and the setting in part proceeds as with mortar. A. Cavazzi, indeed, did obtain a gelatinous mass by grinding fresh plaster of Paris with water, and crystals were subsequently formed; he therefore assumed that a highly hydrated intermediate product (colloid) is formed which subsequently loses water and becomes crystalline. I. Traube also favours A. Cavazzi's hypothesis; he found that the influence of cations on the setting is all-important, that of the anions is very small; the order in which cations influence the setting is the reverse order in which they precipitate colloids from soln. This points to a preliminary gel formation in the setting.

There is an apparent expansion during the setting of plaster, and the utility of plaster of Paris in the preparation of moulds, etc., depends on this quality which enables it to fill the mould and take a sharp impression on the surface.

Mouldmakers habitually make an allowance for the expansion of plaster. R. J. Friswell reported that up to about 1880, the expansion of plaster in setting was utilized in Persia as a means of executing criminals. The criminals were placed in hollow stone columns and surrounded with wet plaster of Paris. At first a little inconvenience was suffered, they would then show signs of distress and scream loudly; finally paralysis and death supervened. This would no doubt occur as the expansion of the plaster compressed the thorax and abdomen.

The expansion of the setting plaster, however, is only apparent; for the actual volume of the set plaster is less than the combined volume of water and hemihydrate before setting. The sp. gr. of the hemihydrate is 2·75, and of the dihydrate 2·32; and, assuming the change during setting to be: $2CaSO_4.H_2O+3H_2O=2(CaSO_4.2H_2O)$, the volume before setting is $3\times18+290/2{\cdot}75=159{\cdot}5$ units, and after setting $2\times172/2{\cdot}32=148{\cdot}1$ units. This corresponds with a contraction of about 7 per cent. J. H. van't Hoff's measurements with a dilatometer showed that during the hydration of plaster, a large contraction occurs during the first half-hour, and this is succeeded by a smaller expansion, which continues during several hours. W. A. Davis interprets this by showing that the first contraction corresponds with the formation of the rhombic modification of gypsum, and the subsequent expansion, with the conversion of rhombic into monoclinic gypsum. As G. P. Grimsley has shown, the outward thrust of the crystals in the direction of their growth also accounts for the sudden apparent expansion which accompanies the setting.

E. Leduc and M. Pellet observed no change of temp. in the setting of alabaster dehydrated at 400°; but if dehydrated at 250°, there is a considerable rise of temp. According to C. Cloez, if anhydrous calcium sulphate be mixed with an equal amount of water, the temp. rises 14° to 22° owing to the formation of the hydrate; in about ten minutes the temp. falls 4° to 6° owing to the dissolution of the hydrate;

and it then rises again, higher than at the beginning, owing to the crystallization from the supersaturated soln. If the hemihydrate is employed, the phenomena are correspondingly modified.

J. F. McCaleb measured the hydration of powdered samples of anhydrite and of selenite (previously heated to bright redness). A gram of the powder was moistened with water, and confined over water in a bell-jar between 25° and 30°; the sample was then dried over sulphuric acid to remove mechanically mixed water.

	1	2	3 weeks.
Anhydrite, Sulzberg .	0·0209	0·0357	0·0493 grm.
Anhydrite, Nova Scotia .	0·0072	0·0155	0·0234 ,,
Calc. selenite, Montmarte .	0·0022	0·0048	0·0073 ,,

The first-named sample also absorbed per gram:

	4	8	12	16	20	28	36 weeks.
Water . .	0·0308	0·0488	0·0629	0·0700	0·0803	0·0873	0·0949 grm.

According to C. Cloez, calcium sulphate dehydrated at 145° at 14°–16°, absorbs 3·7 per cent. of moisture from the atm. in 1 hr.; 4·27 per cent. in 2 hrs.; 5·7 per cent. in 3½ hrs.; 7·57 per cent. in 19 hrs.; 7·77 per cent. in 27 hrs.; and 7·93 per cent. in 74 hrs. There is no sign of the formation of a definite hydrate on the resulting composition-time curve. According to V. Zunino, when artificial gypsum, dehydrated at 200° or 230°, is heated in a current of steam, it re-absorbs all its water of crystallization; if dehydrated at 240°, it absorbs 75 per cent.; if at 250°, 32 per cent.; if at 260°, 11 per cent.; and over 260°, it absorbs no water, while natural selenite loses this property when calcined to 300°. E. Leduc and M. Pellet found that alabaster dehydrated at 120° begins to set 8 mins. after mixing with water, and has finished in 16 mins.; if dehydrated at 250°, the beginning and ending of the setting are respectively 4 and 6 mins.; if dehydrated at 450°, the setting begins in 4 mins. and is not completed in 5 hrs.; if dehydrated at 600°, it gives a solid mass after some days; and no signs of setting occur with alabaster dehydrated at 650°–800°; while gypsum heated to 1185° forms a friable mass.

The manufacture of plaster of Paris is comparatively simple. The selected raw material is partially dehydrated, and finely ground. If the boiling, as it is called, is conducted in iron vessels called kettles, the grinding is usually done first. The escape of the water in kettle boiling gives the powder the appearance of a boiling liquid. The powder is agitated in order that the material may be as uniformly heated as possible. If the burning is performed in ovens or rotary cylinders, the raw material is preferably fed into the furnace in lumps, and the fine grinding follows the burning. The dehydration may be conducted between 100° and 200°, but in practice the temp. is kept at about 130°. The product contains about one-fourth the original amount of water, and is completely converted into the hemihydrate.

F. Schott, F. Knapp, M. Zeidler, and V. Zunino have shown that if gypsum be heated to a temp. exceeding 200°, all the water of crystallization is expelled, and anhydrous calcium sulphate is formed. P. Rohland and R. K. Hursh agree that above 200° an anhydrous sulphate is formed which hydrates slowly without setting. The former assumes that the non-setting form is of high mol. wt., and, at about 525°, dissociates into simpler mols., forming a second modification of the anhydrous sulphate which sets very hard without expansion, and he considers this to be flooring gypsum. The setting qualities, however, are not really lost when gypsum is calcined above 200°, but instead of, say, about a quarter of an hour being required as in the case of ordinary plaster of Paris, the anhydrous plaster requires some days or even weeks for hardening. This product is called *flooring plaster—Estrichgips*. R. Grengg said that flooring plaster consists of anhydrite and calcium oxide in solid soln., partly crystalline and partly glassy. According to J. H. van't Hoff and G. Just, the total dehydration of gypsum occurs at about 190°, the capacity to bind water is at first retained, and is only gradually lost, either by more intense or by longer heating. The higher the temp. of calcination of the flooring plaster the slower the setting. Thus, with gypsum calcined for 10 hrs. at 200°, 93 per cent. was set in 23½ hrs., and in a sample calcined at 300°, only 56 per cent. was set in 21 hrs. Again, 69 per cent. of a sample of commercial flooring gypsum was set in 13 days, and with a sample of the same material calcined 10 hrs. at 400°, only 39 per cent. had set in the same time. A further calcination at a higher temp. produced dead-burning, and the sample showed no signs of hardening even after weeks. According to P. Rohland, when heated above 600°, a third variety of the anhydrous sulphate is formed which is *vollständig totgebrannt*, and neither sets nor hardens, so that it is of little industrial interest. J. H. van't Hoff and G. Just continue: There is no evidence to show that after dead-burning a new binding capacity appears at a high temp., in which case even natural anhydrite would be suitable for making flooring gypsum. P. Rohland's figures for the supposed transition temp. have not therefore been confirmed. *Dead-burnt plaster* and natural anhydrite dissolve in water with extreme slowness, and they show no tendency to form supersaturated soln., a condition which, according to H. le Chatelier's theory, is necessary for the setting.

M. Glasenapp has shown that if plaster be heated below the critical temp. the product retains the crystalline form of gypsum; and above that temp. it acquires the granular structure characteristic of flooring plaster. At a red heat some basic sulphate is formed which may play some part in the hardening, for a product with 83 per cent. calcium oxide still sets quite hard without appreciable change of vol.—*vide infra*, Scott's selenitic cement. F. A. Wilder has described the manufacture of flooring plaster.

The work of D. C. Winterbottom and A. L. Keane on the supposed modifications of anhydrite may be solely due to differences in the fineness of the particles. Even natural anhydrite will set if ground sufficiently fine; and A. C. Gill found finely ground anhydrite and rough lumps of dead-burnt plaster were both largely converted into crystals of gypsum after standing covered with water in glass bottles for seven years. A. L. Keane also found gypsum calcined at 600°, and ground to particles 0·05 mm. diameter behaved like dead-burnt plaster, but when reduced to particles 0·005 mm. diameter, it set quite rapidly, forming a hard mass.

It is probable that Grecian and mediæval plasters, made by burning gypsum, were types of flooring plaster. The hardening of these plasters has not been closely investigated; M. Gary has done a little work on the subject; and Wo. Ostwald and P. Wolsky have studied the colloidal processes occurring in the setting, by measuring the viscosity of suspensions of burnt gypsum at various periods of time and with various additions—alkali chloride, acetic acid, gelatine, etc. O. Frey recommended regulating the time of setting of plaster of Paris by mixing definite proportions of ordinary plaster of Paris and flooring plaster.

According to J. L. Gay Lussac, the hardness of plaster of Paris when set is greater the harder the raw gypsum. This statement has not been confirmed. If the raw gypsum carries a large proportion of impurities, or if certain materials be added to the plaster after burning, the product sets more slowly. The slow-setting plasters are used in structural work and sometimes marketed as *cement plasters*. Normal plaster of Paris, made from a fairly pure gypsum, sets in from five to fifteen minutes after mixing with water, while the cement plaster may set in from one to two hours, or even more. P. Rohland found that the speed of re-hydration or setting is dependent on the grain-size of the plaster; and A. Ditte showed that the speed of setting may also be modified by the nature of the soluble salts in the water employed in mixing the plaster, for anhydrous calcium sulphate is more rapidly hydrated in the presence of alkali chlorides than in water, and this the more with potassium than with sodium chloride. P. Rohland found that the presence of salts like potassium sulphate, sodium chloride, aluminium chloride, calcium chromate, and potassium dichromate accelerate, while borax and boric acid retard the setting; and calcium chloride has no appreciable influence, hence salts which accelerate the action are called *accelerators*, and those which retard the setting are called *retarders*. P. Rohland found that in general, substances which increase the solubility of the gypsum accelerate the setting, and those which decrease the solubility of gypsum retard the rate of setting. I. Traube found that the order of setting from the most rapid is with $\frac{1}{2}N$-soln. hydrochloric acid, oxalic acid, sulphuric acid, trichloroacetic acid, tartaric acid, boric acid, phosphoric acid, dichloroacetic acid, chloroacetic acid, acetic acid, propionic acid, and citric acid. The effect of potassium hydroxide is nearly the same as that of hydrochloric acid. No effect was observed with chloral hydrate, amyl alcohol, propionitrile, mannitol, paraldehyde, methyl alcohol, and methyl ethyl ketone. With 10 grms. of plaster of Paris and 4 c.c. of $\frac{1}{2}N$-KCl, setting occurred almost instantly; with 5 c.c., in 2·5 mins.; with 7 c.c., in 4 mins.; with 15 c.c. setting had not occurred in 10 mins. Further, with 7 c.c. of a sat. soln. of potassium chloride setting occurred in 12 mins.; with a $\frac{1}{2}N$-soln., in 4·5 mins.; with a $\frac{1}{4}N$-soln., in 5·5 mins.; and with $\frac{1}{16}N$-soln., in 19 mins. Hence there is a maximum velocity of setting with soln. of medium conc. W. Rohland, and I. Traube found that substances of a colloidal nature—*i.e.* glue, gelatine, etc.—interfere with the formation of crystals, and retard the setting. For instance, a small proportion of gelatine or glue retards the setting of plaster of Paris, while a larger proportion completely inhibits the formation of crystals and prevents the setting. It is said that the ancient Romans used blood to retard the setting of plaster of Paris, numerous patents have been taken for the use of organic matter in this connection—*e.g.* glue, tankage from packing houses, prepared hair, sawdust, etc. The glues and gelatines increase the viscosity of the soln., and retard circulation so that the growing crystal exhausts its immediate neighbourhood, and new material is more slowly supplied.

The salts which accelerate the setting of plaster of Paris do not necessarily act in the same way on flooring plaster. Thus, ammonium chloride, calcium chloride, magnesium chloride, aluminium chloride, and potassium dichromate retard the setting of flooring plaster and accelerate that of plaster of Paris; sodium chloride, potassium sulphate, aluminium sulphate, and potassium nitrate accelerate that of both plaster of Paris and flooring plaster; while borax retards the setting of both plasters. Quick-setting plaster of Paris probably contains a little crystalline gypsum which provides nuclei for the crystallization of the supersaturated soln. in setting. Hence, gypsum is an accelerator; and natural anhydrite a retarder.

The so-called *hard-finish plasters* are used for producing a smooth white surface in internal building work, etc. *Keene's cement* is one such, and it is made by calcining a fairly pure gypsum at a red heat; the resulting anhydrous calcium sulphate is immersed in a bath of potash alum soln., dried, and again burned at a high temp. The product is then ground to a fine-grained powder, which, when mixed with water, hardens comparatively slowly. Another peculiarity is that the partially set cement may be reworked with water, and it sets apparently as well as if the setting had not been interrupted. This type of plaster is therefore sharply distinguished from the ordinary plaster cements derived from gypsum. In *Martin's cement*, sodium or potassium carbonate is used as well as alum, and the burning is conducted at a higher temp. The so-called *parian cement* is made by incorporating borax with gypsum in a similar manner; and in *Mack's cement*, flooring plaster is mixed with about 0·4 per cent. of anhydrous sodium or potassium sulphate. The mechanism of the setting of hard-finish plaster has not been established. *Scott's selenitic cement* is a compound cement made by mixing hydraulic lime with 2 to 5 per cent. of gypsum, either by grinding the two components in the dry state, or by slaking lime with an aq. soln. of gypsum. The different plasters derived from gypsum have therefore been classed in the following manner:

I. The temp. of calcination does not exceed 200° C., and the product consists mainly of hemihydrated calcium sulphate.

   1. Produced by the calcination of the purer forms of gypsum without the addition of foreign materials before or after calcination—*e.g.* PLASTER OF PARIS.

   2. Produced by the calcination of less pure gypsums, or by the addition of retarders to plaster of Paris—*e.g.* CEMENT PLASTERS.

II. The temp. of calcination exceeds 200° C., and the product is anhydrous calcium sulphate.

   1. Produced by the calcination of gypsum—*e.g.* FLOORING PLASTER.
   2. Produced by the recalcination of flooring plaster or dead-burned plaster with alum, borax, etc.—*e.g.* HARD-FINISH PLASTERS.

§ 18. The Solubility of the Sulphates of the Alkaline Earths

Gypsum is the stable form of calcium sulphate under ordinary conditions of temp. and in contact with air, but the hemihydrate and anhydrite often exist as metastable forms, because of the slowness of the transformation to gypsum. In water, gypsum is stable up to about 66°, when it passes into natural anhydrite; while in the presence of other salts, the transformation temp. is lowered, as previously indicated. In spite of this, the solubility of gypsum can be determined in these different menstrua far above the transformation temp. because of the slowness of these transformations. Many misconceptions regarding the properties of gypsum have arisen, and many of these were not cleared until the researches of J. H. van't Hoff and allied workers had yielded extensive and precise knowledge of various transformations of calcium sulphate. This work is outlined in J. H. van't Hoff's *Untersuchungen über die Bildungsverhältnisse der ozeanischen Salzablägerungen insbesondere des Stassfürter Salzlagers* (Leipzig, 1912).

The accurate determination of the **solubility** of calcium sulphate in water has presented many unforeseen difficulties which have not all, even yet, been satisfactorily explained. J. C. G. de Marignac[1] showed that the early observations of the solubility of calcium sulphate by C. F. Bucholz, F. von Giese, A. B. Poggiale, M. Tipp, L. de Boisbaudran, A. H. Church, E. Erlenmeyer, A. Cossa, and K. Möller are inaccurate because insufficient precautions have been taken to provide against the great tendency of this salt to form supersaturated soln. He said that "it is exceedingly easy to obtain such soln., and they are very slow to come to equilibrium, even in the presence of an excess of solid gypsum." A. Cavazzi obtained supersaturated soln. with 0·947 grm. $CaSO_4$ or 1·1976 grms. $CaSO_4.2H_2O$ per 100 c.c. J. C. G. de Marignac found that when a quantity of plaster of Paris is shaken with water for five minutes, and rapidly filtered, the filtrate is five times more conc. than a sat. soln. of gypsum. The supersaturated soln. soon becomes turbid, deposits crystals, and attains normal conc. J. C. G. de Marignac's data, grams of salt per 100 grms. of water, are :

	0°	18°	24°	32°	38°	41°	53°	72°	86°	99°
$CaSO_4.2H_2O$.	0·241	0·259	0·264	0·270	0·272	0·270	0·267	0·256	0·240	0·222
$CaSO_4$ . .	0·190	0·205	0·209	0·213	0·215	0·214	0·211	0·202	0·189	0·175

G. A. Hulett showed that the conc. of a soln. in equilibrium with a plane surface is different from that of a soln. in equilibrium with a curved surface, and this the more the greater the curvature ; further, the solubility of the finely divided gypsum is appreciably greater than that of the coarse-grained solid—*e.g.* he found the solubility was increased 20 per cent. by decreasing the size of the particles to 0·3μ. He found that the solubility of particles over 0·002 mm. in diameter is 15·33 millimols per litre at 25°, and of particles 0·0003 mm. diameter 18·2 millimols per litre. In the latter case, the excess separates from the soln. if it be brought in contact with particles not less than 0·002 mm. diameter—*vide* **1**. 10, 1. The soln. sat. with the fine grains is in an unstable condition, and the coarser grains slowly grow at the expense of the finer grains until the conc. of the soln. is in the state of equilibrium characteristic of one in contact with a plane surface of the solid; he calls this a *normally saturated solution.* J. C. G. de Marignac, and J. H. Droeze took care to have an excess of finely divided gypsum distributed throughout the liquid, but even then the results are rather high, because, although the soln. were in equilibrium with the solid, gypsum is a very soft mineral, easily ground to fine powder, and the soln. were not therefore in a state of normal saturation. G. A. Hulett found it necessary to remove all the fine particles before he could obtain normal saturation. If the powder be not removed, equilibrium is not attained after five days' stirring ; while if the stirring be too rapid, the abrasion from the soft gypsum continually yields a fine powder, and a normally sat. soln. is never attained. G. A. Hulett and L. E. Allen's determinations of the solubility of calcium sulphate in a state of normal saturation (here partly interpolated), and expressed in grams of calcium sulphate, $CaSO_4$, per 100 grms. of soln., are :

	0°	10°	30°	40°	50°	60°	80°	100°
Grm. of $CaSO_4$	0·1759	0·1928	0·2090	0·2097	0·2038	0·1996	0·1802	0·1619
Solid phase	$CaSO_4.2H_2O$					$CaSO_4$		

The early workers found a change in the direction of the solubility curve, and the results of J. C. G. de Marignac and J. H. Droeze give 38° as the temp. of maximum solubility; while those of G. A. Hulett and L. E. Allen give 40° as the temp. of greatest conc. The conc. of the normally sat. soln. thus increases as the temp. rises up to 40°, and subsequently decreases, being nearly the same at 90° as it is at 0°; and at 107° it has decreased 12 per cent. more. There is no abrupt break in the curve at 40°. The uniformity of the vap. press. curves of gypsum excludes the idea of explaining the change at 40° by assuming the appearance of a new phase; thermodynamics connects the change at 40° with the change in the sign of the heat of soln., and this is supported by M. Berthelot's observations on the heat of precipitation of the dihydrate above and below 40°. The downward course of the curve above 40° is explained by W. A. Davis as follows: The crystallographic character of the solid phase in the solubility determinations has not been investigated, and, therefore, it is not certain if the two branches of the curve really correspond with the same form of the dihydrate. By analogy with F. Mylius and J. von Wrochem's work on the calcium chromates, the two branches of the gypsum curve may belong to α- and β-forms of the dihydrate, a transition of one form into the other occurring at 38°; for the solubility of α-$CaCrO_4.2H_2O$ decreases with temp. while that of the β-form increases. Moreover, the formation of a mono- or hemi-hydrate is not excluded; it is certain that a form of the hemihydrate can be produced from gypsum at 100°. G. A. Raupenstrauch represented the solubility of gypsum, S, at $\theta°$ between 0° and 38° by the expression: $S=0\cdot1771+0\cdot00187162(\theta-0\cdot8)-0\cdot0000247095(\theta-0\cdot8)^2$; and between 38° and 100° by $S=0\cdot2117-0\cdot000192371(\theta-38\cdot8)-0\cdot00001000029(\theta-38\cdot8)^2$.

B. Guillon, and W. A. Tilden and W. A. Shenstone found a solubility of 0·049 at 151·2°; 0·031 at 169·6°; 0·027 at 180°; 0·016 at 220·4°; and 0·018 at 245°—the last result is probably a little too large. There are also A. C. Melcher's determinations of the so-called soluble anhydrite as an unstable phase. Expressing the results in millimols per litre:

	18°	50°	100°	156°	218°
Gypsum	15·69	14·47	9·13	—	—
Soluble anhydrite	—	—	9·00	2·29	—
Anhydrite	—	—	4·62	1·22	0 20

The combined results of G. A. Hulett and L. E. Allen on gypsum, and of B. Guillon on the solubility of soluble anhydrite, are shown graphically in Fig. 41. Anhydrite is the stable solid phase above 60°, and its solubility decreases rapidly with rising temp., and at 218° its value is one-fortieth that of gypsum at 18°; the solubility curve of soluble anhydrite cuts that of gypsum at about 97°, whereas J. H. van't Hoff's vap. press. measurements place the transition temp. of these two forms at 93°. The plotting of J. C. G. de Marignac's solubilities furnishes two curves which intersect at the maximum, at 38°. W. A. Davis has shown that when J. C. G. de Marignac's and G. A. Hulett and L. E. Allen's solubility data are plotted on the same chart, and the two limbs of the latter's curve be extended, they intersect on J. C. G. de Marignac's curve at 38°. W. A. Davis believes that the differences in the two sets of results are due to differences in the nature of the gypsum used, and to the presence in the gypsum of impurities modifying the changes in dimorphous gypsum.

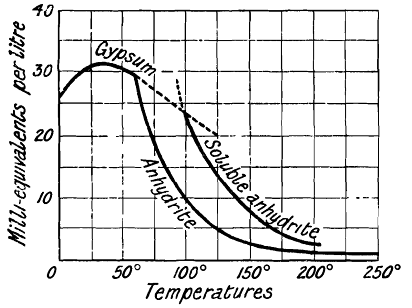

FIG. 41.—Solubility of Calcium Sulphate in Water.

According to G. A. Hulett and L. E. Allen, the ratio of the solubility of soluble anhydrite to that of ordinary anhydrite is almost the same at 100° as at 156°, namely, 2·48 at 100° and 2·37 at 156°. This, said A. C. Melcher, agrees with the assumption that soluble anhydrite is really another form of the anhydrite, and not a hydrate. From the relation $d \log (S_1/S_2)=(Q/RT^2)dT$, it follows that when the ratio of the solubilities $S_1 : S_2$ is constant, the heat of transition Q is zero, and this is not so likely to be the case for the transition of an anhydride into a hydrate, as for the transition of one form of a given substance into another.

According to A. Goldammer, the solubilities of different varieties of dihydrated calcium sulphate in water—grams of salt in 100 grms. of water—are :

	0°	15°	30°	37·5°	45°	60°	90°	100°
Precipitated . . .	0·178	0·201	0·210	0·216	0·211	0·207	0·186	0·180
Native	0·179	0·201	0·210	0·213	0·211	0·206	0·187	0·180
Powdered selenite .	0·174	0·203	0·213	0·215	0·213	0·207	0·187	0·180

These numbers are in close agreement, as should be the case if the soln. were in equilibrium. Other determinations of the solubility have been made by F. Kohlrausch and F. Rose, and A. F. Hollemann, but here again the results are too high, possibly owing to G. A. Hulett's effect. J. F. McCaleb measured the ratio of dissolution of anhydrite and gypsum in water by exposing 6–9 sq. cms. of surface to 4 litres of distilled water contained in tall jars at 20°, and found pink micaceous gypsum lost 0·2219 grm. under similar conditions ; honey-yellow selenite, 0·1177 grm. ; and grey massive anhydrite, 0·0666 grm. Similarly :

	First	Second	Third	Fourth	Fifth week.
Gypsum, white massive . .	0·2219	0·4638	0·6788	0·8168	0·8768 grm.
Selenite, honey-yellow . .	0·1177	0·2021	0·3250	0·4179	0·4893 „
Anhydrite, grey massive .	0·0666	0·0999	0·1514	0·1881	0·2398 „

According to F. Rinne, the rate of soln. of the faces of a crystal of gypsum is not the same in different directions, although G. A. Hulett found that no change in form occurs when a crystal of gypsum stands a long time in contact with a sat. soln. of calcium sulphate.

Strontium sulphate is sparingly soluble in cold or hot water. According to T. C. Hope,[2] a litre of boiling water dissolves 0·266 grm. R. Brandes reported that a litre of water dissolves 0·0665 grm. of strontium sulphate at 11°, and 0·282 grm. at 100° ; R. Fresenius, 0·145 grm. at 14°, and 0·104 grm. at 100° ; J. C. G. de Marignac, 0·154 to 1·167 grm. at ordinary temp. ; P. Kremers, 0·187 grm. ; T. Andrews, 0·278 grm. ; and P. Schweitzer, 0·0970 to 0·133 grm. F. Kohlrausch found 0·1133 grm. per litre at 2·85° ; 0·1135 grm. per litre at 10·18° ; 0·1143 grm. per litre at 18°, and also at 32·26° for natural and artificial strontium sulphate ; and he reported that a litre of water at 2·85° dissolves 0·1133 grm. of strontium sulphate ; at 17·4°, 0·1143 grm. ; and at 32·3°, 0·1143 grm. J. Wolfmann found for 100 grms. of water the solubility :

	0°–5°	10°–12°	20°	30"	50°	80°	90°	95°–98°
$SrSO_4$ . .	0·0983	0·0994	0·1479	0·1600	0·1629	0·1688	0·1727	0·1789

F. C. Calvert reported that barium sulphate has a solubility of 0·00125 grm. per litre ; R. Fresenius gave 0·0025 grm. per litre of cold or hot water ; and, expressing the results in grams per 100 c.c. of water, F. Kohlrausch obtained :

	0·77°	3·35°	18°	26·75°	34°
$BaSO_4$ . .	0·000171	0·000207	0·000230	0·000266	0·000291

A. C. Melcher found in milli-eq. per litre :

	18°	25°	50°	100°
$BaSO_4$ . .	0·0190	0·0212	0·0288	0·0354

R. Fresenius and E. Hintz, W. Böttger, Z. Karaoglanoff, A. F. Hollemann, and F. W. Küster have also made observations on this subject. G. A. Hulett obtained similar results with respect to the solubility of barium sulphate of different size of grain as those he obtained with solubility of calcium sulphate. For particles of a grain size not under 0·0019 mm. diam., the solubility is 2·29 millimols per litre; and for particles below 0·0001 mm. diameter, 4·15 millimols per litre—*vide* **1.** 10, 1.

H. Rose [3] reported that cold *hydrochloric acid* dissolves a little calcium sulphate, but boiling dil. acid dissolves much more. The solubility at 25° and at 102° has been determined by G. Lunge. Expressing the results in grams of HCl and of $CaSO_4$ per 100 c.c. of soln.:

Grms. HCl		0	1	2	3	4	6	8
Grms. $CaSO_4$	25°	0·208	0·72	1·02	1·25	1·42	1·65	1·74
	102°	0·160	1·38	2·38	3·20	3·64	4·65	—

This shows the solubility increases with the increasing conc. of acid and with temp. C. R. Fresenius found a litre of cold 8·5 per cent. hydrochloric acid dissolved 2·11 grms. of strontium sulphate, and a litre of cold 4·8 per cent. nitric acid dissolved 2·31 grms. According to H. Rose, cold hydrochloric or nitric acid does not dissolve appreciable quantities of heavy spar, or artificial barium sulphate after many days' contact; the boiling acids, however, do attack barium sulphate, so that the filtered liquid gives a precipitate with both barium chloride and sulphuric acid; and R. Piria and E. Siegle also found that by washing precipitated barium sulphate with dil. hydrochloric or nitric acid, a similar result is obtained. F. C. Calvert, G. S. Fraps, E. C. Nicholson and D. S. Price, H. M. Noad, and C. Gutkowsky have made observations on this subject. Expressing the results in grams per 100 c.c., it follows that:

	Hydrochloric Acid			Nitric Acid			
	1·82	3·65	7·29	3·15	6·31	12·61	31·52
$BaSO_4$	0·0067	0·0089	0·0101	0·0070	0·0107	0·0170	0·0241

The solubility of barium sulphate in hydrochloric acid has been measured by W. Ostwald, by E. T. Allen and J. Johnston, and by J. M. Kolthoff and E. H. Vogelenzang. Expressing the results in milligrams per litre of acid, at 20°:

N-HCl	0·003	0·016	0·08	0·16	0·3	0·5	1·0	1·5	2·0	5·0
$BaSO_4$	2·6	4·3	9·4	11·1	34·3	67*	84*	103	101	86*

Those marked with an asterisk are by W. Ostwald, the others are by E. T. Allen and J. Johnston. For strontium and barium sulphates, W. Ostwald found:

	$SrSO_4$					$CaSO_4$			
N-HCl	0·1	0·5	1·0	2·0	5·0	0·1	0·5	1·0	2·0
Mgrm.	3·25	2·20	1·72	0·96	0·29	22·96	15·75	11·51	7·61

A. Gawalowsky found barium sulphate to be soluble in *chlorine water*. A. R. Haslam found that 100 c.c. of 40 per cent *hydrobromic acid* dissolve 0·04 grm. of barium sulphate; and the same amount of 40 per cent. *hydriodic acid* dissolve 0·0016 grm.

The solubility of gypsum in *nitric acid* at 25° is also raised much as it is with hydrochloric acid; but the increase in solubility is not so great with *chloroacetic acid* and with *formic acid*. W. Ostwald's values for nitric, monochloroacetic, and formic acids are shown in Table VI. O. Aschan found that 100 c.c. of a sat. soln.

of barium sulphate in 95 per cent. formic acid at 18·5° contain 0·01 grm. of that salt. Table VII embodies W. Ostwald's data for these acids expressed in mgrms. of salt dissolved per mgrm. of acid diluted to the extent indicated. With the more conc. soln. of acids nitric acid dissolves barium sulphate more readily than hydrochloric acid, but with the acids of lower conc., the solvent action is nearly the same. R. Fresenius found a litre of 15·6 per cent. *acetic acid* dissolves 0·1275 per cent. of strontium sulphate; and E. Siegle noted that barium sulphate is less soluble in this acid than in nitric or hydrochloric acid.

According to H. Endemann, calcium sulphate is more readily soluble in dil. *sulphuric acid* than in water. H. Struve found 100 parts of sulphuric acid of sp. gr. 1·82 dissolved 2 parts of calcium sulphate, and 100 parts of fuming sulphuric acid, 10·17 parts of the same salt. Liès Bodart and E. Jacquemin observed that 100 parts of conc. sulphuric acid dissolved 2·5 parts of calcium sulphate, and the soln. on standing became turbid. F. K. Cameron and J. F. Breazeale give the following data, where the numbers represent the number of grams of H_2SO_4 or $CaSO_4$ per litre of soln.:

TABLE VII.—SOLUBILITIES OF CALCIUM, STRONTIUM, AND BARIUM SULPHATES IN DILUTE ACIDS.

Conc. of acid.	Hydrochloric acid.			Nitric acid.			Monochloroacetic.		Formic acid.

Grms. H_2SO_4	.	0·00	0·48	4·87	48·67	75·00	97·35	146·01	292·02
Grms. $CaSO_4$ 25°	.	2·126	2·128	2·144	2·727	2·841	2·779	2·571	1·541
Grms. $CaSO_4$ 35°	.	—	2·209	2·451	3 397	—	3 606	3·150	—
Grms. $CaSO_4$ 43°	.	2·145	2·236	2·456	3·843	4·146	—	4·139	2·481

There is thus a maximum in the solubility curve at 25° somewhere near soln. with 75 grms. H_2SO_4 per litre, and 2·84 grms. $CaSO_4$ per litre; at 35°, with 85 grms. H_2SO_4 and 3·70 grms. $CaSO_4$; and at 43°, with 105 grms. H_2SO_4 and 4·26 grms. $CaSO_4$. The sp. gr. of the soln. were measured, and F. K. Cameron and J. F. Breazeale inferred that there is a condensation not alone of the soln., but of the solvent itself. For example, at 25°, a litre of the soln. containing 0·49 grm. of sulphuric acid, and 2·128 grms. of calcium sulphate, weighs 1002·493 grms., while the weight of an equal vol. of water is 997·12 grms. It is stated that the results are not satisfactorily explained by the ionization theory, although it is possible that complex ions of the type $Ca(SO_4)_2''$ or $HCa(SO_4)_2'$ are formed; but an examination of the solid phases, and the determination of the acidity of the soln. before and after adding calcium sulphate, gave no information on this point. H. Endemann, however, found that by keeping the time and temp. constant the amount of glucose produced by heating dextrine with dil. sulphuric acid is dependent on the conc. of the acid. He found that with a given conc. of sulphuric acid, sufficient glucose was produced to reduce 0·220 grm. of copper; and by adding potassium sulphate to the acid soln. the glucose reduced 0·168 grm. of copper; and with an eq. amount of calcium sulphate 0·180 grm. of copper. It was therefore inferred that some of the sulphuric acid united chemically with the salt, which prevented it reacting with the dextrine. It was also assumed that just as potassium sulphate and sulphuric acid furnish potassium hydrosulphate, $KHSO_4$, so do calcium sulphate and sulphuric acid give a calcium hydrosulphate.

According to J. J. Berzelius, if anhydrous calcium sulphate be digested with hot sulphuric acid, **calcium hydrodisulphate,** $Ca(HSO_4)_2$, crystallizes out on cooling; and the colourless, transparent, prismatic crystals can be dried on porous tiles. They are decomposed into calcium sulphate and free sulphuric acid when exposed to moist air, or when treated with water. According to C. Schultz, anhydrous calcium sulphate separates from a boiling soln. of calcium sulphate in conc. sulphuric acid; calcium hydrosulphate, $Ca(HSO_4)_2$, separates from the soln. at 100°; and **calcium hydrotetrasulphate,** $CaSO_4.3H_2SO_4$, at ordinary temp. If a soln. of one part of calcium sulphate in 10 parts of sulphuric acid be evaporated, a crop of crystals of anhydrite is produced; and if the soln. be cooled, prismatic crystals of $CaSO_4.3H_2SO_4$ are formed. They melt to a mush at 100°. T. Garside also obtained crystals of the acid sulphate from a sulphuric acid soln. of calcium sulphate. In addition to these two acid sulphates, H. A. G. Willoughby obtained **calcium hydrotrisulphate,** $2CaSO_4.H_2SO_4$, in coarse irregular rhombic plates. F. Bergius made some inaccurate measurements of the solubility of calcium sulphate in sulphuric acid owing to his soln. not being in equilibrium with the solid phases. J. Kendall and A. W. Davidson found the f.p. of soln. of calcium sulphate in sulphuric acid to be:

Per cent. $CaSO_4$ . .	0·0	1·99	4·00	4·84	6·63	7·59
F.p. (stable form) .	10·4	7·2	2·2	19·1	45·4	55·1
F.p. (unstable form) .	—	—	—	13·5	39·7	49·4
Solid phases	H_2SO_4			$CaSO_4.3H_2O$		

Soln. with over 8 molar per cent. $CaSO_4$ deposited crystals when warmed. The curves, Fig. 42, illustrate the results obtained.

T. C. Hope reported that strontium sulphate is soluble in conc. sulphuric acid, and is re-precipitated by water. Similar observations were made by M. H. Klaproth, G. Moretti, etc. T. Andrews reported that water acidulated with sulphuric acid dissolves less strontium sulphate than does water alone; and, according to R. Fresenius, a litre of such a liquid dissolves 83 to 91 mgrms. of strontium sulphate. Working at ordinary temp., Liès Bodart and E. Jacquemin reported that strontium sulphate dissolves in sulphuric acid less readily than barium sulphate, and that 100 grms. of conc. sulphuric acid dissolve 2·2 grms. of strontium sulphate; H. Struve, that 100 grms. of the conc. acid dissolve 5·58 grms. of strontium sulphate, and 100 grms. of the fuming acid, 9·77 grms.; E. Varenne and M. Pauleau, that 100 grms. of 91 per cent. sulphuric acid dissolve 0·08 grm. of strontium sulphate. F. Bergius found that absolute sulphuric acid dissolves 21·7 grms. of strontium sulphate per 100 c.c. of sat. soln., and the solid phase is $SrSO_4.14H_2SO_4$. T. Garside found that 100 grms. of sulphuric acid, sp. gr. 1·843, at 70°, dissolve 14 grms. of strontium sulphate, and that on raising the temp. the soln. deposits cubic and octahedral crystals, while if the soln. at 70° be cooled tabular crystals appear. C. Schultz found boiling sulphuric acid dissolves 15 per cent. of strontium sulphate; no salt separates on cooling, and on dilution crystalline strontium sulphate is obtained. If the warm soln. be digested with an excess of strontium sulphate, or if potassium sulphate be dissolved in it, granular crystals of **strontium hydrosulphate,** $Sr(HSO_4)_2$, were produced which formed plates of the hydrated salt, $Sr(HSO_4)_2.H_2O$, by exposure to moist air.

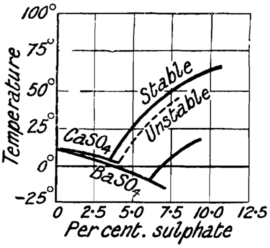

FIG. 42.—Freezing-point Curves of Binary Mixtures of Sulphuric Acid with Barium or Calcium Sulphate.

According to E. Varenne and M. Pauleau, 100 grms. of 91 per cent. sulphuric acid dissolve 0·0317 grm. of barium sulphate precipitated from the chloride, or 0·0658 grm. precipitated from the nitrate—the difference is attributed to the presence of adsorbed nitrate forming nitric acid. Working at ordinary temp., Liès Bodart and E. Jacquemin found 100 parts of conc. sulphuric acid dissolve 2·22 parts of barium sulphate. H. Struve, and C. C. Selleck measured the solubility of barium sulphate in sulphuric acid, and found 100 parts of an acid, sp. gr. 1·32, dissolve 5·6 parts of barium sulphate, and an acid, sp. gr. 1·90, dissolve 15·89 parts of the same salt. Z. Karaoglanoff also made observations on this subject. T. Garside found that when 14 parts of barium sulphate are added to 100 parts of sulphuric acid, sp. gr. 1·843, and the mixture stirred, a nearly clear soln. is obtained; when this is heated to 100°, needle-shaped crystals separate which do not redissolve in the cold acid; when the temp. is raised to 170°, the needle-shaped crystals are replaced by others of a prismatic shape which increase in quantity as the temp. is raised. At the b.p., the acid still retains in soln. 8·5 to 9·0 parts of the salt.

According to J. J. Berzelius, barium sulphate, or, according to Liès Bodart and E. Jacquemin, barium oxide, borate, phosphate, chloride, etc., dissolve in conc. sulphuric acid, forming a soln. which furnishes acicular crystals of the acid sulphate, **barium hydrosulphate,** $Ba(HSO_4)_2$. J. J. Berzelius prepared barium hydrosulphate, $Ba(HSO_4)_2$, by allowing barium sulphate to stand for some days in contact with warm conc. sulphuric acid when small crystals of the hydrosulphate separated out, and prismatic crystals were formed as the soln. cooled. C. Schultz digested a soln., sat. at 100°, with a not too large excess of barium sulphate, until the separation of crystals of the hydrosulphate began. The soln. then contained less barium sulphate than the original soln. sat. at 100°. The crystals melt over 100° with partial decomposition. According to Liès Bodart and E. Jacquemin, they are decomposed by water, alcohol, or ether; and, according to J. J. Berzelius, and C. Schultz, they form a soln. in moist air from which acicular crystals of the dihydrated hydrosulphate, $Ba(HSO_4)_2.2H_2O$, separate. In J. D. Barter's study he obtained evidence of the existence of $3BaO.8SO_3.7H_2O$, and $4BaO.5SO_3.6H_2O$. J. Kendall and A. W. Davidson obtained crystals of **barium hydrotetrasulphate,** $BaSO_4.3H_2SO_4$, and found the f.p. of soln. of barium sulphate in sulphuric acid to be:

Per cent. $BaSO_4$	0·0	2·12	5·46	6·70	6·70	7·30	8·59
F.p.	10·4	6·6	−3·2	−7·3	5·7	12·4	23·0
Solid phase	H_2SO_4				$BaSO_4.3H_2SO_4$		

Soln. containing more than 7 molar per cent. of barium sulphate deposited crystals on heating, which redissolved on cooling. The results are plotted in Fig. 42.

According to P. P. von Weimarn, the solubility of barium sulphate in sulphuric acid, when the amounts of H_2SO_4 are expressed in grams per 100 grms. of solvent, and the $BaSO_4$ in grams per 100 c.c. of solvent, at 20°, is:

H_2SO_4	73·83	78·04	83·10	85·78	88·08	96·17	96·46
$BaSO_4$	0·0030	0·0135	0·0800	0·3215	1·2200	4·9665	18·6900
Solid phases	$BaSO_4.H_2SO_4$			$BaSO_4.2H_2SO_4.H_2O$		$BaSO_4$.	

E. Volchonsky reported that, at ordinary temp., the solid phase of soln. containing 87·36 per cent. and 92·48 per cent. sulphuric acid respectively has the composition in each case, $BaSO_4.(H_2SO_4)_2:H_2O$, but at 93° the solid phase at the lower conc. consists of 94·94 per cent. $BaSO_4$, that of the higher conc. consists of 68·16 per cent. $BaSO_4$ and 31·26 per cent. H_2SO_4, the salt being anhydrous and crystallizing in needles. As the temp. rises so the solubility of the compound, $BaSO_4.(H_2SO_4)_2.H_2O$, increases, whilst that of the salt, $BaSO_4.H_2SO$, decreases. The curve for the three solid phases, $BaSO_4$; $BaSO_4.H_2SO_4$; $BaSO_4.(H_2SO_4)_2.H_2O$, is given. The temp. of decomposition of the last salt is about 53°, and its transformation into $BaSO_4.H_2SO_4$ and into $BaSO_4$ are both endothermic reactions. The compound $BaSO_4.H_2SO_4$, deomposes at about 158°–160°, and its transformation into $BaSO_4$ is also an endothermic reaction. According to F. Bergius, 100 c.c. of a sat. soln. of barium sulphate in absolute sulphuric acid contain 28·51 grams of barium sulphate with the solid phase $BaSO_4.30H_2SO_4$, but the results are inaccurate, since the soln. were not in equilibrium with the solid phase. E. H. Riesenfeld and H. Feld electrolyzed a soln. of barium sulphate in 90 per cent. sulphuric acid, and showed that the so-called acid sulphate is really a complex acid, $H_2[Ba(SO_4)_2]$; and, added J. Meyer and W. Friedrich, 100 c.c. of 97·86 per cent. sulphuric acid at 25° dissolves 14·91 grms. of barium sulphate as barium hydrodisulphate, or *hydrobariosulphuric acid*, or *hydrosulphatobaric acid*, $H_2Ba(SO_4)_2$. By electrolysis, the complex accumulates in the anode compartment and can be crystallized from the anode liquor.

W. C. Taber found that the solubility of calcium sulphate is increased by *phosphoric acid*, but the curve has a maximum; at 25°, this is attained when the conc. of the phosphoric acid is 230 grms. per litre, and this soln. dissolves 8 grms. of calcium sulphate per litre. The sp. gr. of the soln. were also measured. T. Scheerer found barium sulphate is soluble in soln. of the alkali phosphates owing to the formation of some soluble barium phosphate. A. Beyer also measured the effect of *carbonic acid* on the solubility of calcium sulphate, and found 100 parts of water sat. with carbon dioxide dissolve 0·465 grm. of this salt. According to P. Carles natural waters may contain both barium hydrocarbonate, $Ba(HCO_3)_2$, and alkali sulphates in soln., and he therefore infers that *alkali carbonates* can dissolve barium sulphate in the presence of carbonic acid. J. Davy found very little difference between the solubility of dihydrated calcium sulphate in water sat. with carbon dioxide under press., and in water alone.

In general, the solubility of calcium sulphate in water is augmented if a salt with no common ion is present, and decreased by the addition of a salt with a common ion. According to F. Margueritte,[4] if a soln. of gypsum be mixed with ammonium, potassium, or sodium nitrate or chloride, the calcium sulphate is alone precipitated when alcohol is added. The presence of *sodium chloride* augments the solubility of calcium sulphate, so that, according to J. B. Trommsdorff, calcium sulphate is not precipitated by sulphuric acid from a soln. containing sodium chloride. N. A. Orloff found a 20 per cent. soln. of sodium chloride dissolved twice as much calcium sulphate as a 1 per cent. soln. M. M. P. Muir investigated the equilibrium of aq. soln. of alkali chlorides and calcium sulphate. Measurements of the solubility of calcium sulphate in aq. soln. of sodium chloride have been made by H. W. F. Wackenroder, J. H. Droeze, G. Lunge, F. K. Cameron and B. E. Brown, C. Cloez, J. B. Trommsdorff, and A. d'Anselme. According to W. A. Tilden and W. A. Shenstone, 100 c.c. of a p per cent. soln. of sodium chloride dissolves the following amounts of calcium sulphate at the temp. stated:

	20°	44°	67°	85°	101°	130°	169°	225°
Per cent. NaCl .	19·90	19·93	19·95	19·90	20·08	19·92	20·05	21·00
Grms. $CaSO_4$.	0·823	0·830	0·832	0·823	0·682	0·392	0·244	0·178

F. K. Cameron gives for the solubility, at 23°, in grams per litre:

Grms. NaCl . .	0·99	10·40	49·17	75·58	129·50	197·20	229·70	315·55
Grms. $CaSO_4$.	2·37	3·54	5·94	6·74	7·50	7·25	7·03	5·37

The last-named soln. was in contact with both gypsum and sodium chloride in the solid phase. The solubility of calcium sulphate in soln. of sodium chloride follows the same general law in showing a maximum point as in aq. soln. for temp. up to 37·5°, above that temp. the existence of a maximum has not been established. Sp. gr. measurements show that there is a condensation of water as a solvent when gypsum and sodium chloride are together brought into soln. G. Arth and M. Crétien stated that when calcium sulphate is dissolved in soln. of sodium chloride at temp. below 62·5° to 65·0°, the soln. apparently contain more lime than is eq. to the sulphuric acid present, and at higher temp. the reverse is the case. If this be correct, it follows that below 62° there is a marked hydrolysis of calcium sulphate in the presence of soln. of sodium chloride; more lime than sulphuric acid passes into soln., and at a higher temp., a new solid phase separates, containing relatively more sulphuric acid than is required by the formula $CaSO_4$. F. K. Cameron has shown that G. Arth and M. Crétien's method of analysis was probably defective, for he could find no appreciable hydrolysis of calcium sulphate ; nor, within a temp. range of 25° to upwards of 80°, could he detect a double salt in soln. of any conc. of sodium chloride. F. K. Cameron and A. Seidell found that the solubility of gypsum in soln. containing up to 9 per cent. of sodium chloride, is but little affected by the presence of solid calcium carbonate, but beyond this conc., the solubility is considerably diminished, so that with soln. with 140 grms. of sodium chloride per litre, the maximum solubility attains 7·5 grms. of gypsum per litre, and in the presence of calcium carbonate this solubility becomes 5·0 grms. per litre, and attains a maximum of 6·35 grms. per litre in soln. containing 80–90 grms. of sodium chloride per litre—with water alone, the maximum solubility is 2·1 grms per litre. A. Manuelli measured the solubility of gypsum in *sea-water* from the Adriatic and in various mixtures of it with distilled water. The results show that an approximately fixed proportion of calcium sulphate is dissolved by sea-water and its aq. soln. containing 12–37 parts of saline residue per 1000. The constancy of the relations is attributed to the enormous extent to which river waters are diluted in the whole mass of sea-water, and not to the attainment of a state of saturation with respect to certain salts. H. Ehlert found 5 and 10 per cent. and sat. soln. of sodium chloride dissolved respectively 0·07005, 0·0934, and 0·22183 grm. of barium sulphate per litre of solvent.

A. Ditte found the solubility of calcium sulphate in aq. soln. of *potassium chloride, potassium bromide,* and *potassium iodide* to be respectively 7·5, 7·3, and 6·00 grms. of $CaSO_4$ in soln. with respectively 125, 200, and 250 grms. of the potassium salt per litre. He added that double salts were formed with respectively 125, 250, and 300 grms. of the potassium salt per litre. According to H. W. F. Wackenroder, strontium sulphate dissolves slowly and completely in a soln. of sodium chloride, while barium sulphate under similar conditions is not appreciably attacked. The last statement is also confirmed by R. H. Brett, and G. C. Wittstein. The strontium salt is precipitated from its soln. in sodium chloride by the addition of sulphuric acid. A. Virck found the solubility of strontium sulphate in aq. soln. of potassium and sodium chlorides to be :

	Sodium chloride.			Potassium chloride.		
Grms. salt in 100 grms. soln. . .	8·44	15·54	22·17	8·22	12·54	18·08
Grms. $SrSO_4$ in 100 grms. solvent .	0·165	0·219	0·181	0·193	0·193	0·251

J. Wolfmann has studied the solubility of strontium sulphate in aq. soln. of the alkali chlorides. R. Fresenius also found that the solubility of barium sulphate is not appreciably affected by the alkali chlorides or *potassium chlorite* soln.

The solubility of calcium sulphate is decreased in the presence of *calcium chloride.* Expressing the results in grams per litre, F. K. Cameron and A. Seidell found at 25° :

$CaCl_2$ . .	0	7·489	11·959	25·770	97·023	192·705	280·303	367·850
$CaSO_4$ . .	2·056	1·244	1·181	1·096	0·841	0·465	0·203	0·032

The solubility of gypsum thus decreases very rapidly as the conc. of the calcium chloride increases ; when the conc. of the latter salt has attained 20 grms. per litre the solubility of the calcium sulphate decreases slowly until, by extrapolation, when the conc. has attained 375 grms. $CaCl_2$ per litre, practically no sulphate would be dissolved. The solubility of calcium sulphate in soln. of the chloride has also been measured by N. A. Orloff, F. K. Cameron and B. E. Brown, and by W. A. Tilden and W. A. Shenstone. The latter worked at temp. ranging from 15° to 195°. A. Virck found that aq. soln. of 8·67, 61·51, and 33·70 grms. of calcium chloride per 100 c.c. dissolved respectively 0·176, 0·185, and 0·171 grm. of strontium sulphate per 100 grms. of solvent. J. Wolfmann measured the solubility of the salt in soln. of the nitrates of the alkaline earths.

F. K. Cameron and A. Seidell measured the solubility of calcium sulphate in soln. of *magnesium chloride*, at 26°, and, expressing the results in grams per litre, found:

$MgCl_2$	0	8·501	19·175	46·640	121·381	206·985	336·985	441·128
$CaSO_4$	2·082	4·258	5·692	7·588	8·622	6·567	2·774	1·385

There is thus a well-defined maximum in the solubility curve attaining 8·8 grms. of calcium sulphate per litre in soln. with about 105 grms. of magnesium chloride per litre. This soln. therefore contains four times as much calcium sulphate as a sat. soln. of this salt alone. Beyond the maximum, the solubility of calcium sulphate decreases quite rapidly as the conc. of the magnesium chloride increases, until, in a soln. containing 370 grms. per litre, the solubility of gypsum is the same as in water alone. Other determinations of the solubility of calcium sulphate in soln. of magnesium chloride have been made by F. K. Cameron and B. E. Brown, and by W. A. Tilden and W. A. Shenstone. A. Virck measured the solubility of strontium sulphate in aq. soln. containing 1·59, 4·05, and 13·63 grms. of magnesium chloride per 100 grms. of soln., and found 100 grms. of the solvent dissolved respectively 0·199, 0·206, 0·242 grms. of strontium sulphate. The solubility of barium sulphite in aq. soln. of *ferric chloride*, *aluminium chloride*, or magnesium chloride was found by G. S. Fraps to decrease in the order named. The last-named salt exercises but a small influence on the solubility. His results expressed in grams of salt per 100 c.c. of soln:

Salt per 100 c.c.		0·1	0·25	0·5	1·0	2·5	5·0	10·0
Grms. $BaSO_4$	$FeCl_3$	0·0058	0·0072	0·0115	0·0123	0·0150	0·0160	0·0170
	$AlCl_3$	0·0033	0·0043	0·0060	0·0094	0·0116	0·0170	0·0175
	$MgCl_2$	0·0030	0·0030	0·0033	0·0033	0·0050	0·0050	0·0050

The subject was also investigated by R. Fresenius, P. Rohland, Z. Karaoglanoff, and by P. Jannasch and T. W. Richards. The latter attribute the effect with ferric chloride to the formation of a soluble double ferric barium sulphate, and add that in a soln. containing ferric chloride, "an accurate determination of sulphuric acid by direct precipitation with barium chloride is not practicable." F. W. Küster found the presence of *chromic chloride*, $CrCl_3$, also augmented the solubility of barium sulphate, and E. White observed similar results with *thorium chloride* soln. Z. Karaoglanoff measured the effect of *lead nitrate* on the solubility of barium sulphate. There is an interaction of the two salts, and the barium sulphate increases in weight.

The solubility of calcium sulphate in soln. of *ammonium chloride* of different conc. has been measured by R. Fassbender, S. Cohn, A. Ditte, etc. W. A. Tilden and W. A. Shenstone measured the solubility in a soln. of ammonium chloride of fixed conc. at temp. between 8° and 120°. Expressing the results in grams of the respective salts per litre, F. K. Cameron and B. E. Brown found at 25°:

NH_4Cl	10·8	46·7	94·5	149·7	198·6	210·0	275·0	375·3
$CaSO_4$	3·9	7·07	8·8	10·30	10·85	10·88	10·60	7·38

The last-named soln. is sat. with respect to the two salts in the solid phase. The solubility of calcium sulphate thus increases with increasing conc. of ammonium chloride until 210 grms. per litre are present, when 10·9 grms. of calcium sulphate are dissolved; while a further increase in the conc. of the ammonium chloride decreases the solubility of the calcium sulphate until both salts are present as solid phases. R. H. Brett reported strontium and barium sulphate to be insoluble in soln. of ammonium chloride, G. C. Wittstein and H. W. F. Wackenroder made a similar observation with respect to barium sulphate; but, according to O. L. Erdmann, 100 parts of a boiling soln. of ammonium chloride can dissolve 0·000435 part of barium sulphate, and, according to H. Ehlert, a litre of a 10 per cent. and of a sat. soln. of ammonium chloride can dissolve 0·15178 and 0·46117 grm. of barium sulphate.

A. Vogel, R. Fassbender, and J. H. Droeze have made some observations on the solubility of calcium sulphate in soln. of potassium or sodium nitrate. The solubility of calcium sulphate in aq. soln. of *sodium nitrate* was found by A. Seidell and J. G. Smith to increase steadily with increasing conc. until the soln. contained 300 grms. of the sodium salt per litre; and beyond this, the amount of sulphate dissolved decreased as the conc. of the nitrate increased. Expressing the results in grams per litre, at 25°:

$NaNO_3$ . .	0	25	50	100	200	300	600	655
$CaSO_4$ . .	2·084	4·252	5·500	7· 00	8·790	9·282	7·886	7·238

The sp. gr. of the soln. were also determined. With *potassium nitrate* likewise, the solubility of the calcium sulphate increased as the conc. of the nitrate increased until 200 grms. of the latter salt per litre were present:

KNO_3 . .	0	12·5	25	50	100	150	200	260
$CaSO_4$ . .	2·084	3·284	4·080	5·255	6·855	7·907	8·688	—

So far the determination of lime or sulphate in soln. are in agreement, but this is no longer the case with more conc. soln. of the nitrate—*e.g.* with 260 grms. of KNO_3 per litre, the sulphate determination furnishes by calculation 6·278 grms. of $CaSO_4$ per litre, and the lime determination, 12·112 grms. of $CaSO_4$. The discrepancy is due to double decomposition and the formation of a new solid phase of syngenite, $Ca(KSO_4)_2.H_2O$. W. D. Harkins and H. M. Paine measured the effect of potassium nitrate on the solubility of calcium sulphate. J. Wolfmann measured the solubility of strontium sulphate in the presence of nitrates of the alkalies and alkaline earths. J. J. Berzelius, R. Fresenius, and M. Mittentzwey found that the solubility of barium sulphate is raised by the alkali nitrates, but is not perceptibly influenced by *barium nitrate*. M. Raffo and G. Rossi found that at room temp. 100 c.c. of sat. soln. of strontium sulphate with various proportions of *calcium nitrate* contained, in grms.:

$Ca(NO_3)_2$ . . .	0·5	1	2	3	4	5	6
$SrSO_4$ . . .	0·0483	0·0619	0·1081	0·1275	0·1489	0·1698	0·1955

H. Ehlert found a litre of a 10 per cent. and a sat. soln. of sodium nitrate dissolved 0·35609 and 1·2959 grms. of barium sulphate at 18°. H. J. Phillips found *copper nitrate* raises the solubility of barium sulphate, but *copper chloride* does not. The solubility of calcium sulphate is steadily depressed when increasing proportions of calcium nitrate are added to the solvent. Thus, expressing the results in grams per litre, at 25°, A. Seidell and J. G. Smith found:

Added salt . .	0	25	50	100	300	400	514	544
$CaSO_4$ with $Ca(NO_3)_2$	2·084	1·238	1·196	1·134	0·759	0·569	—	0·346
$CaSO_4$ with $Mg(NO_3)_2$	2·084	5·772	7·884	9·920	14·000	14·683	15·040	—

Z. Karaoglanoff measures the effects of *calcium chloride* and *strontium chloride* on the solubility of barium sulphate. A. Seidell and J. G. Smith found no sign of a maximum value in the solubility of calcium sulphate in soln. of *magnesium nitrate*, but the solubility of the sulphate increases with increasing proportions of the nitrate, and in a nearly sat. soln. of the nitrate, the solubility is nearly seven times as great as it is in pure water The solubility of calcium sulphate in soln. of *ammonium nitrate* has been determined by R. Fassbender, J. H. Droeze, S. Cohn, and F. K. Cameron and B. E. Brown. Expressing the results in grams of salt per litre, at 25°, the latter find:

NH_4NO_3 .	10	55	150	300	550	750	1000	1400	Sat
$CaSO_4$.	3·18	5·80	8·88	10·80	12·02	12·20	11·81	10·02	7·55

showing that the solubility increases rapidly as the conc. of the ammonium salt increases, then gradually approaches a maximum as the conc. attains 750 grms. of the ammonium salt per litre, when 12·02 grms. of calcium sulphate is dissolved. From this point, the solubility of calcium sulphate decreases with increasing conc.

of ammonium nitrate, until both salts exist as solid phases. P. Rohland measured the solubility of barium sulphate in soln. of ammonium nitrate.

Z. Karaoglanoff found that the solubility of barium sulphate in different electrolytes is determined by the anion and cation. The anion SO_4'' diminishes the solubility; the NO_3'-ion increases it; and the Cl′-ion is indifferent. Of the cations, Ba·· decreases the solubility of barium sulphate, while K·, Na·, Sr··, Pb··, Fe···, and H·-ions increase it; and Ca··-ions are indifferent. The solubility of calcium sulphate in aq. soln. of *ammonium sulphate, sodium sulphate, potassium sulphate, rubidium sulphate,* and *cæsium sulphate* is discussed in connection with the double salts of these components. T. Andrews found strontium sulphate dissolves less readily in aq. soln. of sodium sulphate than in water. W. D. Harkins and H. M. Paine, and J. M. Bell and W. C. Taber have measured the effect of *cupric sulphate* on the solubility of calcium sulphate, and, expressing the results in grams per litre, at 25°, the latter found :

CuSO_4 .	1·144	6·048	14·814	29·543	49·382	97·950	196·021	224·916
CaSO_4 .	2·068	1·944	1·760	1·688	1·744	1·931	2·076	2·088

There is a decrease in the solubility of calcium sulphate with increasing proportions of cupric sulphate until a minimum of 1·688 grms. of calcium sulphate is obtained with 30 grms. of cupric sulphate. This is in agreement with the general depression of the solubility of a salt produced by the addition of a common ion. With a further addition of cupric sulphate, there is a sharp rise in the solubility of calcium sulphate, and this is followed by a slower rise as the proportion of copper sulphate increases until both salts are present as solid phases which occurs when the soln. has 2·08 grms. of calcium sulphate and 224·916 grms. of copper sulphate per litre The remainder of the curve would represent the solubility of cupric sulphate in soln. of calcium sulphate, and since the solubility of the latter is small, it will probably have but little effect on the solubility of cupric sulphate. This is in agreement with the value 22·29 grms. per 100 grms. of water found for the solubility of cupric sulphate in water alone. The sp. gr. of the soln. were also determined. H. von Euler found that at 17° a sat. soln. contained 2·31 grms. of calcium sulphate and 7·235 grms. of *silver sulphate,* and had a sp. gr. of 1·0083 ; at 25°, a sat. soln. contained 2·61 grms. of calcium sulphate, 8·11 grms. of silver sulphate, and had a sp. gr. of 1·010. The solubility of calcium sulphate in soln. of *magnesium sulphate* has been investigated by R. Fassbender, W. D. Harkins and H. M. Paine, J. H. Droeze, E. E. Basch, and F. K. Cameron and J. M. Bell. Expressing the results in grams per litre, the latter found at 25° :

MgSO_4 . .	0	6·38	10·64	21·36	64·14	128·28	149·67	355·0
CaSO_4 . .	2·046	1·507	1·471	1·478	1·608	1·627	1·597	0·501

There is a minimum in the curve with soln. having approximately 13 grms. of magnesium sulphate and 1·46 grms. of calcium sulphate per litre ; from this point, the solubility gradually increases with increasing amounts of magnesium sulphate to a maximum with about 105 grms of magnesium sulphate, and 1·64 grms. of calcium sulphate per litre ; from this point, the solubility decreases again until the soln. is sat. with both salts, which occurs with a conc. of 355 grms. of magnesium sulphate, and 0·50 grm. of calcium sulphate per litre. The sp. gr. of the soln. were also measured. C. Diehl, and F. Field found calcium sulphate to be readily soluble in a cold sat. soln. of *sodium thiosulphate,* and more rapidly when heated. The former assumes that the two salts in soln. react producing a double salt. He reported strontium sulphate to be insoluble in a soln. of sodium thiosulphate. R. Fresenius, and T. Salzer reported barium sulphate to be distinctly soluble in a soln. of sodium thiosulphate. L. Dobbin has also emphasized the fact that the presence of thiosulphate greatly retards or entirely prevents the precipitation of barium sulphate. Dil. hydrochloric or nitric acid also dissolves appreciable amounts of barium sulphate in the presence of sodium thiosulphate. Several analytical processes have been devised which are stultified owing to the solubility of barium sulphate in this menstruum. H. de Sénarmont found the solubility of barium sulphate is not appreciable in soln. of *sodium sulphide* at 250°.

J. W. Marden measured the solubilities of barium, strontium, and calcium sulphate in soln. of *ammonium acetate*, and expressing the conc. of the ammonium acetate soln. in grams of salt per 100 grms. of soln., and that of the sulphate in grams per 100 grms. of soln., at 25°, found :

Amm. acetate	0	2·13	5·34	10·68	21·37
$CaSO_4$	0·2085	0·454	0·754	1·146	1·755
$SrSO_4$	0·0151	0·0451	0·0732	0·0942	0·015
$BaSO_4$	0·00023	—	—	—	0·016

The sp. gr. of some of these soln. were also measured. G. C. Wittstein found the solubility of calcium sulphate is raised in the presence of *ammonium succinate ;* O. Popp made a similar observation with respect to *ammonium borate*, and found that when a boiling soln. is cooled, calcium borate crystallizes out. R. Spiller found that the solubility of barium sulphate is much influenced by *citrates*, and J. Wolfmann measured the solubility of strontium sulphate in salts of the organic acids. G. Magnanini found that at 20°, while water dissolved 0·2238 grm. of calcium sulphate per 100 grms. of soln., a 0·005*N*-soln. of *potassium hydrotartrate*, $KHC_4H_4O_6$, dissolved 0·2323 grm., and the same soln. with 5 per cent. of tartaric acid dissolved 0·2566 grm. of calcium sulphate. Again, a 10 per cent. soln. of alcohol dissolved 0·0970 grm. of calcium sulphate per 100 grms. of soln., a 0·005*N*-soln. of potassium hydrotartrate in 10 per cent. alcohol dissolved 0·0866 grm. of calcium sulphate, and a 0·0025*N*-soln. of potassium hydrotartrate in 10 per cent. alcohol with 5 per cent. of tartaric acid, dissolved 0·1086 grm. of calcium sulphate per 100 grms. of soln. V. Teodossiu found that a 0·2 molar soln. of *ammonium citrate* at 20° dissolved in 3 hrs. 2·59 grms. of $CaSO_4$; 0·68 grm. of $SrSO_4$; and 0·21 grm. of $BaSO_4$.

A. M. Ossendowsky found that 100 grms. of *glycerol* of sp. gr. 1·256 dissolve 5·17 grms. of calcium sulphate between 15° and 16° ; and E. Asselin, 100 grms. of glycerol of sp. gr. 1·114, dissolve 0·95 grm. of calcium sulphate at ordinary temp. F. Stolle measured the solubility of calcium sulphate in soln. of *sugar* of different conc. between 30° and 80°. The solubility is depressed by increasing the conc. of the sugar, and it is also depressed by raising the temp. although some anomalies appear about 70°. E. Sostmann has also made observations on this subject. According to J. M. Kolthoff and E. H. Vogelenzang, at 19°, 25 and 50 per cent. *ethyl alcohol* dissolve respectively 19 and 0 mgrms. of strontium sulphate per litre ; and 50 per cent. alcohol with respectively $\frac{1}{10}N$-HCl and $\frac{1}{10}N$-NH_4Cl dissolve 120 and 40 mgrms. of strontium sulphate per litre. Strontium sulphate is said to be insoluble in absolute alcohol, and scarcely soluble in aq. alcohol. A. Gawalowsky found barium sulphate to be appreciably soluble in soln. of *hydrogen peroxide.*

§ 19. The Properties of the Sulphates of the Alkaline Earths

According to J. H. van't Hoff and F. Weigert,[1] the **crystals** of anhydrous calcium sulphate occurs in two modifications: (i) the stable rhombic bipyramids of anhydrite, with axial ratios $a:b:c=0{\cdot}8932:1:1{\cdot}008$; and (ii) the metastable soluble calcium sulphate which, in contact with water, very easily passes to gypsum, and by longer contact with boiling water, passes into anhydrite. The metastable form is readily produced by the dehydration of gypsum below 100°, and, according to A. Lacroix, it probably forms triclinic crystals which show plagioclase twinning, but W. A. Davis says that its close relationship with the hemihydrate, and its straight extinction, show that it is more probably rhombic. No change in crystalline form is observed when the hemihydrate is converted into soluble anhydrite, or when the latter is converted into the former. R. Grengg found that the hexagonal prisms of the hemihydrate obtained by digesting gypsum with warm nitric acid, or by heating gypsum with a conc. soln. of sodium chloride, are repeated by twinned rhombic crystals. Gently heating the prisms in paraffin increases the double refraction, without altering the external form and soluble anhydrite is produced. Insoluble anhydrite is formed at 360°, and the crystals, still rhombic, are arranged in parallel fibres, giving the appearance of optically uniaxial crystals.

Strontium sulphate forms rhombic bipyramids of celestine, with axial ratios $a:b:c=0{\cdot}7790:1:1{\cdot}2800$; and barium sulphate forms isomorphous bipyramids with axial ratios $a:b:c=0{\cdot}8152:1:1{\cdot}3136$. A. Lacroix reported a sample of barytes from Templeton near Quebec (Canada) in monoclinic crystals. He claimed this to be an example of dimorphism, and named the mineral *michellevite* after A. Michel-Lévy. The mixed crystals of barium and strontium sulphates occur in nature as indicated in connection with the occurrence of these earths. J. F. W. Johnston obtained acicular crystals of hemihydrated calcium sulphate belonging to the rhombic system; and J. H. van't Hoff also obtained needle-like crystals of this hydrate from gypsum. According to A. Lacroix, these crystals belong to the hexagonal system, although F. Mylius and J. von Wrochem obtained rhombic crystals of the related hemihydrated calcium chromate. According to W. A. Davis, both forms of the hemihydrate as well as soluble and natural anhydrite all form needles with reactangular ends, and have a straight extinction. The prismatic crystals of dihydrated calcium sulphate, gypsum, belong to the monoclinic system; they have axial ratios $a:b:c=0{\cdot}6898:1:0{\cdot}4132$, and $\beta=98°\ 58'$; they are isomorphous with the corresponding dihydrated calcium chromate, $CaCrO_4.2H_2O$. The optical and electrical axes of gypsum have been determined by H. Rubens. W. A. Davis showed that under the microscope, gypsum crystals consist of small plates with oblique ends (often twinned), or long needles; they show an extinction between crossed nicols at an angle of $52\frac{1}{2}°$ to the long direction. H. Gaudefroy said that the passage from the hemihydrate to the soluble form of anhydrite at 120°–130°, is not accompanied by a change in the form or size of the crystals. The anhydrous salt, however, is less refractive and has a double refraction almost twice that of the hemihydrate. **X-radiograms** of anhydrite have been studied by F. Rinne, and of gypsum by E. Hjalmar, and H. Haga and F. M. Jaeger. The **corrosion figures** of celestine have been studied by F. Rinne and M. Kemter.

W. Grahmann studied the isomorphism of the three anhydrous sulphates of the alkaline earths. The heating curves show a transition at 1193° with calcium sulphate, at 1152° with strontium sulphate, and at 1149° with barium sulphate. Strontium and barium sulphates are miscible in all proportions in both α- and β-forms, and baryto-celestite is therefore a true isomorphous mixture. Calcium and strontium sulphates are completely miscible in the α-form above the transition temp., but in the β-form they are isodimorphous. Addition of strontium sulphate to calcium sulphate first raises the transition temp. up to about 20 mols per cent. strontium sulphate; then up to 80 mols per cent. the transition temp. gradually falls to a minimum at 1010°. The sat. β-mixed crystals co-existing at the eutectic temp. contain 55 to 82 mols per cent. strontium sulphate. The sp. gr. curves indicate that the form of strontium sulphate isomorphous with anhydrite should have a density of 3·55, while the second form of calcium sulphate should have a sp. gr. of 3·29. Barium sulphate and calcium sulphate are likewise isodimorphous and their miscibility is slight, at most 5 mols per cent. of calcium sulphate in the barium sulphate crystals. It is suggested that the term *baryto-celestine* should be confined to minerals containing between 10 and 90 mols per cent. of barium and strontium sulphate.

Numbers have been given [2] for the **specific gravity** of anhydrous calcium sulphate, ranging from 2·736 by H. G. F. Schröder to 3·102 by E. Filhol. N. S. Manross gave 2·969, A. Gorgeu 2·980, and H. Struve 3·028 (12°) for artificial crystals of anhydrite; E. Madelung and R. Fuchs gave 2·9369–2·9468 (0°) for anhydrite; and A. Schrauf, 2·983. J. F. McCaleb found that after heating calcium sulphate to

	200°.	Dull redness.	Bright redness.	M.p.	Fusion.	Anhydrite.
Sp. gr. . .	2·577	2·912	2·890	2·796	2·654	2·907

J. F. W. Johnston gave 2·757 for the sp. gr. of crystals of hemihydrated calcium sulphate, $2CaSO_4.H_2O$; A. Moye gave 2·75; and E. Madelung and R. Fuchs, 2·3081–2·3123 (0°) for gypsum. A. Kenngott gave 2·317 as the mean of fifteen measurements of gypsum, and values ranging from F. Stolba's 2·3057 to A. le Royer and J. B. A. Dumas' 2·322 have been given for the sp. gr. of dihydrated calcium sulphate, $CaSO_4.2H_2O$. O. Pettersson gave 2·3228 (18°) and 2·2745 (19·4°) for the sp. gr. of the powdered dihydrate. The sp. gr. of selenite is between 2·30 and 2·33 and of natural anhydrite 2·92 to 2·98. A. Moye found the sp. gr. of the completely dehydrated salt to be 2·86.

The published values of the sp. gr. of celestine range from F. Mohs' 2·86 to A. Breithaupt's 3·973; E. Madelung and R. Fuchs gave 3·9631–3·9684 (0°) for celestine; and N. S. Manross gave 3·927; and A. Gorgeu, 3·9 for artificial crystals of strontium sulphate; and the numbers for the precipitated strontium sulphate range from C. J. B. Karsten's 3·5883 to J. Schweitzer's 3·9702 (18°); and the last named also gave 3·6679 to 3·6949 (18°) for the ignited precipitate. The reported values for the sp. gr. of barytes range from F. E. Neumann's 4·429 to G. Rose's 4·872. E. Madelung and R. Fuchs gave 4·4657–4·4741 (0°) for barytes; and N. S. Manross gave 4·179 and A. Gorgeu 4·44 to 4·50 for artificial crystals of barium sulphate. The values for precipitated barium sulphate range from H. G. F. Schröder's 4·022 to J. Schweitzer's 4·4881 (18°); the last named gave 4·2688 (18°) for the precipitate dried at 95°, and 4·2942 for the ignited precipitate. E. Wiedemann gave 4·3964 at 14·5° and 4·3963 at 14·9°. Earl of Berkeley found a mean value of 4·4701 between 15·05° and 17·35°, with a deviation of 0·0011 between the maximum and minimum. The best representative values for the sp. gr. of the sulphates at about 15°, are:

	$BaSO_4$	$SrSO_4$	$CaSO_4$ (natural anhydrite)	$CaSO_4$ (soluble anhydrite)	$CaSO_4.\frac{1}{2}H_2O$	$CaSO_4.2H_2O$
Sp. gr. .	4·45	3·84	2·96	2·86	2·75	2·32

A. Lacroix found the monoclinic variety he obtained from Templeton to have a sp. gr. of 4·39 (15°). F. Stolba found the sp. gr. of a sat. soln. of calcium sulphate at 15° to be 1·0022; F. K. Cameron, at 26°, 1·0026; and at 31°, 1·0031. G. A. Hulett and L. E. Allen gave for sat. soln.:

	0°	10°	30°	35°	40°	55°	75°
Sp. gr. .	1·00197	1·00173	0·99789	0·99612	0·99439	0·98796	0·97772

Anhydrite, celestine, and of barytes are each stated to have a **hardness** between 3 and 3·5; while that of gypsum is given between 1·5 and 2.

According to A. Johnsen,[3] cooling by liquid air diminished the **plasticity** of gypsum. P. von Bjerken gave 360 kgrms. per sq. mm. for the **elastic modulus** of gypsum; P. Drude and W. Voigt, 5910 kgrms. per sq. mm. for that of barytes. W. Voigt also measured the elastic modulus of rhombic crystals of barytes along the different axes, and obtained maximum and minimum values of 9582–3715 kgrms. per sq. mm. L. A. Coromilas likewise obtained maximum and minimum values for monoclinic crystals of gypsum—8870–3130 kgrms. per sq. mm. For the **elastic number**—ratio of transverse contraction to longitudinal extension—of samples of grey and red barytes, P. Drude and W. Voigt gave respectively 0·273 and 0·288. W. Voigt gave for the **compressibility** of barytes $1·93\times10^{-6}$ kgrm. per sq. mm. E. Madelung and R. Fuchs gave for gypsum $2·45—1·53\times10^{-6}$ megabars per sq. cm.; for anhydrite, $1·76—1·90\times10^{-6}$ megabars per sq. cm.; celestine, $1·57—1·63\times90^{-6}$ megabars per sq. cm.; and for barytes, $1·74—1·78\times10^{-6}$ megabars per sq. cm.

J. L. Gay Lussac [4] did not decompose the neutral sulphates of the alkaline earths by fire. According to E. Mitscherlich, calcium sulphate melts when heated in a platinum crucible over a blast gas-blowpipe, some sulphur trioxide is given off, and the residue has an alkaline reaction; J. B. J. D. Boussingault found 0·5 to 2·0 grms. of calcium sulphate, when heated over a blast gas-blowpipe, lost all its sulphur trioxide in 20 min. R. Bunsen also found some sulphur trioxide was lost when calcium sulphate was heated over Bunsen's flame. Confirmatory observations on the loss of sulphur trioxide have been made by F. Schott, K. Zulkowsky, etc. By extrapolation from H. Müller's or G. Galcagni and G. Mancini's f.p. curves of mixtures of calcium sulphate and the alkali sulphates, the **melting point** of calcium sulphate is between 1350° and 1375°, but the salt decomposes so readily at 1000°, that an accurate determination cannot be made. As indicated above, W. Grahmann found that calcium sulphate can be melted in an electric furnace without decomposition, and the molten sulphate freezes at 1450°; the cooling curve shows a transition point at 1193°; strontium sulphate has a transition point at 1152°; and barium sulphate at 1149°. J. B. J. D. Boussingault made similar observations with respect to the action of heat on strontium and barium sulphates as those he made on the calcium salt; and M. Darmstadt likewise observed a loss of sulphur trioxide when strontium sulphate is heated in a crucible over Bunsen's flame. F. Jeremin found that when heated in the electric arc, calcium sulphate is reduced to calcium sulphide; and with the barium salt he found some barium sulphate appeared to be volatilized, possibly owing to alternate reduction and oxidation. N. T. de Saussure melted barium sulphate to a white enamel; R. Hare melted barytes in the oxy-hydrogen blowpipe; and F. O. Doeltz and W. Mostowitsch found that barium sulphate, prepared from barium chloride and sulphuric acid, loses weight at 1300°, and that the m.p. on platinum foil is 1453°; when heated for half an hour between 1550° and 1582°, it volatilized completely. The behaviour of barium sulphate when heated depends to some extent on the way it has been prepared; that obtained from ammonium sulphate and barium hydroxide, fused after heating in air for 10–20 mins. on platinum at 1580°, and lost 9 per cent. in weight. W. Vernadsky found that calcium and strontium sulphates over 1200° each pass into a second rhombic modification, and W. Grahmann found that anhydrite, celestine, and heavy spar pass from the β- to α-, probably monoclinic, modifications as the temp. rises above the transition points indicated in Table VIII. E. Jänecke saw that gypsum has an incongruent m.p. at

TABLE VIII.—SOME THERMAL CONSTANTS OF THE ALKALINE EARTH SULPHATES.

	$CaSO_4$.	$SrSO_4$.	$BaSO_4$.
Molecular weight	136·16	183·66	233·46
Melting point	1450°	1605°	1580°
Transition temperature	1193°	1152°	1149°
Time of transformation	60	110	100 secs.

107°, and the liquid which is obtained by compressing gypsum in very dil. soln., the residue has the composition $CaSO_4.\frac{1}{2}H_2O$. O. Ruff and W. Plato obtained a flattened eutectic at 900° with mixtures of barium sulphate with 65 to 82 molar per cent. of barium chloride.

K. E. Guthe gave 0·000025 for the **coefficient of linear expansion** of gypsum between 12° and 25°. G. Linder [5] found the **specific heat** of crystallized anhydrite to be 0·1753 between 0° and 100°, and 0·1908 between 0° and 300°; R. Weber gave 0·1802 at 0°; and for gypsum, 0·254 at 0°; while H. Kopp gave 0·259 between 16° and 46°. For celestine, the latter gave 0·135 between 18° and 51°; and for ignited artificial strontium sulphate, H. V. Regnault gave 0·1428 between 21° and 99°; and 0·1128 for barytes between 10° and 98°. According to P. N. Laschtschenko, the sp. ht. of barytes increases regularly up to about 500°, being 0·114 at 150°; 0·115 at 170°; 0·125 at 300°; and 0·129 at 500° and 1050°. R. Weber found the **heat conductivity** at 0° $K_0=0{\cdot}0123$ cal. per cm. per sec. per degree for anhydrite, $K_0=0{\cdot}0009$ at 0° for artificial gypsum, and $K_0=0{\cdot}0031$ at 0° for natural gypsum. He also gave for the conductivity of anhydrite at θ°, $K=K_0(1+0{\cdot}0024\theta)$. H. Hecht found that if D denotes the sp. gr. and C the sp. ht., what he calls the temp. conductivity $K=a^2DC$, where $a^2=0{\cdot}0030$.

J. Thomsen [6] found the **heat of formation** of anhydrous calcium sulphate to be (Ca, S, 40)=317·4 Cals.; (Sr, S, 40)=330·9 Cals.; (Ba, S, 40)=340·2 Cals.; (Ca, O_2, SO_2)=248·97 Cals.; (Sr, O_2, SO_2)=259·82 Cals.; (Ba, O_2, SO_2)=266·49 Cals.; $Ca(OH)_{2aq.}+SO_{3aq.}=31{\cdot}14$ Cals., similarly, for strontium hydroxide 30·71 Cals., and for barium hydroxide 36·90 Cals.—including the heat of precipitation. M. Berthelot gave (CaO, SO_3)=84 Cals.; (SrO, SO_3), both solid, 95·6 Cals.; and (BaO, SO_3)=102 Cals.; $Ca(OH)_{2solid}+H_2SO_{4solid}=CaSO_{4solid}+H_2O_{solid}+98{\cdot}8$ Cals., similarly, for strontium sulphate, 118 Cals., and for barium sulphate, 132·0 Cals. R. de Forcrand gave for the **heat of hydration,** $CaSO_{4anhydrite}+2H_2O_{liquid}=-3{\cdot}61$ Cals.; he also gave $CaSO_4.2H_2O=\alpha\text{-}CaSO_4.\frac{1}{2}H_2O+1\frac{1}{2}H_2O-3{\cdot}8$ Cals., with $\beta\text{-}CaSO_4.\frac{1}{2}H_2O$, —4·025 Cals., and with $\gamma\text{-}CaSO_4.\frac{1}{2}H_2O$, —4·25 Cals.; and for the conversion of α-, β-, and γ-forms to anhydrite and liquid water, 0·19, 0·415, and 0·64 Cal. respectively. A. Potilitzin gave $(CaSO_4, 2H_2O)$=9·30 Cals.; and $\frac{1}{2}(2CaSO_4.H_2O, 3H_2O)$, 6·10 Cals. J. Thomsen gave —0·60 Cal. for the **heat of solution** of $CaSO_4.2H_2O$; and M. Berthelot found the heat of soln. of $CaSO_4.2H_2O$ to be almost zero at ordinary temp.; negative, a little below 15°; and positive, above 25°. According to R. de Forcrand, the heat of soln. of $CaSO_4.2H_2O$ at 10° is —0·65 Cal.; of $2CaSO_4.H_2O$, 3·56 Cals.; of anhydrous calcium sulphate which had been previously heated to 155°, 5·655 Cals. at 10°, and previously heated to redness, 2·92 Cals. at 10°. M. Berthelot found the heat of soln. of strontium sulphate to be almost zero at ordinary temp., positive below 15°, and negative above 25°. J. Thomsen gave 5·58 for the heat of soln. of barium sulphate; and A. C. Melcher represented the value at T° K. by $Q=30800-85{\cdot}2T$, which gives for 18°, 6 Cals.

The **index of refraction** of anhydrite is moderate, and the double refraction is high. The mean values of the indices of refraction from A. Mühlheims',[7] J. Danker's, and K. Zimanyi's observations for the D-line are, $\alpha=1{\cdot}5696$, $\beta=1{\cdot}5755$, and $\gamma=1{\cdot}6135$; and $\gamma-\alpha=0{\cdot}0439$. The index of refraction of anhydrite has been determined by J. Danker, A. Mühlheims, and K. Zimanyi; of celestine by A. Arzruni, M. Grunenberg, G. H. Williams, and E. Artini; and of barytes by A. Arzruni, J. Danker, K. Feussner, J. C. Heussner, A. Mühlheims, A. Offret, and C. Pulfrich. The indices of refraction for the C-, D-, F-lines for anhydrite (A. Mühlheims), celestine (A. Arzruni), and barytes (A. Arzruni) are:

	Anhydrite.			Celestine.			Barytes.		
Line	α	β	γ	α	β	γ	α	β	γ
C	1·56722	1·57295	1·61056	1·61954	1·62120	1·62843	1·63351	1·63457	1·64531
D	1·56933	1·57518	1·61300	1·62198	1·62367	1·63092	1·63609	1·63712	1·64795
F	1·57472	1·58079	1·61874	1·62790	1·62960	1·63697	1·64254	1·64357	1·65469

The mean refractive index of anhydrite is given as 1·59; of celestine, 1·62; and of barytes, 1·64. The mean double refraction of anhydrite is given as 0·045; of celestine, 0·007; of barytes, 0·012. Gypsum or selenite is optically positive with the plane of the optic axes parallel to the (010)-face at ordinary temp. The mean values of the indices of refraction for the *D*-line, from the observations of V. von Lang, C. Klein, C. Viola, and H. Dufet, are $\alpha : \beta : \gamma = 1{\cdot}5205 : 1{\cdot}5227 : 1{\cdot}5298$, with $\gamma - \alpha = 0{\cdot}0093$ as the mean value of the double refraction. Other observations have been made by A. J. Angstrom, F. Kohlrausch, A. Matthiessen, G. Quincke, C. Pulfrich, and A. E. H. Tutton. A. Hutchinson and A. E. H. Tutton's values for the refractive index of gypsum at different temp. and with light of different wave-lengths, λ, are shown in Table IX.

TABLE IX.—INDICES OF REFRACTION OF GYPSUM.

The mean refractive index of gypsum is taken as 1·52; and the mean double refraction as 0·010.

In 1826, E. Mitscherlich[8] showed that gypsum suffers a larger change in the position of its optic axes with a change of temp. than any other substance then known. At ordinary temp. it is biaxial, with an optic axial angle of 60°, but on raising the temp., the angle diminishes until in the neighbourhood of 100°, the axes come together, producing, in convergent polarized light, the rectangular cross, and circular rings of a uniaxial crystal. Beyond that temp., the axes again separate, but in the direction at right angles to their former one. On allowing the crystal to cool, the phenomena are repeated in the reverse order. This has been called *Mitscherlich's experiment.* He found the inversion temp. to be 91·9°. The crossed-axial-plane dispersion is exhibited by brookite; the triple tartrate of potassium sodium, and ammonium; rubidium sulphate; cæsium selenate; ammonium selenate; cæsium magnesium sulphate; cæsium magnesium selenate; and monoclinic ethyltriphenyl pyrrolone. A. E. H. Tutton has shown that the phenomenon is due to very low double refraction combined with a close approximation of the intermediate index of refraction to one of the extreme indices, and to the fact that change of wave-length of the light or change of temp., or both, cause the intermediate index to approach still nearer to the extreme one in question until it becomes identical with it, and eventually to pass it, the relative positions of the two indices thus becoming reversed. The uniaxial rectangular cross and circular rings are produced at the critical point of identity. This critical point is a function of both wave-length and temp.; it is a fixed one only for a particular wave-length and an assigned temp. A. E. H. Tutton and A. Hutchinson found that the temp. at which selenite becomes uniaxial, given by the former, were a little too high, and that the corrected temp. of optical uniaxiality of gypsum, for different wave-lengths, are:

671 (Li)	656 (H_α=C)	589 (Na=D)	573	535 (Tl)	486 (H_β—F)
90·2°	90·4°	90·9°	91·0°	90·8°	90·1°

E. H. Kraus and L. J. Youngs obtained 89·67°–91·6°. E. Goens showed that the directions of maximum and minimum transparency and reflective power indicate the positions of the optic axes of gypsum.

W. W. Coblentz's[9] measurements of the **absorption spectrum** of selenite and anhydrite are shown in Fig. 43, the former by the continuous line, the latter by the dotted line. With anhydrite there are small absorption bands at 1·9, 3·2, 5·7, 6·15, and 6·55μ, and a large band at 4·55μ due to the SO_4 group. All the absorption bands of selenite coincide with those of water excepting the 4·75μ band of water is shifted to 4·6μ. W. H. Julius showed that the absorption spectrum of a chemical compound is not the composite of the bands of the constituent elements, for the molecules are changed. In selenite, the absorption spectrum is a composite of the bands characteristic of calcium sulphate, $CaSO_4$, and water. The water of crystallization of selenite, $CaSO_4.2H_2O$, is therefore assumed by W. W. Coblentz to be in the mol. state, and the water and anhydrous calcium sulphate to crystallize together, building up a complex crystal much as it is possible to grow a crystal of a mixture of alums. This is assumed because the absorption spectrum of the hydrated salt, $CaSO_4.2H_2O$, is a composite of the spectra of anhydrite, $CaSO_4$, and water, H_2O. If the water were chemically combined in selenite, the absorption bands of water would not appear. The large absorption band with selenite at 4·6μ is characteristic of sulphates. It is generally assumed that if the water passes off from crystals in stages at one, two, or more fixed temp., the water is present as an integral part of the compound, whereas if the water is expelled continuously on a gradually rising temp., it is inferred that absorbed water is involved. Against these assumptions, W. W. Coblentz shows that the absorption spectrum indicates that, in selenite, the water is not chemically combined, although when heated, the water comes off in stages, whereas in tremolite, E. T. Allen and J. K. Clement found that the water comes off continuously, but the absorption bands show no signs of the contained water. The water is given off gradually from the zeolites between 100° and 400°, but it is inferred that the water is not chemically combined to form one sp. mol. because as with opal and selenite, the absorption spectrum is a composite of the spectra of the anhydrous mineral and water.

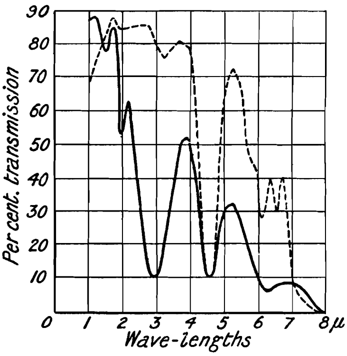

FIG. 43.—Absorption Spectra of Selenite and Anhydrite.

W. W. Coblentz's values for the absorption spectra of barytes and celestine are indicated by the continuous curves in Fig. 44. The reflection curves of anhydrite, celestine, and barytes are represented by the dotted lines. All show the harmonic bands at 4·55μ and 9·1μ, as in the case of anhydrite. The region 6μ to 7μ is characteristic of the sulphate. T. Liebisch and H. Rubens studied the optical behaviour of strontianite in the ultra-red rays.

According to P. Bary,[10] calcium sulphate shows no **phosphorescence** when exposed to **X-rays** or **Becquerel rays,** while barium sulphate does phosphoresce under these conditions. E. Wiedemann, and H. Jackson studied the luminescence of calcium sulphate, particularly when mixed with manganese sulphate, on exposure to **cathode rays.** Colourless selenite crystals decompose at a low temp. without showing thermo-luminescence. According to E. Newbery and H. Lupton, when selenite is exposed to **radium rays,** certain parts are coloured brown. The blue colour of some varieties of anhydrite, celestine, and barytes can be discharged by heat; and some colourless specimens are coloured blue by exposure to radium rays. The crystals exhibit a green phosphorescence during exposure to radium. P. Schuknecht found the spectrum of the phosphorescence produced by Röntgen and cathodic rays extends far into the ultra-violet.

K. Przibram and E. Kara-Michailova[11] studied the effect of the high-potential discharge on the surface of a plate of gypsum. J. Königsberger and K. Schilling found rhombic barium sulphate conducted an electric current electrolytically, by ions. A. C. MacGregory, W. Böttger, and others have measured the **electrical conductivity** of aq. soln. of calcium sulphate. G. A. Hulett and L. E. Allen measured the eq. conductivity of sat. soln. between 0° and 65°. F. Kohlrausch found a cm. cube of sat. soln. at 18° had a conductivity $\lambda=18\cdot85\times10^{-4}$ rec. ohms. A. C. MacGregory found the temp. coeff. between 18° and 26° to be 0·023 per degree. F. Kohlrausch and F. Rose, A. F. Hollemann, A. C. Melcher, and A. C. MacGregory have measured the electrical conductivity of soln. of strontium and barium sulphates, and from the results calculated the solubility of the salt in water. For sat. aq. soln. at 18°, F. Kohlrausch found for precipitated barium and strontium sulphates $\lambda=2\cdot4\times10^{-6}$ and 127×10^{-6} rec. ohms respectively; and for heavy spar and celestine, respectively $\lambda=2\cdot7\times10^{-6}$ and 127×10^{-6} rec. ohms; and for a sat. soln. of gypsum $\lambda=1885\times10^{-6}$ rec. ohms. For the conductivity of a sat. soln. of heavy spar at $\theta°$ between 10° and 26°, he found $\lambda=2\cdot7\times10^{-6}\{1+0\cdot0232(\theta-18)+0\cdot00010(\theta-18)^2\}$;

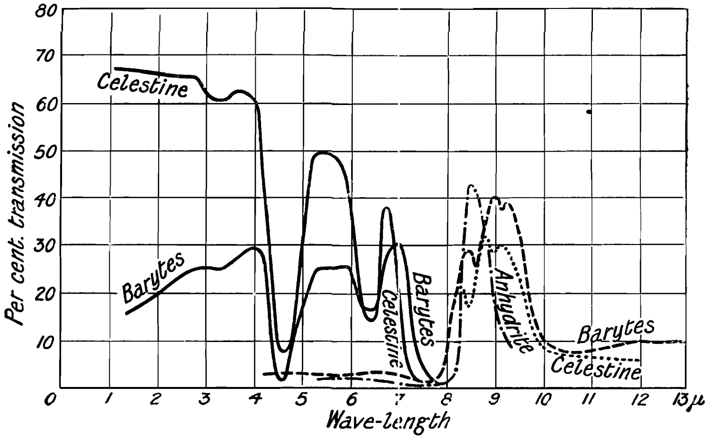

FIG. 44.—Absorption Spectra of Barytes and Celestine.

and for celestine, $\lambda=127\times10^{-6}\{1+0\cdot0230(\theta-18)+0\cdot00009(\theta-18)^2\}$. G. A. Hulett suggested a sat. soln. of gypsum as a standard for conductivity determinations; he represented the conductivity between 10° and 30° by $0\cdot002208+0\cdot0_445(\theta-25)+0\cdot0_61626(\theta-25)^2$; and the sp. conductivity λ is related with the conc. C, in mgrm. mols per litre, by $C=-0\cdot354+5211\lambda+841400\lambda^2$. P. Walden measured the conductivity of soln. of strontium sulphate in conc. sulphuric acid. B. D. Steele and R. B. Denison found the **transport number** for the cation in $0\cdot005N$-soln. of calcium sulphate to be 0·441; J. F. Daniell and W. A. Miller also experimented on the subject in 1844. J. A. Muller represented the **heat of ionization,** q, of barium sulphate at the absolute temp. T by $-q=105502\cdot32-696\cdot357T+1\cdot2118T^2$. G. N. Lewis and M. Randall calculated the activity coeff. of the ions.

According to R. Fellinger,[12] the **dielectric constants** of barytes for the α-, β-, and γ-axes, for definite wave-length, are respectively 6·17, 10·09, and 7·00; and, according to W. Schmidt, for wave-lengths of 75 cms., these constants are respectively 6·65, 12·20, and 7·70, and for celestine respectively 7·70, 18·5, and 8·20. For gypsum, C. B. Thwing gave 5·61; J. Curie, 6·33; H. Starke, 5·04; and M. von Pirani, 5·66. According to S. Meyer, the **magnetic susceptibility** of anhydrite is $-0\cdot38\times10^{-6}$ at 17°; and of gypsum, $-0\cdot36\times10^{-6}$. P. Pascal gave for the mol. coeff. of magnetization of $BaSO_4$, 713×10^{-7}; $SrSO_4$, 597×10^{-7}; $CaSO_4$, 496×10^{-7}; and $CaSO_4.\frac{1}{2}H_2O$, 557×10^{-7}.

B. Unger[13] found that when heated in a stream of **hydrogen,** calcium sulphate is reduced to the sulphide which, according to O. Schumann, is mixed with about one-seventh of calcium oxide. Strontium under similar conditions furnishes the sulphide mixed with one-thirteenth of oxide. Hydrogen likewise reduces barium sulphate. Anhydrous calcium sulphate obtained by heating selenite to redness, or by evaporation with conc. sulphuric acid, is not hygroscopic and does not change in weight on exposure to air; the anhydrous salt made by heating selenite sufficiently to expel the water without loss of sulphuric anhydride is hygroscopic. The latter also gives off sulphuric acid more readily than the former. E. Jacquemin found **water vapour** reduces red-hot barium sulphate forming carbon monoxide, hydrogen sulphide, and barium oxide. R. A. Tilghmann passed water vapour over a red-hot mixture of calcium sulphate and sodium chloride, and obtained sodium sulphate and hydrogen chloride. According to F. Knapp, the silica of the containing vessel plays a part in this reaction. According to O. Siemens, if water vapour is passed over a molten mixture of sodium chloride with twice its weight of calcium sulphate, hydrogen chloride, sulphur dioxide, and hydrogen sulphide are evolved; and a mixture of carbon dioxide and water vapour produces only sulphur dioxide and hydrogen chloride. The residue contains undecomposed sodium chloride, sodium hydroxide, calcium sulphide, and oxide, and small quantities of sodium thiosulphate and sodium sulphite; according to H. L. Buff, the iron of the containing vessels plays an essential part in the reaction. According to E. Ebler and K. Herrdegen, a mixture of **calcium hydride** with barium sulphate when ignited by the thermite process forms a mixture of calcium oxide and barium sulphide: $BaSO_4+4CaH_2=BaS+4CaO+4H_2$; a little barium oxide and calcium sulphide may be formed. The hydrogen does not appear to take part in the reaction. This furnishes a means of getting insoluble sulphates into soln. Some of the sulphates of the heavy metals give the metal itself.

According to M. Cari-Mantrand, **chlorine** transforms red-hot calcium sulphate into the chloride; and **hydrogen chloride** acts in a similar way, liberating sulphur dioxide and oxygen; according to C. Hensgen, the decomposition is complete at a dull red heat; as found by J. B. J. D. Boussingault, the reaction is facilitated by mixing the sulphate with carbon, when calcium chloride, sulphur, carbon monoxide, and hydrogen sulphide are formed. Strontium and barium sulphates, according to J. B. J. D. Boussingault and C. Hensgen, are also completely transformed at a bright red heat by hydrogen chloride into the corresponding chloride. A. B. Prescott found that when 1·00 grm. of calcium, strontium, or barium sulphate is evaporated with 4·035 grms. of **hydrochloric acid** containing 1·251 grms. of HCl, no appreciable quantity of sulphate is decomposed. P. Chroustchoff, and W. Ostwald studied the distribution of sulphuric acid between barium and strontium salts. The contamination of barium sulphate with chlorides when precipitated in the presence of chlorides led G. Hulett and L. H. Duschak and others to suggest that *barium chlorosulphate* is formed, $(BaCl)_2SO_4$, or $Cl.Ba.HSO_4$. The chloride, however, may be simply adsorbed by the sulphate.

C. Matignon and F. Bourion found that when calcium sulphate is heated in a stream of **sulphur chloride,** S_2Cl_2, it is also converted into calcium chloride, and barium sulphate is similarly converted into barium chloride. When barium sulphate is heated with **carbon** to 600°–800°, $BaSO_4+2C=BaS+2CO_2$; and to 1000°–1100°, $BaSO_4+4C=4CO+BaS$. If in an electric furnace with insufficient carbon for complete reduction, $3BaSO_4+BaS=4SO_2+4BaO$, as in C. S. Bradley and C. B. Jacobs' process for barium chloride—*q.v.* The action of carbon on the sulphates of the alkaline earths in the electric arc furnace was studied by E. Kunheim. E. H. Riesenfeld has also studied the reduction of the sulphates of the alkaline earths by carbon and by methane. According to H. Quantin, the vapour of **carbon tetrachloride** converts red-hot barium sulphate into barium chloride and carbon dioxide, carbonyl chloride, and pyrosulphuryl chloride, $S_2O_5Cl_2$. B. Neumann and G. Kotyga studied the action of **ammonium hydroxide** on calcium sulphate; and B. Neumann and W. Gellendien, the action of **ammonium carbonate** on the same salt. H. Rose converted barium sulphate into the chloride by igniting it with **ammonium chloride,** although R. Fresenius found the reaction is incomplete. According to F. Sestini, and A. Violi, when calcium sulphate is heated with **sulphur,** it forms sulphur dioxide and calcium sulphide ; and analogous results were obtained with strontium and barium sulphates. F. le Play and A. Laurent, and C. Stammer reduced calcium sulphate to the sulphide by heating it with **carbon** or **carbon monoxide,** and B. Unger, by heating it with **water-gas.** L. Marino found that the reduction of barium sulphate to barium sulphide is effected by reducing gases better than by coal, which is generally employed at present. The reduction with hydrogen, methane, water-gas, illuminating gas, etc., occurs at about the same temp., as these gases inflame with oxygen, and the temp. of reduction can be lowered by the aid of suitable catalysts, just as combination with oxygen can be favoured by the same means. For commercial purposes the best results are obtained with water-gas, the reduction occurring at 525°–540°. In practice a temp. of 600°–625° is employed. L. Marino and D. Danesi also noted that strontium sulphate requires a higher temp. for the reduction, and calcium sulphate a temp. still higher. The product with barium sulphate is always the sulphide ; with strontium sulphate, the sulphide and a trace of oxide and thiosulphate ; and with calcium sulphate, sulphide, and small quantities of the oxide and thiosulphate. E. Jacquemin reduced strontium and barium sulphates with moist carbon monoxide. According to E. H. Jenkins, hydrated calcium sulphate does not absorb gaseous **ammonia,** but if some of the water is expelled from the hydrate ammonia is absorbed; for example, a sulphate with 0·7 per cent. of water, absorbed 2·27 per cent. of ammonia at ordinary temp. E. Berger used a mixture of sodium or potassium nitrate with 40 per cent. of calcium silicide as a priming mixture for the reduction of calcium or barium sulphate with red **phosphorus.** According to G. Moretti, **arsenic oxide** drives out sulphur dioxide from heated strontium sulphate. A mixture of **iron** filings with barium, strontium, or calcium sulphate was found by A. d'Heurèuse to form ferric oxide and the corresponding sulphide ; *e.g.* $3BaSO_4+8Fe=3BaS+4Fe_2O_3$, but with a less proportion of the sulphide some ferrous sulphite may be produced ; he also found **zinc** reduces strontium sulphate at a dull red heat forming zinc oxide, and strontium oxide and sulphide ; the action with barium or calcium sulphate is similar, but the mixture detonates at dull redness.

Sintered mixtures of calcium oxide and sulphate furnish *Scott's selenitic cement,* as previously indicated. There is no evidence that an oxysulphate is here formed. F. K. Cameron and S. M. Bell studied the ternary system, $CaO—CaSO_4—H_2O$, but found no signs of the formation of a *calcium oxysulphate.* Expressing the results in grams per litre, they found at 25° :

CaO . . .	0	0·062	0·349	0·939	1·222	1·242	1·150	1·166
$CaSO_4$.	2·126	2·030	1·853	1·634	1·588	1·214	0·666	0·00
Solid phases	$CaSO_4.2H_2O$				$CaSO_4.2H_2O+Ca(OH)_2$	$Ca(OH)_2$		

The results are plotted in Fig. 45. The curve *AB* shows that the solubility of calcium hydroxide in an aq. soln. of calcium sulphate is nearly constant, but is slightly more in the more conc. soln. of the sulphate. The curve *BC* shows that the solubility of calcium sulphate decreases regularly as the conc. of the latter increases.

It does not follow that the equilibrium constant in reactions which take place in soln. will be independent of the nature of the solvent. Thus, L. Pissarjewsky and A. Levites found that the equilibrium constant in the reaction, $CaSO_4+2KOH\rightleftharpoons K_2SO_4+Ca(OH)_2$, in a 10 per cent. mannitol soln. is eleven times, and in a 24 per cent. glycerol soln. nine times less than it is in water. This means that the respective solvents do not act as simple catalytic agents. According to J. F. John,[14] barium sulphate is completely decomposed when boiled down to dryness with a soln. of **potassium hydroxide** and the product is a mixture of barium hydroxide and potassium sulphate ; but H. Rose found that barium sulphate is not attacked by a boiling soln. of the alkali hydroxide freed from carbon dioxide, while if carbon dioxide is present barium carbonate is formed. C. J. B. Karsten, on the other hand, reported that barium hydroxide dissolves in a conc. aq. soln. of sodium sulphate between 15° and 19°, and as the soln. is diluted, barium sulphate and sodium hydroxide remain in soln. H. Rose, and H. Reinsch found that no perceptible action occurred when a cold or boiling soln. of **ammonium carbonate** acts on barium sulphate for 20 hrs. A large number of observations have been made on the reaction between aq. soln. of fused **alkali carbonates** and the sulphates of the alkaline earths. There is a difficulty in determining the composition of the product obtained by fusing the two constituents, because, when subsequently treated with water, the reaction may be reversed. Boiling the sulphate with a soln. of sodium or potassium carbonate results in a partial decomposition of the sulphate, but the effect is reversed on cooling. W. Meyerhoffer found that a fused mixture of barium carbonate and potassium sulphate deposits very little, if any, barium sulphate on cooling, but when this mixture is treated with water, a reaction sets up, so that no matter whether barium carbonate is fused with potassium sulphate, or potassium carbonate with barium sulphate, the amount of barium carbonate in the residue is 90–95 per cent. The reaction in aq. soln. in the heterogeneous system: $K_2CO_3+BaSO_4 \rightleftharpoons K_2SO_4+BaCO_3$, is reversible with $BaSO_4$ and $BaCO_3$ as solid phases. From C. M. Guldberg and P. Waage's law, $C_1C_2=K'C_3C_4$, where C_1, C_2, C_3, and C_4 respectively denote the conc. of the salts in the order stated in the chemical equation, the constant $K=C_1/C_3$, when the conc. of the solid phases are regarded as constant. W. Meyerhoffer, however, showed that the ratio $C_1 : C_3$, that is $K_2CO_3 : K_2SO_4$, varies not only with the temp. but also with the conc. of the soln. The system has also been studied by E. Ramann and H. Sallinger. Similar remarks apply to the system: $Na_2CO_3+BaSO_4=Na_2SO_4+BaCO_3$. W. Spring has investigated the influence of press. of 600 atm. on mixtures of solid sodium carbonate and barium sulphate, and reported the conversion of as much as 80·31 per cent. of barium sulphate to the carbonate—*vide* **1.** 13, 18. The corresponding reactions with strontium sulphate were investigated by P. Berthier, H. Grüneberg, H. Rose, and F. J. Malaguti; and with calcium sulphate by P. Berthier. W. Herz studied the equilibria in the systems containing a sulphate of calcium or strontium and an aq. soln. of sodium carbonate.

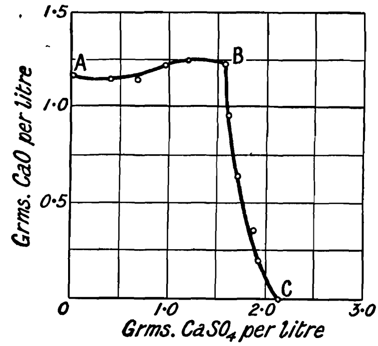

FIG. 45.—Mutual Solubility of Calcium Oxide and Sulphate in Water at 25°.

According to J. B. Trommsdorff, C. J. B. Karsten, H. L. Buff, and A. Levol, no reaction occurs when calcium sulphate is fused with **sodium chloride.** C. J. B. Karsten, and P. Berthier similarly melted barium sulphate with sodium chloride. W. O. de Coninck and L. Arzalier found that barium sulphate is partially decomposed when heated with an aq. soln. of **potassium chloride** for 5 months. According to J. Treumann, a boiling soln. of **ammonium chloride** decomposes a little strontium sulphate. W. O. de Coninck and L. Arzalier found that barium sulphate is partially decomposed when heated with an aq. soln. of **methylamine hydrochloride** for 620 hrs. at 100°. H. Rose melted barium sulphate with **calcium chloride,** and stated that barium chloride and calcium sulphate are formed. P. Chrustschoff and A. Martinoff found that when strontium sulphate is treated with a soln. of **barium chloride,** about 50 per cent. is converted into barium sulphate and strontium chloride in about a couple of hours, and the reaction is complete in a few more hours. P. Berthier, J. J. Berzelius, and T. Scheerer and E. Drechsel fused mixtures of barium sulphate and **calcium fluoride,** and obtained crystalline masses corresponding to $BaSO_4.CaF_2$, but there is nothing to show that a compound is formed. J. Smithson analyzed a Derbyshire mineral of sp. gr. 3·75 containing 51·5 per cent. $BaSO_4$, and 48·5 per cent. calcium fluoride; it was therefore called *fluoro-heavy spar.* P. A. Dufrénoy analyzed the rhombohedral crystals of a mineral called *dreelite,* sp. gr. 3·3, and hardness exceeding that of calcspar. It contained 61·73 per cent. of $BaSO_4$ and 14·27 per cent. of $CaSO_4$; or $BaSO_4 : CaSO_4 = 5{\cdot}2$, as well as some silica, alumina, calcium carbonate, and water.

Uses of gypsum, celestine, and barytes.—Alabaster and mammillated gypsum are used as ornamental stones. Gypsum is used in the preparation of plaster of Paris—which is often sold under various special trade names, for wall plaster, etc. —and of various cements—Keene's cement, Martin's cement, parian cement, etc. Finely-ground gypsum is sold as *mineral white,* or *terra alba,* and is used as filling for paper; in finishing cotton goods; in adulterating paints and various other substances in manufacturing crayons; etc. Gypsum is used by some breweries for hardening the water—*brewer's gypsum*—on the assumption that hard water gives better results—due, it is said, to the greater solvent action of such water on the albuminous matters in the malt. Gypsum is used in making some polishing powders; as a fertilizer for restoring sulphates to certain soils—*e.g.* the hop districts of Kent and Sussex. It is also used as a retarder for the setting of Portland cement. Strontianite and celestine are the main sources of strontium compounds which are mainly used in pyrotechny, and in the beet-sugar industry. The uses of barytes are mainly dependent on the fact that it is a heavy white mineral, cheap, and chemically inert. Precipitated barium sulphate is the *blanc fixe,* and *permanent white* of commerce. The finest qualities are finely ground and used in the preparation of white paints; it is also used as an adulterant for white-lead in paint. Ground barytes—it may be water-floated, or air-elutriated—is admixed with white-lead and zinc oxide, and used in place of white-lead for making paint. The powdered barytes is also tinted with dyes and likewise used as a pigment—*e.g.* the para-red paints have 90 per cent. of barium sulphate.[15] Barytes is used in filling wall papers, glazed paper, rubber goods, linoleum, oil-cloth, flannel, shoddy cloth, etc. It has several minor uses—*e.g.* it is employed as a fluxing agent in certain operations. Barytes and witherite are the main sources of the barium compounds.

§ 20. The Complex Sulphates of the Alkalies and Alkaline Earths

According to H. Müller,[1] mixtures of calcium sulphate and lithium sulphate form neither double salts nor mixed crystals; the f.p. curve is of simple V-type descending from the m.p. of α-lithium sulphate at 874° to the eutectic at 700° with about 18 mol per cent. of calcium sulphate, and rising to near 1350° the extrapolated m.p. of calcium sulphate. The cooling solid undergoes a transformation corresponding with the change to β-lithium sulphate at 572°.

P. Berthier melted together equi-molar proportions of sodium and calcium sulphates and obtained a mass with a fracture like chalcedony. H. Müller obtained evidence of the double salt **sodium calcium pentasulphate,** $CaSO_4.4Na_2SO_4$, on the f.p. curve of mixtures of the component salts, but he could not obtain glauberite, $CaSO_4.Na_2SO_4$, by fusing equi-molar proportions of the two salts, because, on cooling, the product dissociates into anhydrite and a eutectic of anhydrite and $CaSO_4.4Na_2SO_4$. The last-named salt is completely miscible with sodium sulphate, and exists in one doubly refracting variety only—sodium sulphate alone has a transition temp. at 233°, and G. Calcagni and G. Mancini found that no polymorphic change is observed with mixtures containing over 7 per cent. of calcium sulphate. The last named also measured the f.p. curve of binary mixtures of sodium and calcium sulphates, and found that the curve rises from 887°, the f.p. of sodium sulphate to the maximum 949°, Fig. 46, corresponding with **sodium calcium tetrasulphate,** $CaSO_4.3Na_2SO_4$, or $Na_6Ca(SO_4)_4$, the calcium analogue of vanthoffite, $MgSO_4.3Na_2SO_4$. The eutectic point is at 917° and 51 per cent. of sodium sulphate corresponding with the composition of glauberite. Other double salts may exist at lower temp. Two liquid layers occur with mixtures containing 73·0–82·6 per cent. of sodium sulphate. G. Calcagni also studied the f.p. curves of the binary systems, $SrSO_4$—Na_2SO_4, and $BaSO_4$—Na_2SO_4. He found a maximum on the m.p. curve of strontium and sodium sulphates corresponding with the formation of **sodium strontium tetrasulphate,** $3Na_2SO_4 SrSO_4$, the strontium analogue of vanthoffite. The addition of barium sulphate to sodium sulphate raises the m.p. of the latter from 887° to 921° for an addition of 21·6 molar per cent. Further proportions of barium sulphate cause very gradual lowering of the f.p. to 913° for a mixture containing 29 molar per cent. $BaSO_4$. From this point the curve rises continuously to the m.p. of barium sulphate, which extrapolation gives as 1345°. The very flat and scarcely appreciable maximum shown by the curve would correspond with **sodium barium heptasulphate,** $BaSO_4.6Na_2SO_4$, but double sulphates of this type are apparently unknown. Between 71 and 100 per cent. Na_2SO_4, the curve shows a point corresponding with the initial crystallization, a second with the temp. of decomposition of the solid soln., and a third with the temp. of transformation of sodium sulphate. The following regions are distinguished: (1) existence of the homogeneous liquid phase; (2) equilibrium between $BaSO_4$ and liquid phase; (3) existence of solid soln.; (4) equilibrium between solid soln., (3) and α-Na_2SO_4—$BaSO_4$; (5) existence of β-Na_2SO_4—$BaSO_4$; (6) equilibrium between solid soln. (3) and β-Na_2SO_4—$BaSO_4$.

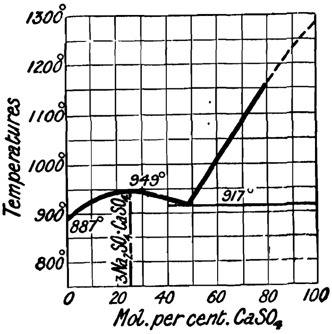

Fig. 46.—Fusion Curve of Calcium and Sodium Sulphates.

The solubility of calcium sulphate is augmented in the presence of sodium sulphate, as was observed by J. H. Droeze, O. Henry, F. K. Cameron and A. Siedell, etc. Expressing the amounts of salt in grams per litre, F. K. Cameron and J. F. Breazeale found, at 15°:

Na_2SO_4 .	2·390	9·535	14·132	24·369	46·150	94·220	146·612	257·100
$CaSO_4$.	1·650	1·457	1·388	1·471	1·650	1·980	2·234	2·650

They also measured the sp. gr. of the soln. The results show that with increasing conc. of the more soluble salt, therefore, there is at first a decrease in the solubility of the calcium salt in accord with the rule for salts with a common ion, and there is then an increase which can be explained by the assumption that there are formed complexes between the solvent and one or more of the solutes, between the two solutes, or a change in the density of the solvent. P. N. Evans inferred that a double salt is formed in soln. because the calcium sulphate cannot be separated from the sat. soln. by salting with sodium sulphate. A. Ditte was unable to isolate a double compound by allowing the mixed soln. to stand for some months.

The salt **sodium calcium disulphate,** $Na_2SO_4.CaSO_4$, or $Ca(NaSO_4)_2$, occurs in nature as *glauberite*. J. Fritzsche described a dihydrated form, $Ca(NaSO_4)_2.2H_2O$, which he prepared by heating gypsum with a small amount of water, and a large excess of Glauber's salts; it was also obtained in fine needle-like crystals at ordinary temp. by adding gypsum to a soln. of one part of sulphuric acid with two of a sat. soln. of sodium sulphate. At 80°, fine prismatic needles of dihydrated **sodium calcium trisulphate,** $2Na_2SO_4.CaSO_4.2H_2O$, are formed, which are readily decomposed by water; but if the mixture be warmed still further fine needles of glauberite appear. The double salt is not obtained by evaporating spontaneously at room temp. a soln. of sodium sulphate sat. with calcium sulphate. The dihydrate loses water when heated and forms the anhydrous double salt. J. B. Hannay, and C. W. Folkard studied the anhydrous double salt. J. H. van't Hoff and D. Chiaraviglio have shown that gypsum and decahydrated sodium sulphate will form glauberite at 25° if the soln. be sat. with both these salts and with sodium chloride as well. Glauberite and gypsum exist together as solid phases only when decahydrated sodium sulphate is not also present. The double salt is not stable in the presence of water alone, and it breaks down into the simple salts, gypsum and Glauber's salt. J. H. van't Hoff showed that the temp. of formation of glauberite is 29° when other salts are absent, but is 14·8° in the presence of sodium chloride; 13° in the presence of sodium chloride and glaserite, or sodium syngenite; 12° in the presence of sodium chloride and astracanite; and 10·4° in the presence of sodium chloride, astracanite, and glaserite, or sodium syngenite. The prismatic crystals of glauberite belong to the monoclinic system, and, according to P. Groth, they have axial ratios $a : b : c = 1·2209 : 1 : 1·0270$, and $\beta = 112° 10\frac{1}{2}'$; they have a sp. gr. 2·64–2·85, and a hardness of 2·5 to 3. According to J. Fritzsche, the crystals dissolve gradually in water, with the separation of gypsum; while J. H. van't Hoff and D. Chiaraviglio found that with a small proportion of water, crystals of Glauber's salts and of gypsum can be detected microscopically in the residue. A soln. of 54 mols of Na_2Cl_2 and 3 mols of Na_2SO_4 in 1000 mols of water does not decompose glauberite. C. W. Folkard said the crystals are insoluble in alcohol, and in a conc. soln. of sodium acetate. J. Fritzsche observed that when heated the crystals lose their transparency, and give up sodium sulphate to water, leaving behind calcium sulphate. J. d'Ans reported the preparation of small doubly refracting needle-like crystals of an acid salt, $n\text{Na}_6\text{Ca}_3(\text{SO}_4)_6.5\text{H}_2\text{O}.\text{Na}_3\text{H}(\text{SO}_4)_2.\text{H}_2\text{O}$, where n ranges from 1·6 to 3. F. K. Cameron, J. M. Bell, and W. O. Robinson have studied the four component system, Na_2SO_4—$CaSO_4$—$NaCl$—H_2O. M. Enderli found that when soln. of sodium and calcium sulphates and a base, or soln. of sodium sulphate and calcium hydroxide, are heated, preferably under press., at a temp. over 100°, the precipitated **sodium tricalcium dihydroxytetrasulphate,** $Na_4Ca_3(SO_4)_4(OH)_2$, is useful as a substitute for caustic alkali in treating straw and wood cellulose; in the preparation of bleaching liquors, formates, lacquers and varnishes; for liming hides, etc. There is nothing to show that the product is a chemical individual.

In 1826, H. Braconnot found a mixture of potassium and calcium sulphate melted more easily than either alone. H. Müller has studied the f.p. curves of mixtures of potassium and calcium sulphates, and his results are illustrated by Fig. 47, a double salt, **potassium dicalcium trisulphate,** $K_2SO_4.2CaSO_4$, or $Ca_2K_2(SO_4)_3$, melting at 1004°, is formed, and like potassium sulphate itself, the complex salt shows enantiotropic dimorphism with a transition temp. at 936°. W. Grahmann's curve is rather different from H. Müller's, since he finds that α-potassium sulphate retains up to 18 molar per cent. of calcium sulphate in solid soln. at high temp., but the solubility diminishes with falling temp., and disappears at the transition temp. The compound $K_2SO_4.2CaSO_4$ decomposes it into β-calcium sulphate and liquid at 1004°; and undergoes a polymorphic change at 938°. There are thus three breaks in the descending branch of the f.p. curve. W. Grahmann found that potassium and strontium sulphates give a similar diagram. The limits of the solid soln. at the eutectic temp. are 0–22 molar per cent. of $SrSO_4$, and **potassium strontium trisulphate,** $K_2SO_4.2SrSO_4$, is resolved into liquid and β-$SrSO_4$ at 980°, and undergoes a transformation at 775°. G. Calcagni found a maximum in the f.p. curve of mixtures of potassium and strontium sulphates corresponding with 90 molar per cent. of K_2SO_4, and a marked thermal change in the solid state corresponds with the formation of **potassium strontium disulphate,** $K_2SO_4.SrSO_4$. W. Grahmann found no evidence of a compound with the system $BaSO_4$—K_2SO_4. The first branch of the f.p. curve, representing the solidification of solid soln., passes through a maximum at 1087°. The limit of saturation is 24 molar per cent. of $BaSO_4$, and the β-modification does not form solid soln. According to G. Calcagni, the addition of barium sulphate to potassium sulphate raises the m.p. to a maximum of 1080° for a concentration of 90 per cent. K_2SO_4. As this composition would correspond with 14 mols of K_2SO_4 per mol of $BaSO_4$, this maximum cannot represent a compound of the two salts. Beyond this concentration of $BaSO_4$, the m.p. falls to 1015° for 60 per cent. K_2SO_4, this being the eutectic temp. Further increase in the concentration of $BaSO_4$ is accompanied by rise of the temp. to the m.p. of the barium salt. The cooling curves of this system show, in general, three changes of direction; exceptions are that corresponding with 95 per cent. K_2SO_4, which represents the eutectic of the decomposition curve of the solid soln., and that corresponding with 60 per cent. K_2SO_4, which is the eutectic mixture of the melting curve. Curves up to 70 per cent. K_2SO_4 exhibit a point corresponding with the crystallization of mixed crystals, another with the decomposition of the solid soln., and a third with transformation of the potassium sulphate. The curves from 60 per cent. K_2SO_4 to $BaSO_4$ show a temp. of primary separation of barium sulphate, a eutectic temp., and a temp. of transformation of the potassium salt.

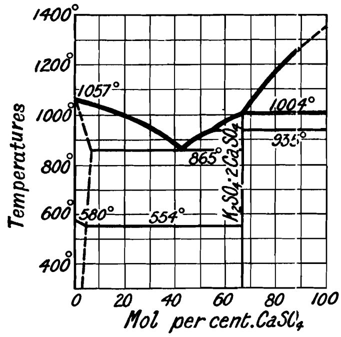

FIG. 47.—Fusion Curve of Calcium and Potassium Sulphates.

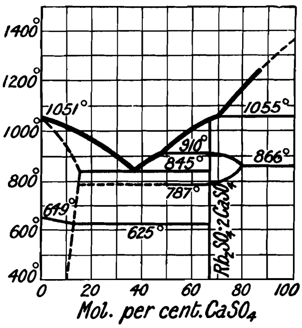

FIG. 48.—Fusion Curve of Calcium and Rubidium Sulphates.

J. H. Droeze, and F. K. Cameron and J. F. Breazeale have measured the solubility of calcium sulphate in soln. of potassium sulphate, and, expressing the results in grams per litre, the latter found at 25°:

K_2SO_4 . . .	5·09	9·85	19·57	28·35	30·66	35·19	40·53	96·00
$CaSO_4$ . . .	1·563	1·446	1·485	1·553	1·587	1·257	0·970	0·257
Solid phase	K_2SO_4					Syngenite		

There are here two intersecting curves, Fig. 49; the upper one represents the solubility of calcium sulphate in a soln. of potassium sulphate, and the lower curve the solubility of syngenite, $K_2SO_4\,CaSO_4.H_2O$, in soln. of potassium sulphate, for this salt appears in soln. with over 32 grms. of potassium sulphate per litre. The triple point at the intersection of these two curves represents a soln. in equilibrium with both potassium sulphate and syngenite as solid phases.

Four double sulphates of potassium and calcium have been reported: (i) Anhydrous potassium dicalcium trisulphate, $K_2SO_4.2CaSO_4$, prepared by H. Müller, was stated to take up water, forming the hydrate $K_2SO_4.2CaSO_4.\frac{1}{2}H_2O$; A. Ditte also described the hydrate $K_2SO_4.2CaSO_4.3H_2O$. The soln. in equilibrium with the double salt and with solid potassium sulphate has nearly the same conc. of the latter salt as the soln. sat. with the double salt and gypsum. Later investigators have not succeeded in preparing this salt from soln. of potassium sulphate. (ii) Hydrated **potassium calcium disulphate,** $CaSO_4.K_2SO_4.H_2O$, was identified as a by-product in the manufacture of tartaric acid by J. A. Phillips about 1850; and soon afterwards it was found to be identical with the double salt associated with sylvine, found by V. von Zepharovich, in the Stassfurt salt deposits of Kalusz, and called by J. Rumpf *kaluszite;* but, on account of its relation with polyhalite, V. von Zepharovich called the salt *syngenite*—from συγγενής, having a common origin. A. Ditte reported a tetrahydrated form of this salt, $CaSO_4.K_2SO_4.4H_2O$; and (iii) J. H. van't Hoff and A. Geiger first obtained hydrated **potassium pentacalcium hexasulphate,** $K_2SO_4.5CaSO_4.H_2O$, by boiling a precipitated calcium sulphate with a 5 per cent. soln. of potassium sulphate. Well-formed crystals of this salt, resembling gypsum, then appear.

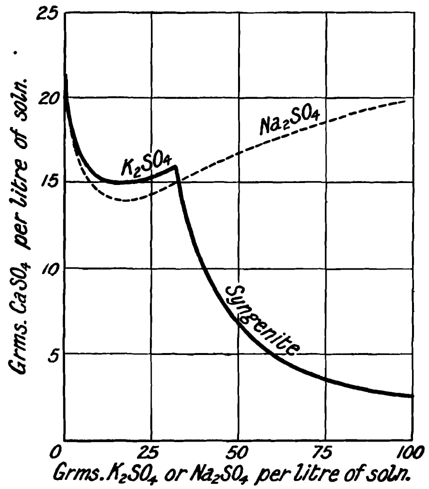

Fig. 49.—Solubility of Calcium Sulphate in Soln. of Potassium and Sodium Sulphates.

H Rose, J. B. Hannay, J. Grosjean, prepared the hydrated potassium calcium disulphate, syngenite, by mixing soln. of the component salts. J. B. Emmet noticed the hardening of calcium sulphate in contact with soln. of potassium carbonate or hydrocarbonate, while potassium nitrate and chloride were without action; F. Schott, A. Ditte, and H. Struve obtained similar results with potassium sulphate, and noted that crystals of syngenite were formed. They also obtained syngenite by the action of potassium nitrate, chloride, bromide, or iodide on gypsum, although R. Fassbender expressed his doubts whether syngenite can be obtained in this way from soln. of potassium chloride because his product corresponded with $CaSO_4.K_2SO_4.2KCl.H_2O$, which is probably a mixture of syngenite and potassium chloride. H. Precht obtained syngenite by treating finely divided krugite with cold water—magnesium sulphate passes into soln., and a mixture of gypsum and syngenite remains. J. d'Ans and others have prepared syngenite by the interaction of anhydrite or gypsum and a soln. of potassium chloride. A. C. Becquerel prepared syngenite by the action of potassium aluminate on gypsum. According to J. H. van't Hoff and H. A. Wilson, syngenite is best prepared by dissolving 120 grms. of potassium sulphate in 1000 grms. of water, and adding to this 100 c.c. of a 20 per cent. soln. of calcium chloride. At first, gypsum separates out, and this is then converted into syngenite, which appears under the microscope in square-ended, needle-like crystals.

W. H. Miller, and V. von Lang regarded the artificial crystals as rhombic; V. von Zepharovich found the crystals from Kalusz to be monoclinic. J. Rumpf supposed this salt in consequence to be dimorphous, but this is wrong, since both natural and artificial crystals are really monoclinic prisms. V. von Zepharovich gave $a:b:c=1{\cdot}3699:1:0{\cdot}8738$, and $\beta=76^\circ$; J. Rumpf, $1{\cdot}3801:1:0{\cdot}8667$, and $\beta=76^\circ\ 9'$; and H. Schreiber, $1{\cdot}352:1:0{\cdot}871$, and $\beta=75^\circ\ 55'$, and when heated to 200°, the last-named found the axial ratios changed to $a:b:c=1{\cdot}359:1:0{\cdot}894$, and $\beta=76^\circ\ 3'$. J. Rumpf, O. Mügge, and H. Schreiber studied the cleavage and twinning of the crystals; V. von Zepharovich, and H. Schreiber, the corrosion figures with water, sulphuric and hydrochloric acids, and sodium hydroxide; and H. Schreiber, the percussion figures, pressure figures, and the scratch-figures. J. Rumpf gave the sp. gr. as 2·252 at 17·5°; V. von Zepharovich, 2·603 at 17·5°; and H. Schreiber, 2·579 at the same temp. The three last named also agree that the hardness is between 2 and 3 on Mohs' scale.

The optical properties of syngenite have been studied by J. Rumpf, V. von Lang, V. von Zepharovich, H. Schreiber, and G. Bartalini. P. Gaubert, O. Mügge, and

H. Schreiber measured the indices of refraction and the dispersion of the crystals. Using for red light $\lambda=0·70652\mu$; for yellow, $\lambda=0·58757\mu$; for green, $\lambda=0·50157\mu$; and for blue, $\lambda=0·47131$, H. Schreiber found the results shown in Table X, for the influence of temp. on the refractive indices and dispersion of syngenite.

TABLE X.—EFFECT OF TEMPERATURE ON THE REFRACTIVE INDICES AND DISPERSION OF SYNGENITE.

H. Struve found that a part of the combined water is expelled at 100°, and all is lost at a higher temp., while at a dull red heat the crystals melt to a liquid which forms a crystalline mass on cooling. H. Rose found the crystals of syngenite are decomposed by water leaving a residue of gypsum and a soln. of the alkali sulphate; and when the crystals, dehydrated at 300°, are treated with water, they swell up to a voluminous mass. V. von Zepharovich said: "When finely powdered syngenite is shaken with distilled water, and quickly filtered, a clear liquid is obtained, which, when warmed, becomes turbid owing to the separation of gypsum. 400 parts of water are needed to dissolve one part of syngenite so that its solubility approaches that of gypsum." The solubility of syngenite in aq. soln. is greater than in water. F. K. Cameron and J. F. Breazeale's solubility curve is shown in Fig. 49. A. Ditte found that a soln. prepared in the cold, becomes turbid when heated to the b.p., and calcium sulphate separates out.

J. A. Philips found the crystals are soluble in dil. hydrochloric acid. Analyses of syngenite were made by H. Rose, F. Schott, F. Ullik, H. Vater, A. Ditte, V. von Zepharovich, and H. Schreiber, and the results agree with the formula, $CaSO_4.K_2SO_4.H_2O$.

The equilibrium conditions for aq. soln. of syngenite and potassium pentasulphate have been studied by J. H. van't Hoff and co-workers, and by J. d'Ans. Syngenite is stable in soln. of the proper conc. at all temp. between 0° and 170°, while potassium pentacalcium sulphate was not stable below 31·8°. From 0° to 31·8°, syngenite is the only stable double salt, above 31·8°; either syngenite or potassium pentacalcium sulphate can exist—the latter with soln. of the lower conc. and the former with soln. of higher conc. According to J. H. van't Hoff, G. L. Voerman, and W. C. Blasdale, the vap. press. p of the sat. soln. at 31·8° in presence of syngenite and gypsum is $\log p=\log p_w+315·7-1·0325T^{-1}$, where p_w denotes the vap. press. of water. Hence the compounds can be formed in salt deposits at 25°, since the vap. press. is less than corresponds with the formula. Table XI indicates the conc. of potassium sulphate required to establish equilibrium with syngenite and the pentacalcium salt, at the temp. indicated.

TABLE XI.—EQUILIBRIUM CONCENTRATIONS OF SOLUTIONS OF POTASSIUM SULPHATE FOR THE DIFFERENT SOLID PHASES.

Temp.	Mols K_2SO_4 per 1000 mols of H_2O.	Mols of K_2SO_4 per 1000 grms. of soln.	Solid phases	Mols K_2SO_4 per 1000 mols of H_2O.	Mols of K_2SO_4 per 1000 grms. of soln.	Solid phases.
0°	2·1	0·119	Syngenite, gypsum.	—	—	—
25°	3·22	0·173	Syngenite, gypsum.	—	—	—
31·8°	3·70	0·20	Syngenite, gypsum, pentacalcium salt.	3·70	0·20	Syngenite, gypsum, pentacalcium salt.
40°	4·4	0·23	Syngenite, pentacalcium salt.	3·8	0·203	Syngenite, pentacalcium salt.
60°	6·8	0·35	Syngenite, pentacalcium salt.	2·4	0·130	Syngenite, pentacalcium salt.
83°	6·9	9·50	Syngenite, pentacalcium salt.	1·3	0·070	Syngenite, pentacalcium salt.

The results indicated in Table XI are plotted in Fig. 50, which gives a clear idea of the conditions necessary for the formation and existence of these double salts. The equilibrium conc. of calcium sulphate for solid syngenite and gypsum, at 0° and 25°, are respectively 0·113 and 0·223 grm. $CaSO_4$ per 1000 mols of water or 0·0064 and 0·012 mols of $CaSO_4$ per 1000 grms. of soln. In Table VIII and Fig. 35, it is of course assumed that sufficient time has been allowed for the soln. to attain a state of equilibrium. The presence of the alkali chlorides also modifies the equilibrium diagram. J. H. van't Hoff and H. A. Wilson studied the equilibrium conditions of soln. sat. with sodium chloride as well as with soln. containing potassium chloride and sodium sulphate. They found at 25°:

SOLN. SAT. WITH	MOLS Na_2Cl_2	K_2Cl_2	Na_2SO_4 PER 1000 MOLS H_2O
NaCl	55·5	—	—
NaCl, KCl	44·5	19·5	—
NaCl, KCl, glaserite . . .	44	20	4·5
NaCl, Na_2SO_4, glaserite . . .	44·5	10·5	14·5
NaCl, Na_2SO_4	51	—	12·5
NaCl, KCl, syngenite, gypsum .	46	19·5	—
NaCl, Na_2SO_4, syngenite, glauberite.	47	5·5	14
NaCl, syngenite, gypsum, glauberite.	50	6	4

According to E. Anderson, virtually all the sulphur in the fuel leads to the formation of sulphates, and in leaching ordinary cement-mill flue dust with water, soln. containing calcium and potassium sulphates are formed, and in amounts required for the formation of either or both syngenite and the pentacalcium salt. There may be also formed carbonates and hydroxides as well as smaller quantities of magnesium salts. When potassium in the collected dust is largely present as chloride, and where sodium chloride is formed, reactions like $2(CaSO_4.2H_2O)+2KCl \rightleftharpoons CaCl_2+K_2SO_4.CaSO_4.H_2O+H_2O$ may occur. E. Anderson and R. J. Nestell studied the equilibrium conditions at 100°.

A. Ditte has reported the formation of radiating masses of needle-like crystals of hydrated **rubidium calcium disulphate**, $Rb_2SO_4.CaSO_4.1\frac{1}{2}H_2O$, or *rubidium-syngenite*, when a mixed soln. of the component salts is allowed to stand in the cold. The salt melts at a red heat and is decomposed by water. The curve, Fig. 36, is considered by J. d'Ans to represent the equilibrium conditions with rubidium and calcium sulphates, and it is to be compared with the corresponding diagram, Fig. 50, for potassium sulphate. Tri-hydrated **rubidium dicalcium trisulphate,** $Rb_2SO_4.2CaSO_4.3H_2O$, takes the place of potassium pentacalcium sulphate. With cæsium and calcium sulphate, between 0° and 100°, J. d'Ans was able to prepare only one double salt, **cæsium dicalcium trisulphate,** $Cs_2SO_4.2CaSO_4$, which is very stable, the stability increasing with the temp. Attempts to prepare *cæsium-syngenite* and a pentacalcium salt were abortive. The temp. limit of the stability of the alkali dicalcium trisulphates falls as the mol. wt. of the alkali metal decreases. This is illustrated in Table XII.

TABLE XII.—TEMPERATURE OF FORMATION OF THE ALKALI CALCIUM SULPHATES.

	Syngenite.		Dicalcium salt.		Pentacalcium salt.		Mol vol. alkali sulphate.
	Upper.	Lower.	Upper.	Lower.	Upper.	Lower.

Rb_2SO_4 . .	42°	—	—	20°	—	—	73·34
Cs_2SO_4 . .	—	—	—	—	—	—	84·58

J. d'Ans has investigated the influence of various foreign salts on the equilibrium diagrams of the alkali calcium sulphates. The f.p. curve of mixtures of rubidium and calcium sulphates, Fig. 48, has been determined by H. Müller, and there is evidence of the formation of an enantiotropic trimorphic **rubidium dicalcium trisulphate,** $Rb_2SO_4.2CaSO_4$, melting at 1043°. The first transition point is 910°–915°, the second at 787°. The double salt, **cæsium dicalcium trisulphate,** $Cs_2SO_4.2CaSO_4$, was likewise obtained by H. Müller from the fused salt. J. d'Ans prepared a number of triple salts by boiling gypsum or a mixture of gypsum and syngenite with a conc. soln. of the sulphates of copper, cadmium, zinc, or nickel. He thus prepared **copper ammonium calcium tetrasulphate,** $Ca_2Cu(NH_4)_2.(SO_4)_4.2H_2O$; and **copper potassium calcium tetrasulphate,** $Ca_2CuK_2(SO_4)_4.2H_2O$.

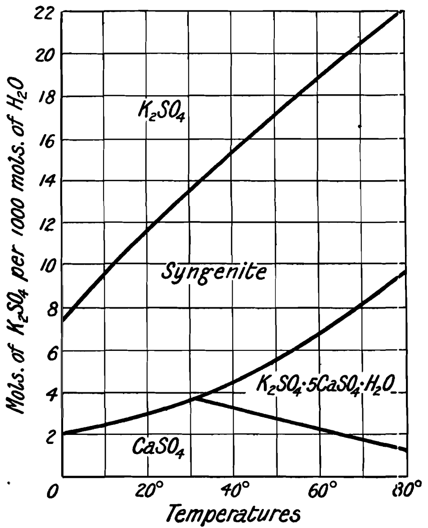

FIG. 50.—Equilibrium Concentration of Potassium Sulphate for the different Solid Phases with Calcium Sulphate.

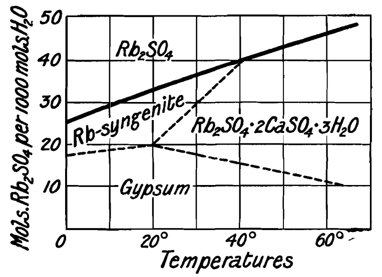

FIG. 51.—Equilibrium Concentration of Rubidium Sulphate for the different Solid Phases with Calcium Sulphate.

H. Rose[2] noticed that a boiling conc. aq. soln. of ammonium sulphate readily dissolves powdered calcium sulphate, and that if an excess of the former salt be employed, a soluble double salt is formed. The solubility of calcium sulphate in soln. of ammonium sulphate has been measured by J. H. Droeze, and by S. Cohn. It was shown that there is a minimum in the solubility curve. E. C. Sullivan found at 25°, calcium sulphate is two-thirds as soluble in a soln. containing 0·1 mol per litre, and twice as soluble in a soln. containing 3 mols per litre as it is in water alone. The sp. conductivity of a conc. soln. of ammonium sulphate is lessened by saturating it with calcium sulphate. Expressing the results in grams per litre, at 25°:

$(NH_4)_2SO_4$	0	0·129	1·033	4·123	8·266	33·065	132·259	264·578
$CaSO_4$	2·083	2·043	1·807	1·540	1·440	1·617	3·330	4·500

The sp. gr. of the soln. were also determined. J. M. Bell and W. C. Taber measured the solubility and sp. gr. of the soln. at 50°. There were breaks in the curve at 416 and 564 grms. of $(NH_4)_2SO_4$ per litre, and between these conc. the solid phase was dihydrated **ammonium calcium disulphate,** $(NH_4)_2SO_4.CaSO_4.2H_2O$. This formula is similar to that obtained by J. Fritzsche for the double sulphate of sodium and calcium. The monohydrated salt, $(NH_4)_2SO_4.CaSO_4.H_2O$, was reported by O. Popp as a constituent of the salt which separated from the waters of the Tuscany boric acid lagoons. R. Fassbender prepared it by dissolving 285 grms. of ammonium sulphate in 800 c.c. of water, and saturating the soln. with gypsum. After evaporation to 500–600 c.c., the mother liquid was filtered at 40°–50° from the crystals of the salt which is isomorphous with the corresponding potassium salt. A. Ditte obtained the double salt from a conc. soln. after allowing it to stand for some days. J. d'Ans called the salt *ammonium-syngenite*, and showed that it exists at 25° and even at lower temp. J. M. Bell and W. C. Taber showed that if the salt be washed with water, there is a partial decomposition; they believed that J. d'Ans' preparation was partially decomposed and that the formula of the salt is really $(NH_4)_2SO_4.CaSO_4.2H_2O$. J. d'Ans also prepared crystals of **ammonium dicalcium trisulphate,** $(NH_4)_2SO_4.2CaSO_4$, by boiling a 40 per cent. soln. of ammonium sulphate with gypsum. The mother liquid was filtered, washed rapidly with water, then with 50 per cent. alcohol, and finally with a mixture of alcohol and ether. The salt is not very stable, and is decomposed by water into ammonium syngenite and gypsum. The range of stability of this salt and of hydrated **ammonium pentacalcium hexasulphate,** $(NH_4)_2SO_4.5CaSO_4.H_2O$, are shown in J. d'Ans' diagram, Fig. 52. The latter salt was obtained in strongly refracting prisms readily decomposed by water. R. Fassbender prepared crystals of the triple salt, **ammonium potassium calcium disulphate,** $(NH_4)KSO_4.CaSO_4.nH_2O$, by diluting a sat. soln. of ammonium sulphate with an equal vol. of water, saturating the soln. with calcium sulphate and then adding a slight excess of potassium sulphate. The salt is decomposed by conc. soln. of various sodium salts or ammonium chloride.

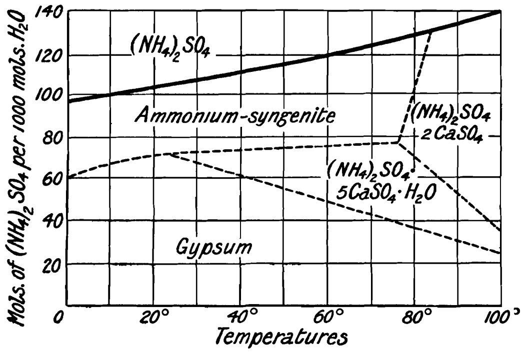

Fig. 52.—Equilibrium Concentration of Ammonium Sulphate for the different Solid Phases with Calcium Sulphate.

The mineral *urvölgyite* or *herrengrundite* occurs in rhombic crystals of sp. gr. 3·132, and with a composition which, according to A. Schenck's and C. A. Winkler's analyses,[3] can be represented by the formula, $CaSO_4.3Cu(OH)_2.CuSO_4.3H_2O$, and it has accordingly been regarded as a *basic calcium cupric disulphate,* although there is nothing to show that it is a chemical individual. S. U. Pickering,[4] in his study of Bordeaux mixture, treated soln. of cupric sulphate with lime-water, and obtained precipitates containing various proportions of calcium hydroxide and sulphate, and cupric hydroxide and sulphate; and precipitates also containing sodium sulphate by precipitating cupric sulphate with lime-water in the presence of an excess of sodium sulphate. Here again there is no evidence which would justify S. U. Pickering's products being regarded as chemical individuals. J. d'Ans obtained small pale blue crystals of what he regarded as dihydrated **ammonium dicalcium cupric tetrasulphate,** $(NH_4)_2Ca_2Cu(SO_4)_4.2H_2O$, by boiling a sufficiently conc. soln. of cupric, calcium, and ammonium sulphates. The mother liquid was drained off, and the crystals washed rapidly first with water, then with dil. alcohol, and finally with a mixture of alcohol and ether. The crystals are fairly stable.

R. Silberberger[5] obtained a white product which he regarded as **potassium barium sulphato-nitrate,** $KNO_3.2BaSO_4$, or $NO_3.Ba.SO_4.Ba.SO_4.K$, by mixing 3–6 grms. of potassium sulphate and 2 grms. of potassium nitrate in conc. soln. with 4·5 grms. of barium chloride. The product is dried on a porous tile over sulphuric acid. It is readily soluble in conc. sulphuric acid. He also made **potassium barium sulphato-chloride,** $KCl.3BaSO_4$, or $Cl.Ba.SO_4.Ba.SO_4.Ba.SO_4.K$, by mixing under similar conditions 3 grms. of potassium sulphate, 3 grms. of potassium chloride, and 4·2 grms. of barium chloride; or respectively 6, 9, and 4 grms. of the components. As previously indicated, J. Smithson described a native *barium calcium sulphato-fluoride.*

§ 21. The Occurrence and Preparation of Carbonates of the Alkaline Earths

The occurrence of witherite, barium carbonate, and of strontianite, strontium carbonate, has been already outlined. They occur in one crystalline form belonging to the rhombic system. Calcium carbonate occurs in nature as rhombohedral *calcspar*, *Iceland spar*, or *calcite* and rhombic *aragonite*. The former is stable at ordinary temp., the latter is metastable. With the exception of quartz, the former variety is the most common of all the minerals. It is the *lapis calcarius* of Pliny. The class includes a series of minerals ranging from Iceland spar, through the *limestones*, *marbles*, and *chalk*. There are enormous quantities of limestone which occur both as original deposit and as a metamorphic mineral. Crystals of calcite are commonly found wherever calcareous soln. have penetrated—*e.g.* in veins, cavities, and amygdules. The attention of physicists was early directed to the fine crystals of calcite largely because of E. Bartholinus, in his *Experimenta crystalli Islandici* (Hafniæ, 1669) studied the cleavage and birefringence; C. Huyghens,[1] in 1690, the laws of double refraction; and E. L. Malus, in 1808, the polarization of light.

Special names have been given to the more peculiar habits of calcite—for instance, there are the so-called *dog-tooth spar*, *nail-head spar*, *slate spar*, and *satin spar*. The latter is a fibrous variety with a silky lustre resembling the satin spar variety of gypsum—the latter is harder than the former. There are several varieties of minor importance which have been named after some admixture, or the colour, use, or locality, and do not generally indicate important structural or chemical differences. For instance, *dolomitic calcite* contains magnesium carbonate; *mangano-calcite* contains up to about 20 per cent. or more manganese carbonate in the form of mixed crystals. In fact, there appears to be a complete series of mixed crystals of calcspar and manganese spar. A. Breithaupt [2] called a specimen he analyzed *spartaite*. A sample from Sterling with some franklinite and zincite was called *calcimangite* by C. U. Shepard. *Ferro-calcite* has ferrous carbonate and turns brown on exposure to air. F. Millosevich obtained a sample of calcite from Cape Calamita, Elba, with about 2 per cent. of cobalt carbonate, and it has been called *cobalto-calcite;* C. F. Rammelsberg and W. Lindgren have reported samples with up to about 5 per cent. of zinc carbonate—*zinco-calcite;* J. Johnston, R. Schöffel and H. Hoefer, J. S. Thomson, A. Lacroix, and J. N. Collie found samples containing up to about 20 per cent. of lead carbonate—*plumbo-calcite;* T. Thomson, and H. Vater have studied *baryto-calcite*—a variety from Cumberland was called *neotype* by A. Breithaupt and F. A. Genth. These workers, and B. Doss have analyzed samples with strontium carbonate, which are accordingly called *strontio-calcite*. According to J. M. F. de Lassone, the so-called *Fontainebleau limestones* have 50–63 per cent. of quartz crystals; the *hislopite* of S. Haughton, from India, is coloured by glauconite

The limestones are more or less impure forms of calcium carbonate; and they occur in many diverse forms—calcareous sinter or tufa or *travertine;* the *tophus* of Pliny, and the *lapis tiburtinus* of Pliny and Vitruvius. At the Mammoth Hot Springs (Yellowstone National Park),[3] the snow-white deposits from the geysers and hot springs form massive terraces of travertine, as the calcium carbonate, held in soln. by carbonated water, is deposited through the escape of the carbon dioxide from its soln. in water—*vide infra.* The formation of *stalactites* and *stalagmites* in caves, and the work of the so-called *petrifying springs*, is due to the same cause. The carbon dioxide may also be abstracted from the water by vegetable organisms—bacteria, algæ, mosses, and aquatic plants like the chara, etc., which, according to J. Walther, and E. J. Garwood, are active agents in the formation of limestones. A. Payen discussed the occurrence of calcium carbonate in plants. G. Steinmann has shown that the albumen present in the organic parts of aquatic animals, may, by fermentation, form ammonium carbonate which would precipitate calcium carbonate from calcareous waters. Calcium carbonate may also be precipitated from river waters charged with calcium carbonate as they enter the sea; and C. Lyell noted that this is taking place in the delta of the Rhône, and S. Sanford, and T. W. Vaughan, along the coast of Florida. Limestone is made up of shells and corals, and the organic remains may be conspicuous or they may be quite obliterated. Chalk is derived from marine ooze. *Pearls* are largely composed of calcium carbonate deposited by the oyster about an invading parasite.

The *sandy, argillaceous, glauconitic, ferruginous, phosphatic,* and *bituminous limestones* owe their names to the corresponding impurities. The so-called *fœtid limestone* or *stinkstone* owes its name to the presence of hydrogen sulphide, which escapes when the stone is struck or bruised. B. J. Harrington found a bed of calcite in Chatham (Canada) with 0·016 per cent. of hydrogen sulphide eq. to 500 c. ins. per c. foot. W. Skey made a similar observation.

Limestones are formed in various ways, but in all cases the primary action involves the separation of calcium carbonate from its soln. in fresh or salt water. Oceanic ooze may form a soft substance like chalk or a mixture of the same with sand or clay; fragments of coral may be broken into fine granules by the waves, and subsequently cemented by the soln. and redeposition of calcium carbonate to form massive *coralline limestone* containing, in the samples examined by S. P. Sharples,[4] 95·37–98·07 per cent. of calcium carbonate, and 0·28–0·84 per cent. of calcium phosphate, with a little organic and earthy matter. Many fossil corals are found in the limestones of Devon. Masses of shell fragments may likewise be cemented, as in the case of the coralline limestone, by the soln. and redeposition of calcium carbonate, so as to form a massive rock suitable for building purposes—*e.g. shell limestone, coquina, oolitic limestone,* etc. Fragments of limestone cemented together by the soln. and deposition of calcium carbonate, or other infiltrations form *breccia.* Some have the fragments of different colour, and are used as ornamental stones; *pudding-stone marble* has rounded pebbles likewise cemented together.

Calcium carbonate may be transported as silt, and solidify to a smooth fine-grained rock—*e.g. lithographic limestone* is a fine-grained compact rock of uniform texture and composition. The lithographic stone from the neighbourhood of Solenhofen, near Munich (Germany), is specially prized—it readily receives delicate markings from engraver's tools, and by etching acids, and it is porous enough to receive and retain the greasy preparation used by the lithographer in transferring and printing. Limestones may have been buried under other sediments, whereby they become more or less modified; the fossils are more or less obliterated, and in the extreme case, a crystalline limestone may be produced. Crystalline limestone or *marble* may be produced from apparently amorphous calcium carbonate, by press. alone, by heat alone, or by the two agents acting together. The fine-grained white statuary *Carrara marble* from quarries at Monte Crestola and Monte Sagro in Italy, and the *parian marble* from the Isle of Paros, are of great historical interest. There are numerous other varieties of white, coloured, and mottled marbles. The ornamental nature of the stone is dependent on variations in colour and texture produced by impurities or inclusions—*e.g.* ferric oxide, mud, clay, etc. Some marbles have the remains of various fossil shells—*e.g.* the *panno-di-morti* is a black marble with white fossil shells; the *verd-antique marble* is clouded with green serpentine inclusions; the so-called *onyx-marbles;* the *fire marble,* etc.

Aragonite is a variety of calcium carbonate which was named after the locality, Aragon (Spain), where it was first found. It crystallizes in a system different from calcite, and it was the earliest known case of dimorphism in the mineral kingdom. In 1788, M. H. Klaproth [5] showed that the two minerals had the same chemical composition, but this was contested by R. J. Haüy and others, who were confused by a too rigid interpretation of the hypothesis that every crystalline substance of definite chemical composition has a characteristic and specific form. H. Stromeyer suggested that the dimorphism is due to the presence of a little strontium in aragonite, but J. W. Döbereiner, C. F. Bucholz and K. F. W. Meissner, and others showed that strontium is not always a constituent of aragonite. The examples of polymorphism established by E. Mitscherlich rendered it necessary to recognize that polymorphism is a specific property. Aragonite is less common than calcite, and it is not always possible to distinguish with certainty the massive forms of these two minerals if the cleavage or sp. gr. cannot be determined. Many concretionary and stalactitic forms of calcium carbonate are regarded as aragonite—*e.g.* the pisolites deposited from the hot springs of Carlsbad (Bohemia); and the white stalactites known as *flos ferri* from the iron mines of Eisenerz (Styria). The pisolitic carbonate formed at the hot springs of Hammam-Meskoutine (Algeria) was regarded by A. Lacroix as a specific variety to which he gave the name *ktypeite,* but H. Vater identified it with aragonite. J. Dreger found aragonite separates from the mineral waters of Rohitsch.

According to W. Meigen,[6] aragonite is coloured lilac when immersed in a soln. of cobalt nitrate, and the colour persists on boiling; calcite under similar conditions remains white in the cold, and is coloured blue on long boiling. Aragonite gives a dark greenish precipitate of ferrous hydroxide when immersed in a soln. of ferrous sulphate, while calcite under similar conditions gives a yellow precipitate of ferric hydroxide. G. Panebianco says that in the ferrous sulphate test, the precipitates are carbonates not hydroxides; and W. Diesel has further discussed this test. S. J. Thugutt has studied the colour discriminations based on organic dyes. J. Kendall found the sp. gr. of vaterite to be identical with that of aragonite; and he attributed the higher values for the solubility to the retention of the last trace of carbon dioxide by the soln.

R. Lang [7] reported a monoclinic variety of calcium carbonate occurring as *rock-milk,* of a texture resembling mould or cotton-wool, as a coating on the crevices of the calcareous tufa near Horb (Würtemberg). He called it *lublinite.* O. Mügge, however, showed that lublinite is merely a pseudomorph of calcite after organic remains, and is not a species. H. Vater prepared spherical aggregates of feebly birefringent crystals of calcium carbonate. We know very little about this form except that it belongs to a system with two optical axes; it generally appears in sphærolites, rarely in needles; it has a feeble double refraction; and like aragonite, it is stained blue by cobalt soln. in a few minutes; and its sp. gr. is about 2·6. G. Linck called it *vaterite.* J. Johnstone and co-workers say that vaterite is not really a definite form of calcium carbonate; since its peculiar properties are due to differences in the size of grain and state of aggregation. O. Bütschli has also prepared an isotropic, gelatinous form—*colloidal calcium carbonate*—by adding potassium carbonate to a soln. of calcium acetate mixed with the white of an egg. The precipitate was washed with alcohol. It is quite stable when dry, but between 200° and 230° it rapidly changes into calcite. J. Johnstone and co-workers say that like vaterite it is not really a definite form of calcium carbonate, and for similar reasons. L. Bondonneau also obtained gelatinous calcium carbonate by passing carbon dioxide into a soln. of lime in sugar mixed with sodium chloride or nitrate.

J. Johnstone and co-workers say that another crystalline form, μ-$CaCO_3$, is produced by precipitation at 60°; it is always accompanied by calcite or aragonite from which it can be separated by flotation in a liquid of sp. gr. 2·6, since its sp. gr. is 2·54 while the other forms have sp. gr. respectively 2·71 and 2·88. The microscopic plates belong to the hexagonal system. The refractive indices are 1·550 and 1·650. It persists indefinitely when dry, but when heated passes into calcite.

As indicated by M. J. Schleiden, A. Payen, and J. Bacon, calcite occurs in the cellular tissue of many phanerogamia—*e.g.* cycadaceæ and cactaceæ. The lithothamnia seaweeds have a framework or skeleton of calcite; and the halimeda contain aragonite. Calcium carbonate is found along with calcium phosphate in the bones of the vertebrata; in egg-shells; and in corals, and the skeletons of the invertebrata—*e.g.* crustacea, mollusca, gastropoda, etc. A. Kelly supposed that a distinct crystalline variety of calcium carbonate is found in the shells of many mollusca, and called it *conchite;* but R. Brauns and H. Vater identified Kelly's conchite with aragonite as was previously supposed.

H. C. Sorby showed that shells composed of aragonite are comparatively rare as fossils, and V. Cornish and P. F. Kendall found that carbonated waters decompose and disintegrate shells of aragonite much more readily than those of calcite, but the difference is attributed rather to structure than to constitution. P. F. Kendall found the shells of the pteropoda are mainly aragonite, and they disappear below 1500 fathoms depth, while the calcite shells of the globigerina are found in the ooze at 2925 fathoms. The upper chalk of England contains only calcite organisms, and P. F. Kendall infers that it was deposited at a depth of at least 1500 fathoms—this is based on the assumption that no aragonite has been converted to calcite subsequent to its deposition. G. Linck has shown that while recent deposits of the oolites are composed of aragonite, the older occurrences are calcitic; and he assumes that the oolites were originally deposited as aragonite and subsequently converted to the more stable calcite. Some shells have a principal mass of calcite with a pearly layer of aragonite; and other associations of these two forms of calcium carbonate are found. During the fossilization of these shells, the aragonite is generally destroyed while the calcite is preserved. The direct separation of calcium carbonate as calcite or aragonite by precipitation is largely conditioned by the temp., and maybe other conditions.

Dry calcium oxide does not absorb carbon dioxide provided moisture be excluded. In 1773, J. B. M. Bucquet[8] said:

> Je conclus qu'il ne suffit pas de rendre à la chaux de l'air fixé pour la convertir en craie, qu'il faut un intermède pour que cette union se fasse, et que cet intermêde est l'eau.

When calcium oxide absorbs carbon dioxide from the air, moisture is simultaneously absorbed. J. Kolb and H. Debray showed that the dried oxides or hydroxides of calcium, barium, magnesium, sodium, and potassium do not increase in weight in an atm. of dry carbon dioxide. The action was studied by H. Rose, A. R. Schulatschenko, F. M. Raoult, K. Birnbaum and M. Mahu, etc., as previously indicated in connection with the action of this gas on calcium oxide; and the reversible reaction; $CaO+CO_2=CaCO_3$, has been discussed in connection with the preparation of calcium oxide. According to F. M. Raoult, the absorption of carbon dioxide by calcium, strontium, and barium oxides proceeds rapidly at 550°, and the temp. rises to 1100°, 1050°, and 1200° with the respective oxides. According to P. Rohland,[9] the immeasurably slow reaction between dried carbon dioxide and dried calcium hydroxide is augmented if one per cent. of water be present. A. R. Schulatschenko found that moist carbon dioxide is more slowly absorbed by calcium hydroxide at 360° than it is at 16°. Moist calcium hydroxide and lime-water rapidly absorb carbon dioxide; and W. Wolters has studied the action of carbon dioxide on milk of lime. According to H. Rose, and C. Scheibler, dry carbon dioxide is not absorbed by dried barium oxide, hydroxide, or monohydrated hydroxide. The gas, however, is rapidly absorbed if moisture be present—*e.g.* carbon dioxide is rapidly absorbed from the air. According to C. Scheibler, if carbon dioxide is passed over the hydroxides of calcium, strontium, and barium, any excess of water will be removed, and the gas thus moistened will act on the hydroxides with the formation of carbonate, but the reaction is not complete even with the octohydrates; he added that the use of carbon dioxide to remove water from the hydroxides or oxides of the alkaline earths does not work as an analytical method. C. Heyer took the contrary view; he found that dry monohydrated strontium hydroxide is completely converted into carbonate by dry carbon dioxide, but only traces of carbon dioxide are absorbed by the dry hydroxide. R. Finkener held that a basic carbonate is formed when dry carbon dioxide is passed over monohydrated strontium hydroxide, but C. Heyer holds that R. Finkener's product is merely a mixture of partially carbonated hydroxide.

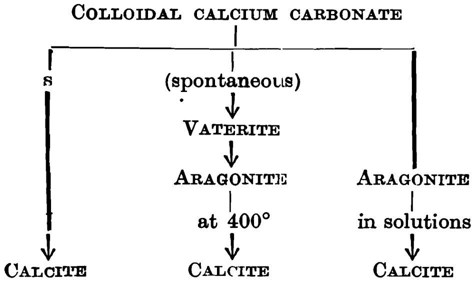
According to H. A. von Vogel,[10] carbon dioxide precipitates amorphous calcium carbonate from lime-water, but on standing the precipitate becomes crystalline; and M. Pettenkofer showed that the crystallization is retarded if an excess of calcium hydroxide be present. He also showed that when air containing carbon dioxide, or an aq. soln. of that gas, is added to lime-water, an appreciable time elapses before the soln. becomes turbid, and he believes that this is due to the formation of a soluble carbonate. G. Rose found that if a little carbon dioxide is passed into a cold soln. of calcium hydroxide, calcite is formed, and aragonite if the soln. is hot. Similar products were respectively obtained by exposing cold and hot soln. to the carbon dioxide of the atm. He reported that calcite is obtained by the action of carbon dioxide on lime-water below 30°; aragonite at temp. above 90°; while a mixture of the two is obtained at intermediate temp. He further found that a conc. and warm soln. of calcium hydroxide furnishes calcite when treated with carbon dioxide; while a very dil. soln. at ordinary temp. furnishes aragonite. H. Watson found that if the liquid from which the calcium carbonate is precipitated is above 30°, aragonite is formed, if below that temp., calcite, and this whether the soln. be seeded with these minerals or not. L. Roon made calcium carbonate by spraying milk of lime in an atm. containing carbon dioxide; J. Faldner dissolved quicklime in a soln. of an ammonium salt, removed the impurities by precipitation and filtration, and saturated the liquid with carbon dioxide under press. so as to precipitate the carbonate, and regenerate the ammonium salt.

The addition of an ammonium carbonate soln. to a cold soln. of calcium chloride furnishes a voluminous flocculent precipitate of calcium carbonate which, according to G. Rose,[11] if immediately filtered and dried, appears under the microscope to consist of opaque granules like grains of chalk; but if this same precipitate be left for some time in contact with the liquid from which it has been precipitated, it collects into microscopic crystals of calcite. Again, if the boiling soln. of ammonium carbonate be added to one of calcium chloride, the precipitate consists of aragonite mixed with a little calcite, while if the admixture be made in the reverse order, small crystals of aragonite are alone obtained. If the crystals be not immediately collected on a filter, washed, and dried, but allowed to remain in the cold mother liquid for about a week, they are completely converted into calcite. The transformation goes more slowly under water. O. Knöfler stated that if precipitated above 17°, the grains of calcium carbonate are crystalline and not amorphous, and J. L. Smith added that in order to get as dense a precipitate as possible the soln. should be warmed at least to 70°. R. Fresenius showed that ammonium carbonate is retained very tenaciously by the precipitated carbonate. According to E. Drechsel, if commercial ammonium carbonate be used as precipitant, some soluble calcium carbonate will be formed. O. Knöfler also found that if strontium or barium carbonate be precipitated below 0° it is crystalline. According to M. Adler, the precipitation of calcium carbonate as aragonite is determined by the temp. of the soln., the conc., the nature of the atm. in which the precipitation is made, and by the press. In the preparation of calcium carbonate from soln. of calcium chloride and ammonium carbonate, the temp. at which the aragonite-form is converted into the calcite-form is increased to a much greater extent by an increase in the conc. of the calcium chloride. Using the ammonium carbonate of such a conc. that on adding the calcium chloride a thick, gelatinous mass is obtained, the limit of temp. for the ammonium carbonate soln. is 32°, whilst the calcium chloride may be used boiling. With dil. soln. at the same temp., the aragonite crystals are at once converted into calcite; the limit of temp. for weak soln. is 22°, and the lower the temp. the smaller and more stable are the crystals of aragonite. The presence of carbonic anhydride in the soln. determines the formation of calcite, and this explains the formation of calcite when the ammonium carbonate is at a high temp., as it is then decomposed, with the formation of carbonic anhydride. Precipitated aragonite-when subjected to a press. of 5–6 atm., is converted into calcite. The aragonite, form is more stable when the soln. is alkaline with an excess of ammonium carbonate, and also when the precipitate is washed with water containing calcium sulphate instead of with pure water. When the aragonite prepared from calcium chloride and ammonium carbonate is separated from the mother liquor and heated to 60°, it is converted into calcite; on the other hand, the aragonite precipitated by sodium carbonate can be heated to 100° without change. H. A. von Vogel obtained similar results with ammonium carbonate and soln. of barium chloride as he obtained with potassium hydrocarbonate.

Calcium carbonate is likewise precipitated when an alkali carbonate is added to a soln. of a calcium salt. J. J. Berzelius emphasized the fact that when calcium carbonate is precipitated by an alkali carbonate, the latter is retained very tenaciously; and in order to remove the adsorbed alkali, C. Heyer recommended calcining the precipitate until it begins to sinter, and then extracting the adsorbed alkali with water—*vide* the double alkali and calcium carbonates. According to H. Rose, if a soln. of potassium hydrocarbonate in 20 parts of water be added to an eq. soln. of barium chloride, one-fourth of the precipitate formed redissolves. The barium carbonate separates when the soln. is allowed to stand, and when an excess of the precipitant is used. Similar results were obtained with a calcium salt and potassium hydrocarbonate. J. B. J. D. Boussingault studied the reaction, and C. J. B. Karsten found that if barium hydroxide be added to a conc. soln. of potassium carbonate no precipitation occurs; but if the soln. be diluted, barium carbonate separates out. J. Bevad[12] attempted to measure the rate of formation of the carbonates of the alkaline earths under different conditions by the action of lithium, sodium, and potassium carbonates on soln. of the corresponding chlorides. He concluded that the speed of formation of the carbonates is greatest during the first five minutes, and it increases at the same rate as the quantity of insoluble salt formed and as the conc. of the salt used for the precipitation increases in the direction from lithium to potassium, and from calcium to barium. The average speeds of the reactions after the first five minutes decrease rapidly with increasing conc. of the alkali carbonate, and in the direction from lithium to potassium, and from calcium to barium. The equilibrium conditions between soln. of calcium chloride and sodium carbonate have been studied by M. M. P. Muir; and between barium chloride and sodium carbonate by J. Morris. The reaction: $Na_2CO_3+Ca(OH)_2\rightleftharpoons CaCO_3+2NaOH$. has been discussed in connection with the caustification of sodium carbonate.

According to G. Rose, if dil. soln. of calcium chloride and sodium carbonate are allowed to diffuse slowly into one another, crystals of aragonite are formed; while if conc. soln. be employed, crystals of calcite are produced. If boiling soln. of the two salts are mixed, aragonite is precipitated; P. Harting obtained similar results. G. Rose further found that if the turbid liquid obtained by mixing calcium chloride and sodium hydrocarbonate be boiled, calcite is formed. F. Senft evaporated soln. of calcium carbonate in ammonium crenate, and obtained crystals of calcite; while calcite was deposited from soln. of the carbonate in aq. carbonic acid. L. M. Michel obtained aragonite by the slow evaporation of a soln. of calcium hydrocarbonate in water sat. with carbon dioxide. Crystals of strontianite and witherite can be prepared in a similar way. In opposition to G. Rose, H. Credner, etc., H. Vater found that while aq. soln. below 30° always gave trigonal calcite, hot soln., particularly when cooled rapidly, gave rhombic aragonite; he observed that when the soln. contained calcium, sodium, and potassium sulphates, chlorides, nitrates, hydrocarbonates, etc., calcite, never aragonite, crystals were always obtained. F. Vetter studied the effect of seeding the crystallizing soln. with aragonite, and found that aragonite does not crystallize from the soln. if the temp. is below 30°; while the seeding of a soln. above 30° with calcite, hinders the formation of aragonite and furnishes calcite crystals. L. Bourgeois heated precipitated calcium carbonate with ammonium chloride or nitrate, urea, and water in a sealed tube at 150°–180°, and obtained crystals of calcite and aragonite; and when the urea was omitted, crystals of calcite alone appeared. He also made crystals of strontianite and witherite by a similar method. C. Friedel and E. Sarasin heated precipitated calcium carbonate with an aq. soln. of calcium chloride in a sealed steel tube for 10 hrs. at 500°, and obtained large crystals of calcite; the formation of aragonite was not observed. M. Kleinstück obtained crystals of calcite by heating precipitated and well-washed calcium carbonate with a neutral soln. of calcium chloride. A. C. Becquerel found that crystals of calcite were formed on a crystal of gypsum which has been for 20 years in contact with a soln. of potassium carbonate, and aragonite crystals with a soln. of potassium hydrocarbonate; A. C. Becquerel also obtained crystals of calcite by leaving gypsum in contact with a soln. of sodium hydrocarbonate of sp. gr. 1·014, and aragonite with a soln. of the same salt of sp. gr. 1·036–1·043. M. Miron and M. Bruneau observed that when a river-water was used to work an aspirator sucking air charged with ammonia gas, the ammonia neutralized the free carbonic acid in the water, and the calcium carbonate, previously held in soln., was deposited in the exit tube in the form of crystals of calcite. Crystals of witherite are obtained in a similar way by using a soln. of barium carbonate in water charged with carbon dioxide. J. Zöega, H. Drevermann, H. Vohl, and H. Vater prepared crystals of calcite or witherite by the slow admixture of the required soln. J. Zöega suspended a bag containing crystallized baryta in a mixed soln. of baryta-water and potassium hydroxide, and allowed the air to act thereon. Calcite crystals were obtained in an analogous manner. According to H. Credner, the presence of a little lead or strontium carbonate, or calcium sulphate, favours the formation of aragonite. M. Bauer used soln. containing a little barium carbonate. F. Cornu obtained aragonite by crystallization from aq. soln. of calcium carbonate in carbonic acid containing a little manganese sulphate; H. Leitmeier found other readily dissociated salts—*e.g.* magnesium chloride—act similarly. Crystals of calcite, aragonite, and dolomite are formed when a soln. of calcium carbonate in water sat. with carbon dioxide is mixed with some magnesium chloride or sulphate and kept at 2°, 20°, and 90°. A larger proportion of aragonite is formed at the higher temp. H. Leitmeier said that only the rhombic form crystallizes from a soln. of calcium hydrocarbonate containing magnesium sulphate; at 20°, the ratio is $H_2O : CaCO_3 : MgSO_4.7H_2O = 1000 : 1 : 10$. W. Meigen and E. Hatschek have studied the crystallization of calcite and aragonite from soln. of calcium chloride and various carbonates. According to G. Rose, if a little chalk, calcite, aragonite, or calcium chloride be dissolved in a molten mixture of sodium and potassium carbonates, and the cold mass extracted with water, a granular mass is obtained which forms calcite crystals on standing 24 hrs. in the cold, whereas if the soln. be boiled, aragonite crystals appear. L. Bourgeois obtained crystals of calcite from a soln. of calcium carbonate in a fused mixture of sodium and potassium chlorides. Crystals of strontianite and witherite were prepared in a similar manner.

G. Linck[13] represents the transformations of the different forms of calcium carbonate by the scheme:



which makes it appear as if calcite is the stable form at ordinary temp. The phases aragonite and calcite are monotropic for they present a case where the two allotropic forms can remain in contact with one another without undergoing transformation, so that it is not clear which of the two forms is the more stable. If the denser form aragonite be heated to about 400°, E. Mitscherlich, and G. Rose found that it passes into the less dense calcite, but on cooling, the reverse transformation does not occur. Both calcite and aragonite crystallize at ordinary press. from solvents. G. Rose, and O. Mügge have shown that the transformation of aragonite into calcite proceeds very slowly at 410°, and even as low as 400°; and at 470° H. E. Boeke converted aragonite from Bilin into calcite. The velocity of transformation of calcite to aragonite was found by H. L. J. Bäckström to be zero for a considerable range of temp., and also decreases with time, so that the law for heterogeneous reactions does not apply. P. N. Laschtschenko found the heats of cooling of aragonite and calcite are the same up to 455°; between 445° and 465° the value for aragonite is greater than for calcite; and the difference increases with the temp. Above 465° the difference becomes less, and at 470° the two values are identical, thus showing that the transformation of aragonite into calcite begins at 445° and is completed at 470°. The beginning of the transformation is characterized by the crystals becoming turbid, and the turbidity disappears at 470°. The sp. gr. determinations at different temp. are in harmony with this conclusion. It is therefore inferred that at temp. exceeding 470°, calcite is alone stable at atm. press. H. E. Boeke showed that pseudomorphs of calcite after aragonite are formed above 470°. H. W. Foote showed that at a temp. of about 100°, calcite is probably more stable than aragonite. G. Tammann suggested that the transformations with aragonite and calcite resemble those with phenol. and illustrated them diagrammatically by curves resembling Fig. 53. If the temp. exceeds the limits *AC*, aragonite is converted into calcite; and calcite is converted into aragonite if the temp. exceeds *BC*, and *CD* represents the effect of press. on the transition temp.:—Aragonite$\rightleftharpoons$Calcite. H. W. Foote believes that calcite is the stable form; his argument is based on the general observation that of two modifications of the same substance the more soluble variety is usually the less stable; aragonite is more soluble than calcite; and is therefore the less stable form. Usually also that modification which is stable at the higher temp. has the lower density—*e.g.* sulphur, mercuric iodide, silica, etc.—here, aragonite, the denser form, is that which is stable at the higher temp. Several other examples are known—*e.g.* arsenious oxide, antimonious oxide, potassium calcium chromate, phosphorus, arsenic, etc. W. Vaubel assumed that aragonite contains a little basic carbonate, $CO_2(O.Ca.OH)_2$, in order to explain the difference in the behaviour of aragonite and calcite; but H. Leitmeier showed that this hypothesis is not valid. J. Johnstone and co-workers say that while aragonite does not change at an appreciable rate into calcite below 400°, yet calcite is the stable form at ordinary press. below 970°, at which temp. it changes irreversibly into α-$CaCO_3$. There are indications that aragonite has a stable field of existence below —100°.

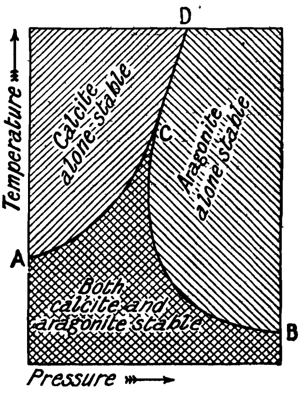


FIG. 53.—Zones of Stability of Calcite and Aragonite.

According to M. Rivière,[14] if carbon dioxide be passed into an aq. soln. of barium sulphide, barium carbonate and hydrosulphide are first formed: $2BaS+H_2O+CO_2=BaCO_3+Ba(SH)_2$; and the hydrosulphide is then decomposed: $Ba(SH)_2+H_2O+CO_2=BaCO_3+2H_2S$. The second reaction was found by A. Scheurer-Kestner to be very slow; and the product always contained sulphur. According to H. W. F. Wackenroder, the precipitated barium carbonate will be free from sulphur if the barium sulphide be mixed with an eq. amount of calcium chloride and the carbon dioxide be passed into the boiling soln. C. F. Claus also converted barium or strontium sulphide into carbonate by boiling it with magnesium chloride to get rid of the hydrogen sulphide, and afterwards treating the liquor with carbon dioxide to precipitate strontium carbonate. H. W. F. Wackenroder digested the sulphide with a soln. of calcium chloride and then passed carbon dioxide into the boiling soln.

The first stage in the conversion of native barium sulphate to carbonate usually involves the reduction of the sulphate to sulphide by heating it with carbonaceous matters as indicated in connection with barium oxide. C. F. Bucholz calcined a mixture of heavy spar, carbon, and sodium chloride; A. Duflos used a mixture of heavy spar, carbon, and sodium sulphate; E. F. Anthon used a mixture of heavy spar, carbon, and potassium carbonate; H. W. F. Wackenroder calcined the heavy spar with carbon, and extracted the soluble matter with a soln. of sugar. Barium saccharate was precipitated by boiling the soln., and by treatment with carbon dioxide was transformed into a soln. of sugar and a precipitate of barium carbonate. The mother liquid from the barium saccharate was evaporated to dryness and calcined for barium carbonate. W. H. Bresler claimed a quantitative yield by treating strontium sulphate in the presence of water and alkali carbonate, at 175°, with carbon dioxide under press. F. Gärtner treated strontium sulphate and a soln. of sodium phenolate with carbon dioxide under press. E. A. Mebus and J. W. Decastro digested the finely ground sulphate with a soln. of ammonium carbonate; F. G. Bolton treated the moist finely ground sulphate with a mixture of carbon dioxide and ammonia.

D. Urquhart and W. A. Rowell treated barium or strontium sulphate with sodium sulphate and sulphite, and heated the mixture with sodium carbonate. H. Grouven ignited a mixture of the sulphate with coal-dust and potassium magnesium sulphate, and extracted the mass with water. The strontium in soln. was precipitated with carbon dioxide.

C. Brunner[15] made barium carbonate by calcining a mixture of barium and sodium chlorides with sodium carbonate; and L. G. G. Daudenart and E. Verbert treated a soln. of barium chloride with magnesium carbonate, and passed in carbon dioxide. W. Spring obtained crystals of barium carbonate by fusing barium sulphate with sodium carbonate; and also by compressing a mixture of the dry salts at 6000 atm. J. H. MacMahon obtained barium carbonate by adding barium sulphide to the ammonium hydrocarbonate obtained from the liquor in the ammonia-soda process.

The following might appear to be a logical corollary from Bertholet's law (1. 7, 5). *Chemical reactions proceed wholly in one direction when one of the products of the reaction is more volatile or less soluble than the others and separates from the sphere of the reaction.* It is, however, necessary to apply caution, for while potash will completely precipitate *insoluble* copper hydroxide from soln. of copper sulphate, potash does not precipitate *insoluble* mercuric oxide from soln. of mercuric cyanide—probably because of the formation of a soluble double salt. Similarly, potassium oxalate will completely precipitate *insoluble* calcium oxalate from soln. of calcium chloride, but potassium oxalate will not precipitate *insoluble* mercuric oxalate from soln. of mercuric chloride. Again, insoluble barium sulphate is attacked by sodium carbonate, $BaSO_{4solid}+Na_2CO_{3soln.}\rightleftharpoons BaCO_{3solid}+Na_2SO_{4soln.}$, so that the reaction appears slightly reversible, even at comparatively low temp. When sodium carbonate is fused with barium sulphate, the latter is converted into the carbonate.

In 1819, J. F. Daniell[16] obtained from a sugar refinery, rhombohedral crystals of a hydrated calcium carbonate. T. Scheerer found in a running stream some small rhombohedral crystals which, when dried between filter-paper, had a composition corresponding with *pentahydrated calcium carbonate*, $CaCO_3.5H_2O$. E. Pfeiffer, W. F. Salm-Horstmar, and C. F. Rammelsberg found similar crystals. A. C. Becquerel obtained similar crystals on the platinum anode by the electrolysis of a soln. of lime in sugar; and T. J. Pelouze obtained these crystals by boiling one part of lime with three parts of sugar—lactose, gum, or starch—and six of water, and then exposing the soln. in a cold place for some six months. T. S. Hunt dissolved freshly precipitated calcium and magnesium carbonates in an aq. soln. of calcium chloride, or magnesium sulphate, and found crystals of the hydrated calcium carbonate gradually deposited while the magnesium carbonate remained in soln. J. Roth used a soln. of sodium hydrocarbonate as solvent.

O. Bütschli obtained crystals corresponding with **hexahydrated calcium carbonate,** $CaCO_3.6H_2O$, from soln. containing the blood of the cray-fish at 0°, and W. Biedermann similarly obtained monoclinic crystals which rapidly passed into the monohydrate on exposure to air. H. Vetter obtained the hexahydrate from sea-water containing calcium hydrocarbonate and magnesium salts. J. Johnstone and co-workers made it by precipitation from an alkaline soln. at 0°. The monoclinic crystals have the axial ratios $a:b:c=1{\cdot}02:1:?$. The refractive indices are $\alpha=1{\cdot}460$; $\beta=1{\cdot}535$; and $\gamma=1{\cdot}545$.

K. Kosmann described a Silesian mineral as *hydrocalcite;* for when dried over sulphuric acid, it corresponded with *dihydrated calcium carbonate*, $CaCO_3.2H_2O$. In 1905, L. Iwanoff described a monoclinic or triclinic mineral from New Alexandria (Russia) with the composition $CaCO_3.nH_2O$, where n is not less than 3. According to N. Krischtofowitsch, this mineral was described in 1872 by K. Jurkiewicz as *Kalkschaum.* P. Tschirwinsky found that L. Iwanoff's mineral is *trihydrated calcium carbonate*, $CaCO_3.3H_2O$, or *trihydrocalcite.* J. Morozewicz has also made observations on the same mineral. With indecisive evidence of this nature, it appears as if there is a di- or tri-hydrocalcite, and a penta- or hexa-hydrocalcite, or possibly mixtures of colloidal calcium carbonate with the anhydrous salt.

§ 22. The Solubility of the Carbonates of the Alkaline Earths

Calcium carbonate is but sparingly soluble in water and its solubility in different solvents has attracted much attention on account of the bearing of the results on geological processes, and on the nature of soil soln. Determinations were made by C. Weltzien,[1] A. Cossa, T. Schlösing, L. F. Caro, A. W. von Hofmann, R. Irvine and G. Young, W. S. Anderson, N Ljubawin, E. Pollacci, etc. The reported numbers for the solubility of calcium carbonate in water in contact with air are somewhat discrepant. For example, R. Fresenius found a litre of water dissolves 0·0602 part of calcium carbonate at ordinary temp., while A. Bineau found 0·02 part; G. Bischof, 0·028 part; L. F. Caro, 0·03 part; J. L. Lassaigne, 0·007 to 0·088 part. A. F. Hollemann, 0·01004 part at 8·7° and 0·0125 part at 23·8°; R. Warington, 0·009852 part at 21°; and F. Gothe gave 0·037 grm. per litre of gas-free water. A. Bineau wrongly inferred that calcium carbonate is less soluble at 100° than at 16°. R. Fresenius found that a litre of water at 100° dissolves 0·0111 part, and E. Pollacci, 0·0143 part of calcium carbonate.

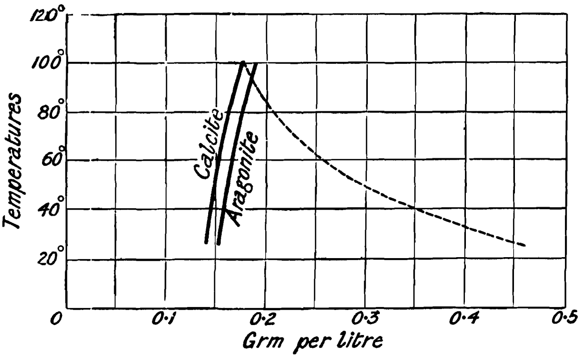

FIG. 54.—Solubility of Calcite and Aragonite in Water.

J. Kendall obtained the results indicated in Fig. 54, for the solubility of calcite and aragonite in a litre of water freed from carbon dioxide and in an atm. freed from the same gas; while the dotted curve represents the solubility of calcite in water exposed to atm. air. The results, in grams per litre, are :

	25°	50°	100°
Calcite	0·0143	0·0150	0·0178
Aragonite	0·0154	0·0162	0·0190

The ratio of the two solubilities at a given temp. is nearly constant as illustrated by the nearly parallel solubility curves. The data for precipitated calcium carbonate and soft chalk are virtually the same as for calcite, so that amorphous calcium carbonate is assumed to be so extremely unstable that solubility data cannot be obtained. J. Kendall also stated that vaterite has the same sp. gr. as aragonite, and that the higher solubility is due to the obstinate retention of a trace of carbon dioxide by the soln. H. L. J. Bäckström found the solubilities in the presence of carbon dioxide at a press. of 742–777 mm. to be for calcite 1·30, 0·943, and 0·765 grms. per litre respectively at 9°, 25°, and 35°, and likewise for aragonite 1·46, 1·066, and 0·876 grms. per litre. F. Kohlrausch and F. Rose showed that a litre of water dissolved :

		2°	10°	18°	26°	34°
$CaCO_3$	precipitated . .	16	21	27	30	— mgrms.
	calcite . . .	4·6	20	26	32	39 „
	aragonite . .	17·6	23·5	30·5	39	48 „
$SrCO_3$	. . . . .	7·7	11	15	—	26 „
$BaCO_3$	. . . . .	—	17	24	—	— „

In harmony with the generalization: *Of two different forms of a compound, the less stable modification is usually the more soluble,* the solubility of aragonite in water is a little greater than that of calcite. Corresponding with this, the equilibrium constant in the reaction between aragonite and potassium oxalate, $CaCO_3 + K_2C_2O_4 \rightleftharpoons CaC_2O_4 + K_2CO_3$, is nearly 1·3 times greater than that in the reaction between calcite and potassium carbonate; similar results were obtained in the precipitation of the heavy metals by calcite and by aragonite. The partial pressure of the carbon dioxide over aragonite is nearly 1·4 times greater than it is with calcite at 8°. and 1·13, at 25°.

The temp. coeff. at 18° for the solubility of calcium carbonate is 0·0008; for strontium carbonate, 0·015; and for barium carbonate, 0·013. Solubilities calculated from the electrical conductivities are erroneous when the salts are appreciably hydrolyzed. D. Gardner and D. Gerassimoff found the conductivity of a sat. soln. of barium carbonate diminishes in the presence of an increasing proportion of sodium hydroxide until it reaches a limiting value 6×10^{-6} in place of $28·6\times10^{-6}$ obtained with water as solvent. The conductivity of a soln. of barium sulphate is not affected by the presence of sodium hydroxide.

The solubility of strontium carbonate in water was found by A. Bineau to be 0·010 grm. per litre; by R. Fresenius, 0·0554 grm. per litre; and 0·080 grm. per litre by P. Kremers. A. F. Hollemann found a litre of water at 8·8° dissolves 0·00082 grm. of strontium carbonate; and at 24·3°, 0·0109 grm.; and for barium carbonate he found 0·016 grm. per litre at 8·8° and 0·024 grm. at 24·2°. A litre of water sat. with CO_2 dissolves 1·19 grms. of strontium hydrocarbonate, and, according to A. M. Pleischl, when the soln. is evaporated it redeposits the strontium carbonate in needle-like crystals. H. N. McCoy and H. J. Smith measured the solubility of strontium carbonate in water containing carbon dioxide at press. ranging from 0·05 to 1·1 atm. A. Bineau also found the solubility of barium carbonate to be 0·0025 grm. per litre of water; R. Fresenius gave 0·0707 grm. per litre at 16°–20°; and 0·068 grm. per litre in boiling water; and P. Kremers gave 0·083 grm. per litre. G. Wagner gives a solubility of 7·25 grms. of barium carbonate per litre with water sat. with carbon dioxide at 4–6 atm. press. According to H. W. Foote and G. A. Menge, the relative solubilities of calcium and barium carbonates at room temp. are $\sqrt[3]{(Ca/Ba)}=1·20$; F. Kohlrausch and F. Rose's data give for this ratio 1·08.

The aq. soln. of calcium carbonate was found by M. Pettenkofer to be neutral towards turmeric, but if the soln. has lost some carbon dioxide the indicator is browned. As shown by A. Laugier, A. M. Pleischl, and G. Rose, if water is boiled with powdered marble or chalk, it colours red-litmus blue. Powdered marble, chalk, Iceland spar, calcite, or aragonite were found by C. A. Kenngott, A. Laugier, A. M. Pleischl, G. Rose, C. R. C. Tichborne, and W. Skey to be alkaline towards litmus or extract of violets; and F. Cornu, that a soln. of phenolphthalein is reddened when the powdered mineral is shaken with water. F. Mohr found that cochineal tincture is coloured violet; but R. Fresenius reported an aq. soln. has a scarcely appreciable alkaline reaction. H. Rose believed that boiling water exerted no chemical action on calcium and barium carbonates. The solubility of calcium carbonate in water at 100° is given by A. W. von Hofmann as 0·034; C. Weltzien, 0·036; R. Fresenius, 0·111; and E. Pollacci, 0·143 grm. per litre. The increased solubility at 100° is not likely to be due to the formation of a hydrate stable at 100°. H. le Chatelier showed that calcium carbonate dissociates in boiling water and loses carbon dioxide, and A. Cavazzi found that in consequence it is not possible to get a soln. of calcium carbonate alone in boiling water, for calcium hydroxide also passes into soln. This quantity depends on the duration of boiling, and on the conc. and vol. of the soln. The limit of the dissociation is attained when 15 c.c. of a soln. of calcium hydroxide, sat. at ordinary temp., is present per litre. The dissociation of calcium carbonate in boiling soln. is prevented if 0·05 grm. of sodium carbonate per litre is present.

F. W. Küster showed that in aq. soln. calcium carbonate is not only ionized, but is also hydrolyzed; and G. Bodländer calculated that between 80 and 83·4 per cent. of calcium carbonate is hydrolysed in aq. soln.; and between 78 and 82 per cent. of barium carbonate is similarly hydrolyzed. Consequently, assuming that the reaction is typified by $CaCO_3+2H_2O\rightleftharpoons Ca(OH)_2+H_2CO_3$, the dissociation of the carbonic acid is determined by the partial press. of the carbon dioxide of the atm. in contact with the soln. It follows from the balanced reaction that the greater the conc. of the carbon dioxide in the soln., the less the solubility of the calcium carbonate. The direct converse actually obtains, for calcium carbonate readily dissolves in aq. soln. of carbonic acid. Sat. lime-water is rendered turbid by carbon dioxide, but as the passage of the gas is continued, the opacity nearly disappears, and if a little more water is added, a clear soln. is obtained. When the aq. soln. is exposed to air, or boiled, normal calcium carbonate is precipitated. It is therefore inferred, by analogy with other cases, that soluble calcium hydrocarbonate, $Ca(HCO_3)_2$, is formed: $CaCO_3+H_2CO_3\rightleftharpoons Ca(HCO_3)_2$. R. Irvine found heat was evolved during the precipitation of the carbonate when carbon dioxide is passed into a soln. of lime-water, and a second rise of temp. occurs when the precipitate begins to dissolve. The second rise of temp. was attributed to the formation of the hydrocarbonate. E. P. Treadwell and M. Reuter found that under press. of one atm., the solubility of calcium carbonate varied continuously with the press. in the gas phase; and at 15°, with a zero partial press. in the gas phase, the molar proportions $CaO : CO_2$ in the soln. exactly correspond with calcium hydrocarbonate. P. N. Raikow found lime-water absorbed enough carbon dioxide to form a hydrocarbonate, and, making a correction for the solubility of carbon dioxide in water, it is claimed that the remaining gas must be bound chemically, since it cannot be removed by mechanical means, and was always present in the requisite amount. A. Cavazzi analyzed soln. of the alleged calcium hydrocarbonate prepared in various ways, and found the results in agreement with the formula $CaO.2CO_2.nH_2O$.

The partial press. of the carbon dioxide in the atm. determines the conc. of the unstable carbonic acid: $H_2CO_3\rightleftharpoons H_2O+CO_2$, in the soln., and the conc. of the carbonic acid, in turn, determines the conc. of the carbonate in soln. While air normally contains about 3 parts of carbon dioxide per 10,000, comparatively small changes in the conc. of this gas in the atm. may bring about the soln. or deposition of large quantities of calcium carbonate. The amount of calcium carbonate which will dissolve in water in contact with air, and the variability of this solubility with the carbon dioxide content of the atm., are of great importance in connection with a number of geological processes. R. C. Wells obtained rather higher solubilities than J. Kendall for calcite and aragonite, possibly because of the greater conc. of the atm. carbon dioxide; and, when the atm. contained between 3·02 and 3·27 parts of carbon dioxide in 10,000, R. C. Wells found the solubility of calcium carbonate in grams per litre to be:

	0°	10°	20°	25°	30°	40°	50°
$CaCO_3$ . .	0·081	0·070	0·065	0·050	0·052	0·044	0·038

T. Schlösing measured the solubility of calcium and barium carbonates in water with carbon dioxide in soln. J. Johnstone calculated the solubility of calcium, carbonate in water, at 16°, from measurements by T. Schlösing, and R. Engel, and expressing the results in gram-atoms of Ca and in mols of $Ca(HCO_3)_2$ per litre, when the partial press. of the carbon dioxide is p atm., found:

p . .	0·000504	0·000808	0·00333	0·0282	0·0501	0·1422	0·5533	0·9841
Ca . .	0·000746	0·000850	0·001372	0 002965	0·003600	0·005330	0·008855	0·01086
$Ca(HCO_3)_2$	0·000731	0·000837	0·001364	0·002961	0·003597	0·005328	0·008854	0·01086

H. N. McCoy and H. J. Smith obtained the following solubilities for calcium carbonate at 25°, in contact with air containing carbon dioxide at partial press. p atm., when the results are expressed in grams per litre of sat. soln.:

p	0·1	1·1	9·9	13·2	16·3	25·4
H_2CO_3 . . .	0·22	2·3	20·6	27·5	34·1	53·2
$Ca(HCO_3)_2$ . .	0·67	1·58	3·62	4·04	4·21	4·22
Solid phase	$CaCO_3$				$Ca(HCO_3)_2$	

These results show that the soln. is sat. with calcium hydrocarbonate when the carbon dioxide exerts about 15 atm. press., and that it should be theoretically possible to convert all the normal carbonate into hydrocarbonate by introducing sufficient carbon dioxide at 15 atm. The reaction is so slow that it would require three months for the complete conversion. A. Cavazzi found the solubility of calcium carbonate in water sat. at one atm. press. to be 1·50 grms. per litre at 0°, and 1·1752 grms. at 15°. A supersat. soln. prepared by passing a very rapid stream of carbon dioxide through a sat. soln. of lime-water at 15° contained 2·29 grms. of calcium carbonate. J. W. Leather and J. Sen measured the solubility of calcium carbonate in contact with air containing 0·8 to 31·6 partial press. of carbon dioxide at 15°, 20°, 25°, 30°, 35°, and 40°, but their results for carbon dioxide are probably too low. They found the solid phase to be always the normal carbonate, and concluded that the solid hydrocarbonate is not stable above 15°. H. Ehlert, and C. A. Seyler and P. V. Lloyd also measured the solubility of calcium carbonate in the presence of an excess of carbon dioxide.

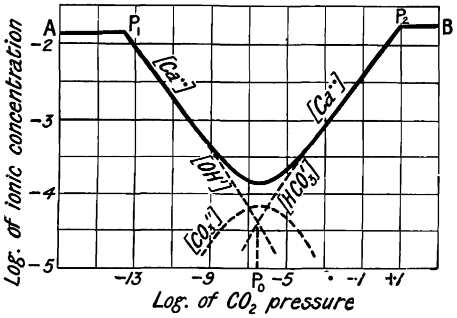

FIG. 55.—Relation between the Partial Pressure of Carbon Dioxide and the Concentrations of the several Ions in the System, $CaO—H_2O—CO_2$, at 16°.

J. Johnstone and E. D. Williamson have shown that the conc. of the calcium carbonate in soln. at equilibrium in the system $CaO—H_2O—CO_2$ can be represented by three curves along which the stable solid phase is hydroxide, carbonate, and hydrocarbonate respectively. In Fig. 55, the stable solid phase along AP_1 is hydroxide; between P_1 and P_2 it is carbonate; and along P_2B it is hydrocarbonate. The curves, Fig. 55, were plotted from Table XIII. J. Johnstone and E. D. Williamson have shown that the equilibrium between the hydroxide $Ca(OH)_2$ and the sat. aq. soln. is affected by a progressive increase from zero to a partial press. P of carbon dioxide in the atm. in contact with the soln., in the following manner: The addition of carbon dioxide is followed by a distribution between the vapour and liquid phases until there is equilibrium between the residual partial press. of the carbon dioxide and the carbonic acid, H_2CO_3, in soln., and, in turn, between the latter and the several ions. The net effect is a definite decrease in the conc. of the hydroxide ions $[OH']$, which requires that more hydroxide be dissolved in order to maintain the constancy of the solubility product $[Ca^{\cdot\cdot}][OH']^2$. Consequently, the total conc., $[Ca^{\cdot\cdot}]$, increases, part of it being now present as carbonate and hydrocarbonate. Otherwise expressed, the apparent solubility of the base increases if the method of analysis is a determination of Ca, and it would decrease if the conc. $[OH']^2$ were determined. This

process continues until the product $[Ca^{\cdot\cdot}][CO_3'']$ reaches the value needed for the precipitation of calcium carbonate—assuming that no supersaturation occurs, and no basic carbonate is formed. This precipitation occurs at a definite value of P, which depends only on the temp. and is about $P_1=10^{-14}$ atm. at 16°. At a given temp., this transition press. is the highest under which solid hydroxide is stable. At P_1 the solubility as measured by the total $[Ca'']$ begins to diminish, because an increase of the partial press. of carbon dioxide increases the conc. $[CO_3'']$, while the product $[Ca^{\cdot\cdot}][CO_3'']$ remains constant so long as $CaCO_3$ is the stable solid phase. This increase of $[CO_3'']$ continues until a definite press. P_0 is reached, and the formation of hydrocarbonate in soln. then becomes the predominant reaction, and the conc. $[CO_3'']$ begins to decrease again. P_0 thus corresponds with a minimum in the solubility curve. At 16°, P_0 is nearly $3{\cdot}73\times10^{-7}$ atm. or about 0·016 grm. of calcium carbonate per litre. As the partial press. of carbon dioxide increases beyond P_0, the conc. of both $Ca^{\cdot\cdot}$ and HCO_3' increase steadily until the precipitation value of the product $[Ca^{\cdot\cdot}][HCO_3']_2$ is reached, when the partial press. is approximately $P_2=15$ atm., and both carbonate and hydrocarbonate are present as solid phases. Beyond P_2, the hydrocarbonate is alone stable, and its total solubility falls off very slowly with a further increase in the partial press. of carbon dioxide.

Again, there can be no real equilibrium in aq. soln. of calcium carbonate except in the presence of a definite press. of carbon dioxide in the atm. in contact with the soln. If a stream of an indifferent gas—free from carbon dioxide—be passed through a soln. of calcium carbonate, the soln. would gradually lose its carbonate and ultimately contain only the hydroxide. For equilibrium in the system: $CaCO_3+H_2CO_3\rightleftharpoons Ca(HCO_3)_2$, $[H_2CO_3]=k[Ca(HCO_3)_2]$; and assuming that the carbonic acid is non-ionized, $i=1$, and that for the hydrocarbonate, $Ca(HCO_3)_2$, $i=2{\cdot}56$, in agreement with f.p. measurements, J. H. van't Hoff writes $\log[H_2CO_3]-2{\cdot}56\log[Ca(HCO_3)_2]=k$, or, if y denotes the conc. of the dissolved lime, corresponding with the conc. of the hydrocarbonate, and if P denotes the partial press. corresponding to the conc. of the carbonic acid, and c be a constant, $y=cP^{0\cdot39}$, so that the quantity of lime dissolved is proportional to the press. of the carbon dioxide raised to the 0·39 power. The limiting case for complete ionization of the hydrocarbonate gives $y=cP^{0\cdot333}$. T. Schlösing found empirically $0{\cdot}92128y=P^{0\cdot37866}$, when P is between zero and unity. If a curve of this type correctly interprets the observed results it is not probable that calcium hydrocarbonate is formed, because the initial solid phase is calcium carbonate, and the curve would be continuous without a break for a change of the solid phase to hydrocarbonate. L. F. Caro showed that the relation is not applicable at higher press. H. Vater investigated the relation between the conc. of the hydrocarbonate and that of the carbon dioxide in soln.

G. Bodländer has studied the equilibrium conditions between the dissolved carbon dioxide and calcium- or barium carbonate. So long as calcium carbonate is the solute, the equilibrium condition is $[Ca^{\cdot\cdot}][CO_3'']=k_1$; when carbon dioxide is introduced, the conc. of the Ca-ions increases, and that of the CO_3-ions decreases. The carbonic acid, H_2CO_3, in soln. ionizes: $H_2CO_3\rightleftharpoons H^{\cdot}+HCO_3'$ and $HCO_3'\rightleftharpoons H^{\cdot}+CO_3''$. The equilibrium condition for the former is $[H^{\cdot}][HCO_3']/[H_2CO_3]=k_2$, and for the latter, $[H^{\cdot}][CO_3'']/[HCO_3']=k_3$; or $k_2[H_2CO_3][CO_3'']=k_3[HCO_3']^2$; and $k_1k_2[H_2CO_3]=k_3[HCO_3']^2[Ca^{\cdot\cdot}]$; but each Ca-ion corresponds with two HCO_3-ions, or $[Ca^{\cdot\cdot}]=\frac{1}{2}[HCO_3']$, and therefore $2k_1k_2[H_2CO_3]=k_3[HCO_3']^3$. By Henry's law, $[H_2CO_3]=k_4[CO_2]$. Consequently. $2k_1k_2k_4[CO_2]=k_3[HCO_3']^3$. All four constants have been determined. J. Walker and W. Cormack found k_2 to be $3{\cdot}04\times10^{-7}$; J. Shields found $k_3=1{\cdot}295\times10^{-11}$; and k_4, calculated from T. Schlösing's data, is 0·04354. Hence, $[HCO_3']=12{\cdot}69\sqrt[3]{k_1}[CO_2]$; and again from T. Schlösing's data, $k_1=28{\cdot}42\times10^{-16}$. Similar results were obtained with barium carbonate. G. Bodländer's value for the solubility product of calcium carbonate is considered to be erroneous owing to the use of an incorrect value for k_3, the secondary ionization constant of carbonic acid. J. Stieglitz calculated $k_3=6{\cdot}20\times10^{-11}$. This secondary constant increases with increasing conc. of the alkali carbonate soln. used in its determination. The **solubility product** of calcium carbonate, calculated by J. Stieglitz, is $k_1=12{\cdot}6\times10^{-9}$; H. N. McCoy and H. J. Smith found $k_1=9{\cdot}3\times10^{-9}$. The latter also give for the solubility product of strontium carbonate, $[\mathrm{Sr}^{\cdot\cdot}][\mathrm{CO}_3'']=k_1$, or $k_1=1{\cdot}567\times10^{-9}$; and for barium carbonate, $[\mathrm{Ba}^{\cdot\cdot}][\mathrm{CO}_3'']=k_1$, or $k_1=8{\cdot}1\times10^{-9}$. J. Johnstone gives for barium carbonate $7{\cdot}0\times10^{-9}$ at 16°, and he found the solubility product of calcium carbonate (calcite) to be $0{\cdot}98\times10^{-8}$, at 16°, and C. A. Seyler and P. V. Lloyd found $0{\cdot}86\times10^{-8}$ at the laboratory temp. The data have been re-calculated by Y. Osaka.

F. K. Cameron and A. Seidell measured the solubility of calcium carbonate in aq. soln. of *sodium chloride*. Expressing the solubilities in grams per 100 c.c. of soln., at 25°, they found with soln. in equilibrium with ordinary air:

NaCl . .	1	4	8	10	15	20	25
$CaCO_3$ . .	0·0112	0·0140	0·0137	0·0134	0·0119	0·0106	0·0085

F. K. Cameron, J. M. Bell, and W. O. Robinson found for soln. in contact with air freed from carbon dioxide, at 25°:

NaCl . .	1·60	5·18	9·25	11·48	16·66	22·04	30·50
$CaCO_3$.	0·0079	0·0086	0·0094	0·0104	0·0106	0·0115	0·0119

and for carbon dioxide at atm. press.:

NaCl . .	1·49	5·69	11·06	15·83	19·62	29·89	35·85
$CaCO_3$ . .	0·150	0·160	0·174	0·172	0·159	0·123	0·103

The solubility curve shows a well-defined maximum corresponding with a soln. containing 0·1402 grm. of normal carbonate per litre. This is about 80 times the amount dissolved by water freed from carbon dioxide. The maximum point with the soln. in equilibrium with air represents a solubility about 2·36 times the result withwater containing no sodium chloride. The sp. gr. of the soln. were also measured. F. K. Cameron, J. M. Bell, and W. O. Robinson also obtained data for the solubility of calcium carbonate in aq. soln. containing both sodium chloride and calcium sulphate, and in aq. soln. containing both sodium chloride and calcium sulphate. E. P. Treadwell and M. Reuter, E. A. Rowe, F. Gothe, H. Cantoni and G. Goguélia, and C. A. Seyler and P. V. Lloyd measured the effect of sodium chloride on the solubility of calcium carbonate. H. Ehlert and W. Hempel likewise measured the solubility in sodium chloride soln. at 5° in contact with an atm. freed from carbon dioxide, and in contact with that gas at 2 atm. press. T. Warynsky and S. Kouropatwinska found a litre of an aq. soln. containing 175·5 grms. of sodium chloride dissolved 0·062 grm. of calcite, or 0·071 grm. of aragonite at 60°.

F. K. Cameron and W. O. Robinson measured the solubility of calcium carbonate in aq. soln. of *potassium chloride*, at 25°, (*a*) in contact with air, and (*b*) in contact with carbon dioxide at one atm. press. Expressing the results in grams of salt per 100 grms. of sat. soln., they found:

KCl . .	0	3·90	7·23	11·10	13·82	18·21	26·00
$CaCO_3$ (*a*) .	0·0013	0·0078	0·0078	0·0076	0·0072	0·0070	0·0060
$CaCO_3$ (*b*) .	0·062	0·145	0·150	0·166	0·165	0·154	0·126

The sp. gr. of the soln. were also measured. E. A. Rowe, and H. Cantoni and G. Goguélia also measured the effect of potassium chloride on the solubility of calcium carbonate. H. Cantoni and G. Goguélia investigated the action of the alkali chlorides on barium carbonate; E. Taponier, the action of *alkali bromides* on barium carbonate. T. Warynsky and S. Kouropatwinska found a litre of an aq. soln. of potassium chloride at 60° dissolves 0·075 grm. of calcite, or 0·093 grm. of aragonite.

The latter also found for the solubility of calcite and of aragonite in aq. soln. of *ammonium chloride*, when the results are expressed in grams per litre, at 60°:

NH_4Cl . .	0	1·07	5·035	10·70	26·76	53·52	160·56
Calcite . .	0·028	0·164	0·333	0·453	0·664	0·934	1·21
Aragonite .	0·041	0·184	0·371	0·505	0·728	1·015	1·36

H. Cantoni and G. Goguélia measured the solubility at 12°–18°, and A. Rindell at 25°. M. Bertrand, and E. A. Rowe also studied the solubility of calcium carbonate in soln. of the ammonium salts. A. Vogel found freshly precipitated calcium carbonate dissolves readily in a cold conc. soln. of an ammonium chloride, but with difficulty after the precipitate has stood for 24 hrs., and calcite or marble dissolves with still greater difficulty. E. A. Rowe, and C. A. Seyler and P. V. Lloyd measured the solubility of calcium carbonate in aq. soln. of *calcium chloride*. The solubilities of barium and strontium carbonates in aq. soln. of *ammonium nitrate*, ammonium chloride, and *ammonium succinate* have been studied by A. Vogel, R. H. Brett, G. C. Wittstein, H. W. F. Wackenroder, D. Smith, H. Demarçay, and H. Cantoni and G. Goguélia. The latter found that strontium carbonate is less soluble in a soln. of ammonium chloride than is calcium or barium carbonate; and they also measured the solubility of barium carbonate in soln. of sodium and potassium chlorides. G. Kernot, E. d'Agostino, and M. Pellegrino found the solubility of barium carbonate steadily increases with increasing proportions of ammonium chloride, and, at 25°, when the soln. contains 5 mols of the chloride per litre, the solubility curve assumes an upward inflexion, probably due to the formation of a double salt. C. J. B. Karsten observed the solubility of barium carbonate in an aq. soln. of calcium chloride; and H. Ehlert and W. Hempel, in aq. soln. of *magnesium chloride*, at 5°, in contact with an atm. freed from carbon dioxide, and also in contact with that gas at a press. of 2 atm.; E. A. Rowe also measured the solubility of calcium carbonate in the same menstruum. C. J. B. Karsten measured the solubility of barium carbonate in a soln. of *zinc chloride*.

R. Irvine and G. Young, W. Howchin, and E. Cohen and H. Raken studied the solubility of calcium carbonate in *sea-water*. R. C. Wells found that sea-water at 1° tends to retain more calcium carbonate in soln. than it does at 25°. Ordinary sea-water at 1° seems to contain so much carbonate that, in contact with the atm. at 1°, it has no appreciable solvent action on calcite; at a higher temp., sea-water undergoes a slow diminution in its carbonate content when agitated in contact with air. The equilibrium in the exchange of carbon dioxide between sea-water and the atm. is so slow, and the bulk of the ocean is so great, that the expected variations in the equilibria with temp. do not occur in the water of the open sea.

F. K. Cameron and A. Seidell measured the solubility of calcium carbonate in soln. of *sodium sulphate* in contact with air at 24°. Expressing the results in grams per litre:

Na_2SO_4 . .	5	10	20	40	80	150	250
$CaCO_3$ . .	0·175	0·232	0·277	0·332	0·400	0·510	0·725

Similarly, F. K. Cameron, J. M. Bell, and W. O. Robinson found at 25°, for soln. in contact with air freed from carbon dioxide:

Na_2SO_4 . .	0·97	1·65	4·90	12·69	14·55	19·38	23·90
$CaCO_3$ . .	0·151	0·180	0·262	0·313	0·322	0·346	0·360

H. Vater, E. A. Rowe, H. Ehlert and W. Hempel, and C. A. Seyler and P. V. Lloyd also measured the solubility of calcium carbonate in aq. soln. of sodium sulphate: the former at 14° in the absence of carbon dioxide, and with that gas at 2 atm. press. C. J. B. Karsten measured the solubility of barium carbonate in a soln. of sodium sulphate. F. K. Cameron and W. O. Robinson, E. A. Rowe, and H. Vater measured the solubility of calcium carbonate in aq. soln. of *potassium sulphate* at 25°; C. A. Seyler and P. V. Lloyd, in an aq. soln. of *calcium sulphate*; and they, as well as H. Ehlert and W. Hempel. and E. A Rowe, in an aq. soln. of *magnesium sulphate.* C. J. B. Karsten observed that calcium carbonate does not dissolve in a conc. aq. soln. of magnesium chloride ; and F. Hoppe-Seyler observed the formation of no dolomite when the soln. of magnesium chloride is allowed to stand in contact with calcium carbonate for a month; some magnesium carbonate, however, is precipitated, and calcium carbonate dissolved. A. Gössmann said that when boiled, a little calcium chloride and basic magnesium chloride is formed. C. J. B. Karsten observed the solubility of barium carbonate in a soln. of *zinc sulphate.* L. Vecchiotti investigated the action of *alkali nitrates* on barium carbonate : $BaCO_3 + 2MNO_3 \rightleftharpoons M_2CO_3 + Ba(NO_3)_2$, where M stands for K, Na, or NH_4. G. Berju and W. Kosinenko, and A. Rindell measured the solubility of calcium carbonate in aq. soln. of *ammonium nitrate* respectively at 1·8° and at 25°. Expressing results in grams per litre, the former found :

NH_4NO_3	0	5	10	20	40	80
$CaCO_3$	0·131	0·211	0·258	0·340	0·462	0·584

C. J. B. Karsten studied the solubility of barium carbonate in a soln. of *calcium nitrate.* J. Spiller noted that the presence of *sodium citrate* raises the solubility of calcium carbonate in water ; and A. Rindell found the solubility of calcium carbonate in aq. soln. containing 0·0625 and 0·500 mol of *triammonium citrate* per litre, at 25°, to be respectively 1·492 and 6·687 grms. per litre. M. le Blanc and K. Novotny measured the solubility of calcium carbonate in aq. soln. of *sodium hydroxide* in contact with air freed from carbon dioxide, and found at 18° and between 95° and 100° :

NaOH	0	0·0001*N*-	0·0010*N*-	0·0100*N*-
$CaCO_3$ at 18°	0·0128	0·0087	0·0042	0·0042 grm. per litre
$CaCO_3$ at 95° to 100°	0·0207	0·0096	0·0069	0·0057 „ „

C. A. Seyler and P. V. Lloyd, and E. A. Rowe measured the solubility of calcium carbonate in aq. soln. of *sodium* and *potassium hydrocarbonate.* H. W. F. Wackenroder measured the solubility of barium carbonate in an aq. soln. of *potassium carbonate.* R. Wegscheider and H. Walter measured the conditions of equilibrium in aq. soln. containing calcium and sodium carbonates, and sodium hydroxide. H. Noll found that the solubility of calcium carbonate in water, free from carbon dioxide, is lessened in the presence of *magnesium carbonate.*

F. Gothe thus summarizes his results : The solubility of calcium carbonate is increased by the presence of *alkali chlorides, nitrates, and sulphates* in the water, but decreased by *alkali carbonates,* and by the *alkaline earth chlorides, nitrates, and sulphates ; ammonium salts* decompose the carbonate and the effect on the solubility cannot be determined. The solubility is increased when the water contains *organic* (*humus*) *substances,* especially when alkali salts are also present, but is decreased in the presence of alkaline-earth salts. E. A. Rowe studied the solubility of calcium carbonate in soln. of *sodium hydrophosphate.*

§ 23. The Properties of the Carbonates of the Alkaline Earths

The **crystals** of the calcite modification of calcium carbonate belong to the rhombohedral class of the hexagonal system or the trigonal system. P. Groth[1] gives for the axial ratio $a : c = 1 : 0{\cdot}8543$, and $\alpha = 101° 55'$. There are more varieties of the crystalline form of calcite than with any other mineral. Count de Bournon, in his *Traité complet de la chaux carbonatée et de l'aragonite* (Londres, 1808), described over fifty, and since then hundreds have been reported. The crystals show four distinct habits—rhombohedral, prismatic, scalenohedral, and tabular. Twinning is also common. R. C. Wells reported the formation of aragonite crystals as a deposit in sea-water kept some years sealed up in glass jars. Calcite is isomorphous with magnesite, $MgCO_3$; mesitite, $Mg_2Fe(CO_3)_3$; ankerite, $Ca(Mg, Fe)CO_3$; dolomite, $MgCO_3.CaCO_3$; chalybite, $FeCO_3$; rhodochroisite or diallogite, $MnCO_3$; sphærocobaltite, $CoCO_3$; calamine, $ZnCO_3$—*vide* Fig. 88, **1**. 11, 10. Calcite is isomorphous with trigonal sodium nitrate; the two compounds have the rhombohedral angles respectively 74° 55′ and 73° 27′. T. V. Barker found that sodium nitrate forms parallel growths on clean fresh cleavage surfaces of calcite, independent of the habit or variety of the latter; but it does not form parallel growths on the other minerals of the calcite family—the necessary condition for parallel and regular growths being closeness of mol. vol. rather than similarity of angle or axial ratios. According to H. le Chatelier, when rhombic strontianite is heated to 820°, it undergoes a reversible transformation into a trigonal modification corresponding with calcite, and W. Vernadsky places the transition temp. at 700°. O. Mügge, L. Bourgeois, and H. Vater showed that trigonal forms of strontium and barium carbonates occur in isomorphous mixtures with calcite. The *neotype* of A. Breithaupt, and the *baryto-calcite*, from Längban (Sweden), and elsewhere, were shown by A. des Cloizeaux to belong to the trigonal system. G. Aminoff described crystals of calcite from Clausthal, with curved faces.

The crystals of aragonite form bipyramids belonging to the rhombic system and these crystals are isomorphous with strontianite, $SrCO_3$; witherite, $BaCO_3$; and cerussite, $PbCO_3$. These carbonates form a eutropic series. The axial ratios of calcite, according to J. Beckenkamp, are $a : b : c = 0·6228 : 1 : 0·7204$; for strontianite, according to J. Beykirch, the axial ratios are $a : b : c = 0·60904 : 1 : 0·72661$; and for witherite, according to W. H. Miller, $a : b : c = 0·5949 : 1 : 0·7413$. Aragonite and potassium nitrate are homomorphous, the axial ratios of the latter are $a : b : c = 0·591 : 1 : 0·701$. T. V. Barker obtained no signs of the formation of parallel growths of potassium nitrate on fresh clean cleavage surfaces of aragonite. The rhombic mixed crystals of calcium and strontium carbonates form the minerals *emmonite* of T. Thomson and *calcio-strontianite* of A. Cathrein; and the rhombic mixed crystals of calcium and barium carbonates form the minerals *bromlite* of J. F. W. Johnston and T. Thomson, or the *alstonite* of A. Breithaupt, found at Fallowfield (Northumberland), and at Alstone (Cumberland). According to T. J. Pelouze, pentahydrated calcium carbonate forms very acute rhombohedral crystals; A. C. Becquerel said the crystals were rhombic prisms with dihedral summits like aragonite; and W. F. Salm-Horstmar, irregular six-sided prisms. W. Biedermann found the crystals of hexahydrated calcium carbonate to be monoclinic; and P. Tschirwinsky, the crystals of trihydrated calcium carbonate to be also monoclinic. The **corrosion** or **etching figures** of calcite have been studied by O. Meyer,[2] L. Lavizzari, V. von Ebner, A. Elterlin, V. Goldschmidt, A. Hamberg, E. Sommerfeldt, etc.

The **X-radiogram** of calcite has been studied by W. H. and W. L. Bragg,[3] M. L. Huggins, F. M. Jäger and H. Haga, B. Davis and W. M. Stempel, F. Rinne, and E. Schiebold—*vide* Fig. 80, **1.** 11, 8—and that of aragonite by W. H. and W. L. Bragg, F. M. Jäger and H. Haga, and F. Rinne. In the calcite rhombohedron lattice, R. W. G. Wyckoff calculated the distance between the carbon atom and three of its nearest oxygen atoms as $1·21 \times 10^{-8}$ cm.; the distance of the calcium atom from the nearest oxygen atom as $2·30 \times 10^{-8}$ cm.; and the shortest distance between the calcium and carbon atoms as $3·04 \times 10^{-8}$ cm. H. Haga and F. M. Jäger also studied the X-radiograms of strontianite and witherite. M. L. Huggins gave for the volume of unit cell 112·7 cub. A. for aragonite, 131·7 cub. A. for strontianite, and 150·6 cub. A. for witherite; for the shortest distance between the carbon and the alkaline earth metal 3·004 A. for aragonite, 3·162 A. for strontianite, and 3·322 A. for witherite; the shortest distance between atoms of calcium and oxygen in aragonite is 1·28 A.

Various members of this carbonate group have been shown to have both the same general arrangement of atoms within the unit of structure and units of about the same size and shape. They are commonly said to be isomorphous with one another. According to W. L. Bragg, and R. W. G. Wyckoff, calcite and sodium nitrate have not only the same sort of grouping of atoms in the unit, but the size and shape of the unit and the absolute distances apart of corresponding atoms are practically identical in the two cases; yet they are not truly isomorphous, even though the crystal structures of calcite and sodium nitrate are more nearly alike than are those of calcite and rhodochrosite, for instance. It is in strict accordance with their crystal structures that, as shown by T. V. Barker, sodium nitrate will grow in parallel orientation upon a crystal of calcite, but not upon a crystal of any of the other members of the group. The difference in the crystal structure of calcite on the one hand and rhodrochoisite and siderite on the other, may account for the fact that, according to W. E. Ford, while a complete series of mixed crystals of the last two is known, calcite and either of the other two are not known to show complete miscibility.

G. Rose [4] gave 2·949 for the **specific gravity** of chalk, and C. J. B. Karsten gave 2·6946. The sp. gr. of aragonite is greater than that of calcite. L. Bourgeois gave for artificial calcite 2·71. The reported values for calcite range from C. J. B. Karsten's 1·7064 to F. E. Neumann's 2·750. V. Goldschmidt obtained values for calcite ranging between 2·713 and 2·735. E. Madelung and R. Fuchs gave 2·7067–2·7121 (0°) for the sp. gr. of calcite. J. Johnstone and co-workers gave 2·71. The reported values of aragonite range from E. Riegel's 2·920 to A. Breithaupt's 2·995. V. Goldschmidt obtained for aragonite values ranging between 2·919 and 2·937: E. Madelung and R. Fuchs gave 2·9325 at 0°; and J. Johnstone and co-workers gave 2·88. P. N. Laschtschenko found an abrupt change in the sp. gr., at 16·5°, of aragonite which had been heated to 465°–470°:

	16·5°	400°	410°	450°	460°	465°	475°	525°	650°
Sp. gr. .	2·9219	2·9278	2·9209	2·9218	2·9231	2·9231	2·7691	2·7711	2·7800

Accordingly, the turbidity and brittleness which H. E. Boeke observed in aragonite crystals at 445° is not connected with its transformation into calcite. B. O. Peirce and R. W. Wilson found the sp. gr. of various samples of marble ranged between 2·69 and 2·75; and M. Websky gave for Carrara marble 2·699–2·732. Y. Tadokoro gave 2·699. The reported values for strontium carbonate range from F. Mohs' 3·605 to C. J. B. Karsten's 3·6245. E. Madelung and R. Fuchs gave 3·7222 (0°); and J. Beykirch gave 3·706 for a variety of strontianite free from calcium. The reported values for barium carbonate or witherite range from A. Breithaupt's 4·24 to E. Filhol's 4·565. E. Madelung and R. Fuchs gave 4·2891. The differences in the values for the sp. gr. are mainly due to the presence of foreign matter in the native carbonates. In illustration it is very rare to find a strontianite free from calcium carbonate, and the formula for by far the larger number of samples of this mineral is better (Sr, Ca)CO_3 than $SrCO_3$. H. G. F. Schröder gave 3·584 for precipitated strontium carbonate, and 4·274 for preciptated barium carbonate. J. Schweitzer obtained 4·2210 for barium carbonate precipitated in the cold, and 4·1848 for barium carbonate precipitated from hot soln. The best representative values are:

	$CaCO_3$ (trigonal)	$CaCO_3$ (rhombic)	$SrCO_3$	$BaCO_3$
Sp. gr. (18°) . .	2·72	2·94	3·70	4·30

H. Vater's estimate for the unknown barium carbonate is 4·05; and his value for vaterite is about 2·6. For the sp. gr. of pentahydrated calcium carbonate, T. J. Pelouze gave 1·783, and W. F. Salm-Horstmar, 1·75. The sp. gr. of hexahydrated calcium carbonate is given by W. Biedermann as 1·752 at 18°; and that of trihydrated calcium carbonate is given by P. Tschirwinsky as 2·626 at 16°. According to F. K. Cameron, the sp. gr. of an aq. soln., sat. at 26°, is 1·0026, and of a soln., sat. at 31°, is 1·0031; and for a soln., sat. at 15°, F. Stolba gave 1·0022.

The **hardness** of aragonite, strontianite, and witherite is given respectively as 55, 14·6, and 9, when that of steatite is unity. G. de Götzen [5] said that calcite free from impurities is as hard as fluorspar. The hardness of calcite on Mohs' scale is usually given as 3; aragonite, $3\frac{1}{4}$–4; strontianite, $3\frac{1}{2}$; witherite, $3\frac{1}{2}$. A. Rosiwal studied this subject. F. D. Adams and J. T. Nicolsen investigated the **deformation by pressure** of marble. According to A. Johnsen, cooling by liquid air diminished the **plasticity** of calcite. F. Rinne, O. Mohr, and F. Loewinson-Lessing have studied the effect of press. on the crystals of calcite. P. Drude and W. Voigt gave 2600 kgrms. per sq. mm. for the **elastic modulus** of marble, C. Bach gave 1900 kgrms. per sq. mm. for that of limestone. W. Voigt, and G. Baumgarten measured the elastic constants of trigonal calcspar and found maximum and minimum values 14298–5128 kgrms. per sq. mm. H. Nagaoka also measured the elastic and torsion moduli of limestone and marble, for the **torsion modulus** he found respectively 1900–3000 and 2200–3000 kgrms. per sq. mm. L. H. Adams, E. D. Williamson, and J. Johnston represented the effect of a change of press. from p_0 to p on the vol. δv per c.c. by $\delta v = 1{\cdot}75\times10^4 + 1{\cdot}39\times10^6(p-p_0)$. The **compressibility** of calcite is $1{\cdot}39\times10^{-6}$ per megabar—W. Voigt gave $1{\cdot}54\times10^{-6}$, E. Madelung and R. Fuchs gave $1{\cdot}33$–$1{\cdot}35\times10^{-6}$ megabars per sq. cm. for calcite; $1{\cdot}53\times10^{-6}$ for aragonite; $1{\cdot}74\times10^{-6}$ for strontianite; and $2{\cdot}02\times10^{-6}$ for witherite.

The action of heat on the carbonates of the alkaline earths has already been discussed both with respect to their decomposition, and with respect to allotropic changes of calcite to aragonite, and *vice versa*. J. L. Gay Lussac and L. J. Thénard[6] stated that strontium carbonate volatilizes with a red light when heated on a piece of charcoal by a stream of oxygen. According to C. H. Pfaff, barium carbonate melts in the oxy-hydrogen blowpipe flame, and H. Abich said that it volatilizes when heated on a piece of charcoal in a stream of oxygen, and glows with a yellow light. H. le Chatelier placed the m.p. of barium carbonate at 795°, while H. E. Boeke said that it partially fuses at 1380° in a current of carbon dioxide, and at a lower temp. when exposed in an open vessel; the lower fusion temp. is attributed to the basic carbonate formed under those conditions. H. E. Boeke found the **melting point** of calcium carbonate to be 1289° under a press. of 110 atm.; that of strontium carbonate, 1497° under a press. of 60 atm.; and that of barium carbonate, 1740° under a press. of 90 atm. According to K. Friedrich, strontium carbonate has an **inversion point** between 920° and 930°; and barium carbonate undergoes two reversible transformations, passing from the γ-form or rhombic and pseudohexagonal form at 811° to the β-form which is hexagonal, and at 982° to the α-form which is cubic. K. Friedrich said that strontium and barium carbonates undergo a mol. transformation below 300°. For the transition of calcite and aragonite *vide supra.* H. Fizeau[7] found $\alpha=0{\cdot}0_42581$ to $0{\cdot}0_42621$ for the **coefficient linear expansion** of a rhombohedral crystal of Iceland spar along the principal crystallographic axis: $\alpha'=-0{\cdot}0_5540$ to $-0{\cdot}0_5562$ along the normal to the crystallographic axis; for the mean of α and α', $0{\cdot}0_5514$; and $0{\cdot}0_5507$ for a plane in the direction of the angle 54° 41′. Hence, when heated, calcite contracts in a direction perpendicular to the principal crystallographic axis. This phenomenon was employed by G. Tschermak as an argument against the isomorphism of calcite with the other rhombohedral carbonates. For aragonite, H. Fizeau found for a temp. of about 40°, $\alpha=0{\cdot}0_41016$ when parallel to the a-axis, $0{\cdot}0_41719$ when parallel to the b-axis, and $0{\cdot}0_43460$ when parallel to the c-axis.

The **specific heat** of calcite was found by H. V. Regnault[8] to be 0·20857 between 20° and 100°; F. E. Neumann, 0·2046 between 20° and 100°; by H. Kopp, 0·203 between 16° and 45°; F. A. Lindemann and W. Nernst, 0·2027; and P. E. V. Oeberg, 0·2042. The latter also found the sp. ht. of calcite to be in good agreement with the additive rule for mixtures. J. Joly found the sp. ht. of water-clear calcite to be 0·2036; for transparent rhombohedra, 0·2044; for hexagonal prisms, 0·2034; and for transparent aragonite, 0.2036. The rhombohedral and rhombic forms of calcium carbonate thus have the same sp. ht. G. Linder measured the effect of temp. on the sp. ht. of calcite, and found

	0°–50°	0°–100°	0°–150°	0°–200°	0°–250°	0°–300°
Sp. ht. . .	0·1877	0·2005	0·2054	0·2093	0·2136	0·2204

and for the following intervals of temp.:

	50°–100°	100°–150°	150°–200°	200°–250°	250°–300°
Mean sp. ht. .	0·1233	0·2153	0·2209	0·2313	0·2546
Increase per 50° .	—	0·94	2·5	4·5	9·1 per cent.

showing that the increase in the sp. ht. increases with rise of temp. For the true sp. ht. at $\theta°$, he found $0{\cdot}1802+0{\cdot}00020150\theta-0{\cdot}0_{6}2320\theta^{2}$. For marble, J. Thoulet and H. Legarde found 0·2164; B. O. Peirce and R. W. Wilson, 0·212 (25°–100°); R. Weber, 0·2028 (0°); and H. Hecht, 0·206 (0°–100°). H. V. Regnault gave for white marble 0·2158 (16°–98°) and for grey marble 0·2099 (23°–98°). Y. Tadokoro gave 0·202 for marble. In addition to J. Joly's value for aragonite, *vide supra*, F. E. Neumann gave 0·2018; H. Kopp, 0·203 (10°–45°); H. V. Regnault, 0·20850 (18°–99°); and G. Linder,

	50°		100°		150°		200°		250°
Sp. ht. . . .	0·2065		0·2121		0·2177		0·2232		0·2286
Percentage increase		2·6		2·6		2·5		2·4	

P. N. Laschtschenko found the curve showing the relation between the temp. and the amount of heat evolved on cooling aragonite cannot be distinguished from that of calcite up to 400°; but at 445°, the heat of cooling aragonite increases rapidly to 465°–470°; after that the curve again coincides with that for calcite although there are indications of a divergence above 600°. H. V. Regnault gave 0·1475 (8°–98°) for the sp. ht. of strontianite, and 0·1104 (11°–99°) for witherite. For the latter, J. Joly gave 0·1086, and P. N. Laschtschenko found

	250°	520°	720°	800°	810°	850°	905°	975°	1030°
Sp. ht. . .	0·116	0·126	0·130	0·130	0·145	0·151	0·158	0·161	0·162

It is inferred that a mol. change occurs at about 800°, in order to explain the abrupt change. W. Nernst and F. Schwers found that the mol. ht. C_p, of calcium carbonate at 88·2° K. to be 8·683, and at 22·3° K., 0·996.

The **heat conductivity** of marble was found by J. D. Forbes[9] to be 0·001 cal. per cm. per sec. per degree difference of temp.; E. Péclet found 0·007; and numbers varying from 0·0054 to 0·00817 have been variously reported by C. Christiansen, C. H. Lees, C. Grassi, K. Yamagawa, G. Stadler, H. Hecht, R. Weber, B. Despretz, G. von Helmersen, O. J. Lodge, etc. B. O. Peirce and R. W. Wilson found that the thermal conductivity of a gram of marble between $\theta°$ and 25° is $0{\cdot}01848(\theta-25)+0{\cdot}001895(\theta-25)^{2}$. Y. Tadokoro gave 0·00555 for marble. For chalk, A. S. Herschel found 0·0022, and R. Weber, 0·0017. For limestone, G. Stadler gave 0·00877. For calcite, A. Tuschmid found the conductivities parallel and perpendicular to the axis are respectively 0·006 and 0·008; C. H. Lees found 0·010 and 0·0084 respectively. E. Jannetaz found for the ratio of the two conductivities 0·913, and F. Stenger, 0·915. R. A. Nelson gave 0·00614 for the conductivity of white marble between 50° and 100°; 0·00524 between 100° and 150°; and 0·00415 between 150° and 200°.

According to J. Thomsen,[10] the **heat of formation** of the carbonates of the alkaline earths: $(Ca, O_2, CO)=240{\cdot}66$ Cals.; $(Sr, O_2, CO)=251{\cdot}02$ Cals.; and $(Ba, O_2, CO)=252{\cdot}77$ Cals. He also found $(CaO, CO_2)=55{\cdot}58$ Cals. in a dry way, and 18·51 in the wet way; the respective values for strontium carbonate are 53·23 Cals. and 20·55 Cals.; and for barium carbonate, 42·49 Cals. and 21·82 Cals. M. Berthelot gave $(BaO, CO_{2\,solid})=50{\cdot}0$ Cals.; and $(BaO, CO_{2\,gas})=56{\cdot}0$ Cals. According to A. Finkelstein, the heat of formation of (CaO, CO_2) is 63·2 Cals. between 915° and 1300°, and J. Thomsen found 62·2 Cals. at ordinary temp., hence the former inferred that the sp. ht. of calcium carbonate must change in the same way as that of the carbon dioxide. According to J. Johnston, the **free energy** of the reaction calcium carbonate→oxide is 41·45 Cals. at 25°; for strontium carbonate, 44·9 Cals.; and for barium carbonate, 51·4 Cals. M. Berthelot gave $Ca(OH)_{2\,aq.}+H_2CO_{3\,aq.}=CaCO_{3\,precipitate}+H_2O+19{\cdot}6$ Cals.; for the corresponding reaction with strontium carbonate (crystalline) he gave 21·0 Cals. and for barium carbonate 22·2 Cals. R. de Forcrand gives $CaO_{aq.}+CO_2=CaCO_3+Aq.+4{\cdot}3$ Cals. J. Thomsen gives for the heat of decomposition of $CaCl_2+Na_2CO_3$ (in 400 mols of water) $=-2{\cdot}08$ Cals.; for the corresponding reaction with strontium chloride, he found 0·23 Cal. R. de Forcrand gives —1·3 Cals. for the heat of transformation of amorphous precipitated calcium carbonate to calcite. P. A. Favre and J. T. Silbermann found the **heat of transformation** of aragonite to calcite to be +2·36 Cals., while H. le Chatelier gave —0·3 Cal., H. Bäckström gave —0·335 Cal. ± 0·100 Cal., and P. N. Laschtschenko, 2·72 Cals. H. W. Foote believes that the heat of formation of calcite is greater than that of aragonite, and therefore the transformation of aragonite to calcite is an exothermal process. H. L. J. Bäckström found the **transition temperature** to be —43° ± 5°, and to be raised 1° per 40 atm. increase of press. Hence, aragonite can never constitute a stable phase under ordinary circumstances.

The **indices of refraction** of calcite,[11] μ_ω for the ordinary ray, and μ_ϵ for the extraordinary rays have been measured from $\lambda = 198\mu\mu$ in the ultra-violet to $\lambda = 759\mu\mu$ in the visible spectrum, and to $\lambda = 2324{\cdot}3\mu\mu$ in the ultra-red.

λ .	198	257	361	394	589	795	800·7	1497·2	2324·3$\mu\mu$
μ_ω .	—	1·76038	1·69317	1·68374	1·65835	1·64886	1·64869	1·63457	—
μ_ϵ .	1·57796	1·53005	1·50228	1·49810	1·48640	1·48216	1·48216	1·47744	1·47392
	Ultra-violet.			Visible spectrum.			Ultra-red.		

	Li 671$\mu\mu$	Na 589$\mu\mu$	Hβ 486$\mu\mu$
μ_ω . . .	1·65368	1·65836	1·66785
μ_ϵ . . .	1·48430	1·48643	1·69080

The mean values for the indices of refraction are 1·63 for aragonite, 1·60 for calcite, and for the mean double refractions, 0·156 and 0·172 respectively. According to F. F. Martens, calcite is opaque for smaller wave-lengths than $\lambda = 199\mu\mu$. E. Ashkinass and T. Liebisch, and H. Rubens have measured the **metallic reflection** of calcite. According to H. Rubens, and E. Merritt, calcite is dichroic in the ultra-red. The ordinary ray has sharp absorption bands at 2·44μ, 2·74μ, and for greater wave-lengths than 3·1μ, it is no longer transparent. The extraordinary ray has absorption bands at 3·28μ, 3·75μ, 4·66μ, and for longer wave-lengths than 5·5μ it is no longer transparent. E. P. Lewis and A. C. Hardy have measured the reflecting power of calcite for the ultra-violet rays; T. Liebisch and H. Rubens, the long-wave infra-red spectrum of strontianite; and B. Davis and W. M. Stempel, the reflection of X-rays. S. Procopiu studied the effect of suspended calcite on birefringence of carbon disulphide, etc.

J. E. Burbank[12] found that minerals which contain calcium are in general strongly influenced by **X-rays,** and calcite gave a pale reddish-yellow phosphorescence which becomes paler when the mineral is heated, and finally vanishes. C. Doelter found calcite is opaque to weak X-rays. W. C. Röntgen found the electrical conductivity of calcite is raised 100 to 200-fold by exposure to X-rays. P. Bary found neither strontianite nor witherite fluoresces when exposed to X-rays, or to **Becquerel's rays.** According to C. Doelter, a specimen of colourless calcite was not affected by exposure to **radium radiations,** but a violet specimen was darkened to a purple-red colour after 10 hrs.' exposure. E. Newbery and H. Lupton found that samples of colourless calcite with minute cleavage planes showed a considerable multiplication and enlargement of the latter, but colourless crystals were otherwise unchanged. A sample of Iceland spar which luminesced under the action of radium, was thermo-luminescent after the removal of the radium. A. Pochettino found calcite to be luminescent when exposed to the action of the cathode rays—**cathodo-luminescence**—and the colour is the same as the phosphorescence produced by exposure to ordinary light; but with aragonite the colour is different. The afterglow persists a long time with calcite. J. Schincaglia found that the fluorescent light of calcite is blood-red in all directions. W. Crookes found that calcite has a straw-yellow luminescence when exposed to the cathode rays, and the glow persists after the current has ceased. The spectrum showed no bands. H. Jackson found that calcite, strontianite, and witherite exhibit a marked cathodo-luminescence; E. Newbery and H. Lupton, that a clear flawless crystal gave a fine red cathodo-luminescence, while a sample of Iceland spar gave a whiter light; the variation in the colour of the glow appears to indicate that it is due to the presence of an impurity and is not an essential property of the pure substance. A piece of native strontianite also gave a fine orange-red glow on one part of the mass under the action of the cathode rays, while the other part remained unaltered. On warming the specimen so treated, a bluish-white glow was observed on the previously inactive part of the mass, while the remainder was quite dark. W. P. Headden and L. Clémandot described the **phosphorescence** of calcite after exposure to sunlight. Some samples phosphoresced 13 hrs. G. F. Kunz and C. Baskerville found a sample phosphoresced after exposure to ultra-violet light. L. de Boisbaudran has studied the effect of impurities—copper and iron—on the phosphorescence of calcite.

W. C. Röntgen[13] studied the **electrical conductivity** of calcite. C. Maragoni examined the directions traversed by electric sparks passing through calcite. F. Kohlrausch measured the specific electrical conductivity of sat. aq. soln. of calcium carbonate at different temp. and found,

	Precipitated.			Calcite.			Aragonite.		
	7·90°	17·38°	25·96°	2·03°	17·44°	34·8°	3·18°	17·60°	31·1°
Conduc. $\times 10^6$	20·29	28·28	36·83	15·28	26·67	41·1	19·46	31·75	47·0

The conductivity of the soln. of calcite is the least and that of aragonite the greatest. This is in agreement with the general observation that the electrical conductivity of the stable modification of a substance is less than that of the labile form. The **dielectric constant** of calcite has been determined by M. Romich and J. Nowak, J. Curie, H. Starke, etc. For directions parallel to the *c*-axis, the reported numbers range from 7·5 to 8·5, and for directions normal to the *c*-axis, 7·7 to 9·9. W. Schmidt gave for calcite with $\lambda=75$, 8·50 and 8·00 respectively for directions perpendicular and parallel to the *c*-axis; and for λ_∞, the mean values of R. Fellinger's and M. von Pirani's determinations are respectively 8·59 and 7·87. W. Schmidt gave for the dielectric constant of aragonite for $\lambda=75$, 9·8 in the direction of the *a*-axis, 7·69 in the direction of the *b*-axis, and 6·84 in the direction of the *c*-axis; for $\lambda=\infty$, R. Fellinger found 9·14 (*a*-axis), and 7·00 (*c*-axis). W. Schmidt found for witherite for $\lambda=75$, the dielectric constants 7·80, 7·50, and 6·35 respectively in the directions of the *a*-, *b*-, and *c*-axes. C. Thwing found 7·37 for the powdered mineral; and 6·13 for marble.

According to Thomson's law, if F be the intensity of the magnetic field, v the vol. of a crystal sphere, then $M=DvF^2$, where D is a constant calculated from the chief axes K_1, K_2, K_3 of the crystal sphere, and the direction cosines λ, μ, ν such that $D=\{\mu^2\nu^2(K_2-K_3)^2+\nu^2\lambda^2(K_3-K_1)^2+\mu^2\lambda^2(K_1-K_2)^2\}^{\frac{1}{2}}$. E. Stenger's and J. Beckenkamp's measurements with calcite did not agree with Thomson's formula; W. König's measurements did. A. P. Wills found the **magnetic susceptibility** of calcite and of marble to range from $-0·6\times10^{-6}$ to $-0·9\times10^{-6}$. P. Pascal gave for the mol. coeff. of magnetization of $BaCO_3$, 589×10^{-7}; $SrCO_3$, 467×10^{-7}; and $CaCO_3$, 382×10^{-7}.

Chemical properties of the carbonates of the alkaline earths—G. Spezia[14] observed no change in calcite and aragonite when kept 6 months under a press. of 7000 atm. When calcium carbonate was heated to redness in a stream of **hydrogen,** A. P. Dubrunfaut stated that it decomposed, forming carbon dioxide, water, and carbon. H. Rose also found some carbon dioxide is given off when dry air or hydrogen is passed over heated strontium carbonate. J. L. Gay Lussac and L. J. Thénard found that when **water vapour** is passed over strontium carbonate below its dissociation temp., carbon dioxide is evolved and strontium hydroxide is formed. E. Donath and A. Lang state that the hardening of a mixture of lime, calcium carbonate, and water is probably due to the formation of *calcium hydroxycarbonate.*

When calcium carbonate is treated with cold **chlorine** water, A. W. Williamson,[15] and A. Richardson observed that hypochlorous acid (*q.v.*) is formed; and this decomposes when heated or when the soln. is evaporated, forming calcium chlorate. C. Matignon and F. Bourion found that when heated in a stream of **sulphur chloride** and chlorine, calcium chloride is formed. P. A. Bolley obtained similar results with barium carbonate. The carbonates are readily soluble in **hydrochloric acid.** J. G. Bogusky found that the quantity of marble decomposed at any instant of time is directly proportional to the conc. of the acid at that instant. J. G. Bogusky and N. Kajander compared the effect of hydrochloric acid with that of **nitric acid** and **hydrobromic acid,** and found the speed of the reaction is inversely as the mol. wt. of the acid. Soln. which have an eq. conc. of acid react with the same velocity, or the mol. reaction velocity of the acid is independent of the chemical nature of the acid. W. Spring found that at a constant temp., nitric, hydrochloric, and hydrobromic acids, as well as **hydriodic acid** and **hypochlorous acid** of eq. conc., react with the same velocity. The action of **acetic acid** is not uniform, but the velocity of attack is less than that of the other acids. W. Spring observed that there is a marked period of induction, *OB*, Fig. 56, and this is followed by a period, *BC*, during which the speed of the reaction is proportional to the conc. of the acid. There is then a period, *CD*, during which the speed of the reaction is greater than what would occur if the rate of the reaction were proportional to the conc. of the acid. W. Spring represents the effect of temp. θ on the velocity V by the exponential equation: $V=k^{20\cdot05\theta}$, where k is a constant. He also found all cleavage surfaces of calcspar are dissolved at the same rate; at 15° a surface cut parallel to the chief axis is dissolved by 10 per cent. hydrochloric acid at the same rate as cleavage surfaces, but at 35°, the former surface is attacked 1·23 times as fast, and at 55°, 1·28 times as fast as the cleavage surface. The speed of dissolution of a surface cut normal to the chief axis is 1·14 times as great as one cut parallel to that axis. W. Spring compared the speeds of dissolution of surfaces perpendicular and parallel to the chief axis with the indices of refraction of the ordinary and extraordinary rays; and G. Cèsaro, with the elasticity of the crystals. W. Spring also found that acids attack aragonite rather more slowly than calcite, for, at 15°, the speed of dissolution of aragonite in 10 per cent. hydrochloric acid is 0·476. L. Lavizzari found that the rates of attack of aragonite on the basal and prismatic surfaces are as 3 : 1. C. Vallée, and M. Geiger studied the action on marble of soln. of acids in ethyl or methyl alcohol. W. Spring showed that if a crystal of calcite be partially immersed in hydrochloric acid, the action is most rapid at the surface, so that the crystal is cut in two pieces. Similar results were observed with sugar and water. If dry calcium, strontium, or barium carbonate be suspended in absolute alcohol, it is attacked by sulphuric, nitric, or acetic acid with extreme slowness—between three and four months being required for complete neutralization. The velocity of the action is slowest with barium carbonate, and fastest with the calcium salt. By introducing water, the speed of neutralization is increased proportionally with the amount of water added. L. Kahlenberg and H. Schlundt found that calcium carbonate is not attacked by a soln. of **hydrogen chloride** in water-free **hydrogen cyanide**. The speeds of dissolution of barium carbonate in hydrochloric and nitric acids has been measured by B. Pawlewsky. H. Cantoni and G. Goguélia [16] found that boiling soln. of **ammonium chloride** react with calcium or barium carbonate as typified by $BaCO_3+2NH_4Cl=BaCl_2+2NH_3+H_2O+CO_2$. They also studied the action of **potassium chloride** or **sodium chloride,** and E. Taponier, **potassium and sodium bromides** as well as **ammonium bromide** on barium carbonate; H. Schreib found the speed of decomposition with calcium carbonate depends on the grain size of the carbonate, and that the

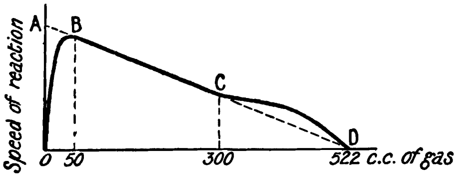

FIG. 56.—W. Spring's Diagram showing the Speed of the Reaction between Calcium Carbonate and Hydrochloric Acid.

decomposition is complete. The solubilities of the alkaline earth carbonates in soln. of the alkali and ammonium chlorides has been previously considered.

F. Sestini[17] found that carbon dioxide is evolved when calcium carbonate is heated with boiling **sulphur,** and calcium sulphide is formed. According to E. Pollacci, when a mixture of calcium carbonate and sulphur is moistened with water and allowed to dry, and the moistening and drying repeated several times, gypsum is formed. A. Cossa denied that the reaction occurs, even if the mixture be boiled 8–10 hrs. It is supposed that the apparent discrepancy is due to the oxidation of the sulphur to sulphuric acid during the drying of the mixture. G. Bellucci found that moist mixtures of calcium carbonate and sulphur form calcium sulphate in 75–80 days; and in the presence of organic matter in 30–35 days. The amount of sulphate formed is small. T. Brugnatelli and P. Pellogio found that in E. Pollacci's experiment some calcium thiosulphate as well as sulphate is formed, and they believe that the sulphur is oxidized at the expense of the water, and not by atm. oxygen. They found tetrathionic and pentathionic acids appear before the sulphuric acid. C. Geitner found that if calcium carbonate be heated with water and sulphur at 120°–130°, calcium sulphite and traces of sulphate are formed; at 150° the liquid is coloured blue, green, and brown, and on cooling it becomes yellow owing to the formation of calcium polysulphide; similar results were obtained with strontium and barium carbonates. According to L. Naudin and F. de Montholon, when calcium, strontium, or barium carbonate, suspended in water at 10°, is treated with a slow current of **hydrogen sulphide,** it is gradually converted into sulphide, the conversion being partial or complete according to the proportion of water present. The soln. is colourless at first, but turns yellow in the air. E. Divers and T. Shimidzu observed that while calcium hydrosulphide is decomposed by carbon dioxide, precipitated calcium carbonate, suspended in water, is decomposed by a stream of hydrogen sulphide. Similar remarks apply to barium carbonate. H. Feigel found that sulphur chloride converted calcium sulphide into a yellow product—possibly calcium sulphochloride, CaS_2Cl_2. L. Kahlenberg and H. Schlundt found that a soln. of sulphur trioxide in water-free hydrogen cyanide does not attack calcium carbonate. A. Gossmann studied the action of **alkali sulphates** on barium carbonate.

A. Scheurer-Kestner[18] observed that when calcium carbonate is calcined with 24 per cent. of carbon, a mixture of 87·8 per cent. of carbon monoxide and 12·2 per cent. of carbon dioxide is evolved. At a red heat, however, A. P. Dubrunfaut found that calcium carbonate is not decomposed by carbon, but if steam be passed over the mixture, carbon monoxide is evolved. A. Finkelstein studied the equilibrium press. of the system containing carbon, barium carbonate, carbon monoxide and dioxide. When heated in the electric arc-furnace, a mixture of calcium carbonate and carbon furnishes calcium carbide (*q.v.*). L. P. Cailletet found that calcium carbonate is not affected by liquid **carbon dioxide**; for the action of gaseous carbon dioxide, *vide infra* hydrocarbonates. H. Debus studied the distribution of carbon dioxide between barium and calcium salts. H. Cantoni and G. Goguélia studied the action of **alkali chlorides**; E. Taponier, the action of the **alkali bromides**; and L. Vecchiotti, the action of the **alkali nitrates.** The observations of R. Bunsen and L. Playfair on the action of **nitrogen** on heated barium carbonate may be regarded as the starting-point of the attempts to bring about the direct synthesis of cyanogen from carbon and atm. nitrogen. According to G. Dragendorff, at a red heat, calcium carbonate is imperfectly decomposed by **phosphorus,** forming carbon and calcium phosphate, and, according to S. Tennant, calcium phosphide. Barium carbonate was found by G. Dragendorff to be decomposed in a limited measure when heated with red phosphorus. A. Frébault and A. Destrem found that when calcium carbonate is treated with **sodium hydrophosphate,** Na_2HPO_4, a basic calcium phosphate and sodium hydrocarbonate are formed. When calcium carbonate is treated with a soln. of **ammonium phosphate,** R. Irvine and W. S. Anderson found an exchange of the acid radicles.

J. L. Gay Lussac and L. J. Thénard found that when a mixture of calcium carbonate and **sodium** is warmed, vivid inflammation occurs, and a black mass is formed which leaves a residue of carbon when treated with hydrochloric acid. J. W. Döbereiner also studied the reaction. The clear melt obtained by fusing barium carbonate with four times its weight of barium chloride, was found, by F Haber and S. Tolloczko, to deposit dendritic carbon on the cathode when electrolyzed at 550°–600°. J. Parkinson and C. Winkler found that **magnesium** completely reduces the carbonates to the corresponding metal. J. A. Hedvall and J. Heuberger found the temp. at which the reaction begins and the heat of the reaction to be respectively 280° and 6·14 Cals. for $BaO+SrCO_3=SrO+BaCO_3$; 240° and 20·14 Cals. for $BaO+CaCO_3=CaO+BaCO_3$; and 400° and 8 Cals. for $SrO+CaCO_3=CaO+SrCO_3$.

J. von Liebig found a conc. soln. of **potassium hydroxide** decomposes calcium carbonate. C. J. B. Karsten observed no change when an aq. soln. of **barium hydroxide** at 15° to 19° is allowed to act ten months on precipitated calcium carbonate—the precipitate remains free from barium, the soln. free from calcium. A. Rosensthiehl found no change occurred when the soln. were boiled. F. Knapp added a little baryta-water to spring-water containing a little calcium hydrocarbonate, and obtained either no precipitate or a slight turbidity. The addition of an excess of baryta-water, or boiling the soln., results in the precipitation of barium and calcium carbonates. According to C. J. B. Karsten, calcium hydroxide is not changed by a conc. soln. of **potassium carbonate**; and a clear soln. of lime-water remains clear when mixed with a conc. soln. of potassium carbonate, and if the soln. be diluted with water, calcium carbonate is precipitated. According to P. Lebeau, mixtures of calcium carbonate with the alkali carbonates decompose completely at about 1000° in vacuo. The dissolution of the mixed carbonates proceeds much less readily than that of calcium carbonate alone, and the dissolution press. of the mixture is always lower than that with calcium carbonate, and higher than that with alkali carbonate for the same temp.; thus, the decomposition of the mixture with cæsium carbonate began at 540°, and the dissolution press. at 1020° was 490° mm.—that of calcium carbonate alone is greater than one atm. It is said that these facts point to the existence of double carbonates of calcium and the alkali metals, possessing different dissociation press. Mixtures with lithium carbonates lose lithium oxide by volatilization.

According to C. J. B. Karsten, a mixture of **sodium chloride** with twice its weight of calcium carbonate melts at a bright red heat—a higher proportion of sodium chloride gives a more fusible mixture, and a smaller proportion of that salt gives a less fusible mixture. The clear melt solidified to a mass with a scaly fracture. P. Berthier made observations on this subject. Similar observations were made by P. Berthier, C. J. B. Karsten, and J. W. Döbereiner with respect to strontium and barium carbonates. W. O .de Coninck and L. Arzalier found that when strontium carbonate is shaken for 4 months with a conc. soln. of **potassium chloride,** some strontium chloride is formed by double decomposition. P. Berthier also observed that equi-molar parts of **calcium chloride** and calcium carbonate form a clear melt; and J. Fritzsche prepared microscopic plates of what he regarded as hexahydrated **calcium chloro-carbonate,** $CaCl_2.2CaCO_3.6H_2O$, by leaving a highly conc. ammoniacal soln. of calcium chloride exposed to air containing carbon dioxide. The crystals are said to belong to the rhombic or monoclinic system; and they are decomposed by water. According to F. B. Guthrie, fused **sodium nitrate** dissolves 0·294 per cent. of calcium carbonate; 0·69 per cent. of strontium carbonate; and 0·916 per cent. of barium carbonate. E. Ramann and H. Sallinger studied the equilibrium conditions in the reaction: $K_2SO_4+BaCO_3\rightleftharpoons K_2CO_3+BaSO_4$.

R. Irvine and W. S. Anderson treated corals with soln. of manganese, zinc, chromium, mercury, and tin chlorides, iron sulphate, nickel, cobalt, copper, lead, and silver nitrates, and ammonium phosphate. The action of salts of nickel and cobalt was very slow, whilst that with salts of copper and manganese was rapid. In most cases there is a direct interchange, the oxide of the metal taking the place of the lime. Silver and mercury salts are deposited as oxides. Freshly prepared and moist barium carbonate precipitates hydroxides or carbonates from hot or cold soln. of many **metal salts**. Thus, H. Rose[19] decomposed cold soln. of the oxy-salts of copper, cadmium, mercury, tin, and palladium. G. Bauck likewise decomposed cupric chloride, but not mercuric or palladous chloride. H. Rose further noted that salts of aluminium and zirconium are incompletely decomposed, while the salts of the sesquioxides of manganese, cobalt (acetate), iron, bismuth, uranium, and rhodium (chloride), and iridic chloride are completely decomposed. Antimonious and arsenious salts are precipitated by barium salts. Cold soln. of calcium, strontium, magnesium, yttrium, and silver are not precipitated. Ferrous and manganous salts, according to H. Rose, are not precipitated, while, according to G. Bauck, they are in great part precipitated—an excess of carbon dioxide hinders the precipitation. C. J. B. Karsten found barium carbonate decomposes soln. of magnesium and calcium chlorides very slowly. W. Meigen compared the action of aragonite and calcite on soln. of salts of the heavy metals.

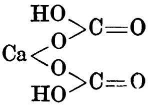
The hydrocarbonates of the alkaline earths.—J. H. Gladstone[20] obtained a white earthy mineral which he called *hovite*, and which contained alumina and silica besides lime and carbon dioxide in the ratio 1 : 1·67 to 1·99, thus corresponding closely with the proportion required for **calcium hydrocarbonate,** $Ca(HCO_3)_2$. The solvent action of aq. soln. of carbon dioxide on the carbonates of the alkaline earths noted by H. Cavendish in 1766, has been previously discussed, and the various phenomena are explained on the assumption that an unstable hydrocarbonate is formed :

$$\begin{matrix}HO\\HO\end{matrix}\!>\!C{=}O$$

Carbonic acid.

$$Ca\!<\!\begin{matrix}O\\O\end{matrix}\!>\!C{=}O$$

Calcium carbonate.



$$Ca\!<\!\begin{matrix}O\!-\!\begin{matrix}HO\\O\end{matrix}\!>\!C{=}O\\O\!-\!\begin{matrix}O\\HO\end{matrix}\!>\!C{=}O\end{matrix}$$

Calcium hydrocarbonate, $Ca(HCO_3)_2$.

F. K. Cameron and W. O. Robinson measured the vap. press., p cm. of mercury, produced when successive amounts of carbon dioxide, w grms., are added to wet calcium carbonate at 0°, and found :

w . . .	0·00	0·014	0·056	0·098	0·140	0·182	0·224	0·252
p . . .	76	84	127	174	220	268	314	346

The curve is approximately a straight line making a large angle with the p-axis. There is therefore no sign of the formation of a new solid carbonate by adding carbon dioxide to wet calcium carbonate below 4·5 atm. press. at 0°.

When the hydrocarbonates of ammonium, potassium, or sodium are added to a soln. of a calcium salts, calcium carbonate is precipitated—less completely, added V. Rose, the greater the proportion of water present. According to C. L. Berthollet, and G. Longchamp, by mixing a soln. of an alkali hydrocarbonate with a soluble barium salt, a soln. of barium hydrocarbonate is obtained if a large proportion of water be used. Soln. of barium hydrocarbonate were also made by J. Setschenoff, P. Carles, etc., and when evaporated furnished a mixture of amorphous and crystalline barium carbonate ; and a crystalline precipitate when the soln. was boiled. According to G. Rose, when the sat. soln. of calcium hydrocarbonate is warmed with the exclusion of air, calcium carbonate is precipitated because the salt is less soluble hot than cold. A. Bineau found that when the soln. is allowed to stand in vacuo, or over solid potassium hydroxide, some calcium hydrocarbonate remains in soln. The passage of an inert gas through a soln. of the hydrocarbonates of the alkaline earths was found by D. Gernez to precipitate the normal carbonate. R. Ludwig and G. Theobald found that soln. of calcium hydrocarbonate deposit calcareous tufa or sinter when in contact with mosses, coniferæ, or algæ. When nascent hydrogen is passed through a soln. of a hydrocarbonate of the alkaline earths, A. Lieben found that formates are produced. F. Ullik found a soln. of calcium hydrocarbonate converts strontium sulphate into carbonate.

Attempts were made by E. H. Keiser and S. Leavitt to isolate the hydrocarbonates of the alkaline earths by adding an excess of alcohol and ether to the aq. soln. of the acid carbonate, made by conducting an excess of carbon dioxide through a soln. of the hydroxide; a white flocculent precipitate was formed which rapidly gave off carbon dioxide and left behind the normal carbonate. By treating a soln. of the chloride of the alkaline earth with a soln. of potassium or ammonium hydrocarbonate both cooled by a freezing mixture, a heavy flocculent precipitate of the hydrocarbonate is formed which can be dried by press. between filter paper in a trough surrounded by a freezing mixture. Analyses by E. H. Keiser and L. McMaster agree with the formula $CaCO_3.1{\cdot}75H_2CO_3$, and with $BaCO_3.1{\cdot}5H_2CO_3$. The products may be $Ca(HCO_3)_2$ or $Ba(HCO_3)_2$, with some admixed or absorbed carbonic acid.

Complex or double salts of the carbonates of the alkalies and alkaline earths.—P. Lebeau [21] obtained small acicular crystals of **lithium calcium carbonate** by fusing a mixture of one mol of calcium carbonate with two mols of lithium carbonate in an atm. of carbon dioxide, and treating the product with a small quantity of water; the salt is decomposed by excess of water, and when heated in a vacuum is dissociated, the dissociation press. for any particular temp. being intermediate between those of the constituent salts. The product of complete dissociation is an isomorphous mixture of lime and lithia in the form of regular octahedral crystals. The formation of these mixed crystals of lime and lithia indicates that the crystals of the latter belong to the cubic system. P. Berthier, and H. le Chatelier melted calcium carbonate with sodium carbonate; the latter employed equi-molar proportions, and obtained a mass with a crystalline fracture which is possibly **sodium calcium carbonate,** $Na_2Ca(CO_3)_2$. A. Lamy obtained turbid soln. by the action of potassium or sodium carbonate on lime-water. J. H. Pratt found pyramidal rhombic crystals of the dihydrated form of this salt, $Na_2Ca(CO_3)_2.2H_2O$, in the borax deposits of California. The mineral was called *pirssonite.* Artificial crystals were made by O. Bütschli, by digesting a mixed soln. of sodium hydroxide and carbonate with calcium carbonate for a few days at 40°–50°. The salt is also made by mixing an excess of a conc. soln. of sodium carbonate with one of calcium chloride, and digesting the amorphous precipitate with the mother liquid for 12 hrs. in a closed vessel on a water-bath. The crystals are rapidly washed with water; then with alcohol and ether; and dried over sulphuric acid. The rhombic pyramidal crystals were found by J. H. Pratt to have the axial ratios $a:b:c=0{\cdot}5662:1:0{\cdot}9019$. According to A. de Schulten, the sp. gr. of the natural crystals is 2·352 (15°), and of the artificial 2·349 (15°). The crystals scratch calcspar but not fluorspar. The salt is stable in the air, and when heated to 100°, but at 130° it loses 14·28 per cent. of water; the residue melts at a red heat; 790°, according to H. le Chatelier; or 813°, according to P. Niggli. The f.p. curve of P. Niggli for binary mixtures of sodium and calcium carbonates is shown in Fig. 57. The salt is slowly decomposed into its components by water. R. Wegscheider has studied the equilibrium conditions of pirssonite, and he found it to be stable at 60° in soln. containing 1·8 to $3{\cdot}7N$-Na_2CO_3 and 2·6 to $1{\cdot}3N$-NaOH; and at 80°, in soln. with 1·9 to $3{\cdot}3N$-Na_2CO_3, and 2·9 to $3{\cdot}0N$-NaOH.

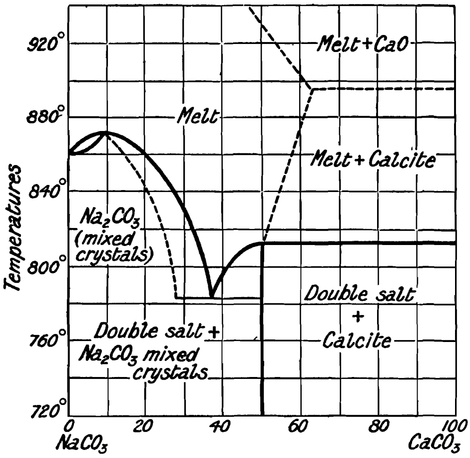


FIG. 57.—Fusion Curve of Binary Mixtures of Sodium and Calcium Carbonates.

The pentahydrated salt, $Na_2Ca(CO_3)_2.5H_2O$, occurs naturally as gaylussacite. G. H. Bauer obtained it as a white powder by adding sodium carbonate to a soln. of a calcium salt above 0°. The gelatinous precipitate was found by J. Fritzsche to form on standing, finely divided calcium carbonate and crystals of gaylussacite. J. Fritzsche obtained this salt by the prolonged action of a conc. soln. of sodium carbonate on amorphous precipitated calcium carbonate; O. Bütschli obtained it by treating the corresponding potassium salt with a conc. soln. of sodium carbonate. M. Barre stated that when precipitated calcium carbonate is boiled with a conc. soln. of sodium carbonate, the dihydrate, not the pentahydrate, is formed. The compound is not formed at 98° unless at least 21·06 per cent. of sodium carbonate is present. According to R. Wegscheider, at temp. exceeding 40°, gaylussacite is not stable, since, in systems containing water and sodium and calcium carbonates, it passes into pirssonite. The minute prismatic crystals of gaylussacite belong to the monoclinic system with axial ratios $a:b:c=1·4897:1:1·442$ and $\beta=101° 33'$. In 1829, G. Barruel analyzed a sample of what was probably impure gaylussacite; its sp. gr. was 2·291. G. H. Bauer found artificial gaylussacite weathers in dry air. According to J. B. J. D. Boussingault, the powdered uncalcined mineral dissolves in water, and is only slightly decomposed thereby. H. Rose also found that the mineral previously heated to 100°, is decomposed by water into its component salts. A. de Schulten has drawn attention to the peculiar fact that gaylussacite loses all its water of crystallization at 100°, while pirssonite loses its water at 130°. According to O. Bütschli, the mineral dehydrated at 105°, re-forms gaylussacite when treated with a conc. soln. of sodium carbonate; but with a conc. soln. of potassium carbonate, hexahydrated **potassium dicalcium pentacarbonate,** $3K_2CO_3.2CaCO_3.6H_2O$, is formed in double refracting hexagonal plates. It is also formed by the action of a very conc. soln. of potassium carbonate on calcium hydroxide, or on precipitated calcium carbonate. H. Molisch also prepared this salt. H. le Chatelier prepared a crystalline mass of **potassium calcium carbonate,** $K_2Ca(CO_3)_2$, melting at 790°, by fusing a mixture of potassium and calcium carbonates. M. Barre obtained prismatic crystals of potassium calcium carbonate, $K_2CO_3.CaCO_3$, which are readily hydrolyzed by water, and at 18°, are stable only with over 59·25 per cent. K_2CO_3. P. Niggli gave 813° for the m.p., and his f.p. diagram for binary mixtures of potassium and calcium carbonates, is shown in Fig. 58. O. Bütschli obtained double refracting rhombohedral crystals of the same salt by rubbing up a little calcium hydroxide with a very conc. soln. of potassium carbonate; or by digesting the same soln. with calcium carbonate at 40°–60°. When either of these salts is treated with sodium carbonate it forms gaylussacite. H. le Chatelier obtained a crystalline mass, m.p. 760°, thought to be the triple salt: **sodium potassium calcium carbonate,** $K_2CO_3.Na_2CO_3.2CaCO_3$, by melting and cooling an eq. mixture of the component salts. P. Niggli studied the systems, $Na_2O—K_2O—CaO—CO_2$, and $NaCl—Na_2CO_3—CaCO_3—CaCl_2$, between 600° and 1000°, and with the carbon dioxide at one atm. press. Similarly, with systems $Na_2O—TiO_2—CO_2$; $K_2O—TiO_2—CO_2$; $K_2O—CaO—TiO_2—CO_2$. The so-called *cupro-calcite* found at Jca, in Peru, and examined by A. Damour and A. Raimondi, has 50·45 per cent. Cu_2O, 10·26 per cent. CaO, 24·00 per cent. CO_2, and 3·20 per cent. H_2O, and it is probably a mixture of calcite and cuprous oxide. H. le Chatelier prepared a crystalline mass, **sodium barium carbonate,** $Na_2Ba(CO_3)_2$, m.p. 740°, by fusing and cooling an eq. mixture of the component salts. Similar results were obtained with **potassium barium**

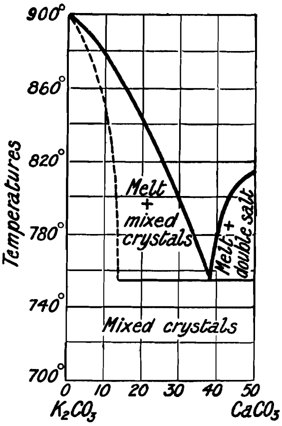

Fig. 58.—Fusion Curve of Binary Mixtures, K_2CO_3—$CaCO_3$.

carbonate, $K_2CO_3.BaCO_3$, m.p. 800°. The crystals are uniaxial and negative; they are stable in air; and decompose above their m.p. with the loss of carbon dioxide. **Sodium strontium carbonate,** $Na_2Sr(CO_3)_2$, m.p. 750°, was made in the same way. M. Barre said that barium and strontium carbonates do not form double salts with the alkali carbonates in aq. soln. The monoclinic mineral *barytocalcite*, described by T. Thomson, has axial ratios $a:b:c=0·7717:1:0·6255$, and $\beta=106° 8'$. This and other analogous mixed crystals, *bromlite* and *neotype*, represent a series of so-called **barium calcium carbonates.** Similarly, also, the minerals *emmonite* and *strontiocalcite* represent **strontium calcium carbonate.** There is no sign of the formation of alkali compounds of strontium or barium carbonate when the latter are digested with soln. of the alkali carbonates. H. le Chatelier prepared the triple salts, **potassium barium calcium carbonate,** $K_2CO_3.0·5BaCO_3.0·5CaCO_3$, m.p. 758°; and **sodium barium calcium carbonate,** $Na_2CO_3.0·5BaCO_3.0·5CaCO_3$, m.p. 660°; and **sodium strontium calcium carbonate,** $Na_2CO.0·5SrCO_3.0·5CaCO_3$, m.p. 720°, by melting together eq. proportions of the constituent salts. Similarly, with the quadruple salt, **potassium sodium barium calcium carbonate,** $K_2CO_3.Na_2CO_3.CaCO_3.BaCO_3$, melting at 690°. There is little evidence that these salts are chemical individuals. According to H. E. Boeke, mixtures of barium and calcium carbonates, under a high press. of carbon dioxide to prevent dissociation, show a eutectic at 1139°, corresponding with $0·47BaCO_3.0·53CaCO_3$. There is no sign of the formation of *barytocalcite*, $BaCO_3.CaCO_3$.

§ 24. Nitrates of the Alkaline Earths

Calcium nitrate occurs as *wall saltpetre*, or *nitrocalcite*, as an effloresecence on walls; in spring waters; and, according to T. Schlösing,[1] in soils. P. Groth has described a specimen of barium nitrate, *barytasaltpetre*, which he found in Chilian saltpetre. The nitrates of the alkaline earths are produced by crystallization from a soln. of the oxides, hydroxides, carbonates, or sulphides in dil. nitric acid. A. Duflos,[2] and F. Kuhlmann precipitated barium nitrate as a crystalline powder by adding a hot sat. soln. of sodium nitrate to a soln. of barium chloride, about one-third of the barium remains in the mother liquid, and it can be recovered by evaporation; F. Muck used a somewhat similar process for barium and strontium nitrates. F. Mohr also obtained barium nitrate from a mixture of barium sulphide and sodium nitrate, but G. C. Wittstein does not recommend the process because of the incompleteness of the exchange.

Anhydrous **barium nitrate,** $Ba(NO_3)_2$, crystallizes during the evaporation of aq. soln. of the nitrate. It is prepared commercially by the action of sodium nitrate on a soln. of barium chloride or barium sulphide. C. H. Hirzel claims to have obtained cubic crystals of *dihydrated barium nitrate*, $Ba(NO_3)_2.2H_2O$, by the evaporation of aq. soln. between 0° and 12°, but this is thought to be a mistake; R. A. Berry obtained **tetrahydrated barium nitrate,** $Ba(NO_3).4H_2O$, isomorphously mixed with 83 per cent. of tetrahydrated strontium nitrate, by saturating the same water with both nitrates, introducing a crystal of the tetrahydrated strontium salt, and evaporating in vacuo over sulphuric acid; if the temp. is much higher than 0°, a mixture of crystals of anhydrous barium nitrate and tetrahydrated strontium nitrate is obtained. Anhydrous **strontium nitrate,** $Sr(NO_3)_2$, crystallizes from hot soln., according to A. Scacchi, at temp. exceeding 25°, although, according to A. L. Baker, by the slow evaporation of a sat. soln. at 32°, he obtained a mixture of anhydrous salt and **tetrahydrated strontium nitrate,** $Sr(NO_3)_2.4H_2O$. J. T. Cooper, and R. Kirwan assumed that the hydrated salt was a pentahydrate, but A. Souchay and E. Lenssen, and A. Laurent showed that the tetrahydrate is produced. A. L. Baker failed to prepare a higher hydrate than this by the slow evaporation of soln. at temp. ranging from 2° to 32°. H. Lescœur could make only the anhydrous salt. According to G. J. Mulder, the transition temp. for the tetrahydrate and the anhydrous salt is 31·3°; Earl of Berkeley and M. P. Appleby gave 29·3°.

At ordinary temp. G. H. Hess, N. A. E. Millon, and J. C. G. de Marignac found that **tetrahydrated calcium nitrate,** $Ca(NO_3)_2.4H_2O$, separates from aq. soln. in monoclinic prisms. H. Lescœur's vap. press. measurements also agree with the formation of this hydrate. J. G. Gilbert prepared calcium nitrate by mixing conc. soln. of calcium chloride and sodium nitrate so that the soln. is sat. with calcium nitrate and sodium chloride at 80°. The precipitated sodium chloride is removed, and the tetrahydrated calcium nitrate precipitates below 30°. The conditions of stability of the different hydrates of calcium nitrate in aq. soln. by H. Bassett and H. S. Taylor are illustrated in Fig. 59; in acid soln., in Fig. 60; and in alkaline soln., in Fig. 61. M. Hasselblatt showed that melted tetrahydrated cadmium nitrate cannot be inoculated with tetrahydrated calcium nitrate, but the former readily inoculated the molten calcium salt. It was therefore inferred that there are two forms of tetrahydrated calcium nitrate, an unstable or β-form isomorphous with tetrahydrated cadmium nitrate, and melting at 39·7°, and the ordinary stable or α-form, melting at 42·6°. H. S. Taylor and W. N. Henderson prepared the unstable β-form by the inoculation of a supersatured soln. of calcium nitrate, over 30°, with a small crystal of tetrahydrated cadmium nitrate. The solubility relations and the equilibrium conditions are illustrated in Fig. 59. Anhydrous **calcium nitrate,** $Ca(NO_3)_2$, is obtained by dehydrating the tetrahydrate at about 170°. N. A. E. Millon reported the hydrate, $Ca(NO_3)_2.3\frac{1}{2}H_2O$, but D. Gernez showed that the latter is impure tetrahydrate, and that it crystallizes from soln. containing less water than corresponds with the tetrahydrate. H. Lescœur prepared **trihydrated calcium nitrate,** $Ca(NO_3)_2.3H_2O$, by adding an equal volume of fuming nitric acid to a sat. aq. soln. of the nitrate, and seeding the soln. with a crystal of the anhydrous salt. H. Bassett and H. S. Taylor prepared the trihydrate by allowing a supersaturated soln. to crystallize at about 45°—*vide* Figs. 59 and 60. H. Lescœur deduced the existence of a tri- or di-hydrate of calcium nitrate, but his method of preparing the latter furnishes a mixture of hydrates and the anhydrous salt. H. Bassett and H. S. Taylor prepared crystals of **dihydrated calcium nitrate,** $Ca(NO_3)_2.2H_2O$, by crystallization from soln. between 48·4° and 51·3°; the dihydrate is stable over a considerable range of nitric acid conc., as illustrated in Fig. 60. No hydrate between $Ca(NO_3)_2.H_2O$ and the anhydrous salt was observed. W. A. Tilden reported hexahydrated calcium nitrate, $Ca(NO_3)_2.6H_2O$, melting at 26·4°; but no one has confirmed this observation. There are thus three hydrates of calcium nitrate whose individuality has been established.

Isolated measurements of the **solubility** of calcium nitrate in *water* have been made by A. B. Poggiale,[3] and G. J. Mulder; the former gave for 100 parts of water at 0°, 84·2; and the latter, 93·1 parts of $Ca(NO_3)_2$. Determinations were also made by J. Legrand, F. Guthrie, F. Mylius, and R. Funk, and F. K. Cameron and W. O. Robinson. Table XIV contains a selection from the results of H. Bassett and H. S. Taylor above —15·7°; and of F. Rüdorff below that temp.; the results are expressed in grams of $Ca(NO_3)_2$ per 100 grms. of sat. soln., when 28·7° is the eutectic temp.; 42·7°, the m.p. of the tetrahydrate; and 51·1°, the m.p. of the

30°	61·57	β	38°	66·65	β	[25°	77·30	$Ca(NO_3)_2$]

69·50 per cent. β-$Ca(NO_3)_2.4H_2O$, and 42·7° with 71·70 per cent. α-$Ca(NO_3)_2.4H_2O$ are reflex points. The corresponding curves for binary systems, $Ca(NO_3)_2-H_2O$, are shown in Fig. 59. The curve *OA* is the ice-line, and *A* is the eutectic point—at —28·7° with 42·9 per cent. of $Ca(NO_3)_2$. The curve *ABC* represents the solubility of the α-tetrahydrate, and *CDE*, that of the trihydrate. The maxima of these curves at *B*, 42·7°, and *D* 51·1°, represent true m.p. The curve *A′B′C′* represents the solubility curve of the β-tetrahydrate, and illustrates the solubility curve of a metastable hydrate with a metastable m.p. The solubility curve *EF* of the dihydrate does not have a true m.p., but exhibits a transition temp., 51·3°, where partial fusion occurs, with the formation of the anhydrous salt and a sat. soln. The curve *FG* above 51·3° represents the solubility of the anhydrous salt. The extensions of the different curves beyond the regions indicated represent supersaturated soln. or metastable states.

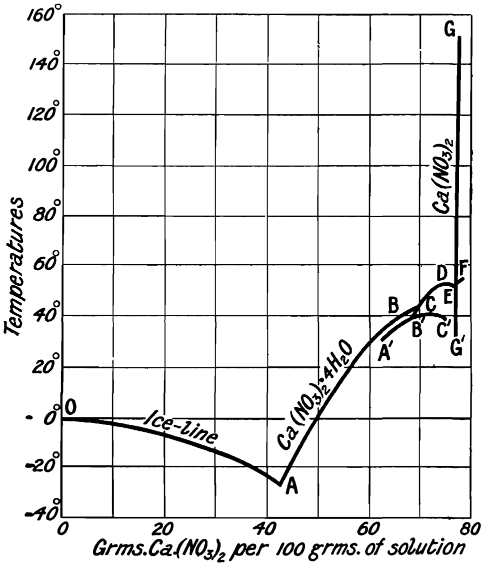

FIG. 59.—Solubility Curve of Calcium Nitrate.

Isolated measurements of the solubility of strontium nitrate in water were made by A. B. Poggiale, G. J. Mulder, and P. Kremers, who gave at 0° respectively 40·16, 39·5, and 43·1 grms. of $Sr(NO_3)_2$ in 100 grms. of water; and at 100°, they gave respectively 119·25, 101·1, and 106·5 grms. Earl of Berkeley and M. P. Appleby's data for the solubility of strontium nitrate, expressed in grams of $Sr(NO_3)_2$ per 100 grms. of water, are:

	0·58°	14·71°	29·06°	30 28°	39·74°	61·34°	78·98°	88·94°
$Sr(NO_3)_2$ . .	40·124	60·867	87·648	88·577	90·086	93·856	97·865	100·136
Solid phase	$Sr(NO_3)_2.4H_2O$			$Sr(NO_3)_2$				

The transition temp. from the tetrahydrate to the anhydrous salt is 29·3°. G. J. Mulder gave 101·1 for the solubility at 100°, 102·3 at 105°, and 102·9 at 107·9°. According to F. Guthrie, the eutectic or cryohydric temp. is —6° with 25·99 per cent. of $Sr(NO_3)_2$. L. C. de Coppet gave —5·75° with 32·4 parts of $Sr(NO_3)_2$ in 100 parts of water.

Isolated measurements with soln. of barium nitrate have also been made by G. J. Mulder, J. L. Gay Lussac, C. J. B. Karsten, and H. Kopp. The following is a selection of the best representative values, expressed in grams of $Ba(NO_3)_2$ per 100 grms. of soln.:

	0°	10°	20°	40°	60°	80°	100°	140°	180°	215°
$Ba(NO_3)_2$ . .	4·8	6·5	8·4	12·4	16·9	21·3	25·5	33·3	40·1	45·8

The solid phase is $Ba(NO_3)_2$. According to F. Guthrie, the cryohydrate contains 5·30 per cent. $Ba(NO_3)_2$, and freezes at —0·9°, and it is not changed by admixture with a little strontium nitrate; and, according to L. C. de Coppet, the cryohydrate has 4·5 parts of $Ba(NO_3)_2$ in 100 parts of water, and it freezes at —0·7°. A. Étard found the solubility curve has but a slight curvature, and between 0° and 210° can be represented by the linear equation $S=4·5+0·2000\theta$; and between 0·4° and about 400°, by $4·5+0·2025\theta$.

According to E. Mitscherlich,[4] conc. *nitric acid* precipitates calcium, strontium, and barium nitrates as crystalline powders from their aq. soln., and the barium nitrate is less soluble in dil. nitric acid than it is in water. He said barium nitrate is precipitated by adding conc. nitric acid to a soln. of barium chloride, and, conversely, barium chloride is precipitated by hydrochloric acid from an aq. soln. of barium nitrate. C. Schultz said that strontium nitrate is insoluble in conc. nitric acid, while H. Wurtz stated that it is sparingly soluble. S. G. Rawson, however, stated that, unlike strontium and barium nitrates, the calcium salt is soluble in conc. nitric acid, and he based a method for the separation of barium and strontium from calcium, upon the insolubility of the nitrates of the two former elements and the solubility of the latter, in conc. nitric acid. H. Bassett and H. S. Taylor have studied the ternary system, $Ca(NO_3)_2—HNO_3—H_2O$, at 25°. The following is a selection from their results, with the conc. expressed in grams per 100 grms. of sat. soln.:

$Ca(NO_3)_2$.	57·98	54·82	40·70	32·50	33·44	27·79	31·09	8·52	5·06	0
HNO_3 .	0	3·33	19·65	33·52	35·63	45·70	40·56	67·20	71·12	96·86
	$Ca(NO_3)_2.4H_2O$				$Ca(NO_3)_2.3H_2O$		$Ca(NO_3)_2.2H_2O$		$Ca(NO_3)_2$	

The results are plotted in Fig. 60, where A represents the aq. soln. in equilibrium with the tetrahydrate; the curve AB represents soln. of nitric acid in equilibrium with this same hydrate; B, a soln.—37 per cent. nitric acid—in equilibrium with the tetra- and tri-hydrates; BC, a soln.—37–43 per cent. nitric acid—in equilibrium with the trihydrate; C, a soln.—43 per cent. nitric acid—in equilibrium with the tri- and di-hydrates; CD, a soln. in equilibrium with the dihydrate; D, a soln. in equilibrium with the dihydrate and anhydrous salt; and DE, a soln. in equilibrium with the anhydrous salt. The dotted lines represent unstable supersaturated soln. According to A. H. Pearson,[5] dil. *acetic acid* dissolves barium nitrate less readily than dil. *hydrochloric acid*; and aqua *ammonia* dissolves barium nitrate less readily than water.

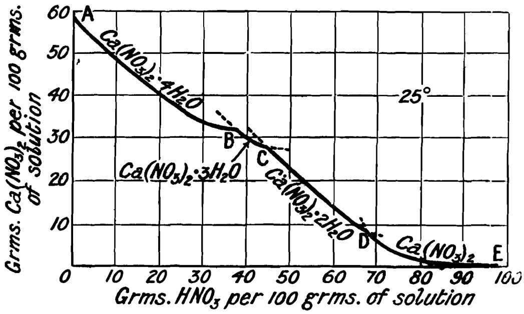

FIG. 60.—Equilibrium Conditions of the Ternary System, $Ca(NO_3)_2—HNO_3—H_2O$, at 25°.

According to F. M. Raoult, the aq. soln. of calcium nitrate absorbs a larger proportion of ammonia than water alone, and this the more, the greater the conc. of the calcium nitrate in soln.—presumably complex ions, $Ca(NH_3)_n{}^{\cdot\cdot}$, are formed. Changes of press. influence the solubility of ammonia in calcium nitrate soln., the same as in aq. soln. The spontaneous evap. of the aq. ammoniacal soln. leaves unchanged calcium nitrate. According to E. C. Franklin and C. A. Kraus, *liquid ammonia* dissolves calcium, strontium, and barium nitrates, and they have measured the electrical conductivities of the soln.; the liquid ammonia soln. of calcium nitrate gives a precipitate when treated with ammonium chloride or bromide, but not with ammonium iodide—with strontium or barium nitrate soln. ammonium iodide gives a crystalline precipitate; ammonium sulphide slowly gives a white precipitate; ammonium chromate or borate also gives a precipitate. C. A. L. de Bruyn found that 100 parts of dried *hydroxylamine* dissolve 11·4 parts of barium nitrate, and if a soln. of potassium sulphate in hydroxylamine be added, no barium sulphate is precipitated. According to T. W. B. Welsh and H. J. Brödersen, 100 grms. of anhydrous *hydrazine* dissolve 5 grms. of strontium nitrate, or 3 grms. of barium nitrate at room temp.

According to C. J. B. Karsten, *potassium hydroxide*, or *sodium hydroxide*, dissolves in a sat. soln. of calcium or barium nitrate without the precipitation of calcium hydroxide; and conversely calcium hydroxide dissolves in conc. soln. of potassium or sodium nitrate.

G. G. Rousseau and G. Tite prepared the dihydrate, $CaO.Ca(NO_3)_2.2H_2O$, by heating a soln. of the nitrate in presence of the oxide at 180°–200°. He said that the needle-like crystals have a longitudinal extinction, and that they are insoluble in alcohol, and decomposed by water. N. A. E. Millon previously prepared a basic nitrate by boiling a soln. of the nitrate with the hydroxide, and extracted the residue with water. A. Werner added milk of lime to a cold sat. soln. of calcium nitrate until it ceased to be dissolved; the soln. was then shaken, and after some minutes set to a semi-solid mass of long needles. This was protected from carbon dioxide, and left for two or three days, after which it was collected on an asbestos filter by means of a filter pump. The basic nitrate thus obtained was dried on glazed porcelain in an atm. free from carbon dioxide. It had the composition $Ca(NO_3)_2.Ca(OH)_2.2\frac{1}{2}–3H_2O$, and lost its water of crystallization at 160°. It was decomposed by water into calcium nitrate and hydroxide. The heat of formation of the anhydrous salt was +2·0 Cals., and a further amount of 8·4 Cals. was developed in the formation of the hydrated salt.

F. K. Cameron and W. O. Robinson studied the ternary system, $CaO—Ca(NO_3)_2—H_2O$, at 25°, and inferred that the solid phases, $Ca(OH)_2$; a solid soln., $CaO.xN_2O_5.yH_2O$; a basic nitrate, $2CaO.N_2O_5.3\frac{1}{2}H_2O$, *i.e.* $Ca_2N_2O_7.3\frac{1}{2}H_2O$; and $Ca(NO_3)_2.4H_2O$, can be in stable equilibrium with alkaline soln. of calcium nitrate. H. Bassett and H. S. Taylor have shown that, owing mainly to complications introduced by the use of impure calcium nitrate, the solid soln. assumed to exist is in reality a part of the curve with calcium hydroxide as equilibrium solid, and that, at 25°, the only basic nitrate is **trihydrated calcium oxynitrate,** $CaO.Ca(NO_3)_2.3H_2O$, not $CaO.Ca(NO_3)_2.3\frac{1}{2}H_2O$. At 100° the trihydrate is no longer stable, and there can exist **dihydrated calcium oxynitrate,** $CaO.Ca(NO_3)_2.2H_2O$; and **hemihydrated calcium oxynitrate,** $CaO.Ca(NO_3)_2.\frac{1}{2}H_2O$, can exist in equilibrium with the soln. There is no indication of any other basic salt intermediate between $Ca(OH)_2$ and $Ca_2N_2O_7$. By plotting the number of grams of "free" calcium oxide with the number of grams of calcium nitrate per 100 grms. of soln., the curves shown in Fig. 61 are obtained—the dotted curve applies for 25°, the other at 100°. The dotted curve *AB* shows that calcium hydroxide can exist at 25° in stable equilibrium with soln. containing less than 44·5 grms. of calcium nitrate per 100 grms. of soln.; small quantities of calcium nitrate lower the solubility of calcium hydroxide, while in the more conc. soln. of calcium nitrate the solubility of the hydroxide is three times its value in aq. soln. The dotted curve *BC* shows that basic salt, $Ca_3N_2O_7.3H_2O$, can exist in stable equilibrium with soln. containing from 44·5 to 57·5 grms. of calcium nitrate per 100 grms. of soln. The salt forms large acicular crystals. The dotted curve *CD* corresponds with tetrahydrated calcium nitrate as solid phase. The curve *FG*, at 100°, corresponds with $Ca(OH)_2$ as solid phase, and the maximum amount of "free" lime in soln. is about five times as great as at 25°; the curve *GHI* ranges from 57 to 70·6 per cent. of calcium nitrate, and corresponds with the crystals of $Ca_2N_2O_7.2H_2O$ as solid phase; the curve *IK* corresponds with the crystals of $Ca_2N_2O_7.\frac{1}{2}H_2O$ as solid phase; and the curve *KL* with anhydrous calcium nitrate as solid phase.

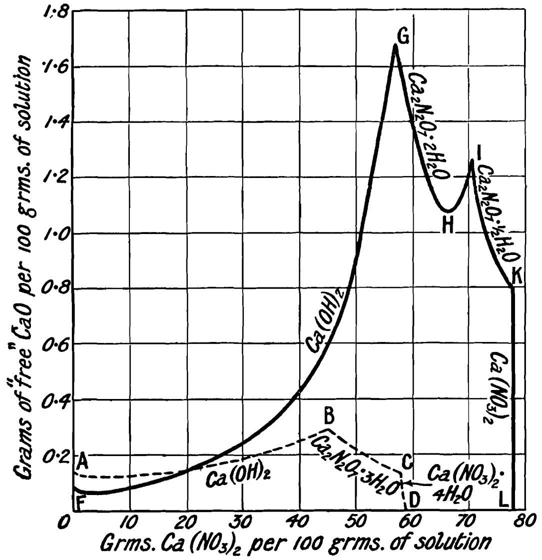

FIG. 61.—Equilibrium Curves in the Ternary System, $CaO—Ca(NO_3)_2—H_2O$, at 25° and at 100°.

A. H. Pearson showed that an aq. soln. of *ammonium chloride* dissolves barium nitrate more copiously than water. G. J. Mulder, and C. J. B. Karsten have also measured the effect of ammonium chloride on the solubility of barium nitrate. A. H. Pearson found an aq. soln. of *ammonium nitrate* dissolves barium nitrate less readily than water. G. J. Mulder has also made observations in this direction. A. H. Pearson also found soln. of *ammonium acetate* dissolve barium nitrate less readily than water. C. J. B. Karsten observed that with *potassium chloride* and barium nitrate, each dissolves without producing a separation, in a soln. of the other; similar results were obtained with *sodium chloride*, and with *sodium nitrate*. G. J. Mulder and H. Kopp also made observations on the effect of sodium nitrate on the solubility of barium, and strontium nitrates. According to A. Müntz, a soln. of calcium nitrate and sodium chloride may form sodium nitrate by double exchange. According to R. Kremann and H. Rodemund, at 25°, the solubilities, expressing conc. in grams per 100 grms. of sat. soln., are:

$Ca(NO_3)_2$ . . .	54·58	53·22	52·73	52·40	37·31	26·91	14·61
$NaNO_3$ . . .	7·25	10·70	12·08	11·88	19·48	24·98	36·12
Solid phase	$Ca(NO_3)_2.4H_2O$		$Ca(NO_3)_2+NaNO_3$	$NaNO_3$			

Analogous results were obtained at 9°. A. Coppadoro studied the ternary system, $Ba(NO_3)_2—NaNO_3—H_2O$, at 30°; the ternary system, $Ba(NO_3)_2—NaCl—H_2O$; and the corresponding quaternary system. G. J. Mulder, C. J. B. Karsten, and H. Kopp studied the solubility of barium nitrate in soln. of *potassium nitrate* and obtained indications of the formation of a double salt. A. Findlay, I. Morgan, and I. P. Morris, and H. W. Foote studied the ternary system, $Ba(NO_3)_2—KNO_3—H_2O$, at 9·1°, 21·1°, 25°, and 35°. No double salt was observed with sodium nitrate; potassium barium tetranitrate, $K_2Ba(NO_3)_4$, or $2KNO_3.Ba(NO_3)_2$, was formed with potassium nitrate. Thus, at 35°, expressing conc. in grams of salt per 100 grms. of soln.:

$Ba(NO_3)_2$ . .	11·39	9·18	8·08	8·42	5·85	5·02	3·02	1·77	0
KNO_3 . .	0	12·99	17·48	19·75	24	26·05	34·87	34·98	35·01
Solid phase	$Ba(NO_3)_2$			+	$2KNO_3.Ba(NO_3)_2$		+	KNO_3	

W. K. Wallbridge prepared the double salt by evaporating conc. soln. of the component salts. The tetrahedral crystals resembled those of barium nitrate. It is remarkable that crystals of double salts of rubidium or cæsium nitrate, or of potassium nitrate with strontium nitrate, could not be prepared. Nor have double salts with calcium nitrate and the alkali nitrates been obtained. A. Fock, and H. Euler measured the solubility of mixtures of *lead nitrate* and barium nitrate at 15°, 25°, 30°, and 47°. F. Margueritte found that when *potassium chlorate* is dissolved in a soln. of barium nitrate, the latter is not so readily precipitated by many reagents. R. Kremann and H. Rodemund have studied the effect of *sodium thiosulphate* on aq. soln. of calcium nitrate, and the reciprocal salt pairs; $Na_2S_2O_3 + Ca(NO_3)_2 \rightleftharpoons CaS_2O_3 + 2NaNO_3$. No double salt is observed, but there is a small region of stability for the triple salt, *sodium calcium nitrato-thiosulphate*, $NaNO_3.CaS_2O_3.Na_2S_2O_3.11H_2O$; this region diminishes with rises of temp. and the invariant transformation temp. is 29°–29·2°, beyond which single salts are formed. According to K. von Hauer, 100 parts of water at 19°–20°, dissolves singly 8·73 parts of barium nitrate or 45·94 parts of strontium nitrate; and if strontium nitrate be added to a sat. soln. of barium nitrate, almost the whole of the barium nitrate is precipitated, and the soln. contains 45·96 parts of salt per 100 parts of water.

Calcium nitrate is readily soluble in *ethyl alcohol*, and in *methyl alcohol*, and the electrical conductivities and the raising of the b.p. of these soln. have been determined, *vide infra*, from which J. Wölfer,[6] and B. Völlmer infer that there is a partial association of the solvent with the salt, or complex ions are formed. According to C. A. Gerardin, barium nitrate is insoluble in absolute alcohol; and in aq. alcohol, the solubility increases linearly with rise of temp. According to H. Rose, 100 parts of absolute alcohol dissolve 0·01176 part and, according to J. R. Hill, 0·02387 part of strontium nitrate; according to the latter, 100 parts of commercial rectified spirit dissolve 0·5 part of strontium nitrate; and, according to H. Rose, 100 parts of a mixture of equal vol. of alcohol and ether dissolve 0·00167 part of strontium nitrate.

J. d'Ans and R. Siegler obtained three types of solubility isothermal curves with mixtures of ethyl alcohol and water and the three nitrates of the alkaline earths: (1) The curve with barium nitrate, which does not form compounds with either water or alcohol, is a straight line, showing a decreasing solubility with increasing alcohol conc. (2) The curve with strontium nitrate, which forms the compound $Sr(NO_3)_2.4H_2O$, with water, but does not form a compound with alcohol, is divided into two branches corresponding with the fact that the hydrated salt is stable in the dil. alcoholic soln., whilst the anhydrous salt is stable in the conc. alcoholic soln. (3) The curve with calcium nitrate, which forms $Ca(NO_3)_2.4H_2O$ with water and $Ca(NO_3)_2.2C_2H_5OH$ with alcohol, consists of three branches. It is found that between the areas in which the hydrate and the alcoholate are stable there is a small metastable region, in which anhydrous calcium nitrate constitutes the solid phase. The observed data are plotted in Fig. 62. It will be observed that barium nitrate forms no hydrate and no alcoholate; and it is almost insoluble in alcohol; strontium nitrate forms a tetrahydrate but no alcoholate; calcium nitrate forms three hydrates and one alcoholate, $Ca(NO_3)_2.2C_2H_5OH$, which was discovered by T. Graham and regarded by him as having the composition $Ca(NO_3)_2.2_2C_2H_5OH$. The solubilities of the

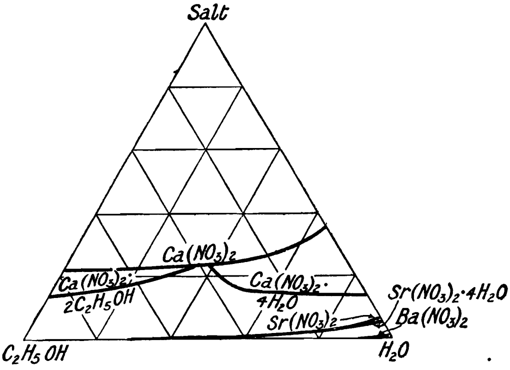

FIG. 62.—Equilibrium Diagram for the Ternary Systems, $M(NO_3)_2$—C_2H_5OH—H_2O.

three nitrates were also determined in some other solvents, at 25°, expressing the results in grams of nitrate in 100 grms. of soln.

	$Ba(NO_3)_2$	$Sr(NO_3)_2$	$Ca(NO_3)_2$
Water	9·55	46·61	82·5
Methyl alcohol	0·50	1·26	65·5
Ethyl alcohol	0·005	0·02	52
Propyl alcohol	—	0·02	36·5
Isobutyl alcohol	—	0·01	25
Amyl alcohol	—	0·003	13·3
Acetone	0·005	0·02	58·5

P. E. Browning gave 0·004 per cent. for the solubility of strontium nitrate in amyl alcohol. Barium nitrate thus dissolves to a slight extent only in all the solvents except water. Strontium nitrate is very slightly more soluble, whilst calcium nitrate is very soluble, except in the cases of *ether*, and *paracetaldehyde*, in which it is not more soluble than the other nitrates. W. Eidmann found calcium nitrate to be insoluble in *methylal*, and barium and strontium nitrates to be soluble in *acetone*, and J. F. Snell observed no layer formation by the soln. of barium nitrate in mixtures of acetone and water. According to A. Naumann, *methyl acetate* dissolves 41 grms. of calcium nitrate per 100 grms. of soln. at 18°, and the soln. has a sp. gr. 1·313. V. Rothmund and N. T. M. Wilsmore measured the solubility of barium nitrate in aq. soln. of *phenol* at 25°; and J. Timmermans has also studied the system.

J. W. Retgers [7] found the **crystals** of anhydrous calcium nitrate to form microscopic octahedra which are singly-refracting and belong to the cubic system; they are isomorphous with strontium and barium nitrates. These crystals have been studied by A. Scacchi, and by L. Wulff, W. J. Lewis, and R. Henriques. According to J. C. G. de Marignac, the crystals of tetrahydrated calcium nitrate form monoclinic prisms with axial ratios $a:b:c=1·5839:1:0·6876$, and $\beta=98° 6'$, and, according to H. de Sénarmont, the monoclinic prisms of the tetrahydrated salt, have the axial ratios $a:b:c=0·6547:1:0·8976$, and $\beta=91° 10'$. The artificial coloration of crystals of tetrahydrated strontium nitrate has been studied by H. de Sénarmont, H. Becquerel, and C. Camichel. S. Nishikawa and K. Hudinuki, and L. Vegard studied the **X-radiograms** of calcium, barium, and strontium nitrates. The **corrosion figures** of crystals of barium and strontium nitrates have been studied by L. Wulff, and by H. Baumhauer. G. Brügelmann studied the isomorphism of mixed crystals of barium nitrate with sodium or potassium nitrate.

The **specific gravity** of crystals of anhydrous calcium nitrate is, according to A. Filhol,[8] 2·240; P. Kremers, 2·472; P. A. Favre and C. A. Valson, 2·504 at 17·9°. The reported values for anhydrous strontium nitrate range from 2·704 at 3·9° of L. Playfair and J. P. Joule, to 3·0061 of J. H. Hassenfratz—M. le Blanc and P. Rohland gave 2·497—and for anhydrous barium nitrate from the 3·16052 at 3·9° of the last named to the 3·404 of H. J. Buignet—M. le Blanc and P. Rohland gave 3·245. The best representative values are 2·444 for calcium nitrate, 2·986 for strontium nitrate, and 3·243 for barium nitrate. For tetrahydrated calcium nitrate E. Filhol gave 1·78; P. A. Favre and C. A. Valson, 1·878 at 18°; and J. M. Ordway, 1·90 at 15·5° for the solid and 1·79 at 15·5° for the liquid; and for tetrahydrated strontium nitrate, E. Filhol gave 2·113; and P. A. Favre and C. A. Valson, 2·249 at 15·5°.

The sp. gr. of aq. soln. of calcium nitrate have been determined by F. Mylius and R. Funk,[9] A. C. MacGregory, G. T. Gerlach, etc. B. Franz gave for soln. of the following percentage composition at 17·5°:

Per cent.	1	5	10	15	20	25	30	40	50	60
Sp. gr., $Ca(NO_3)_2$	1·009	1·045	1·086	1·129	1·174	1·222	1·272	1·385	1·515	1·666
Sp. gr., $Sr(NO_3)_2$	—	1·041	1·085	1·131	1·181	1·235	1·292	1·422	—	—
Sp. gr., $Ba(NO_3)_2$	1·009	1·042	1·087	—	—	—	—	—	—	—

G. T. Gerlach, A. C. MacGregory, etc., have given values for the sp. gr. of soln. of strontium nitrate; and C. J. B. Karsten, A. Michel and L. Krafft, etc., for barium nitrate. P. Kremers' values for strontium and barium nitrates are indicated above. Earl of Berkeley and M. P. Appleby give for soln. of strontium nitrate sat. at the different temp:

	0·58°	14·71°	29·06°	30·28°	39·74°	61·34°	78·89°	88·94°
Sp. gr.	1·28561	1·39380	1·51098	1·51441	1·51282	1·51048	1·51091	1·51174

J. Wagner gave for the viscosity of aq. soln. $0{\cdot}125N$-, $0{\cdot}25N$-, $0{\cdot}5N$-, and N- of calcium nitrate at 25° the respective values 1·0076, 1·0218, 1·0533, and 1·1172 when the value for water is unity; for $0{\cdot}125N$-, $0{\cdot}25N$-, $0{\cdot}5N$-, and N-soln. of strontium nitrate, under similar conditions, he gave the respective values 1·0114, 1·0240, 1·0491, and 1·150; and for $0{\cdot}125N$-, $0{\cdot}25N$-, and $0{\cdot}5N$-soln. of barium nitrate the respective values 1·0084, 1·0214, and 1·0437. He also measured the effect of temp. on the viscosity of these soln. S. de Lannoy represented the vol. v of soln. of strontium nitrate at θ° by the formula $v=v_0(1+a\theta+b\theta^2)$, where v_0 is the volume at the initial temp., and a and b are constants for the ranges of conc. and temp.:

Per cent. $Sr(NO_3)_2$	4	4	8	8	15	15	25
Temperature	0°–40°	40°–82°	0°–40°	40°–75°	0°–40°	40°–75°	0°–75°
a	$0{\cdot}0_4 98$	$0{\cdot}0_4 55$	$0{\cdot}0_3 1525$	$0{\cdot}0_3 126$	$0{\cdot}0_3 2766$	$0{\cdot}0_3 2038$	$0{\cdot}0_3 371$
b	$0{\cdot}0_5 337$	$0{\cdot}0_5 4775$	$0{\cdot}0_5 344$	$0{\cdot}0_5 41$	$0{\cdot}0_5 2413$	$0{\cdot}0_5 2685$	$0{\cdot}0_5 176$

N. A. Tschernay represented the **thermal expansion** between 0° and 60° of a soln. of a mol of calcium nitrate in 50 mols of water by $v=1+0{\cdot}0001719\theta+0{\cdot}0000035 31\theta^2$; and of a mol of strontium nitrate in 100 mols of water by $v=1+0{\cdot}0001787\theta+0{\cdot}0000035 57\theta^2$. G. Jäger found the **thermal conductivity** of 20, 36, and 40 per cent. soln. of strontium nitrate to be respectively 96·4, 92·3, and 92·8 when that of water is 100. H. V. Regnault[10] found that **specific heat** of solid barium nitrate to be 0·1523 between 13° and 98°; and H. Kopp found for crystalline strontium nitrate, 0·181 between 17° and 47°. J. C. G. de Marignac measured the sp. ht. of soln. of nitrates of the alkaline earths and found for soln. with n mols of water per mol of $Ca(NO_3)_2$, at 21·51°,

n	10	15	25	50	100	200
Sp. ht., $Ca(NO_3)_2$	0·6255	0·6856	0·7597	0·8463	0·9116	0·9510
Sp. ht., $Sr(NO_3)_2$	—	—	—	0·8169	0·8905	0·9348
Sp. ht., $Ba(NO_3)_2$	—	—	—	—	—	0·9299

T. Carnelly[11] gave 561°±6° for the **melting point** of anhydrous calcium nitrate; 645°±3° for strontium nitrate; and 593°±1° for barium nitrate. W. Ramsay and N. Eumorfopoulos gave 499° for calcium nitrate; 570° for strontium nitrate; and 575° for barium nitrate; H. le Chatelier gave 592° for barium nitrate; and W. D. Harkins and G. L. Clark found 595·53°. For the m.p. of tetrahydrated calcium nitrate, J. L. R. Morgan and P. T. Owen gave 42·31°; J. d'Ans and R. Siegler, 42·89°±0·03°; S. U. Pickering, 42·4°; and T. W. Richards, and H. Bassett and H. S. Taylor, 42·7° for stable $\alpha Ca(NO_3)_2.4H_2O$; the latter gave 39·7° for unstable β-$Ca(NO_3)_2.4H_2O$; H. Bassett and H. S. Taylor also gave 51·1° for the m.p. of trihydrated calcium nitrate, and they found that the dihydrate does not possess a true m.p. as indicated in Fig. 61. S. U. Pickering gave 33·49 Cals. for the **heat of fusion** of tetrahydrated calcium nitrate.

The fusion curves of barium, strontium, or calcium nitrate with lithium, sodium, or potassium nitrate, have been partially studied but no evidence of the formation of double salts has been obtained. According to A. W. C. Menzies and N. N. Dutt,[12] the V-eutectic with calcium and sodium nitrates is near 240° with 50 per cent. of each component; with calcium and potassium nitrates, it is nearer 210° with 42 per cent. of calcium nitrate—F. Guthrie found the eutectic at 251° with 25·86 per cent. of calcium nitrate, A. W. C. Menzies and N. N. Dutt also studied the ternary system, $Ca(NO_3)_2$—KNO_3—$NaNO_3$, and found the ternary eutectic approximated to 175° with 30 : 50 : 20 eq. per cent. of the respective salts. E. J. Maumené gave the m.p. of the mixture $NaNO_3+Ca(NO_3)_2$ as 235°, A. W. C. Menzies and N. N. Dutt found 261°. W. D. Harkins and G. L. Clark found for barium and sodium nitrates the eutectic near 300° with about 8 or 9 eq. per cent. of the sodium salt; for the barium and potassium nitrates a eutectic near 310° with nearly 80 eq. per cent. of the potassium salt; and for the ternary system, $Ba(NO_3)_2$—KNO_3—$NaNO_3$, the ternary eutectic is 214·1° with 5 : 50 : 45 eq. per cent. of the respective salts. E. J. Maumené measured the m.p. of the mixtures $Ba(NO_3)_2+KNO_3$ and $Ba(NO_3)_2+NaNO_3$; and of $Sr(NO_3)_2+KNO_3$ and $Sr(NO_3)_2+NaNO_3$. F. Guthrie found the eutectic point with barium and potassium nitrate corresponded with 29·53 per cent. of the barium salt and a temp. of 278·5°; he also found that a eutectic at 285° with potassium and strontium nitrates corresponding with 25·81 per cent. of the latter salt. W. D. Harkins and G. L. Clark determined the m.p. of a few points in the ternary system, $Sr(NO_3)_2$—KNO_2—$NaNO_3$, and the ternary eutectic is not far from 208·4° with the respective eq. percentages 9 : 50 : 49. Attempts to deal with the ternary system, $Ba(NO_3)_2$—KNO_3—$LiNO_3$, were abandoned because when over 10 eq. per cent. of the first-named salt was present oxygen was rapidly evolved—even so low as 266°.

The cryohydric temp. of the three salts are indicated in connection with the solubilities of the salts in water. H. C. Jones and F. H. Getman's values for the **lowering of the freezing point** $d\theta$ of soln. of calcium nitrate with the conc. C expressed in mols per litre:

C . .	0·042	0·104	0·208	0·415	1·038	1·660	2·075	2·905	3·320
$d\theta$ . .	0·200°	0·470°	0·910°	1·820°	5·070°	8·680°	11·600°	19·320°	24·320°
$d\theta/C$ . .	4·76	4·52	4·37	4·39	4·89	5·23	5·59	6·65	7·33

The increase in the value of $d\theta/C$ with conc. soln. owing to the formation of hydrates is not so marked as with soln. of the halides. S. Arrhenius, and S. U. Pickering also studied the f.p. of soln. of this salt. H. C. Jones and F. H. Getman also found soln. of strontium nitrate gave a minimum value of $d\theta/C$=4·00 in 0·15N-soln. For soln. of barium nitrate, mols per litre, H. Hausrath found for C=0·000383, 0·002681, and 0·008552; $d\theta$=0·002140°, 0·01401°, and 0·04311°; and $d\theta/C$=5·58, 5·22, and 5·05 respectively. F. M. Raoult also measured the lowering of the f.p. of soln. of barium nitrate.

The **boiling point** of a sat. soln. containing 351·2 grms. of calcium nitrate in 100 grms. of water was found by J. Legrand[13] to be 150°; P. Kremers gave 152°; and G. T. Gerlach gave for soln. with w grms. of $Ca(NO_3)_2.2H_2O$ in 100 grms. of water;

w . .	12	25·5	68·5	152·5	607	1376	2614	10880
B.p. . .	101°	102°	105°	110°	130°	140°	145°	150°

T. Griffiths found the b.p. of a sat. soln. of strontium nitrate is 106·8° with 113 grms. of the salt in 100 grms. of water; P. Kremers gave 107·5° to 108°; G. J. Mulder, 107·9°, and for a soln. with w grms. of $Sr(NO_3)_2$ in 100 grms. of water, G. T. Gerlach gave

w . .	12	24	63·6	89·6	97·6	105	112·2	116·5
B.p. . .	100·5°	101°	103°	104·5°	105°	105°	106°	106·3°

T. Griffiths found the b.p. of a sat. soln. of barium nitrate is 101·1° with 36·18 grms. of the salt in 100 grms. of water; P. Kremers, 102·5°; G. J. Mulder, 101·9°; and J. L. Gay Lussac, 101·65°; G. T. Gerlach found the b.p. of a soln. of barium nitrate, when w is 12·5, 26, and 27·5, is respectively 100·5°, 101°, and 101·1°. J. M. Ordway gave 132° for the b.p. of melted tetrahydrated calcium nitrate. S. Arrhenius calculated for the mol. **raising of the boiling point** of 0·0643N-, 0·1073N-, and 0·179N-soln. of calcium nitrate, the respective values 4·72, 4·62, 4·58; A. Smits, for 0·0429N-, 0·0848N-, 0·4142N-, and 0·9005N-soln. of strontium nitrate, the respective values 1·166, 1·156, 1·190, and 1·215; or the values of i are respectively 2·24, 2·22, 2·19, and 2·34. A. Smits also found, for 0·0461N-, 0·0868N-, 0·4233N-, and 0·8890N-soln. of barium nitrate, the respective values of $d\theta/C$, 1·140, 1·210, 1·101, and 1·025, or the values of i are respectively 2·71, 2·33, 2·12, and 1·92.

G. Tammann[14] has measured the lowering of the **vapour pressure** of water at 100° by soln. of the nitrates of the alkaline earths:

	$Ca(NO_3)_2$			$Sr(NO_3)_2$			$Ba(NO_3)_2$		
Grms. of salt .	6·69	44·40	168·13	7·30	45·32	78·58	5·83	18·28	32·32
Lowering v.p. .	13·1	104·2	403·4	11·0	69·1	123·1	6·0	18·8	32·4 mm.

H. Lescœur gives 9·3 mm. for the vap. press. of a sat. soln. of tetrahydrated calcium nitrate at 20°, and he has measured the changes of vap. press. during the dehydration of a soln. of the salt, and the hydration of the anhydrous salt. According to W. Müller-Erzbach, the vap. press. of the tetrahydrate is 0·6 to 0·7 of that of water, and the salt loses its water of crystallization under the same press.; the accidental formation of the trihydrate showed 0·11 for the relative press. for the first mol and 0·04 for the two last mols. F. M. Raoult measured the lowering of the vap. press. of soln. of barium nitrate. J. Waddell compared what T. Graham called the invaporation or the absorption of water by lithium nitrate and the nitrates of the alkaline earths. He found lithium nitrate to be the least absorbent, the calcium salt was more absorbent, the strontium salt still more, and the barium salt was the most absorbent. R. O. E. Davis and co-workers measured the vap. press. of ammonical soln. of calcium nitrate; and considered that soln. of calcium nitrate are most promising for practical use as an absorbent for ammonia.

According to J. Thomsen,[15] the **heat of formation** is $(Ca, N_2, 3O_2)$, 203·23 Cals.; (Ca, O_2, N_2O_4), 207·21 Cals.; (Sr, O_2, N_2O_4), 223·83 Cals.; $(Sr, N_2, 3O_2)$, 219·85 Cals.; (Ba, O_2, N_2O_4), 229·72 Cals.; and $(Ba, N_2, 3O_2)$, 225·74 Cals. M. Berthelot gave with solid components (CaO, N_2O_5), 59·2 Cals.; (SrO, N_2O_5), 76·2 Cals.; (BaO, N_2O_5), 81·4 Cals.; $Ca(OH)_2+2HNO_3$, all in dil. soln., 27·8 Cals.; similarly for $Sr(OH)_2+2HNO_3$, 27·8 Cals.; and $Ba(OH)_2+2HNO_3$, 27·8 Cals. J. Thomsen gave for the **heat of solution** of a mol of $Ca(NO_3)_2$ in 400 mols of water 3·95 Cals.; for $Sr(NO_3)_2$, 4·62 Cals.; $Ba(NO_3)_2$, 9·40 Cals.; and for $Ca(NO_3)_2.4H_2O$, —7·25 Cals. S. U. Pickering found 3·943 Cals. for the heat of soln. of $Ca(NO_3)_2$ in water, and 8·710 Cals. in alcohol; and for $Ca(NO_3)_2.4H_2O$, —8·354 Cals. in water, and —1·835 Cals. in alcohol. E. von Stackelberg measured the heat of soln. Q of n mols of barium nitrate in 100 mols of water and found $Q=10638-8108n+608n^2$ cals. F. R. Pratt measured the heats of dilution of soln. of barium and strontium nitrates.

The **index of refraction** of crystals of strontium nitrate for Na-light is 1·57, according to A. Fock;[16] and 1·5665, according to M. le Blanc and P. Rohland—while J. Behr's value 1·5878 is considered to be incorrect. H. Topsöe and C. Christiansen found for crystals of barium nitrate 1·5665 for the *C*-line; 1·5711 for the *D*-line; and 1·5825 for the *F*-line; A. Fock found 1·5716 and M. le Blanc and P. Rohland, 1·5711 for the *D*-line; J. Behr, 1·5655 for the Li-line; 1·5699 for the Na-line; and 1·5735 for the Tl-line.

According to H. de Sénarmont, the crystals of tetrahydrated strontium nitrate gave a strong negative **double refraction.** The anomalous double refraction of the crystals of anhydrous strontium and barium nitrates has been studied by H. Marbach, L. Wulff, W. J. Lewis, F. Klocke, and J. Morel. The indices of refraction of aq. soln. of calcium nitrate have been studied by H. C. Jones and F. H. Getman, and B. C. Damien; the latter found for a soln. sp. gr. 1·7621, at 12·3°; 1·46436 and 1·48341 respectively for H_α and H_γ; 1·46308 and 1·48142 respectively for a soln. of sp. gr. 1·7580 at 17·0°; 1·45782 and 1·47534 respectively for a soln. of sp. gr. 1·7425 at 34·1°; and 1·45201 and 1·46813 respectively for a soln. of sp. gr. 1·7252 at 53·2°. M. le Blanc and P. Rohland found for 10·5 and 25·51 per cent. soln. of strontium nitrate, of sp. gr. 1·095 and 1·2440 respectively, the refractive indices for the *D*-line 1·3387 and 1·3459 respectively; and for 6·08 and 6·97 per cent. soln. of barium nitrate of sp. gr. 1·0517 and 1·0597 respectively, the refractive indices 1·3398 and 1·3408 respectively. S. Koskinen and V. J. Saarialho also studied the optical properties of soln. of barium nitrate. The respective **refraction equivalents** of solid and soln. of strontium nitrate by the $(\mu-1)M/D$ formula are 20·33 and 20·40; and of barium nitrate, 22·98 and 22·27; similarly, by the $(\mu^2-1)M/(\mu^2+1)D$ formula, 11·72 and 11·83 for strontium nitrate, and 13·22 and 12·94 for barium nitrate. W. N. Hartley[17] has studied the **absorption spectra** of soln. of calcium and barium nitrates. C. Schaefer and M. Schubert measured the infra-red spectrum of strontium and barium nitrates. W. Crookes observed that calcium nitrate gives an orange-yellow **phosphorescence** with a continuous spectrum when exposed to cathode rays. P. Bary found strontium and barium nitrate fluoresces when exposed to X-rays or to Becquerel's rays. P. Heinrich noted the luminescence which occurs when barium oxide is treated with nitric acid in the dark.

P. Wenger and A. Lubomirsky[18] studied the electro-reduction of barium nitrate in aq. soln. The equivalent **electrical conductivity,** λ, of soln. of the nitrates of the alkaline earths was measured by F. Kohlrausch and E. Grüneisen, at 18°. H. C. Jones and co-workers measured the mol. conductivity, μ, and the percentage **degree of ionization,** a, of soln. of the nitrates of the alkaline earths containing a mol of salt in v litres of water.

L. Wöhler found 10·8 rec. ohms for the difference in the conductivities of soln. of strontium nitrate at dilutions between $v=32$ and $v=1024$; the corresponding difference with soln. of barium nitrate was 12·7 rec. ohms. H. C. Jones and co-workers also measured the temp. coeff. of the conductivities.

G. Kümmell, and K. Drucker also discussed the degree of ionization of soln. of these salts. Measurements have also been made of the conductivity of aq. soln. of calcium nitrate soln. by A. C. MacGregory, S. Arrhenius, H. C. Jones, etc. A. C. MacGregory gives 0·0219 for the temp. coeff. of the conductivity of soln. of calcium nitrate between 18° and 26°; and 0·0224 for soln. of strontium nitrate between 10° and 26°; H. C. Jones also gave values for this constant. H. C. Jones and C. G. Carroll have measured the electrical conductivities of soln. of nitrates of the alkaline earths in methyl and ethyl alcohols; R. J. Holland, in methyl alcohol soln. containing benzene, toluene, xylene, and turpentine; H. C. Jones and E. C. Bingham, in water containing ethyl or methyl alcohol, or acetone; C. A. Kraus and J. E. Bishop, in propyl alcohol; and E. C. Franklin and C. A. Kraus, in soln. in liquid ammonia. The **transport numbers** of the ions have been determined by W. Hittorf, and many others.[19] G. N. Lewis and M. Randall calculated the activity coeff. of the ions of barium nitrate. The **pyroelectricity** and **piezoelectricity** of crystals of barium nitrate have been studied by W. Hankel. A. Heydweiller found the **dielectric constant** of barium nitrate to be 3·42 for $\lambda=478$ cm. P. Pascal gave for the mol. **coefficient of magnetization** of barium nitrate, 665×10^{-7} units.

Calcium nitrate decomposes when heated above its m.p., and gives off oxygen, nitrogen, and nitrogen peroxide. The residue obtained with partially decomposed calcium nitrate is phosphorescent in the dark, and it is the so-called *Baldwin's phosphorus*. Barium oxide, mixed maybe with some barium peroxide, remains as a solid when the nitrate has all decomposed; barium nitrite is an intermediate stage in the decomposition. The nitrates of the alkaline earths detonate feebly when strewn over red-hot coke, and when mixed with organic matter they detonate slightly when heated. Strontium and barium nitrates decompose if heated near their m.p. According to M. Rivière,[20] only a trace of nitrogen peroxide is produced. According to B. N. Gottlieb, and E. E. Basch, in heating barium nitrate, for the purpose of recovering the nitric acid, it is best to heat the salt as rapidly as possible without fusion. The former analyzed the gases evolved by heating barium nitrate to different temp. E. J. Maumené found that when calcium, strontium, or barium nitrate is mixed with an equi-molar proportion of sodium or potassium nitrate, it can be fused without decomposition, but W. D. Harkins and G. L. Clark found that while mixtures of barium and potassium nitrates could be readily fused without decomposition, mixtures of barium and lithium nitrates, with over 40 eq. per cent. of the latter decomposed, and ternary mixtures of these three nitrates decomposed when over 10 eq. per cent. of the barium salt was present. Molten tetrahydrated calcium nitrate decomposes, and when a third of the water has been lost, the anhydrous salt begins to separate; similar remarks apply to tetrahydrated strontium nitrate. The latter salt, according to H. J. Brooke, and A. Souchay and E. Lenssen, effloresces rapidly in air, and loses all its water at 100°; on the contrary, according to N. A. E. Millon, tetrahydrated calcium nitrate deliquesces rapidly in air and loses the water in vacuo over conc. sulphuric acid. F. W. Smither found tetrahydrated calcium nitrate retains one-fourth of its water very tenaciously at 97°–98°, although it is given off very slowly at this temp.

According to F. Kuhlmann,[21] when **hydrogen** is passed over red-hot barium nitrate, the hydroxide is formed; according to J. W. Thomas, gaseous **hydrogen chloride** does not change anhydrous or hydrated barium, strontium or calcium nitrates; according to K. Stammer, **carbon monoxide** reduces red-hot barium nitrate forming the carbonate and oxide; according to J. Lang, **lead** vigorously reduces hot barium nitrate, forming a trace of nitrite; according to J. W. Slater, **arsenic** forms arsenic trioxide when boiled with an aq. soln. of barium nitrate, but **phosphorus** is not attacked; and, according to C. J. B. Karsten, trituration of a dry mixture of **potassium sulphate** and barium nitrate is attended by the same double decomposition. E. M. Walton found a powdered mixture of barium nitrate and **sodium carbonate** liquefies with the absorption of heat, so that the temp. initially at 21·3° fell to —13·7°.

According to E. Lucius, barium nitrate unites with **barium acetate** to form a double salt. W. C. de Baat,[22] in his study of the ternary system, NH_4NO_3—$Ba(NO_3)_2$—H_2O, at 30°, found no evidence of the formation of a double salt of barium nitrate, and **ammonium nitrate**; nor in his study of the quaternary system, $Ba(NO_3)_2$—NH_4NO_3—$AgNO_3$—H_2O, at 30°, did he find any evidence of the formation of a double salt with barium nitrate and **silver nitrate.** N. Busvold claims to have made white needle-like crystals of **calcium hydroxynitrate,** $2Ca(OH)_2.Ca(NO_3)_2.2H_2O$, by crystallization from a soln. of calcium oxide in one of calcium nitrate. C. L. Parsons and H. P. Corson found the mutual solubility of barium hydroxide and nitrate in aq. soln. at 25°. A soln. containing 5·02 parts of barium oxide, and 11·48 parts of barium nitrate in 100 parts of water, is sat. with respect to $Ba(OH)_2.8H_2O$ and $Ba(NO_3)_2$. The solubility of each is thus increased by the presence of the other. Similarly, also, C. L. Parsons and C. L. Perkins found a soln. of strontium oxide and nitrate is sat. with the hydrated hydroxide and nitrate when it contains 1·76 parts of strontia, and 81·06 parts of strontium nitrate in 100 parts of water at 25°. In neither case was any evidence of basic nitrates—*strontium hydroxynitrate* or *barium hydroxynitrate*—obtained.

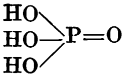
§ 25. The Normal Phosphates of the Alkaline Earths

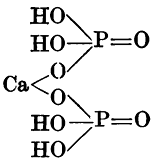
If the notation were consistent, orthophosphoric acid should be $P(OH)_5$, and the orthophosphates derivatives of this acid; but through some aberration, the acid $O : P(OH)_3$ is called orthophosphoric acid, and the derivative salts, orthophosphates. The calcium salts of this acid, H_3PO_4, whose individuality has been established, are indicated in Table XVI. Their relationship with orthophosphoric acid is illustrated by the graphic formulæ

TABLE XVI.—THE CALCIUM ORTHOPHOSPHATES.

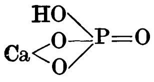
Empirical formula.	Ratios $CaO : P_2O_5 : H_2O$.	Orthophosphate.	Calcium.
$Ca(H_2PO_4)_2$ . .	$CaO.P_2O_5.2H_2O$	Monocalcium	Dihydrophosphate
$Ca(H_2PO_4)_2.H_2O$.	$CaO.P_2O_5.3H_2O$	,,	,,
$CaHPO_4$ . .	$2CaO.P_2O_5.H_2O$	Dicalcium	Hydrophosphate
$CaHPO_4.2H_2O$.	$2CaO.P_2O_5.5H_2O$	,,	,,
$Ca_3(PO_4)_2$ . .	$3CaO.P_2O_5$	Tricalcium	Phosphate
$Ca_3(PO_4)_2.H_2O$.	$3CaO.P_2O_5.H_2O$	,,	,,
$Ca_4P_2O_9$ . .	$4CaO.P_2O_5$	Tetracalcium	Oxyphosphate
$Ca_4P_2O_9.4H_2O$.	$4CaO.P_2O_5.4H_2O$	,,	,,
$Ca_{10}P_6O_{25}$ . .	$10CaO.3P_2O_5.H_2O$	Decacalcium	Oxyhexaphosphate



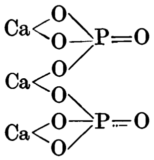
H_3PO_4



$Ca(H_2PO_4)_2$

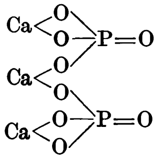


$CaHPO_4$

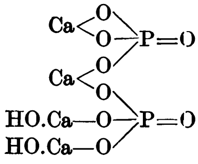


$Ca_3(PO_4)_2$

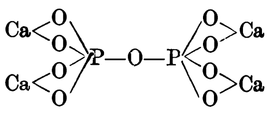
The oxyphosphate or hydroxyphosphate has been variously represented:



$Ca_3(PO_4)_2.CaO$



$Ca_3(PO_4)_2Ca(OH)_2+3H_2O$



$Ca_4P_2O_9$

H. Bassett prefers the last formula. According to A. Werner's scheme,[1] it is

$$\underset{\mathrm{Ca_4P_2O_9}}{\mathrm{Ca}\left[\mathrm{Ca}<\begin{matrix}\mathrm{CaPO_4}\\ \mathrm{CaPO_4}\end{matrix}\right]\mathrm{O}} \qquad \text{or} \qquad \underset{\mathrm{Ca_4P_2O_9.4H_2O}}{\mathrm{Ca}\left[\mathrm{Ca}<\begin{matrix}\mathrm{CaPO_4}\\ \mathrm{CaPO_4}\end{matrix}(\mathrm{H_2O})_4\right]\mathrm{O}}$$

Normal calcium phosphate, and calcium hydro- and dihydro-phosphates are all unstable in the presence of water, for they break down into solids containing more lime than the original solid, and in the soln., the ratio of acid to lime is greater than in the original solid. This was clearly shown by H. E. Causse's investigation [2] on the solubility of the calcium phosphates in soln. of phosphoric acid. The composition of aq. soln. containing calcium hydroxide and phosphoric acid has been investigated by F. K. Cameron, A. Seidell, and J. M. Bell, and by H. Bassett. A selection from the results of the last-named is indicated in Table XVII, and the results for the three-component system, $CaO—P_2O_5—H_2O$, in the region of the orthophosphates, are illustrated by Fig. 63.

TABLE XVII.—CONDITIONS OF EQUILIBRIUM OF THE CALCIUM ORTHOPHOSPHATES IN AQUEOUS SOLUTIONS OF PHOSPHORIC ACID.

The regions for the phosphoric acids and for calcium hydroxides as solid phases are probably very small, and they are shown diagrammatically in Fig. 63. At each of the three quintriple points—21°, 36°, and 152°—in addition to soln. and vapour phases, there are three solid phases in equilibrium as indicated in Table XVIII.

TABLE XVIII.—QUINTRIPLE POINTS WITH SOLUTIONS OF CALCIUM PHOSPHATES.

Temp.	Solid phases.	100 grms. of soln. contain	
		P_2O_5 grms.	CaO grms.
21°	$Ca(H_2PO_4)_2.H_2O$; $CaHPO_4$; $CaHPO_4.2H_2O$	23·50	5·81
36°	$CaHPO_4$; $CaHPO_4.2H_2O$; $Ca_3(PO_4)_2.H_2O$	0·140	0·0514
153°	$Ca(H_2PO_4)_2$; $Ca(H_2PO_4)_2.H_2O$; $CaHPO_4$	54·00	5·60

There are other quintuple points which have not been so well explored. F. K. Cameron, A. Seidell, and J. M. Bell, from their examination of the system at 25°, concluded that no definite compound exists between $CaHPO_4.2H_2O$ and $Ca(OH)_2$, but only a series of solid soln. Against this, H. Bassett showed that two phosphates more basic than calcium hydrophosphate can exist in stable equilibrium with an aq. soln. at 25°, and probably at higher temp. These are normal calcium phosphate, $Ca_3(PO_4)_2$, and calcium hydroxyhexaphosphate, $3Ca_3(PO_4)_2.Ca(OH)_2$. He found that $Ca_4P_2O_9.H_2O$ or $Ca_4P_2O_9.5H_2O$ did not appear under these conditions.

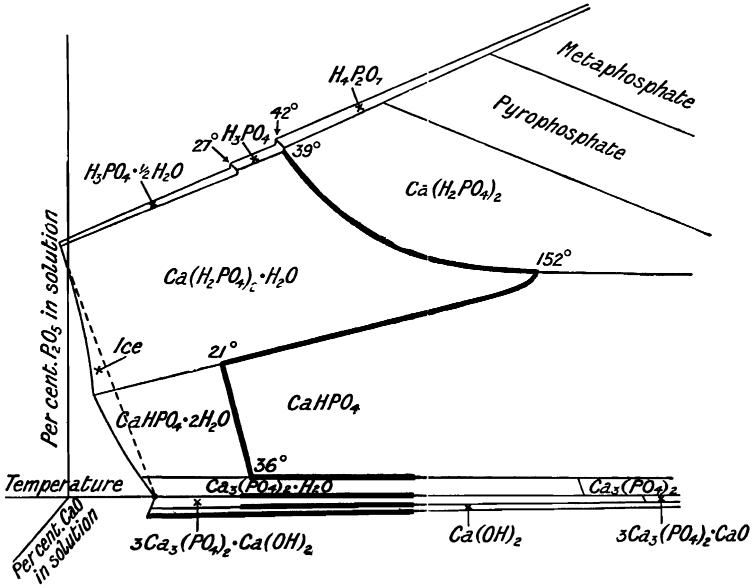

FIG. 63.—Equilibrium Conditions in the Ternary System, $CaO—P_2O_5—H_2O$, in the Region of the Orthophosphates—partly diagrammatic.

Tricalcium phosphate, tertiary calcium phosphate, tribasic calcium phosphate, normal calcium phosphate, or **calcium orthophosphate,** $Ca_3(PO_4)_2$, is represented in nature by crystals of the hydrated mineral *ornithite*, which is found in Sombrèro (West Indies), and which, according to A. A. Julien,[3] has the composition $Ca_3(PO_4)_2.2H_2O$. The mineral, however, is far from being a satisfactory representative owing to its admixture with other substances. It is also supposed to occur in bones. Yellowish-white *collophanite*, $Ca_3(PO_4)_2.H_2O$, was reported by F. Sandberger in the guano beds of Sombrèro (West Indies), and an analogous snow-white mineral, named *monite*, was reported by C. U. Shepard in the guano beds of Mona (West Indies). The sp. gr. of the former was given as 2·70, and the hardness 5, while the sp. gr. of the latter was given as 2·1, and the hardness 2. The two are now supposed to be the same mineral species. C. U. Shepard's *pyroclasite* from Moneta (West Indies) is probably a mixture of collophanite and monetite: $6CaHPO_4.Ca_3(PO_4)_2.H_2O$. When coral is treated with a soln. of ammonium phosphate, R. Irvine and W. S. Anderson found an interchange between the acid radicles, and they add that the reaction accounts for the formation of calcium phosphate deposits in rainy climates, through the excreta of birds deposited on coral or calcium carbonate. The reaction does not occur in the absence of a solvent—water.

F. K. Cameron and A. Seidell have stated that the normal phosphate prepared by precipitation is non-crystalline, and a reasonably pure and crystalline product with well-defined characteristics of a definite mol. species has not been prepared. According to R. Warington, it is obtained by precipitation on adding trisodium phosphate or disodium hydrophosphate to an ammoniacal soln. of calcium chloride; or, according to J. J. Berzelius, by dropping diammonium hydrophosphate into a similar soln. W. Windisch and W. Dietrich found the precipitates obtained by boiling primary potassium phosphate with increasing proportions of calcium hydrocarbonate show an increasing proportion of calcium, and range from the secondary to the primary calcium phosphate, and some entrained alkali phosphate. J. N. von Fuchs, and R. Warington treated a soln. of phosphoric acid with calcium oxide and obtained the impure normal phosphate. M. Berthelot found that the precipitate obtained by treating a soln. of a calcium salt with normal alkali phosphate is not wholly normal calcium salt, but a mixture of that salt with a little calcium hydrophosphate, $CaHPO_4$. W. A. Withers and A. L. Field studied the reaction between calcium nitrate and dipotassium hydrophosphate in aq. soln. Soon after mixing the reaction is considered to be $4K_2HPO_4+4Ca(NO_3)_2=Ca_3(PO_4)_2+Ca(H_2PO_4)_2+8KNO_3$, and after a few minutes the stable condition is represented by $4K_2HPO_4+3Ca(NO_3)_2=Ca_3(PO_4)_2+2KH_2PO_4+6KNO_3$. If an excess of calcium nitrate is used, the unstable state is either not produced, or it persists an exceedingly short time. The normal calcium phosphate undergoes partial hydrolysis and is converted into calcium hydrophosphate; the extent of the hydrolysis is roughly proportional to the conc. of the dihydrophosphate present, and is slightly diminished by an excess of calcium nitrate. G. M. de Toni prepared **colloidal calcium orthophosphate** by mixing with continued agitation hot normal soln. of sodium phosphate and calcium chloride containing sufficient protective colloid—gelatin, gum arabic, blood serum, and starch—not sucrose or caramel. The sol may also be obtained by mixing a soln. of orthophosphoric acid with one of calcium hydroxide containing gelatin.

R. Warington found that the precipitated normal phosphate dried in vacuo retained two mols of water, and 6·35 per cent. when dried at 100°. G. C. Wittstein found that the air-dried precipitate retains five mols of water; R. Ludwig, 5·5 mols; the latter also found that after standing three years, the precipitate retained 3·5 mols of water, and when dried at 100°, one mol. The technical preparation of calcium phosphate by extracting basic slag or phosphorite with hydrochloric acid and treating the soln. with calcium hydroxide was discussed by A. Gawalowsky. The salt is also obtained by digesting bone-ash with hydrochloric or nitric acid, boiling the soln. to eliminate carbon dioxide, and precipitating calcium phosphate by the addition of aqua ammonia—the product may be here contaminated with some magnesium ammonium phosphate, calcium fluoride, ferric and aluminium phosphates, etc.

Analogous methods furnish **strontium orthophosphate,** $Sr_3(PO_4)_2$; L. Barthe claims to have prepared it free from other phosphates, by evaporating a mixture of a cold ammoniacal soln. of 90 grms. of crystalline sodium hydrophosphate and one of 100 grms. of crystalline strontium chloride; both soln. should be free from carbon dioxide. The colloidal precipitate was washed by decantation, and dried at 100°. T. Graham prepared **barium orthophosphate,** $Ba_3(PO_4)_2$, as a flocculent precipitate by adding a soln. of barium chloride to one of normal sodium phosphate; according to M. Traube, this product contains foreign salts which cannot be washed out, and he preferred to make it by saturating phosphoric acid with barium carbonate. L. V. R. Ouvrard obtained crystals of normal barium phosphate by saturating fused sodium, ortho-, pyro-, or meta-phosphate, at a red heat, with barium oxide; and extracting the slowly cooled product with water. The addition of a little sodium chloride favours the crystallization, but if a large proportion is used, a chlorophosphate is formed. M. Berthelot has studied the conditions of equilibrium between barium chloride and ammonium phosphate.

Precipitated normal calcium phosphate is an amorphous powder, which after calcination has a white earthy appearance. Similar remarks apply to precipitated strontium and barium orthophosphates; L. V. R. Ouvrard's crystals of the latter salt were tabular and belonged to the cubic system. P. Gaubert claimed to have made the so-called liquid crystals of calcium phosphate. According to A. de Schulten, crystals of artificial monetite had a sp. gr. 1·05. L. V. R. Ouvrard's crystals of normal barium phosphate had a sp. gr. 4·1 at 16°.

H. Bassett[4] found that water is retained very tenaciously by calcium phosphate, and is not expelled by several hours' calcination in a muffle; S. Gabriel mentioned that over one per cent. of water in bone phosphate is not driven off by ignition, but it is expelled by strong ignition with silica. J. M. van Bemmelen also found water to be retained very tenaciously by fossil bones. Calcined calcium phosphates are often a pink colour, particularly with the basic phosphates, bone-ash, etc. A. Cossa stated that ceria earths are present in bone-ash, but H. Bassett and S. Gabriel could not confirm this, and the latter could not obtain the pink colour with cerium or manganese salts and pure calcium phosphate. G. Bergeron and L. l'Hôte, and F. Raoult and H. Breton noted the constant presence of traces of copper in animal tissues, and H. Bassett believes that the pink coloration of calcined basic calcium phosphates is due to the presence of traces of copper. It might be added, however, that the humidity of the atm. in the earlier stages of the calcination for bone-ash, as well as whether the carbon is burnt out early or late in the calcination, may give respectively white and pink ashes. Similar remarks apply to china clays.

N. T. de Saussure,[5] and J. P. J. d'Arcet found that normal calcium phosphate can be melted to a porcelain-like mass. O. Nielsen gives 1550° for the **melting point** of calcium orthophosphate. H. V. Regnault found 0·1992 for the **specific heat** of normal calcium phosphate between 15° and 98°. The **heat of formation,** according to M. Berthelot, is $3Ca(OH)_2+2H_3PO_4=Ca_3(PO_4)_2+6H_2O+64$ Cals.; and $3CaO_{aq.}+2H_3PO_{4aq.}=3H_2O+Ca_3(PO_4)_2+58{\cdot}4$ to 60·8 Cals. when an eq. of each component is dissolved in six litres of water at 16°; and similarly with strontium phosphate, 30·30 Cals. The heat of the reaction between normal sodium phosphate and strontium chloride is —1·76 Cals. for the amorphous salt and 14·18 Cals. for the crystalline; the corresponding reaction with barium chloride is thermally neutral for amorphous barium orthophosphate; and for the crystalline salt, 32·32 Cals. are developed. The heat of neutralization, $3Sr(OH)_2+2H_3PO_4=Sr_3(PO_4)_2+6H_2O$, is 65·40 Cals. for the amorphous salt, and 97·4 Cals. for the crystalline salt; and with a soln. of barium hydroxide and orthophosphoric acid, 68·40 Cals. for amorphous barium orthophosphate, and 100·80 Cals. for the crystalline salt.

According to P. Bary,[6] normal strontium phosphate does not luminesce when exposed to X-rays, or to Becquerel's rays. E. Newbery and H. Lupton found that many coloured phosphorites are decolorized when heated. A sample of French phosphorite gave no visible **thermo-luminescence,** but when a sample of Spanish phosphorite was gently warmed, it appeared to take fire, and emitted a beautiful and brilliant yellow glow which lasted from 30 to 60 secs., and then disappeared, after which further heating had no effect. By exposing the heated inert sample to radium for about six days, no external change was perceptible, but the power of emitting the yellow light was restored, and the glow was brighter and more lasting than that of the original specimen. No change of colour was observed by exposing the original samples to **radium rays,** but the thermo-luminescence was always increased by this treatment. A bright yellow light was emitted when the original sample of Spanish phosphorite was exposed to **cathode rays,** and there was no diminution of the effect with time. A specimen deprived of thermo-luminescence by strongly heating regained this property with increased brilliancy by exposure to the cathode rays. W. Crookes noted an orange-yellow phosphorescence with a continuous spectrum when calcium phosphate was exposed to the cathode rays.

A. Lassieur said that calcium phosphate at 1300° is reduced by **hydrogen** to a mixture of calcium oxide and phosphorus; only traces of phosphine and calcium phosphide are formed. Possibly a basic phosphate is produced as an intermediate compound. When normal calcium phosphate is heated in a stream of **chlorine** there is very little action, but M. Cari-Mantrand[7] found that when mixed with carbon, it produces carbon monoxide and free phosphorus, or if the amount of carbon suffices only for the reduction of the lime, phosphorus pentoxide is formed; and J. Riban found that a mixture of carbon and normal calcium phosphate readily reacts with chlorine mixed with carbon monoxide : he said that the carbon suffers no perceptible change, and that the reaction takes place in two stages : $Ca_3(PO_4)_2+2CO+2Cl_2=Ca(PO_3)_2+2CO_2+2CaCl_2$, followed by $Ca(PO_3)_2+4CO+4Cl_2=2POCl_3+4CO_2+CaCl_2$; the reaction begins at 180°, and is rapidly completed between 330° and 340°. M. Cari-Mantrand also found that a mixture of carbon and calcium phosphate, at a bright red heat, reacts with **hydrogen chloride,** as with chlorine, forming carbon monoxide and free phosphorus. According to H. E. Quantin, when calcium phosphate is heated to redness in a stream of the vapour of **carbon tetrachloride,** phosphoryl chloride is first formed, and this is converted into phosphorus pentachloride. According to W. Crum, calcium phosphate is readily dissolved by **hydrochloric acid** and converted into dihydrophosphate, $Ca(H_2PO_4)_2$; 100 parts of the dil. acid dissolve 198 to 225 parts of normal calcium phosphate—the calculated amount is 218·3 parts. According to G. Bischof, 100 grms. of the acid of sp. gr. 1·153 (31 per cent. HCl), at 17°, dissolves, when diluted with w grms. of water :

w	0	1	4	7	10	13	16	19	grms.
$Ca_3(PO_4)_2$	25·3	45·0	62·3	64·7	68·0	71·9	69·5	69·7	„

According to J. Piccard, a mol of normal phosphate is completely dissolved by a soln. containing four mols of HCl, and if shaken with a soln. containing two mols of HCl, and filtered rapidly, half the phosphoric oxide is extracted, but if the mixture be allowed to stand, it slowly deposits crystals of calcium hydrophosphate, $CaHPO_4$, the reaction is fast if the mixture be heated: $CaH_4(PO_4)_2+Ca_3(PO_4)_2=4CaHPO_4$. E. Erlenmeyer also obtained crystals of what he regarded as a *chlorophosphate*—compounds of calcium phosphate and chloride—from the soln. According to K. Birnbaum and A. S. Packard, the soln. of calcium phosphate, in not a large excess of hydrochloric acid, becomes turbid when heated, owing to the separation of calcium hydrophosphate, $CaHPO_4$, and, according to J. Piccard, the same salt is obtained by adding alcohol or sodium acetate to the soln. A hydrochloric acid soln. of normal barium phosphate was found by E. Erlenmeyer to give crystals of barium chloride, and of barium dihydrophosphate, $Ba(H_2PO_4)_2$, or, when an excess of acid is used, phosphoric acid is formed. When the boiling soln. is evaporated, crystals of the chlorophosphate, $BaCl_2.4Ba(H_2PO_4)_2$, separate. Unlike barium and calcium orthophosphates, the hydrochloric acid soln. of strontium phosphate does not yield a chlorophosphate.

According to J. B. Senderens,[8] when calcium phosphate is boiled with water and **sulphur,** calcium thiosulphate is formed very slowly ; with barium phosphate, the decomposition is very slow and does not proceed further than barium hydrophosphate, $BaHPO_4$. According to A. Béchamp, if finely divided calcium phosphate, suspended in water, be treated with **hydrogen sulphide,** a liquid is obtained which reddens blue litmus, colours sodium nitroprusside bluish-violet, and contains 190 to 240 mgrms. of normal calcium phosphate per litre. The action of soln. of **sulphurous acid** on the calcium phosphates resembles that of other acids ; with conc. acid soln., calcium dihydrophosphate is the stable solid ; with less conc. soln., calcium hydrophosphate is the stable solid ; while in dil. soln. a more basic phosphate separates, which B. W. Gerland believes to be an addition product of normal calcium phosphate and sulphurous acid. B W. Gerland found that artificial and natural calcium phosphate, as well as bone ash, dissolves in sulphurous acid so that one mol P_2O_5 passes into soln. for 4 to 6 mols of SO_2. These soln. smell and taste a little less strongly of sulphur dioxide than do eq. aq. soln. of that gas. If the soln. be allowed to stand in air, or in vacuo, warmed over 18°, or mixed with alcohol, a precipitate of variable composition is produced ; a precipitate is formed if hydrogen or some other gas is passed into the soln. If the mixed soln. still contains a moderate proportion of sulphur dioxide, the precipitate is either calcium hydrophosphate or a mixture of that salt with calcium sulphate ; if very little sulphur dioxide be present, the precipitate approximates to *calcium sulphito-hydrophosphate*, $2CaHPO_4.CaSO_3.H_2O$, or $Ca_3(PO_4)_2.SO_2.2H_2O$. It is claimed that this substance is a chemical individual, and not a mixture of calcium hydrophosphate and sulphite, since it does not behave like a sulphite—*e.g.* it is stable in oxidizing agents like chlorine—but E. Rotondi believed it to be a mixture of the two salts in question. The soln. of calcium phosphate in sulphurous acid precipitates a mixture of normal calcium phosphate, calcium hydrophosphate, and calcium sulphate when treated with ammonia; the soln. also gives precipitates with barium chloride, magnesium chloride, ferric chloride, lead acetate, and cupric acetate. According to E. Rotondi, when normal barium phosphate is suspended in water, and treated with sulphur dioxide, barium sulphide is precipitated, and barium dihydrophosphate, $Ba(H_2PO_4)_2$, passes into soln.

Moderately conc. **sulphuric acid** was found by J. J. Berzelius to convert calcium phosphate into a mixture of phosphoric acid and calcium sulphate. The reaction between calcium phosphate and sulphuric acid has been studied by J. Kolb, A. Millot, R. Weber, J. Piccard, H. Joulie, W. Crum, H. P. Armsby, and E. Erlenmeyer. If one to two mols of sulphuric acid be used for a mol of normal calcium phosphate, and enough water to make the whole into "slip," A. Millot found that calcium dihydrophosphate and calcium sulphate are formed; and if less than one mol of sulphuric acid be used, half the calcium phosphate remains unchanged. H. P. Armsby found that the amount of soluble phosphate, $CaH_4(PO_4)_2$, which is formed by the sulphuric acid depends on the temp. and on the duration of the action; and he assumed that calcium dihydrophosphate is initially formed by the action of the acid, and that this then reacts with the unchanged calcium phosphate to form the monohydrophosphate, $Ca_3(PO_4)_2+CaH_4(PO_4)_2=4CaHPO_4$. A. Millot further showed that with two mols of sulphuric acid per mol of normal phosphate, 96·63 per cent. of soluble phosphate is formed. and with the equi-molar proportions of acid and normal phosphate, 48·72 per cent. of soluble phosphate is formed. A. Millot, and J. Piccard showed that on standing the proportion of soluble phosphate in the product decreases owing to the formation of the monohydrophosphate; while J. Kolb supposes that free phosphoric acid is formed by the action of two mols of sulphuric acid on one mol of calcium phosphate, which on standing forms the soluble dihydrophosphate, $Ca(H_2PO_4)_2$. A. Gossmann studied the action of **alkali sulphates** on barium phosphate.

Calcium dihydrophosphate is much more soluble than the other calcium phosphates; and a mixture of this salt with calcium sulphate is used as a fertilizer under various names: *superphosphate, acid phosphate,* and *soluble lime phosphate.*[9] It is prepared by treating rock or bone phosphate with sulphuric acid—generally chamber acid—approximately 60 per cent. H_2SO_4, and of sp. gr. 1·55. Rather less acid is employed than is needed to convert all the lime in excess of that required to form the dihydrophosphate, into calcium sulphate, because, if the theoretical amount of acid is used, the resulting product is of a pasty consistency, difficult to handle, and it is so acid as to be considered harmful to vegetation. The water and the acid forms hydrated calcium dihydrophosphate, $Ca(H_2PO_4)_2.H_2O$, and gypsum, $CaSO_4.2H_2O$. On standing exposed to the air some water is absorbed, and the undecomposed phosphate reacts with the dihydrophosphate to form the less soluble hydrophosphate. This process is known as *the reversion of the superphosphate;* and the process of reversion is accelerated by the presence of iron oxide and alumina, which form slightly soluble phosphates. When mixed with soil, the superphosphate rapidly and completely reverts; this is shown by the fact that the aq. extract of such a soil is no richer in phosphoric acid than that of an untreated soil.

The four component system, $CaO—H_3PO_4—H_2SO_4—H_2O$, has been partially studied by F. K. Cameron and J. M. Bell, and they represent their results by a series of diagrams resembling Fig. 64. *O* represents a sat. soln. of lime in water. On the *Ox*-axis, *A* represents a soln. in equilibrium with calcium hydrophosphate and the limiting solid soln.; and *B*, a soln. sat. with both calcium hydro-, and dihydro-phosphate. On the *Oy*-axis, *C* represents a soln. sat. with both calcium hydroxide and gypsum, and *D* a soln. in equilibrium with both gypsum and anhydrite. The fields over which the calcium phosphates can exist are very narrow. The data for 25° are shown in Table XIX.

TABLE XIX.—PHASES IN THE QUATERNARY SYSTEM, $CaO—P_2O_5—SO_3—H_2O$, AT 25°.

Fig. letter.	Grms. P_2O_5 per litre.	Grms. SO_3 per litre.	Grms. CaO per litre.	Soild phases.
O	0	0	1·17	$Ca(OH)_2$
A	3	0	1·5	Solid soln.; $CaHPO_4.2H_2O$
B	317	0	77	$Ca(H_2PO_4)_2.H_2O$; $CaHPO_4.2H_2O$
C	0	0·9	1·9	$Ca(OH)_2$; $CaSO_4.2H_2O$
D	0	317·5	1	$CaSO_4.2H_2O$; $CaSO_4$
E	3	0·9	1·5	Solid soln.; $CaSO_4.2H_2O$; $CaHPO_4.2H_2O$
F	317	0·6	77	$CaSO_4.2H_2O$; $CaHPO_4.2H_2O$ · $Ca(H_2PO_4)_2.H_2O$
G	545	0·2	38	$CaSO_4.2H_2O$; $CaSO_4$; $Ca(H_2PO_4)_2.H_2O$

The changes which occur by raising the temp. have been partially investigated. The point *F* moves to the right, *G* to the left. At 66° the two points meet, and there is a sextuple point where the six phases—soln., vapour, $CaSO_4$, $CaSO_4.2H_2O$, $CaHPO_4.2H_2O$, and $Ca(H_2PO_4)_2\ H_2O$—are in equilibrium. At higher temp. the gypsum field disappears, and anhydrite is the stable solid.

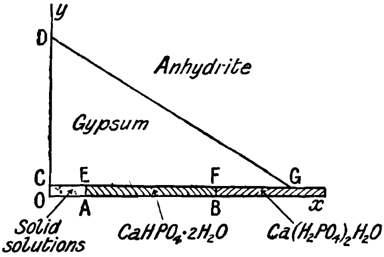

FIG. 64.—Phases of the Four Component System: $CaO—H_3PO_4—H_2SO_4—H_2O$.

F. K. Cameron and J. M. Bell thus described the leaching of a superphosphate, containing calcium dihydrophosphate and gypsum, by water at 25°. Stage I. The addition of water to monocalcium phosphate crystals causes a partial change to dicalcium phosphate and a soln. saturated with respect to both phosphates. A small amount of gypsum will also pass into the soln. Stage II. If water be added to this soln., or if the soln. be drained away and fresh water added, more of the monocalcium phosphate will disappear and dicalcium phosphate will be formed. The net effect of this leaching is to wash out some free phosphoric acid, together with considerable quantities of calcium and a very small quantity of gypsum. If the addition of water is rapid, the time for this change may be very short indeed. During this change the composition of the soln. is represented by the point *F* of Fig. 64, and if equilibrium conditions are obtained the composition of the soln. will remain constant until all the monocalcium phosphate disappears. It will be observed that the greater part of the original calcium phosphate has been removed. This may be partially represented by the equation: $CaH_4(PO)_2=CaHPO_4+H_3PO_4$, all the phosphoric acid in excess of the compound $CaHPO_4$ being leached away, together with a considerable amount of the diphosphate, which is dissolved. Upon the removal of some of the soln. and the dilution of the residue by fresh water, the composition of the leachings will change rapidly until the point *E* is reached. Stage III. Here another change takes place, the crystalline dicalcium phosphate giving up phosphoric acid, which carries some of the phosphate into soln. The solid changes to a solid soln. of lime and phosphoric acid, and upon continued leaching this solid soln. changes gradually to that solid soln. which in sat. gypsum soln. dissolves unchanged, *i.e.* the ratio of lime and phosphoric acid which have gone into soln. is the same as in the solid soln. Over this range of conc. gypsum has a much higher solubility, and it will probably disappear before the solid soln. have all disappeared. Stage IV consists in the slow soln. in water of a relatively insoluble solid soln. of lime in phosphoric acid, which contains relatively more lime than would be required by the formula $Ca_3(PO_4)_2$.

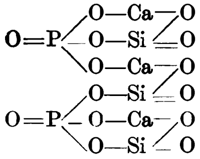
According to O. Nielsen,[10] the reduction of normal calcium phosphate by **carbon** begins at 1400°. According to P. Berthier, a mixture of calcium phosphate, silica, and carbon at a white heat forms calcium silicate, carbon monoxide, and phosphorus; and a mixture of ten parts of calcium phosphate with five of quartz and five of clay gives, when heated in a carbon crucible, three parts of phosphorus, and the quantity of the latter increases when the proportion of silica is increased. T. Schlösing found that when normal calcium phosphate is heated white-hot in a stream of **carbon monoxide,** the phosphorus is quantitatively liberated. According to O. Nielsen, normal calcium phosphate is not reducible by carbon monoxide, and A. Lassieur also said no reduction occurs at 1300°. When a mixture of water vapour and **carbon dioxide** is passed over heated calcium phosphate, C. Seybold and F. Heeder found that calcium hydrophosphate is first produced: $Ca_3(PO_4)_2+CO_2+H_2O=CaCO_3+2CaHPO_4$, and this in turn decomposes producing calcium tetrahydrophosphate: $2CaHPO_4+CO_2+H_2O=CaCO_3+CaH_4(PO_4)_2$. G. von Georgievics passed carbon dioxide into water holding normal calcium phosphate in suspension, and obtained calcium hydrophosphate and carbonate; the latter dissolves as calcium hydrocarbonate, and the soln. can then dissolve normal phosphate so that the ratio Ca : PO_4 in soln. lies between that required for $CaHPO_4$ and $Ca_3(PO_4)_2$. J. B. A. Dumas observed that Seltz-water, which contained considerable quantities of carbon dioxide in soln., etches ivory in a similar way to a dil. soln. of hydrochloric acid; J. L. Lassaigne also observed that at 10°, water sat. with carbon dioxide dissolves a small quantity of calcareous material from human bones; and J. von Liebig found that a litre of water, sat. with carbon dioxide, dissolved 0·6626 grm. of bone-phosphate, of which 0·500 grm. separated out on boiling. R. Maly and J. Donath, and J. Joffre made similar observations. R. Warington noted that the presence of carbon dioxide raised the solubility of calcium phosphate in water; and in view of the converse effect of calcium salts on the solubility, it might have been anticipated that carbonic acid would act in the same way. J. Davy observed that water sat. with carbon dioxide under press. dissolved more calcium phosphate than did water alone. According to J. Joffre, a litre of water dissolves 0·009 grm. of normal calcium phosphate under conditions where water sat. with carbon dioxide dissolves 0·153 grm.; and T. Schlösing found the solubility increases as the proportion of carbon dioxide increases. According to A. Rindell, an aq. soln. of carbon dioxide in contact with normal calcium phosphate contains:

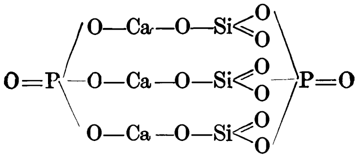
CO_2 . . .	1·95	3·91	7·81	15·63 millimol per litre
CaO . . .	0·11	0·10	0·17	0·44 grm. per litre
P_2O_5 . . .	3·32	2·90	1·77	3·30 grms. per litre

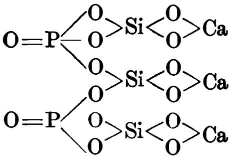
R. Warington has also discussed the increased solubility of bone-ash in aq. soln. of carbon dioxide; C. P. Williams made a similar observation on phosphorites; and L. Dusart and J. Pelouze found gelatinous calcium phosphate is more soluble in water carrying carbon dioxide than it is in water free from that gas. A precipitate was formed by boiling the soln. in carbonic acid. F. K. Cameron and A. Seidell found that carbonic acid soln. like aq. soln. dissolve less calcium phosphate when sat. with calcium carbonate than when free from the latter salt. Sat. soln. of calcium sulphate and carbon dioxide dissolve rather less calcium phosphate than if gypsum is absent. A. Barillé studied the effect of increased press. of carbon dioxide on the solubility of calcium phosphate, and found that calcium hydrophosphate and hydrocarbonate are formed, and that the latter decreased the solubility of the hydrophosphate. H. Ehlert and W. Hempel drew no general conclusions from their study of the solubility of calcium phosphate in aq. soln. of a number of salts in the absence and in the presence of carbon dioxide at 2 atm. press. With conc. soln. of the salt, and carbon dioxide at 2 atm. and 14°, the following numbers of grams per litre of normal calcium phosphate were dissolved :

NH_4Cl	$(NH_4)_2SO_4$	$MgCl_2.6H_2O$	$MgSO_4.7H_2O$	K_2SO_4	NaCl	$NaNO_3$	$Na_2SO_4.10H_2O$
1·293	5·885	2·892	3·6001	4·765	0·641	0·864	3·227

with $MgCl_2.KCl.6H_2O$, 1·154 ; with $MgSO_4.K_2SO_4.MgCl_2.6H_2O$, 2·491 ; and with water, 0·228. B. Foster and H. A. D. Neville studied the solubility of the phosphate in sat. soln. of carbon dioxide containing ammonia, and found with increasing proportion of ammonia, the quantity of phosphate passing into soln. increased at first rapidly, and then more slowly , the solubility of the phosphate being then almost directly proportional to the amount of ammonia present. According to W. Windisch and W. Dietrich, if soln. of primary **potassium phosphate** are boiled with increasing proportions of calcium hydrocarbonate, the resulting precipitates show increasing percentages of calcium corresponding to a transition from secondary to tertiary calcium phosphate, and the increase in alkalinity of the filtrate (due to formation of secondary potassium phosphate) becomes less rapid as the proportion of hydrocarbonate is increased. The alkalinities of the filtrates are lower than the calculated values, the differences being ascribed to entrainment of soluble alkaline compounds with the precipitates. An aq. soln. of carbon dioxide was found by R. Warington, and L. Dusart and J. Pelouze, to dissolve normal calcium phosphate, and the soln., on standing, slowly deposits calcium hydrophosphate and carbonate. According to O. Nielsen, when a mixture of normal calcium phosphate and **silica** is heated in a neutral atm., no phosphorus pentoxide is liberated ; silica begins to react chemically with normal calcium phosphate at about 1150°. There is a well-defined maximum at 1630°, in the m.p. curve of SiO_2—$Ca_3(PO_4)_2$ mixtures for $Ca_3(PO_4)_2.3SiO_2$, or **calcium trisilico-phosphate,** $Ca_3Si_3P_2O_{14}$. The fusion curve is shown in Fig. 65. This compound is readily reduced by carbon and, according to R. Müller, the evolution of phosphorus begins at about 1150°. O. Nielsen suggests these possible formulæ for the silicophosphate :







and he prefers the third since it harmonizes with the easy reducibility of the compound, and its decomposition into $CaSiO_3$, etc.

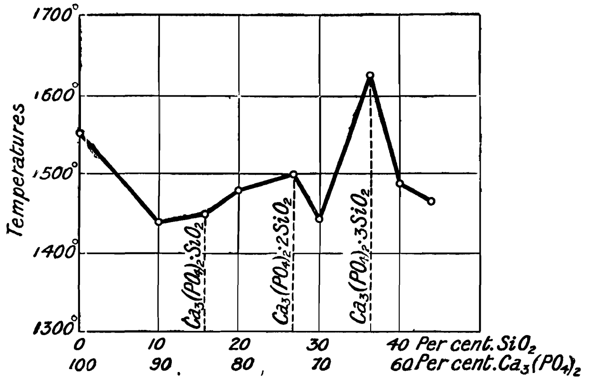


Fig. 65.—Fusion Temperatures of Mixtures of Silica and Normal Calcium Phosphate.

The fusion curve of mixtures of calcium oxyorthophosphate, $Ca_3(PO_4)_2.CaO$, and calcium orthosilicate, Ca_2SiO_4, has been explored by H. Blome. There are two maxima corresponding with the two **calcium silicophosphates,** $4CaO.P_2O_5+2CaO.SiO_2$ and $4CaO.P_2O_5+4(CaO.SiO_2)$. The solubility curve of the mixtures in a soln. of conclusions from their study of the solubility of calcium phosphate in aq. soln. of a number of salts in the absence and in the presence of carbon dioxide at 2 atm. press. With conc. soln. of the salt, and carbon dioxide at 2 atm. and 14°, the following numbers of grams per litre of normal calcium phosphate were dissolved :

NH_4Cl	$(NH_4)_2SO_4$	$MgCl_2.6H_2O$	$MgSO_4.7H_2O$	K_2SO_4	NaCl	$NaNO_3$	$Na_2SO_4.10H_2O$
1·293	5·885	2·892	3·6001	4·765	0·641	0·864	3·227

with $MgCl_2.KCl.6H_2O$, 1·154 ; with $MgSO_4.K_2SO_4.MgCl_2.6H_2O$, 2·491 ; and with water, 0·228. B. Foster and H. A. D. Neville studied the solubility of the phosphate in sat. soln. of carbon dioxide containing ammonia, and found with increasing proportion of ammonia, the quantity of phosphate passing into soln. increased at first rapidly, and then more slowly ; the solubility of the phosphate being then almost directly proportional to the amount of ammonia present. According to W. Windisch and W. Dietrich, if soln. of primary **potassium phosphate** are boiled with increasing proportions of calcium hydrocarbonate, the resulting precipitates show increasing percentages of calcium corresponding to a transition from secondary to tertiary calcium phosphate, and the increase in alkalinity of the filtrate (due to formation of secondary potassium phosphate) becomes less rapid as the proportion of hydrocarbonate is increased. The alkalinities of the filtrates are lower than the calculated values, the differences being ascribed to entrainment of soluble alkaline compounds with the precipitates. An aq. soln. of carbon dioxide was found by R. Warington, and L. Dusart and J. Pelouze, to dissolve normal calcium phosphate, and the soln., on standing, slowly deposits calcium hydrophosphate and carbonate. According to O. Nielsen, when a mixture of normal calcium phosphate and **silica** is heated in a neutral atm., no phosphorus pentoxide is liberated ; silica begins to react chemically with normal calcium phosphate at about 1150°. There is a well-defined maximum at 1630°, in the m.p. curve of SiO_2—$Ca_3(PO_4)_2$ mixtures for $Ca_3(PO_4)_2.3SiO_2$, or **calcium trisilico-phosphate,** $Ca_3Si_3P_2O_{14}$. The fusion curve is shown in Fig. 65. This compound is readily reduced by carbon and, according to R. Müller, the evolution of phosphorus begins at about 1150°. O. Nielsen suggests these possible formulæ for the silicophosphate :

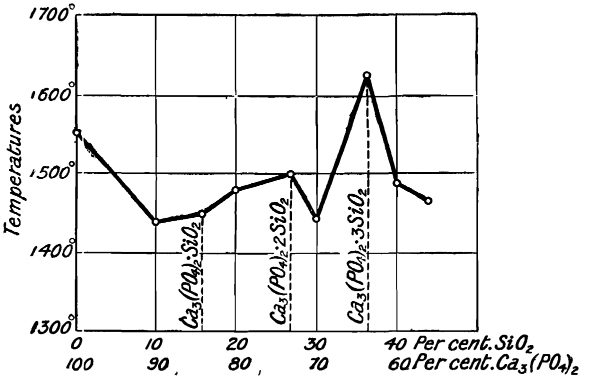

FIG. 65.—Fusion Temperatures of Mixtures of Silica and Normal Calcium Phosphate.

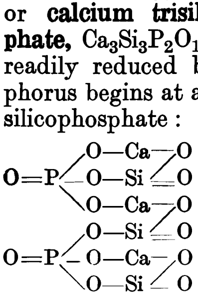

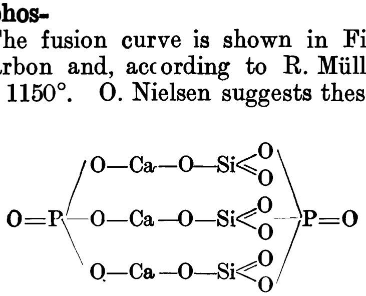

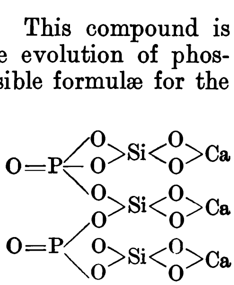

and he prefers the third since it harmonizes with the easy reducibility of the compound, and its decomposition into $CaSiO_3$, etc.

The fusion curve of mixtures of calcium oxyorthophosphate, $Ca_3(PO_4)_2.CaO$, and calcium orthosilicate, Ca_2SiO_4, has been explored by H. Blome. There are two maxima corresponding with the two **calcium silicophosphates,** $4CaO.P_2O_5+2CaO.SiO_2$ and $4CaO.P_2O_5+4(CaO.SiO_2)$. The solubility curve of the mixtures in a soln. of citric acid also shows two corresponding maxima. The cake obtained by slowly cooling the former product; the cooling mass appears to decompose into free lime, and the solubility in citric acid is augmented. The slower the cooling between 1800° and 1400°, the more marked these changes, while slow cooling below 1400° seems to have no influence on the result. Slow cooling is thus said to favour the formation of a form of calcium silicophosphate soluble in a soln. of citric acid. If the mixture $4CaO.P_2O_5+CaO.SiO_2$ be slowly cooled, the product is completely soluble in citric acid, but contains no free lime. The silicophosphate soluble in citric acid may be the same in both cases. According to T. Dieckmann and E. Houdremont, the silicophosphate $5CaO.P_2O_5.SiO_2$, has a sp. gr. 3·01; it melts at 1760°; and it has a percentage solubility of 96·2 in citric acid—*vide infra*, calcium oxyphosphates.

According to P. Berthier, bone-ash readily dissolves in fused **sodium carbonate,** forming when cold a marble-like mass; at a white-heat, some carbon dioxide is given off; F. Wöhler found that calcium phosphate is decomposed by fusion with sodium carbonate, but the double decomposition is not complete if four times the amount of alkali carbonate be present. Calcium phosphate was found by H. Rose to be partially decomposed by repeatedly boiling it with an aq. soln. of sodium carbonate, and he suggested that a compound of calcium carbonate, and normal phosphate is formed. F. J. Malaguti showed that the reaction, $Ca_3(PO_4)_2+3Na_2CO_3 \rightleftharpoons 3CaCO_3+2Na_3PO_4$, is reversible. R. Fresenius, C. Neubauer, and E. Luck found that calcium phosphate is incompletely decomposed by a boiling soln. of **sodium hydrocarbonate.** J. Pinnow found that the reaction between calcium hydrophosphate or between calcium carbonate and sodium hydrophosphate furnishes normal sodium phosphate if a sufficient excess of base is present, and the carbon dioxide is removed by water vapour, $6CaHPO_4+3Na_2CO_3=2Ca_3(PO_4)_2+2Na_3PO_4+3CO_2+3H_2O$. The action has also been studied by F. Bolm, L. Grünhut, and L. Wolfrum. The reaction $3CaHPO_4+2NaHCO_3=Ca_3(PO_4)_2+Na_2HPO_4+2CO_2+2H_2O$ is accompanied by a number of side reactions. J. von Liebig, and R. Fresenius, C. Neubauer, and E. Luck found that calcium phosphate is transformed into oxalate by boiling it with a soln. of **ammonium oxalate.**

W. Crum has measured the solubility of calcium phosphate in various **organic acids**—acetic acid, malic acid, lactic acid, and tartaric acid—and A. Rindell, the solubility in acetic and citric acids. G. Paturel found that acetic acid has a relatively greater solvent action than citric acid. J. Langel, and E. Erlenmeyer investigated the solvent action of ammonium citrate on the calcium phosphates; the latter worked with (*a*) a soln. of **diammonium citrate** of sp. gr. 1·09; (*b*) a soln. of **triammonium citrate** of sp. gr. 1·09; and (*c*) a one-fourth per cent. soln. of **citric acid.** One to two per cent. of the phosphate was added to soln. (*a*) and (*b*), and 0·25 per cent. to soln. (*c*). The temp. kept between 35° and 38°. His results are indicated in Table XX. A. Terreil found that every 100 grms. of citric acid neutralized with ammonia dissolved 7·01 grms. of the phosphate, and when neutralized with potash, 1·90 grms., and he concluded that a soln. of ammonium citrate has a greater solvent action on basic calcium phosphate than have soln. of **potassium citrate** or **sodium citrate.** R. Fresenius, C. Neubauer, and E. Luck also noted the marked solvent action of ammonium citrate. E. Kröber studied the effect of bacteria on the solubility of "insoluble" phosphates.

TABLE XX.—SOLVENT ACTION OF VARIOUS CITRATE SOLUTIONS ON NORMAL CALCIUM PHOSPHATE.

	Per cent. of the original P_2O_5 dissolved.		
	(*a*)-soln.	(*b*)-soln.	(*c*)-soln.
Air-dried $Ca_3(PO_4)_2+11H_2O$	100	55·46	83·84
Dried at 50°, $8Ca_3(PO_4)_2+15H_2O$	100	52·30	—
Ignited $Ca_3(PO_4)_2$	93·23	31·92	53·36

G. Bischof[11] said that nitric and hydrochloric acid behave similarly. He found 100 grms. of nitric acid of sp. gr. 1·230, at about 17°, dissolves, when diluted with *w* grms. of water :

w . .	0	0·827	3·309	8·273	10	13	15·718	40 grms.
$Ca_3(PO_4)_2$.	36·785	43·226	43·050	45·589	52·831	52·857	46·368	43·078 grms.

W. Crum found that **nitric acid** readily dissolves calcium phosphate transforming it into calcium tetrahydrophosphate. According to E. Duvillier, normal barium phosphate is converted by nitric acid completely into orthophosphoric acid and barium nitrate, only when the acid is sufficiently conc. to make the barium nitrate insoluble, and J. F. Persoz found that glacial acetic acid precipitates this salt from the soln. of calcium phosphate in nitric acid. H. E. Causse has studied the solubility of calcium phosphate in **phosphoric acid** of different conc.; the soln. when evaporated spontaneously deposits crystals of calcium dihydrophosphate—*vide infra.* H. Bassett found :

Temp.	Grms. per 100 grms. sat. soln.		Solid phase.
	CaO.	P_2O_5.	
100°	2·503	53·71	$Ca(H_2PO_4)_2$; $Ca(H_2PO_4)_2.H_2O$
115°	5·623	43·60	$Ca(H_2PO_4)_2.H_2O$; $CaHPO_4$
132°	4·327	53·43	$Ca(H_2PO_4)_2$; $Ca(H_2PO_4)_2.H_2O$
169°	4·489	63·95	$Ca(H_2PO_4)_2$

J. A. Völcker[12] found that a litre of cold water dissolves 31 mgrm. of calcined, and 79 mgrm. of precipitated calcium phosphate in seven days ; and the aq. soln. does not give a precipitate when treated with ammonia, but it is rendered turbid by ammonium oxalate, or by silver, uranium, and ferric salts, or, according to R. Phillips, by lead salts. According to R. L. Maly and J. Donath, 100 parts of water dissolve 0·00236 part of gelatinous normal calcium phosphate, or 0·00256 part of the ignited phosphates, or 0·003 part of bone powder. The reports by different authorities of the so-called solubility of calcium phosphate in water are conflicting. The soln. has an acid reaction, and the solid residue contains more base than before contact with water. Indeed, F. K. Cameron and L. A. Hurst[13] have shown that if normal calcium phosphate, or calcium hydro- or dihydro-phosphate be placed in water, some phosphoric acid passes into soln. and calcium hydroxide separates to form, maybe, a more basic and less soluble phosphate, or a mixture whose solubility is decreased by its presence. While the phosphoric acid in soln. tends to increase the solubility of the phosphate, the base, even though in soln. in correspondingly smaller amounts, exerts a greater effect in decreasing the solubility. Therefore, the addition of increasing amounts of water produces a relatively smaller, though in actual amount a larger soln. and decomposition of the salt. It is not therefore strictly correct to speak of the soln. of calcium phosphate in water ; rather is it a soln. of the products of the hydrolysis of the phosphate which itself is present, if at all, only in small quantities. The relative masses of the solid phosphate and solvent have a marked effect on the amount of hydrolysis ; the temp. also has a marked influence ; the size of the particles of the solid phosphate affects the result in that the smaller the particles the more rapid or complete the dissolution ; adsorption phenomena occur ; and the reactions between water and the solid phosphate are rather slow, so that in much of the recorded work, there is nothing to show that the final equilibrium conditions had been attained. Strictly normal calcium phosphate has not been prepared in the wet way. F. K. Cameron and A. Seidell found that with two samples of calcium phosphate one, A, containing a 0·14 per cent. excess of lime, and the other, B, 2·83 per cent. excess of acid, and using 5, 10, 20, and

40 grms. of the phosphate per litre, the amounts of PO_4 dissolved (grams per litre) were, at 25° :

Grms. phosphate per litre . .	5	10	20	40
A grms. PO_4 per litre . . .	0·068	0·113	0·185	0·310
B grms. PO_4 per litre . . .	0·109	0·189	0·324	0·558

thus showing that the source and mode of preparation of the calcium phosphate have an important influence, and that the absolute values of the results have very little value as physical constants. The system in equilibrium is somewhat complex, because, under certain conditions of conc. and temp., many definite mol. species—mono-, di-, or tri-calcium phosphates or hydrates—may be formed as solid phases in contact with the soln. as illustrated in Figs. 63 and 64. R. Warington showed that normal calcium phosphate containing slightly more calcium oxide than is required by the formula is decomposed by boiling in water for two hours to such an extent that the soln. contained about three times as much phosphoric acid as calcium oxide. Cold water also decomposes the phosphate to a lesser degree. The amount of phosphoric acid which water would extract was found to depend on the relative masses of the phosphate and water which are brought into contact. The solid residue remaining after many extractions was found by R. Warington, and J. H. Aeby to approximate $3Ca_3(PO_4)_2.Ca(OH)_2$, although F. Wibel held that the composition of the residue is not constant.

According to J. L. Lassaigne,[14] the solubility of calcium phosphate in water is much favoured by the presence of the salts of the alkali metals. T. Thomson, for example, found this to be the case with *sodium chloride.* J. von Liebig, J. L. Lassaigne, R. Maly and J. Donath, A. Rindell, H. Ehlert and W. Hempel, and L. Mandl made similar observations with sodium chloride soln. F. K. Cameron and L. A. Hurst found that *potassium chloride* exerts a decomposing as well as a solvent action on calcium phosphate, and with an increasing conc. of the soln. with respect to potassium chloride, the calcium phosphate yields a decreasing amount of phosphoric acid and an increasing amount of base. A. Corcelle studied the action of *alkali sulphates* on normal barium phosphate. H. Ehlert and W. Hempel also studied the effect of soln. of *potassium sulphate, sodium sulphate, magnesium chloride, magnesium sulphate,* and the double salts $MgCl_2.KCl.6H_2O$, and $MgSO_4.K_2SO_4.MgCl_2.6H_2O$. J. von Liebig, H. Ehlert and W. Hempel, and F. K. Cameron and L. A. Hurst obtained similar results with *sodium nitrate.* The latter noted that the soln. of sodium nitrate also exerts a decomposing action on the phosphate. F. Wöhler, H. Ehlert and W. Hempel, and R. Warington found *ammonium chloride* has a marked influence in raising the solubility; similar results were observed by G. C. Wittstein and A. Rindell with *ammonium nitrate,* by J. von Liebig and H. Ehlert and W. Hempel, with *ammonium sulphate,* by B. Foster and H. A. D. Neville in *ammonium carbonate;* and by G. C. Wittstein with *ammonium succinate.* G. de Morveau, L. Hünefeld, and G. C. Wittstein have also studied the solubility of calcium phosphate in ammonium salts. G. Magnanini found a litre of 0·005*N*-*potassium bitartrate,* when sat. with calcium phosphate, contained 0·08 grm. Ca, and 0·181 grm. H_3PO_4 at 25°. According to H. Grandeau, when normal strontium phosphate is melted with an *alkali sulphate* it forms a double phosphate which is never free from strontia. Similarly also with normal barium phosphate. When barium phosphate is shaken with a cold aq. soln. of an equal wt. of potassium sulphate, W. L. Kölreuter found it is converted into barium sulphate, and the same result is obtained if twice the weight of Glauber's salt be used. C. Scheibler also found that freshly precipitated normal barium phosphate is converted into barium sulphate by a soln. of *calcium sulphate* in phosphoric acid.

The marked solvent action of ammonium salts on calcium phosphates has been also noted by J. B. A. Dumas, R. Warington, R. Maly and J. Donath, etc. A. Terreil found that when 100 grms. of the acid were neutralized with ammonia, the following amounts in grams of normal calcium phosphate were dissolved :

Ammonium.	Chloride.	Nitrate.	Sulphate.	Acetate.	Tartrate.	Citrate.	Malate.
Grms. $Ca_3(PO_4)_2$.	0·655	0·309	1·050	0·255	4·56	6·01	1·12

L. N. Vauquelin, F. Wöhler, and A. A. Hayes observed the effect with *starch*, *glue*, and other *organic substances* ; H. Minssen and B. Tacke with *humic acid ;* and M. Mercadante with a soln. of *albumen ;* L. Mandl with soln. of *gelatine*, *sugar*, or albumen ; and A. Bobierre showed that calcium phosphate found in the residues of sugar refineries, is held in soln. by *calcium sucrate*. J. J. Berzelius obtained what was probably an adsorption product with *barium nitrate* by the precipitation of barium phosphate from soln. of barium nitrate. F. K. Cameron and A. Seidell found that the presence of *calcium sulphate* slightly increases the amount of phosphoric acid dissolved from normal calcium phosphate—H. P. Armsby found a decrease. R. Warington, A. Terreil, and F. K. Cameron and A. Seidell found that the presence of *calcium carbonate* decreases the amount of phosphoric acid dissolved. F. K. Cameron and L. A. Hurst have measured the effects of soln. of *calcium chloride*, of calcium chloride and hydrochloric acid, and of *calcium nitrate*, from which it appears that an increased conc. with respect to the lime salt decreases the amount of phosphoric acid entering into the soln. They ascribe this effect to " the formation of a common ion from both substances, and a forcing back of the solubility of calcium phosphate in consequence of a lessening of the amount of phosphoric acid entering the soln."

H. Grandeau [15] heated barium pyrophosphate with a large excess of potassium sulphate to 800°–1000°, and obtained a mixture of barium sulphate and potassium phosphate ; but between 1400° and 1500°, a double salt, mixed with barium sulphate, is produced. H. Rose prepared **barium potassium phosphate,** $BaKPO_4$, by heating a mixture of potassium carbonate and barium pyrophosphate ; the product decomposed when leached with hot water. L. V. R. Ouvrard obtained transparent crystals of this salt by melting together mol. proportions of barium oxide and potassium phosphate, and extracting the slowly cooled mass with water. A. de Schulten obtained **decahydrated barium potassium phosphate,** $BaKPO_4.10H_2O$, by mixing boiling dil. soln. of potassium phosphate and barium hydroxide in an excess of a soln. of potassium silicate ; and obtained on cooling cubic crystals without action on polarized light, and which effloresced in air. H. Grandeau, H. Rose, and L. V. R. Ouvrard prepared **potassium strontium phosphate,** $KSrPO_4$, and **potassium calcium phosphate,** $KCaPO_4$, in a similar manner.

L. B. G. de Morveau obtained a clear glass by melting barium oxide with twice its weight of sodium hydrophosphate ; and J. J. Berzelius noted the solubility of barium oxide in fused sodium ammonium hydrophosphate. M. Berthelot studied the reactions between barium and sodium hydroxides and phosphoric acid, and between barium chloride, alkali phosphate, and phosphoric acid. A. Quartaroli found that on saturating a mol of phosphoric acid with an eq. of calcium or barium oxide, and two eq. of sodium (or potassium) hydroxide, contrary to the statement of M. Berthelot, precipitation of two-thirds of the phosphoric acid with the formation of $Ca_3Na_6(PO_4)_4$, or of $Ba_3Na_6(PO_4)_4$ does not occur, for scarcely one-third of the phosphoric acid is precipitated in the form of tri- and tetra-basic phosphates. Two-thirds of the phosphoric acid remains in soln. as tri- and di-basic phosphates. Hence, bases added in eq. quantities to phosphoric acid distribute themselves unequally between the soln. and the precipitate, and, as the latter is partly composed of tetrabasic phosphates, the soln. must contain a certain amount of dibasic phosphates. An exception to this is met with when a soln. of phosphoric acid containing one eq. of baryta and two eq. of sodium hydroxide is left for a long time ; one atom of sodium and one of barium (less than was calculated by M. Berthelot) then pass into the insoluble condition and precipitate a little less than half of the phosphoric acid. Nor when one mol. of phosphoric acid is sat. with one eq. each of lime (or baryta) and sodium (or potassium) hydroxide is it found that two-thirds of the phosphoric acid is precipitated with formation of insoluble double phosphates containing eq. quantities of calcium and sodium. In this case, too, the bases are unequally distributed between the precipitate and the soln., the latter containing mono- and dibasic phosphates and the former di- and tri-basic, and in some cases tetra-basic phosphates.

H. Rose obtained a **barium sodium phosphate,** $BaNaPO_4$, by a process analogous to that which he employed for the corresponding potassium compound, and found it behaved similarly towards water. According to A. Villiers, a mixture of soln. of barium chloride and sodium hydrophosphate is acid towards phenolphthalein; if the soln. be made alkaline by the addition of baryta-water, it again becomes acid in about an hour. Baryta-water is added until the soln. remains alkaline after standing some time. The precipitate is well washed and dried at 120°–130°. The composition of the granular mass corresponds with $NaBaPO_4$. Cold water has no action, hot water extracts soda. A. de Schulten made **decahydrated barium sodium phosphate,** $BaNaPO_4.(9 \text{ or})10H_2O$, by a process analogous to that used for the corresponding potassium compound; the crystals are tetrahedral; they effloresce in air; and, according to A. Joly, they have a heat of formation of 50·8 Cals. L. V. R. Ouvrard made **sodium strontium phosphate,** $NaSrPO_4$, by dissolving strontium oxide, phosphate, or sulphate in molten sodium ortho-, pyro-, or meta-phosphate. It was also made by H. Rose by the method employed for the potassium salt. **Octodecahydrated sodium strontium phosphate,** $NaSrPO_4.18H_2O$, was made by A. Joly by mixing dil. soln. of one eq. of sodium hydrophosphate with two of strontium chloride ; the gelatinous precipitate soon becomes crystalline. Sodium hydroxide is then added to the mother liquid until it remains permanently neutral towards phenolphthalein. A gelatinous precipitate is formed which likewise soon becomes crystalline. H. Rose made **sodium calcium phosphate,** $NaCaPO_4$, by the method employed for the potassium salt. A. Ditte made it by fusing a gram of normal calcium phosphate with 50 grms. of sodium or potassium chloride, and adding more than 11 per cent. of sodium phosphate to the fused mass. The cold product was extracted with water. L. V. R. Ouvrard slowly cooled a sat. soln. of calcium oxide, chloride, fluoride, or sulphate in fused sodium pyro- or ortho-phosphate, and extracted the mass with water. The presence of sodium chloride favours the crystallization If an excess of halide be employed apatite or wagnerite is formed. The crystals have a sp. gr. 2·9 at 20° ; and they are soluble in dil. acid. When the fused phosphate was not sat. with calcium oxide, L. V. R. Ouvrard obtained monoclinic needles of the composition $3Na_2O.3CaO.2P_2O$, of sp. gr. 2·1 at 20°, and soluble in dil. acid. H. Rose prepared **lithium calcium phosphate,** $LiCaPO_4$, by heating equi-mol. parts of calcium pyrophosphate and lithium carbonate and washing the cold mass with hot water.

H. Lasne dissolved 10 grms. of calcium carbonate in dil. hydrochloric acid, and then added a gram of calcium oxide, and 15 grms. of citric acid in order to keep the calcium phosphate in soln., which was then made feebly ammoniacal. In about 24 hrs., a conc. soln. of ammonium phosphate was added, and the soln. allowed to crystallize at not too high a temp. The crystals of **ammonium calcium phosphate,** $(NH_4)CaPO_4.7H_2O$, were washed with aq. ammonia. According to A. de Schulten, the monoclinic crystals have the axial ratios $a : b : c = 0·5256 : 1 : 0·5932$, and $\beta = 91° 26'$. The sp. gr. is 1·561 at 15°. The salt loses ammonia and water when exposed to the air, and, according to H. Lasne, it loses 6·28 per cent. in weight when kept for six weeks in a closed vessel. At 100°, all the water is evolved. The salt is incompletely decomposed by cold water, in 45 mins., and completely by hot water, forming normal calcium and ammonium phosphates. J. W. Davis also studied this salt. A. H. Church's analysis of the mineral *tirolite* corresponds with the formula, $2Ca_3(PO_4)_2.2Cu(OH)_2.CaCO_3.2H_2O$, and it is probably a mixture.

§ 26. Hydrophosphates of the Alkaline Earths

The more important calcium phosphates reported in beds of guano are *monetite*, $HCaPO_4$; *brushite*, $HCaPO_4.2H_2O$; *metabrushite*, $HCaPO_4.1\frac{1}{2}H_2O$; *stoffertite*, $CaHPO_4.4\frac{3}{4}H_2O$, of C. Klein [1]; *martinite*, $2H_2Ca_5(PO_4)_4.H_2O$; *collophanite*, $Ca_3(PO_4)_2.H_2O$. There are thus several hydrated and one anhydrous calcium hydrophosphate. The mineral monetite studied by C. U. Shepard, and A. de Schulten has the composition $CaHPO_4$. It was found at Moneta, West Indies. J. von Liebig reported the occurrence of concretions of calcium hydrophosphate in the guano of Jarvis Island; A. H. Hassall found it as pathological concretions in animal bodies; D. Ples, F. A. Abel, and F. Wöhler reported crystals in the wood of the teak (*tectonia grandis*); and F. Wöhler and A. E. Mermet and B. Delachanal in the urinary canal of the sturgeon.

J. J. Berzelius [2] obtained **calcium hydrophosphate,** $CaHPO_4$, also called *dicalcium phosphate*, contaminated with normal calcium phosphate by dropping a soln. of disodium hydrophosphate into an excess of a soln. of calcium chloride; on the other hand, if a soln. of calcium chloride be dropped into one of disodium hydrophosphate, calcium hydrophosphate is first formed, which in the presence of an excess of disodium hydrophosphate, decomposes into $Ca_4H(PO_4)_3$ and phosphoric acid, which latter, according to J. J. Berzelius and C. L. Berthollet, reforms some disodium hydrophosphate. Hence, said R. Warington, the liquid is first alkaline, then neutral, and finally acid, and only in the last case is calcium hydrophosphate obtained. G. E. Davis found that ammonium sodium hydrophosphate behaves like disodium hydrophosphate.

In W. Palmaer and J. Wiborgh's process, a soln. of sodium perchlorate is electrolyzed, $NaClO_4+H_2O=NaOH+HClO_4$, and the resulting perchloric acid is allowed to act on rock phosphate: $6HClO_4+Ca_3(PO_4)_2=2H_3PO_4+3Ca(ClO_4)_2$, and the filtered soln. is treated with the sodium hydroxide obtained at the cathode: $2H_3PO_4+4NaOH+3Ca(ClO_4)_2=2CaHPO_4+4NaClO_4+Ca(ClO_4)_2+4H_2O$. The resulting sodium perchlorate soln. is regenerated: $4NaClO_4+Ca(ClO_4)_2+Na_2CO_3=6NaClO_4+CaCO_3$. It is claimed that low-grade natural phosphates can be utilized by this process.

W. Skey made **strontium hydrophosphate,** $SrHPO_4$, by precipitation from a soln. of strontium chloride by sodium hydrophosphate, and, according to L. Barthe, the precipitate is free from other phosphates if a soln. of 70 grms. of crystalline strontium chloride be poured into a soln. of 100 grms. of crystalline sodium hydrophosphate—both soln. should be feebly acid, and the temp. not over 50°. A. de Schulten employed a modification of this process. J. J. Berzelius prepared **barium hydrophosphate,** $BaHPO_4$, by precipitation from a soln. of barium chloride by sodium or ammonium hydrophosphate. W. Skey, and A. de Schulten employed modifications of this process. R. Ludwig noted that if an excess of ammonium hydrophosphate is employed, the precipitate contains rather more barium oxide than corresponds with the formula $BaHPO_4$. E. Erlenmeyer obtained crystals of the barium salts by boiling a soln. of the normal phosphate in aq. phosphoric acid. According to J. H. Debray, and E. Erlenmeyer, the anhydrous salt is generally obtained by boiling calcium tetrahydro-diphosphate with water or alcohol. J. Piccard obtained calcium hydrophosphate by adding alcohol to a soln. of bone-ash in hydrochloric acid; H. E. Causse by adding ammonia to a soln. of calcium phosphate mixed with alkali acetate; R. E. Ghislain, by neutralizing with milk of lime a soln. of a natural phosphate in hydrochloric acid; B. W. Gerland, by adding alcohol to a soln. of calcium phosphate in sulphurous acid; and W. Baer, by adding calcium chloride to a soln. of disodium hydrophosphate in conc. acetic acid. According to A. Millot, boiling soln. of calcium chloride, disodium hydrophosphate and acetic acid furnish a mixture of calcium hydrophosphate with normal phosphate.

According to A. Barillé, if a soln. of calcium dihydrophosphate be treated with ammonia, half the phosphoric acid is precipitated as calcium hydrophosphate, and half remain in soln. as ammonium phosphate. If this soln. be treated with calcium chloride, the remainder of the phosphoric acid can be precipitated as calcium hydrophosphate, and ammonium chloride remains in soln. The latter reaction probably occurs in a number of stages—ammonium chloride and calcium hydrophosphate and dihydrophosphate are first formed; the latter then splits into normal calcium phosphate and phosphoric acid; and the two then react, forming calcium hydrophosphate. A. Barillé gradually added 1·454 kgrms. of hydrochloric acid, sp. gr. 1·17, to a kgrm. of bone-ash suspended in hot water. The soln. was mixed with three litres of hot water, and dil. to 10 litres. The filtrate was then slowly mixed with 442 grms. of ammonia, sp. gr. 0·925, diluted 1 : 20. The feebly acid liquid was filtered off, and the washed precipitate dried at 60°. A. Barillé thought that this product was $CaHPO_4.4H_2O$, but it was probably colloidal.

H. Vohl obtained crystals of calcium hydrophosphate by the slow diffusion of calcium chloride and disodium hydrophosphate through a diaphragm; or, according to A. Drevermann, through a layer of water. A. C. Becquerel obtained the crystals by the action of a soln. of disodium hydrophosphate on calcspar. A. de Schulten prepared crystals of the anhydrous salt—*monetite*—by heating the hydrated salt or brushite with water in a tube at 150°. The crystals are also obtained by dissolving the amorphous precipitate in a weak acid, and allowing the soln. to stand, or to be heated—*e.g.* C. Boedeker dissolved half the precipitate in the calculated quantity of cold hydrochloric or nitric acid, and added thereto the other half of the precipitate. Crystals were deposited when the mixture was allowed to stand 48 hrs. G. Vorbringer saturated a hydrochloric acid soln. of bone-ash with ammonia, dissolved the precipitate in acetic acid, and warmed the soln. to precipitate ferric phosphate. When the filtrate was conc. by slow evaporation, crystals of the desired salt were obtained. J. Percy dissolved freshly precipitated calcium hydrophosphate suspended in water sat. with carbon dioxide, and obtained crystals of the acid phosphate by spontaneous evaporation. R. Warington, E. Reichardt, and L. Dusart and J. Pelouze employed an analogous process.

A. de Schulten prepared crystals of **dihydrated calcium hydrophosphate,** $CaHPO_4.2H_2O$, or *brushite,* by the action of calcium carbonate on phosphoric acid of sp. gr. 1·05. T. Chandelon prepared dihydrated calcium hydrophosphate, entirely soluble in ammonium citrate, by treating raw calcium phosphate with 15 to 25 per cent. sulphuric acid; the resulting soln., containing 7 to 12 per cent. P_2O_5, was cooled, and neutralized with cooled lime-water. The salt separated on cooling the soln. to 0°. The precipitates of calcium hydrophosphate obtained by treating hydrochloric acid soln. of calcium phosphate with ammonia have a variable proportion of water, and, according to H. Bassett, the precipitates are variable mixtures of the dihydrate with the anhydrous salt. The degree of hydration of the precipitate depends on the temp. and on the acidity of the soln. According to H. Bassett's vap. press. measurements *sesquihydrated calcium hydrophosphate,* $CaHPO_4.1\frac{1}{2}H_2O$, does not exist as a chemical individual, and *metabrushite* is a mixture of the dihydrated and anhydrous salts. The colloidal precipitate contains variable proportions of water, and in the older literature many hydrates have been reported which probably represent different stages in the dehydration of the colloidal hydrophosphate:

G. Vorbringer precipitated what he regarded as $CaHPO_4.\frac{1}{6}H_2O$ from boiling soln. of calcium phosphate in phosphoric acid; when dried over conc. sulphuric acid, K. Birnbaum found the product was free from water. B. W. Gerland obtained a product with the composition $CaHPO_4.\frac{1}{2}H_2O$, by adding alcohol to a sulphurous acid soln. of calcium phosphate, and drying the washed precipitate in a water-oven; and A. Millot obtained a product of the same composition by heating an acetic acid soln. of calcium phosphate to 50°–60°. L. Dusart and J. Pelouze obtained a precipitate corresponding with $CaHPO_4.2\frac{1}{2}H_2O$, by neutralizing a soln. of calcium tetrahydro-diphosphate with calcium carbonate; but J. H. Debray, and R. Warington obtained the dihydrate under these conditions. The sesquihydrate, $CaHPO_4.1\frac{1}{2}H_2O$, was reported by M. Raewsky to be precipitated by adding calcium chloride to a soln. of disodium hydrophosphate: by W. Skey, by allowing an acid soln. to stand for some time; and by C. Delattre, by the dehydration of the dihydrate at 150°. A. Barillé thought that the product obtained by his process had the composition $CaHPO_4.4H_2O$.

C. Neuberg and C. W. Neimann [3] prepared **colloidal barium hydrophosphate** by neutralizing a methyl alcohol soln. of barium hydroxide with aq. phosphoric acid, using phenolphthalein as indicator. A slight excess of acid does no harm. The gelatinous precipitate becomes pulverulent when dried. C. Neuberg and B. Rewald prepared **colloidal strontium hydrophosphate** and also **colloidal calcium hydrophosphate** in a similar manner.

According to A. de Schulten,[4] the crystals of anhydrous calcium hydrophosphate are triclinic prisms with axial ratios $a : b : c = 0·6467 : 1 : 0·8744$, and axial angles $\alpha = 64° 57'$, $\beta = 90° 17'$, and $\gamma = 94° 22'$; while the crystals of the dihydrated salt are monoclinic prisms; according to J. D. Dana, they have the axial ratios and axial angle $a : b : c = 0·6221 : 1 : 0·3415$, and $\beta = 95° 18'$; triclinic crystals of monetite, $CaHPO_4$, $a : b : c = 0·6467 : 1 : 0·8244$, and $\alpha = 84° 57'$, $\beta = 90° 17'$, and $\gamma = 94° 22'$; A. de Schulten gave for the rhombic crystals of strontium hydrophosphate, $SrHPO_4$, the axial ratios $a : b : c = 0·6477 : 1 : 0·8581$; and for the rhombic prisms of barium hydrophosphate, $a : b : c = 0·7133 : 1 : 0·8117$.

The **specific gravity** of anhydrous calcium hydrophosphate, $CaHPO_4$, according to H. Bassett, is 2·892 at 16°/4°, 2·886 at 100°/4°, and, by extrapolation, 2·881 at 152°/4°; and of the dihydrate $CaHPO_4.2H_2O$, 2·306 at 16·5°/4°. G. E. Moore's value for the sp. gr. of brushite, $CaHPO_4.2H_2O$, is 2·208. A. A. Julien obtained numbers between 2·288 and 2·362 at 15·5° for the sp. gr. of metabrushite,

$CaHPO_4.1\frac{1}{2}H_2O$. A. de Schulten gave 2·317 for the sp. gr. of brushite, 2·929 for the sp. gr. of monetite, $CaHPO_4$, 3·544 for the sp. gr. of strontium hydrophosphate, $SrHPO_4$, at 15°; and 4·165 for that of barium hydrophosphate, $BaHPO_4$. The **hardness** of brushite and of stoffertite is 2–2½ on Mohs' scale.

The work of F. K. Cameron and J. M. Bell, and of H. Bassett shows that above 25°, solid calcium hydrophosphate changes into the anhydrous salt: $CaHPO_4.2H_2O \rightleftharpoons CaHPO_4+2H_2O$. This transition temp. is an invariant point with five phases—anhydrous and dihydrated calcium hydrophosphate, monohydrated calcium dihydrophosphate, soln., and vapour—in equilibrium. The two former found that in the presence of potassium chloride, the lime content of soln. containing calcium oxide and phosphoric oxide in equilibrium with calcium hydro- and dihydrophosphates, is slightly increased. According to W. Baer,[5] anhydrous calcium hydrophosphate loses water at a red heat, and forms calcium pyrophosphate; and before the blowpipe, J. J. Berzelius stated that it fuses to a colourless glass. According to M. Berthelot, the heat of formation [6] of calcium hydrophosphate from a soln. containing an eq. of calcium oxide and phosphoric acid, per six litres, is 24·50 Cals. at 16°; and with strontium oxide, 25·30 Cals. A. Joly found the heat of precipitation of amorphous calcium hydrophosphate from a mixture of disodium hydrophosphate and calcium chloride is —2·92 Cals. and the heat of crystallization is +2·87 Cals., so that the total heat is nearly zero. A. Joly found the reaction between strontium chloride and sodium hydrophosphate takes place in three stages with thermal values respectively —1·86, +5·95, and —5·92 Cals. The heat of precipitation of dihydrated calcium hydrophosphate from a soln. of its components was found by A. Joly to be 26·90 Cals., and for the heat of formation of crystallized dihydrated strontium hydrophosphate from phosphoric acid and strontium hydroxide, he gives 25·20 Cals. According to A. Joly, amorphous barium hydrophosphate is precipitated from a mixed soln. of barium chloride and sodium hydrophosphate without any perceptible thermal change, and crystallization occurs with the evolution of 1·21 Cals. The heat of neutralization of equi-mol. parts of phosphoric acid and barium hydroxide, both in soln., is 27·80 Cals. The indices of refraction of stoffertite are $\mu_\alpha=1{\cdot}5392$; $\mu_\beta=1{\cdot}5455$; and $\mu_\gamma=1{\cdot}5509$. According to C. Delattre,[7] A. Millot, A. Joly and E. Sorel, and G. Viard, when calcium hydrophosphate is boiled with water, calcium dihydrophosphate goes into soln. and the normal phosphate is precipitated, and, according to E. Reichardt, calcium hydrophosphate is slowly decomposed by cold water and rapidly by hot water, and the liquid acquires an acid reaction. C. Delattre found that a state of equilibrium is attained, but, according to A. Rindell, this state is attained very slowly, for 252 hrs. are needed with 10 grms. of the salt in a litre of water, and the ratio CaO : H_3PO_4, in soln. is 1·56. In Fig. 66, by H. Bassett, *DE* represents a part of the $CaHPO_4$-curve; and *EF* represents the composition of soln. at 50·7° in equilibrium with monohydrated normal calcium phosphate, $Ca_3(PO_4)_2.H_2O$. According to A. Rindell,

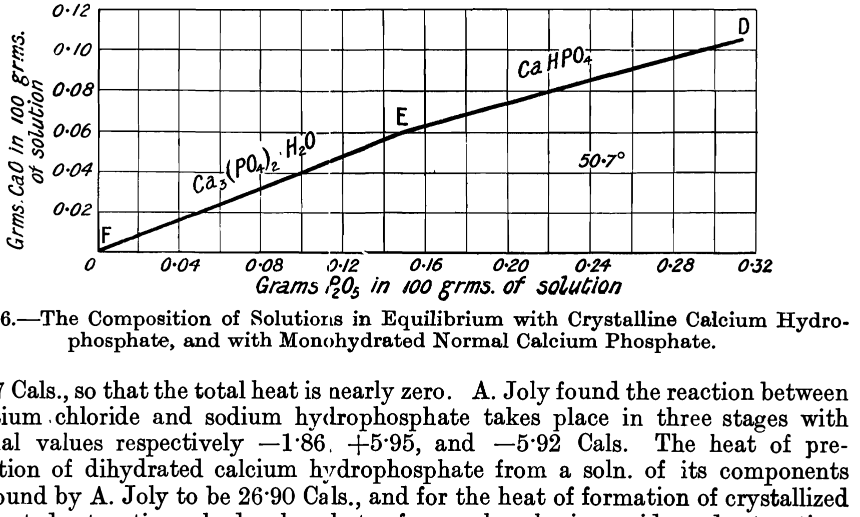

FIG. 66.—The Composition of Solutions in Equilibrium with Crystalline Calcium Hydrophosphate, and with Monohydrated Normal Calcium Phosphate.

the solubility of anhydrous calcium hydrophosphate in water free from carbon dioxide is represented, in grams per litre, by:

	30°	40°	50°	60°	68°	72·9°	100·1°
CaO . .	0·0414	0·0590	0·0667	0·0723	0·0985	0·1031	0·1046
P_2O_5 . .	0·0866	0·1364	0·1630	0·1747	0·2234	0·2478	0·2461

and the solubility of dihydrated salt, also in grams per litre:

	24°	30°	40°	50°	60°	68°	72·9°	100·1°
CaO .	0·0806	0·0954	0·1557	0·2617	0·4347	0·3409	0·3154	0·3109
P_2O_5 .	0·1678	0·2066	0·3434	0·6182	1·0530	0·8245	0·7624	0·7591

There appears a maximum in the solubility curve of the dihydrate. The results show that the degree of hydration of the salt has an important influence on the solubility, or else on the speed at which equilibrium is attained, on the assumption that this condition has not been attained in the case of the anhydrous salt. A. Joly and E. Sorel successively extracted one part of calcium hydrophosphate with 100 parts of water and found that the water acquired an acid reaction, and the solid became gelatinous, and approximated $Ca_3(PO_4)_2.\frac{1}{2}H_2O$; they also determined the composition of the solid residue after various quantities of calcium hydrophosphate had been extracted with equal quantities of water; they ascribed the formula $Ca_3(PO_4)_2.8CaHPO_4.2H_2O$ to one of these solid residues, but it is more probable that this is a mixture of two solid phases, or one of a series of solid soln. J. Joffre extracted the calcium dihydrophosphate with a very large proportion of water, and stated that the solid residue was composed of calcium hydrophosphate and normal calcium phosphate. K. Buch subjected calcium hydrophosphate to a continuous leaching by removing the soln. and adding more water. After 53 successive extractions, the hydrophosphate was converted to normal phosphate, but he added that "it is difficult to decide at the present time whether this stage is the limit of the decomposition, or whether the transformation may be carried further to a basic compound so that normal calcium phosphate is to be considered as a stable intermediate step. Several facts, especially the numerous basic phosphates occurring in nature, are evidence for the latter alternative." F. K. Cameron and A. Seidell found that, unlike normal calcium phosphate, and calcium dihydrophosphate, this salt is but slightly decomposed by water, and appears to dissolve mainly as such; and it is the only calcium phosphate which is stable under water under ordinary conditions. L. N. Vauquelin reported strontium hydrophosphate to be insoluble in water, but it is only sparingly soluble in that menstruum. F. J. Malaguti reported that 100 parts of water dissolve 0·01 part of barium hydrophosphate; and G. Bischof, that 100 parts of water dissolve 0·0486 part of the barium salt at 20°. The old observers —*e.g.* K. Birnbaum, L. Dusart and J. Pelouze, A. Barillé, etc.—did not notice that the proportion CaO : P_2O_5 is different in the soln. from what it is in the original salt.

According to A. Rindell, the solubility of the salt is different in water with *carbon dioxide* in soln., and the solubility increases with increasing proportions of carbonic acid; for example, expressing conc. in milli-mols per litre, at 30°:

	$CaHPO_4$				$CaHPO_4.2H_2O$			
CO_2 . .	1·95	3·91	7·81	15·63	1·95	3·91	7·81	15·63
CaO . .	0·93	1·04	1·54	2·32	1·67	1·71	1·92	2·80
P_2O_5 .	1·24	1·31	1·85	2·40	2·65	2·50	2·20	2·98

L. Dusart and J. Pelouze, and A. Barillé noted the increased solubility of calcium hydrophosphate in water containing carbon dioxide in soln. J. Setschenoff found barium hydrophosphate is not completely soluble in water sat. with carbon dioxide. A soln. of barium chloride and sodium hydrophosphate sat. with carbon dioxide gives no precipitate if less than 7·16 grms. per litre of the last-named salt are present. F. K. Cameron and A. Seidell found that rather more calcium hydrophosphate is dissolved by water and by water carrying carbon dioxide than by the same solvent sat. with gypsum.

J. J. Berzelius, and W. Baer found that calcium hydrophosphate is readily soluble in *hydrochloric acid* and *nitric acid*, and less readily soluble in *acetic acid.* K. Birnbaum found that it dissolves more readily in dil. than in conc. acetic acid. L. N. Vauquelin found strontium hydrophosphate is soluble in *phosphoric acid*, as well as in nitric and hydrochloric acids. Barium hydrophosphate is soluble in phosphoric acid with the formation of barium dihydrophosphate. Similar remarks apply to hydrochloric acid; G. Bischof found it to be very soluble in acetic acid; he also found that nitric acid of sp. gr. 1·275 has but little action on barium hydrophosphate, but the action increases with increasing dilution of the acid, and reaches a maximum when ten times the amount of water has been added to the acid. E. Duvillier has studied the effect of nitric acid of various conc. on barium hydrophosphate. A. Rindell, and A. A. Ramsay measured the solubility of calcium hydrophosphate in acetic acid and in *citric acid;* and H. E. Causse, the solubility in *lactic acid*, and in *phosphoric acid.* According to B. W. Gerland, the salt is readily soluble in *sulphurous acid*—the soln. contains $CaO : P_2O_5 : SO_2$ in the ratios 2 : 1 : 2. The soln. of calcium hydrophosphate loses its sulphur dioxide more readily than a soln. of normal calcium phosphate. A current of sulphur dioxide passed through water in which barium hydrophosphate is suspended forms sparingly soluble barium sulphite, and free phosphoric acid.

J. von Liebig found that the presence of *sodium chloride*, *sodium nitrate*, or *ammonium sulphate* raises the solubility of calcium hydrophosphate. A. Rindell studied the effect of sodium chloride, *ammonium nitrate*, etc., on the solubility of calcium hydrophosphate; he found sodium chloride and sodium nitrate have nearly the same influence. With *sodium acetate*, larger quantities of lime are dissolved; and, according to K. Birnbaum, the aq. soln. with sodium acetate becomes turbid when boiled. R. Ludwig found barium hydrophosphate is soluble in water containing *barium chloride* or sodium chloride in soln., and therefore an excess of barium chloride does not precipitate the phosphoric acid completely from a soln. of sodium hydrophosphate. K. Kraut found that calcium hydrophosphate dissolves slowly in soln. of *ammonium chloride*, and when boiling, phosphoric acid is extracted faster than the calcium oxide. R. H. Brett, and G. C. Wittstein stated that strontium hydrophosphate is readily soluble in cold soln. of ammonium chloride, *ammonium nitrate*, or *ammonium succinate*, and is partly precipitated by a small proportion of aq. ammonia and completely precipitated by a large proportion. They also obtained similar results with barium hydrophosphate. A. Herzfeld and G. Feuerlein, and A. Grupe and B. Tollens found it dissolves copiously in *ammonium citrate.* The solubility is so much augmented by the presence of this salt that A. Rindell assumes complex salts are formed. J. Langel also investigated the subject. According to A. Millot, dihydrated calcium hydrophosphate dissolves rapidly in an ammoniacal soln. of ammonium citrate while the anhydrous salt dissolves slowly. According to F. J. Malaguti, by boiling it with an eq. soln. of *sodium carbonate* or *potassium carbonate* for four hours, 25 to 33 per cent. of the calcium hydrophosphate was decomposed, and conversely, by boiling eq. soln. of sodium or potassium hydrophosphate 39 to 41 per cent. of calcium carbonate was converted into hydrophosphate; analogous results were obtained with the strontium and barium salts. When a mixture of eq. quantities of barium hydrophosphate and *potassium sulphate* in aq. soln. is boiled, for four hours, F. J. Malaguti found that 35 per cent. of the former is decomposed. According to H. Bassett, dry *ammonia* gas has no action on either calcium hydrophosphate or on dihydrated calcium hydrophosphate at ordinary temp., but above 80°, the dihydrate gives off water which decomposes the salt partially. This soln. rapidly absorbs ammonia gas, forming normal calcium phosphate and diammonium phosphate: $3(CaHPO_4.2H_2O)+2NH_3=Ca_3(PO_4)_2+(NH_4)_2HPO_4+6H_2O$; neither NH_4CaPO_4 nor $Ca(NH_4HPO_4)_2$ is formed.

§ 27. Dihydrophosphates of the Alkaline Earths

H. Bassett[1] prepared *monocalcium phosphate*, or **calcium dihydrophosphate**, $Ca(H_2PO_4)_2$, by digesting in a porcelain dish at 160°, a mixture of 8·65 grms. of precipitated calcium carbonate, 25 grms. of yellow phosphorus, and a conc. soln. of phosphoric acid. In about $6\frac{1}{2}$ hrs., the solid was drained by suction and rapidly washed with acetone, and then with ether. According to H. Bassett, anhydrous calcium dihydrophosphate can be obtained by evaporating at 160° a soln. containing phosphoric acid and lime when the ratio of $P_2O_5 : CaO$ is greater than 3; if this ratio be less than 3, the **monohydrated calcium dihydrophosphate,** $Ca(H_2PO_4)_2.H_2O$, is formed. When the anhydrous salt is exposed to air it gradually passes into monohydrate. J. J. Berzelius prepared hydrated calcium dihydrophosphate by evaporating a soln. of the hydrophosphate in nitric or phosphoric acid—if hydrochloric acid be employed, E. Erlenmeyer found a double salt of calcium chloride and dihydrophosphate is formed, although W. Whitthread mixed a conc. hydrochloric acid soln. of calcium phosphate with calcium carbonate until the evolution of carbon dioxide had ceased, and found that when the clear decanted liquid was cooled, crystals of the hydrated salt were formed. It is necessary that the soln. be conc. K. Birnbaum prepared crystals of the salt by the evaporation of a phosphoric acid soln. of the salt over sulphuric acid. Hydrated calcium dihydrophosphate was obtained by L. Prunier and A. Jouve, J. Stoklasa, and G. Pointet, by slowly evaporating a soln. of calcium hydrophosphate in the calculated quantity of phosphoric acid. L. Barthe made **monohydrated strontium dihydrophosphate,** $Sr(H_2PO_4)_2.H_2O$, by adding 100 grms of phosphoric acid in a 5 per cent. soln. to an excess of strontium hydrophosphate, and evaporating the filtered soln. in vacuo. The gelatinous mass slowly crystallizes, and it is contaminated with a little hydrophosphate. J. J. Berzelius likewise prepared **barium dihydrophosphate,** $Ba(H_2PO_4)_2$, by the slow evaporation of a soln. of barium hydrophosphate in phosphoric acid: and E. Mitscherlich, by adding ammonia to a mixed soln. of sodium dihydrophosphate and barium chloride.

Anhydrous calcium dihydrophosphate forms long prismatic crystals which, according to K. Haushofer,[2] belong to the triclinic system and have the axial ratios $a : b : c = 1·9250 : 1 : 0·7332$, with the axial angles $\alpha = 86° 34'$, $\beta = 91° 8'$, and $\gamma = 96° 17'$, and the crystals of the monohydrated calcium salt form thin triclinic plates which, according to K. Haushofer, have the axial ratios $a : b : c = 0·4753 : 1 : 0·5448$, and axial angles $\alpha = 98° 40'$, $\beta = 118° 21'$, and $\gamma = 83° 16'$. E. Erlenmeyer said the crystals of the calcium salt are thin rhombic plates, and the crystals of the barium salts are triclinic, but H. Dufet found the barium salt forms rhombic crystals with axial ratios $a : b : c = 0·7602 : 1 : 0·8238$. The sp. gr. of the monohydrated calcium salt was given by H. Schröder as 2·020; H. Bassett found 2·220 at 16°/4°, 2·147 at 100°/4°, and by extrapolation, 2·120 at 152°/4° for the monohydrated salt; and for the anhydrous salt, $Ca(H_2PO_4)_2$, 2·546 at 15·5°/4°, 2·461 at 100°/4°, and, by extrapolation, 2·420 at 152°/4°.

J. J. Berzelius,[3] and K. Birnbaum stated that the crystals of hydrated calcium dihydrophosphate are hygroscopic, but J. Stoklasa said that if free from phosphoric acid, this salt is not hygroscopic, but free phosphoric acid splits from the salt when heated in a sealed tube. According to E. Erlenmeyer, the crystals of the barium salt are stable in air. According to H. Bassett, when rapidly heated, monohydrated calcium dihydrophosphate melts in its water of crystallization. K. Birnbaum detected no change when the crystals of the hydrated calcium salt are kept over sulphuric acid; at 100° the water of monohydrate is given off; at 150° a change occurs; and at 200° a mixture of metaphosphoric acid and calcium pyrophosphate is formed: $2Ca(H_2PO_4)_2 = Ca_2P_2O_7 + 2HPO_3 + 3H_2O$; at a higher temp. the mixture of the two phosphates is said to melt and $Ca_2P_4O_{12}$ results. H. Bassett found the range of existence of the monohydrate to be very great, ranging from 0° up to about 160°. According to E. Erlenmeyer, and J. J. Berzelius, when the crystals of barium dihydrophosphate are heated, they swell up and lose water like alum, and readily melt to a colourless glass. According to W. Spring, the hydrated calcium salt under press. decomposes at ordinary temp.: $Ca(H_2PO_4)_2.H_2O = CaHPO_4 + H_3PO_4 + H_2O$.

According to M. Berthelot,[4] the heat of formation from half a mol of CaO, and a mol of phosphoric acid, in six litres of water, at 16°, is 14·8 Cals.; similarly for the monohydrated strontium salt, 15·05 Cals.: and for the barium salt, 24·5 Cals.

E. Erlenmeyer[5] found that when calcium dihydrophosphate is mixed with a greater proportion of water than 1 : 700, solid calcium hydrophosphate is formed, and the soln. contains more acid than corresponds with $Ca(H_2PO_4)_2$. H. Wattenberg said one part of salt dissolves in 144 parts of water without other change, and H. Otto stated that one part of phosphate in 25 parts of water suffered no decomposition. Between 10° and 20°, J. Stoklasa found that with a gram of monohydrated calcium dihydrophosphate, and

		Water	1	25	50	75	150	200 grms.
In soln.	CaO	.	0·1624	0·1900	0·2063	0·2148	0·2180	0·2236 grm.
	P_2O_5	.	0·4902	0·5259	0·5486	0·5598	0·5642	0·5668 grm.

as the proportion of water is increased, the absolute quantity of lime and phosphoric acid dissolved increases, but the conc. of the soln. falls rapidly. J. Stoklasa represented the action of cold water by the equation: $n\mathrm{Ca(H_2PO_4)_2.H_2O+H_2O} = (n-1)\mathrm{Ca(H_2PO_4)_2.H_2O+CaHPO_4+2H_2O+H_3PO_4}$, for equal parts of water and salt, $n=4$. With increasing proportions of water the proportion of salt dissolved increases, so that with 200 parts of water very little decomposition—0·1 per cent.—occurs, and virtually all passes into soln.—$n=1024$. Phosphoric acid and calcium hydrophosphate form calcium dihydrophosphate quantitatively if in soln. with over 200 parts of water. A. Joly found that by mixing varying proportions of water and calcium dihydrophosphate, the resulting solid phase was calcium hydrophosphate, while the soln. contained both lime and phosphoric acid. G. Viard also studied the composition of the soln. and solids resulting from the mixing of calcium dihydrophosphate with varying proportions of water at 100°; in every case, anhydrous calcium hydrophosphate was formed which differs from the hydrated salt in being insoluble in acetic acid.

According to H. Bassett, the curve *AB*, Fig. 67, represents the composition of soln. in equilibrium with $Ca(H_2PO_4)_2.H_2O$ at 50·7°; the point *A*, soln. in equilibrium with both $Ca(H_2PO_4)_2$ and $Ca(H_2PO_4)_2.H_3O$; the curve *BC*, soln. in equilibrium with $CaHPO_4$. Corresponding curves for soln. at 40° and 25° are shown in the same diagram. The relation of the different solid phases is shown in Fig. 67. According to J. Stoklasa, some of the older observations of the action of water on this salt were made on samples, contaminated with phosphoric acid; F. K. Cameron and A. Seidell found that a soln. of calcium dihydrophosphate is a soln. of the decomposition products rather than of the salt itself. The presence of calcium sulphate does not materially affect the proportion of phosphoric acid passing into soln., but the conc. and acidity of the soln. are reduced in amounts practically eq. to the added calcium carbonate. A. Joly has studied the action of water on the calcium salt; J. Langel, the action of ammonium citrate.

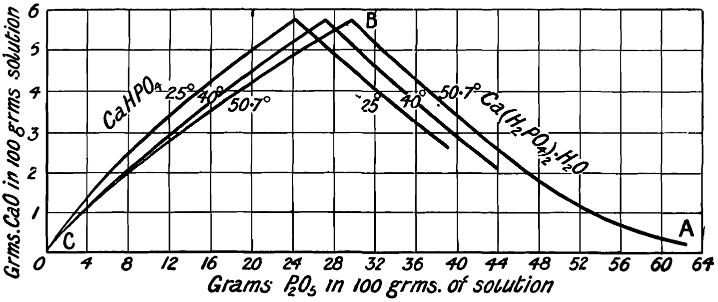

FIG. 67.—The Composition of Solutions in Equilibrium with Crystalline Calcium Hydro- and Dihydrophosphates.

According to E. Erlenmeyer, the crystals of the barium salt have an acid reaction. According to J. J. Berzelius, the barium salt is soluble in phosphoric and some other acids; and it is decomposed by large quantities of water into barium hydrophosphate and an aq. soln. of phosphoric acid.

The behaviour of different proportions of barium dihydrophosphate in 100 c.c. of water at 15° is indicated in Table XXI, which embodies a selection from A. Joly's data. Further studies have been made by A. Joly and E. Sorel, and by G. Viard. E. Erlenmeyer found that if the soln. of calcium dihydrophosphate be heated to boiling, calcium hydrophosphate separates out, and $2CaO : 3P_2O_5$ remains in soln., but, according to K. Birnbaum, the proportion of calcium oxide in soln. increases with dilution, so that a one per cent. soln. is not decomposed by boiling. The presence of calcium sulphate, or of ammonium chloride or sulphate, retards the decomposition. No precipitation occurs if four parts of acetic acid to one of phosphoric acid be present. A. Reynoso found that when heated to 280° with water, the salt splits into phosphoric acid and normal calcium phosphate. A precipitate of calcium hydrophosphate is produced, according to J. H. Debray, by boiling the soln. with calcium chloride; according to L. Dusart and J. Pelouze, by neutralization with sodium carbonate; according to E. Erlenmeyer, by mixing the solid with normal calcium phosphate, or by standing a long time, or by boiling the soln. with absolute alcohol; or, according to K. Birnbaum, by adding sodium or calcium acetate. The latter also found that free acetic acid hinders the precipitation with sodium acetate, one mol of acetic acid to two mols of phosphoric acid is required in the cold, and nine mols of acetic acid to two mols of phosphoric acid are required for a boiling soln. A. Frébault and J. A. Destrém found that calcium carbonate is not precipitated from the aq. soln. by sodium carbonate, for the reaction is $Ca(H_2PO_4)_2 + Na_2CO_3 = Na_2HPO_4 + CaHPO_4 + CO_2 + H_2O$. E. Erlenmeyer found the calcium salt is not altered by dry ether, but when boiled with absolute alcohol, calcium hydrophosphate is formed. According to H. Bassett, a little dry ammonia gas is absorbed by the anhydrous salt at ordinary temp., but at 100°, the gas is rapidly absorbed, and an unstable compound, $(NH_4)_2Ca(HPO_4)_2$, is formed, showing that the salt does not first break down into calcium hydrophosphate and phosphoric acid. The compound $Ca(NH_4)_2(HPO_4)_2$ is not stable in the presence of the water formed in the reaction. The decomposition products are diammonium phosphate and dihydrated calcium hydrophosphate, and the reaction comes to an end when sufficient calcium hydrophosphate has been formed to absorb all the water. With the monohydrated salt and dried ammonia, $(NH_4)_2Ca(HPO_4)_2$ and water are formed in aq. soln., the compound $(NH_4)_2Ca(HPO_4)_2$ first formed is not stable but decomposes so that the end-reaction appears to be $Ca(H_2PO_4)_2.H_2O + 2NH_3 = CaHPO_4 + (NH_4)_2HPO_4 + H_2O$; or $3Ca(H_2PO_4)_2.H_2O + 8NH_3 = Ca_3(PO_4)_2 + 4(NH_4)_2HPO_4 + 3H_2O$. According to A. Joannis, a mol of calcium dihydrophosphate fixes two atoms of potassium when digested with a soln. of potassium in liquid ammonia, and if an excess of the latter is used, potassium amide and hydrogen are formed.

A. A. Julien[6] reported the occurrence of a mineral *zeugite* in Sombréro (West Indies), which has a composition corresponding with $8CaO.P_2O_5.nH_2O$, and a sp. gr. 2·988–3·030.

It does not form crystals, but appears rather as a crust on the surface of phosphorites. It is rather more acidic than the normal phosphate, and is possibly a mixture of normal phosphate with an acid phosphate—possibly $Ca_3(PO_4)_2.CaHPO_4.nH_2O$. J. J. Berzelius, and R. Warington obtained a product of analogous composition by adding calcium chloride to an ammoniacal soln. of phosphoric acid—the latter in excess—if the calcium salt be in excess, the normal phosphate is produced. R. Warington, and J. N. von Fuchs obtained the normal phosphate by adding calcium chloride to an excess of an ammoniacal soln. of disodium hydrophosphate. C. Tissier precipitated the product $8CaO.3P_2O_5$ by adding sodium borate to a soln. of calcium phosphate in hydrochloric acid, or an acidified mixture of a calcium salt with disodium hydrophosphate When the gelatinous precipitate is dried in vacuo, R. Warington found that it lost 9·65 per cent. of water; when dried at 100°, 5·37 per cent. of water. The product has a neutral reaction, but gives an acid soln. when treated with water; it is reprecipitated by adding ammonia to its soln. in an acid.

Various other acid phosphates have been reported, but these are probably mixtures. J. J. Berzelius[7] obtained $4CaO.3P_2O_5$ by adding alcohol to a sat. aq. soln. of phosphoric acid and calcium phosphate. J. J. Berzelius also obtained what has been regarded as $Ba_3H_6(PO_4)_4$ in an analogous manner. M. Raewsky stated that calcium dihydrophosphate is decomposed by alcohol into phosphoric acid and $3CaO.2P_2O_5.4H_2O$, and after drying at 100°, A. Millot found the product had the composition $Ca_3H_6(PO_4)_4.2H_2O$; J. Piccard obtained a product $17CaO.9P_2O_5.10H_2O$ from a soln. of calcium oxide in phosphoric acid. J. Piccard found that a soln. of calcium chloride in phosphoric acid, or bone-ash in hydrochloric acid, gives a precipitate of $CaHPO_4$ when treated with alcohol; and E. Erlenmeyer obtained a similar product by boiling calcium dihydrophosphate, $Ca(H_2PO_4)_2.H_2O$, with absolute alcohol.

§ 28. Pyrophosphates of the Alkaline Earths

A. Schwarzenberg[1] prepared anhydrous **calcium pyrophosphate,** $Ca_2P_2O_7$, by heating calcium hydrophosphate, $CaHPO_4$, **strontium pyrophosphate,** $Sr_2P_2O_7$, and **barium pyrophosphate,** $Ba_2P_2O_7$, were prepared in a similar manner. L. V. R. Ouvrard obtained the strontium salt by very slowly cooling a soln. of strontium sulphate in molten potassium pyrophosphate or of strontium oxide in molten sodium meta- or pyro-phosphate; he also made the barium salt in an analogous way. Barium pyrophosphate was stated by L. V. R. Ouvrard to form rhombic prisms, of sp. gr. 3·9 at 20°. C. N. Pahl did not melt barium pyrophosphate by strongly heating it. According to F. Wibel, when the calcium salt is heated with calcium carbonate, carbon dioxide is given off, and normal calcium phosphate is formed. H. Rose found that when calcium pyrophosphate is melted with an excess of sodium carbonate, a portion remains unconverted into orthophosphate—*vide* the double alkali calcium pyrophosphate—he also found that although barium pyrophosphate is more readily attacked by fused alkali carbonate, than calcium or strontium pyrophosphate, the reaction is in no case quantitative. H. Struve found that when barium pyrophosphate is heated in a stream of hydrogen, phosphine is evolved and the orthophosphate is formed. T. Dieckmann and E. Houdremont gave 3·09 for the sp. gr. of calcium pyrophosphate; 1230° for the m.p.; and 1·6 for the percentage solubility in citric acid.

O. Nielsen gave 1250° for the m.p. of calcium pyrophosphate. According to H. Rose, aq. soln. of barium chloride and pyrophosphoric acid give a precipitate of hydrated barium pyrophosphate when ammonia is added. C. N. Pahl precipitated the hydrated salt by treating an aq. soln. of sodium pyrophosphate with an ammoniacal soln. of barium chloride; A. Schwarzenberg, by treating an aq. soln. of sodium pyrophosphate, $Na_4P_2O_7$, with a soln. of barium chloride; C. H. Hess, by treating a soln. of pyrophosphoric acid with barium hydroxide; C. N. Pahl's preparation dried at 100° was reported to have the composition **dihydrated barium pyrophosphate,** $Ba_2P_2O_7.2H_2O$; and in the case of strontium, **dihydrated strontium pyrophosphate,** $Sr_2P_2O_7.2\text{–}2\frac{1}{2}H_2O$. A. Schwarzenberg's preparation has the composition **monohydrated barium pyrophosphate,** $Ba_2P_2O_7.H_2O$, and in the case of strontium, **monohydrated strontium pyrophosphate,** $Sr_2P_2O_7.H_2O$. G. von Knorre and E. Oppelt likewise prepared $Sr_2P_2O_7.2\text{–}2\frac{1}{2}H_2O$ by dissolving strontium pyrophosphate in pyrophosphoric acid, or by the action of sodium pyrophosphate in the presence of free pyrophosphoric acid on strontium chloride. The hydrated calcium salt was prepared by W. Baer, G. von Knorre and E. Oppelt, H. Rose, and A. Schwarzenberg by similar methods, but the analyses of W. Baer, and of G. von Knorre and E. Oppelt corresponded with **tetrahydrated calcium pyrophosphate,** $Ca_2P_2O_7.4H_2O$. These salts when first precipitated are often gelatinous, and difficult to filter and wash, but they often crystallize on standing or during the washing. According to A. Schwarzenberg, they are all somewhat soluble in water, readily soluble in mineral acids, sparingly soluble in acetic acid, and insoluble in sodium pyrophosphate. W. Baer observed the dissolution of the calcium salt in acetic acid, and, according to A. Schwarzenberg, the soln. in sulphurous acid, precipitates crystals of the salt on standing or boiling; the soln. of the barium salt in sulphurous acid gives a precipitate of barium sulphate on standing. H. Rose found that the salts are partially attacked by a boiling soln. of sodium carbonate. According to H. W. F. Wackenroder, hydrated barium pyrophosphate is insoluble in a soln. of ammonium chloride; while K. Birnbaum showed that the soln. in hydrochloric acid gives no precipitate when sodium acetate is added.

Several hydropyrophosphates of the alkaline earths have been reported. C. N. Pahl prepared rhombic plates of dihydrated **calcium dihydropyrophosphate,** $CaH_2P_2O_7.2H_2O$, by partially decomposing calcium pyrophosphate with soln. of oxalic acid. By boiling tetrahydrated calcium pyrophosphate for a long time with water, and washing the product with boiling water until the filtrate was free from acid, G. von Knorre and E. Oppelt obtained $Ca_2P_2O_7.CaH_2P_2O_7.3H_2O$; they also prepared crystals of $Ca_2P_2O_7.2CaH_2P_2O_7.6H_2O$, by allowing mixed soln. of sodium dihydropyrophosphate and calcium chloride to stand for a long time; with very conc. soln. a flocculent precipitate is obtained at once. The product is very sparingly soluble in hot water, and the soln. on cooling deposits crystals of the salt; the salt is also precipitated if the aq. soln. is acidified with acetic acid. C. N. Pahl reported the following hydrated **strontium dihydropyrophosphates**: $Sr_2P_2O_7 : SrH_2P_2O_7 : H_2O$ $=9 : 1 : 5$, $9 : 1 : 18$, $9 : 1 : 20$, $4 : 1 : 3$, and $4 : 1 : 8$ or 12; while G. von Knorre and E. Oppelt reported $3 : 1 : 1$ or 2, and $2 : 1 : 6$. Similarly with hydrated **barium dihydropyrophosphates,** C. N. Pahl reported $4 : 1 : 9$, $3 : 1 : 5$, $2 : 1 : 5$, and $5 : 4 : 12$; while G. von Knorre and E. Oppelt reported $1 : 1 : 3$. There is little to show whether these products are mixtures or chemical individuals.

G. Tammann obtained a product which he regarded as **sodium barium pyrophosphate,** $Na_4Ba_4(P_2O_7)_3$, by melting a mol of ammonium sodium hydrophosphate with a mol of a barium salt, and vigorously stirring the mass while it is cooling. The prismatic crystals are readily soluble in hot nitric or hydrochloric acid. W. Baer obtained a hydrated sodium barium pyrophosphate by gradually adding barium chloride to a boiling soln. of sodium pyrophosphate. L. V. R. Ouvrard prepared **potassium strontium pyrophosphate,** $K_2SrP_2O_7$, by slowly cooling a soln. of strontium oxide or orthophosphate in molten potassium meta- or pyro-phosphate. After extracting with water, hexagonal plates, derived from octahedra, are obtained. The sp. gr. is 2·9 at 20°; the salt is soluble in dil. acids. W. Baer obtained a hydrated form of **sodium strontium pyrophosphate** by a process analogous to that he used for the corresponding barium compound. L. V. R. Ouvrard prepared **potassium calcium pyrophosphate,** $K_2CaP_2O_7$, by a process like that he employed for the strontium salt; the crystals were similar and their sp. gr. was 2·7 at 20°. K. A. Wallroth, and L. V. R. Ouvrard prepared a crystalline powder of **sodium calcium pyrophosphate,** $4Na_2O.5CaO.P_2O_5$, by melting ammonium sodium hydrophosphate with calcium oxide. The monoclinic plates have a sp. gr. 2·7 at 20°; they are soluble in acids. W. Baer obtained a hydrate, $Na_2Ca.P_2O_7.4H_2O$.

C. U. Shepard's[2] mineral *pyrophosphorite*, from the West Indies, has a composition corresponding with $Mg_2P_2O_7.4\{Ca_2P_2O_7.Ca_3(PO_4)_2\}$; its sp. gr. was 2·50–2·53; its hardness, 2–3½. P. Jolibois studied the phosphates formed by mixing calcium hydroxide and phosphoric acid, and obtained crystals of a mixed **calcium ortho-pyrophosphate,** $Ca_2P_2O_7.Ca_3(PO_4)_2.10H_2O$, which is slowly converted into dicalcium phosphate in the presence of an excess of phosphoric acid.

F. Schwarz[3] reported the formation of plates of **calcium triphosphate,** $5CaO.3P_2O_5$, or $Ca_5(P_3O_{10})_2$, by mixing dil. soln. of sodium triphosphate and of a calcium salt. The precipitate was dried on a porous tile; it is soluble in an excess of the calcium salt. He prepared **barium triphosphate,** $Ba_5(P_3O_{10})_2$, in a similar manner. T. Fleitmann and W. Henneberg prepared **calcium tetraphosphate,** $3CaO.2P_2O_5$, or $Ca_3P_4O_{13}$, by treating a soln. of the sodium salt with one of a calcium salt; or by melting the sodium salt with calcium chloride. They also prepared **barium tetraphosphate,** $Ba_3P_4O_{13}$, in a similar way, and stated that the barium salt is infusible, while H. Lüdert said that it fuses in a platinum crucible to a colourless glass.

§ 29. Metaphosphates of the Alkaline Earths

Various precipitates of undetermined composition have been reported[1] to be formed when a soln. of an alkali metaphosphate or metaphosphoric acid is treated with a soln. of a salt of the alkaline earths under various conditions. H. Rose stated that an aq. soln. of phosphoric acid gives with a soln. of barium hydroxide or chloride a precipitate which is soluble in a great excess of metaphosphoric acid, and the soln. is not precipitated by aq. ammonia. What has been regarded as **barium monometaphosphate,** $Ba(PO_3)_2$, was obtained by R. Maddrell[2] by heating barium carbonate with an excess of orthophosphoric acid for a long time at 316°. The white residue is insoluble in water and dil. acids, but it is decomposed by conc. sulphuric acid. R. Maddrell's salt is not decomposed by digestion with alkali carbonates, and therefore, said T. Fleitmann, the nature of the combined acid cannot be determined. R. Maddrell prepared what have been regarded as **strontium monometaphosphate,** $Sr(PO_3)_2$, and **calcium monometaphosphate,** $Ca(PO_3)_2$, in a similar manner to the barium salt. O. Nielsen gave 1020° for the m.p. of calcium metaphosphate, $(CaP_2O_6)_n$. T. Dieckmann and E. Houdremont gave 2·65–2·85 for the sp. gr.; and 970°–980° for the m.p.

A. Glatzel[3] evaporated a soln. of barium carbonate with about one per cent. excess of orthophosphoric acid, first on a water-bath, then on a sand-bath, and finally at 400°. The resulting cake was coarsely powdered, and washed with cold water acidified with a few drops of nitric acid. The white crystalline powder was regarded as **barium dimetaphosphate,** BaP_2O_6. The salt melts at a red heat, and passes into tetrametaphosphate. Barium dimetaphosphate is not altered by hydrochloric or nitric acid, but it is completely decomposed by hot conc. sulphuric acid. When melted with sodium carbonate, it forms sodium orthophosphate, Na_3PO_4 ; and when digested with aq. soln. of the alkali carbonates, it gives double salts whose composition led A. Glatzel to regard it as a dimetaphosphate. A. Glatzel similarly prepared **strontium dimetaphosphate,** SrP_2O_6, and **calcium dimetaphosphate,** CaP_2O_6. T. Fleitmann obtained a crystalline precipitate of **dihydrated barium dimetaphosphate,** $BaP_2O_6.2H_2O$, by mixing ammonium dimetaphosphate with barium chloride ; good crystals are obtained when a mixture of the conc. soln. has stood some time. Part of the water is lost at 150°, and all at a red heat. A. Glatzel said that the salt which has lost its water of crystallization, still remains a dimetaphosphate. T. Fleitmann showed that the salt does not melt at a red heat, and A. Glatzel said it does melt, but passes into the tetrametaphosphate. According to T. Fleitmann, the salt which has been heated to redness does not form sodium dimetaphosphate when digested with an aq. soln. of sodium carbonate, while the uncalcined salt does so. Barium dimetaphosphate is less soluble in water than is the case with the tetrametaphosphate. A. Glatzel showed that 100 parts of water dissolve two parts of water. According to T. Fleitmann, boiling conc. hydrochloric or nitric acid has but little action, while conc. sulphuric acid readily decomposes the salt. It unites neither with sodium nor ammonium dimetaphosphate. A. Glatzel similarly prepared **dihydrated strontium dimetaphosphate,** $SrP_2O_6.2H_2O$, and T. Fleitmann, **dihydrated calcium dimetaphosphate,** which are analogous to the barium salt.

A. Glatzel prepared **ammonium barium dimetaphosphate,** $(NH_4)_2Ba(PO_3)_4.2H_2O$, by mixing a dil. soln. of ammonium dimetaphosphate with barium chloride. If the soln. be not very dil., the barium salt is alone obtained. It is sparingly soluble in acids, and is completely decomposed by conc. sulphuric acid. The water of crystallization is expelled by feeble calcination, and when strongly heated it loses ammonia and phosphoric oxide. With slow cooling, barium tetraphosphate is formed. A. Glatzel also prepared in a similar way **ammonium strontium dimetaphosphate,** $(NH_4)_2Sr(P_2O_6)_2.2H_2O$, and **ammonium calcium dimetaphosphate,** $(NH_4)_2Ca(P_2O_6)_2.2H_2O$. T. Fleitmann also prepared the latter salt by adding alcohol to a mixed soln. of calcium chloride and an excess of ammonium dimetaphosphate; if calcium chloride be in excess, calcium dimetaphosphate is precipitated. The crystals do not lose their water at 100°, they are sparingly soluble in water, and are not decomposed by acids. A. Glatzel prepared fine needles of **potassium barium dimetaphosphate,** $K_2Ba(P_2O_6)_2.4H_2O$, from very dil. soln. of potassium dimetaphosphate and barium chloride. The corresponding sodium barium dimetaphosphate, $Na_2Ba(P_2O_6)_2.4H_2O$, was prepared in a similar manner; he also made **potassium strontium dimetaphosphate,** $K_2Sr(P_2O_6)_2.4H_2O$; **sodium strontium dimetaphosphate,** $Na_2Sr(P_2O_6)_2.4H_2O$; **potassium calcium dimetaphosphate,** $K_2Ca(P_2O_6)_2.4H_2O$; and **sodium calcium dimetaphosphate,** $Na_2Ca(P_2O_6)_2.4H_2O$.

T. Fleitmann and W. Henneberg,[4] and C. G. Lindbom prepared **barium trimetaphosphate,** $Ba_3(P_3O_9)_2.6H_2O$, by mixing a soln. of one part of the sodium salt with a soln. of 2 or 3 parts of barium chloride; if other proportions are employed, a double salt is produced. According to H. Rose, no precipitation occurs with strontium chloride. The filtrate furnishes rhombic crystals which become acid, and lose two-thirds their water when heated on a water-bath. T. Fleitmann and W. Henneberg say that the salt does not melt at a red heat, but it thereby becomes insoluble in acids, because, according to C. G. Lindbom, it is converted into the hexametaphosphate. The crystals have a neutral reaction, and lose no water over sulphuric acid, all the water is lost at 180°. At ordinary temp., A. Wiesler found 100 c.c. of water dissolve 0·2589 grm. of salt: and the aq. soln., at a dilution $v=128$, 512, and 2048, has an eq. conductivity 64·7, 89·4, and 125·5 respectively. The salt is readily soluble in hydrochloric acid.

C. G. Lindbom prepared prismatic crystals of **ammonium barium trimetaphosphate,** $(NH_4)Ba(PO_3)_3.H_2O$, by adding to a soln. of sodium barium trimetaphosphate sufficient ammonium sulphate to precipitate half the barium. The salt does not lose its water at 100°, and at red heat it loses water and ammonia, and melts to a clear glass soluble in hydrochloric acid. C. G. Lindbom prepared crystals of **potassium barium trimetaphosphate,** $KBa(PO_3)_3.H_2O$, by adding to barium trimetaphosphate, or to sodium barium trimetaphosphate, sufficient potassium sulphate to precipitate half the barium. This salt is less soluble in water than the corresponding ammonium or sodium barium triphosphate. The crystals at a red heat melt to a white enamel, which is soluble in hydrochloric acid. T. Fleitmann and W. Henneberg obtained prisms of **sodium barium trimetaphosphate,** $NaBaP_3O_9.4H_2O$, from a mixed soln. of one part of barium chloride and 2 to 3 parts of sodium triphosphate. The salt is more soluble in water than barium trimetaphosphate. The crystals effloresce in air, and lose 9·86 per cent. of water at 100°, at a higher temp. they lose the remaining water. According to C. G. Lindbom, the feebly calcined salt slowly dissolves in boiling hydrochloric acid, and the clear glass obtained at a red heat dissolves easily in that acid. T. Fleitmann and W. Henneberg prepared crystals of **sodium strontium trimetaphosphate,** $NaSrP_3O_9.3H_2O$, by the spontaneous evaporation of a mixed soln. of one part of strontium chloride with three of sodium trimetaphosphate. The corresponding **sodium calcium trimetaphosphate,** $NaCaP_3O_9.3H_2O$, was prepared by T. Fleitmann and W. Henneberg, and by C. G. Lindbom.

According to A. Glatzel,[5] **barium tetrametaphosphate,** $Ba_2P_4O_{12}$, is formed when the dimetaphosphate is melted, and slowly cooled. The small white crystals are incompletely decomposed by sulphuric acid; completely decomposed by fusion with sodium carbonate; and when digested with an aq. soln. of an alkali carbonate, alkali tetrametaphosphate is formed. **Strontium tetrametaphosphate,** $Sr_2P_4O_9$, and **calcium tetrametaphosphate,** $Ca_2P_4O_{12}$, correspond with the barium salt. **Octohydrated barium tetrametaphosphate,** $Ba_2P_4O_{12}.8H_2O$, was obtained by A. Glatzel as a white crystalline powder by adding an excess of barium chloride to a soln. of sodium tetraphosphate. 100 parts of water dissolve 1·54 parts of the salt. It loses its water of crystallization at a dull red heat. Before calcination, it is attacked by nitric acid, but after calcination only by conc. sulphuric acid. When melted and slowly cooled it forms anhydrous $Ba_2P_4O_{12}$. **Octohydrated strontium tetrametaphosphate,** $Sr_2P_4O_{12}.8H_2O$, and **octohydrated calcium tetrametaphosphate,** $Ca_2P_4O_{12}.8H_2O$, were prepared in a similar manner; 100 parts of water dissolve 1·818 parts of the former, and 2·0 parts of the latter. G. Tammann made what he regarded as *barium ditetrametaphosphate*, $BaBa_2(PO_3)_6.12H_2O$, by treating a soln. of barium chloride with a soln. of $K_2Na_4(PO_3)_6$, or $Li_2Na_4(PO_3)_6$. The white powder melts when heated in the blast flame.

According to H. Rose,[6] hexametaphosphoric acid, prepared by the action of hydrogen sulphide on the silver salt, furnishes a flocculent precipitate of **barium hexametaphosphate,** $Ba_3P_6O_{18}$, when added to a soln. of barium hydroxide or chloride; a soln. of hexametaphosphate also gives a voluminous precipitate with barium chloride, and the filtrate has an acid reaction. The precipitate dissolves in an excess of the sodium hexametaphosphate soln. and no precipitation occurs when ammonia is added. According to T. Graham. an aq. soln. of the salt obtained by calcining sodium dihydrophosphate, gives a gelatinous precipitate when treated with barium chloride. The precipitate gives off water at a red heat, and sinters; it then dissolves with difficulty in nitric acid. When boiled with water, it slowly forms a soln. of barium dihydrophosphate, $Ba(H_2PO_4)_2$. According to H. Wackenroder, barium hexametaphosphate is insoluble in an aq. soln. of ammonium chloride. H. Lüdert prepared **strontium hexametaphosphate,** $Sr_3P_6O_{18}$, by adding the sodium salt to a soln. of strontium nitrate. The white flocculent precipitate is almost insoluble in water, it melts to a clear glass when heated; and it is soluble in dil. acids. T. Scheerer showed that the precipitation of strontium compounds by alkali sulphates and carbonates is influenced by sodium hexametaphosphate. According to H. Rose, an aq. soln. of hexametaphosphoric acid does not give a precipitate with calcium chloride, but a precipitate is obtained with a soln. of calcium hydroxide if the latter is in excess. H. Lüdert, and H. Rose also prepared **calcium hexametaphosphate,** $Ca_3P_6O_{18}$, and it resembles the strontium and barium salts. G. Tammann prepared what he regarded as **potassium strontium hexametaphosphate,** $K_2Sr_2P_6O_{18}$, by digesting the product obtained by melting potassium dihydrophosphate, with a soln. of strontium chloride for two months. J. J. Berzelius also made a clear glass by melting sodium hexametaphosphate with calcium oxide or carbonate, and this may contain some *sodium calcium hexametaphosphate.* T. Scheerer prepared a product which has been regarded as *barium sulphatophosphate* with variable proportions of phosphate and sulphate by adding dil. sulphuric acid to a mixture of a soln. of sodium hexametaphosphate with a large excess of dil. hydrochloric acid and barium chloride. It is probably a mixture of the sulphate and phosphate.

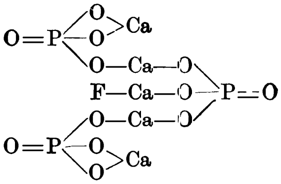
§ 30. Complex Phosphates of the Alkaline Earths

Calcium fluoride or chloride unites with normal calcium phosphate, forming calcium fluo-orthophosphate, or chloro-orthophosphate. **Calcium fluotriorthophosphate,** $3Ca_3(PO_4)_2.CaF_2$, or $Ca_5(PO_4)_3F$, is represented by the mineral *apatite*, sometimes called *fluoro-apatite*, to distinguish it from the isomorphous *chloro-apatite*, or **calcium chlorotriorthophosphate,** $3Ca_3(PO_4)_2.CaCl_2$, or $Ca_5(PO_4)_3Cl$. Both minerals occur in isomorphous mixtures, and are included as varieties of the mineral species: apatite. Apatite is the most important and the most widely distributed natural phosphate; it occurs [1] in all classes of rocks—igneous, metamorphic, and sedimentary; but it is more common in rocks with the lower proportions of silica. It is found in the titaniferous magnetites of Norway, Adirondacks, etc. J. H. L. Vogt [2] has suggested that when apatite occurs as a vein mineral, it has been formed by pneumatolytic agencies. W. M. Hutchings, and J. H. L. Vogt have reported the presence of apatite in lead-furnace slags. S. Meunier, and C. Vélain also found crystals of apatite in the ashes of burnt vegetation. A. Damour reported a hydrated variety, *hydro-apatite*, $3Ca_3(PO_4)_2.CaF_2.3H_2O$, of sp. gr. 3·10, and hardness $5\frac{1}{2}$, occurring as white concretions.

Apatite was at first confused with other minerals—fluorspar, aquamarine, amethyst, schorl, and chrysolite—but in 1786, A. G. Werner [3] recognized it as a distinct mineral species, and gave it the name apatite, from ἀπατάω, to deceive. Various synonyms have been employed for more or less impure varieties—*e.g. moroxite, lazurapatite, phosphorite, hydroapatite, pseudoapatite, sombrérite, osteolite, staffelite, francolite, eupyrochroite, talcapatite*, etc. The analyses of M. H. Klaproth, and of L. N. Vauquelin showed that it contained lime and phosphoric acid. B. Pelletier and L. Donadei recognized chloro- and fluoro-apatites in Estremadura phosphorites, and G. Rose showed that the chlorine and fluorine are interchangeable. Numerous analyses have been reported.[4] T. Scheerer, and W. C. Brögger found cerium in a Norwegian apatite; A. Cossa, and I. Bellucci and L. Grassi, cerium, lanthanum, and didymium; and F. Zambonini, praseodymium.

The analyses of fluoapatite correspond with $CaF.Ca_4(PO_4)_3$, or $3Ca_3(PO_4)_2.CaF_2$:



The fluorine may be partly replaced by chlorine, or hydroxyl, $Ca(F, Cl, OH).Ca_4(PO_4)_3$. In some cases J. A. Völcker, and J. L. Hoskins-Abrahall found too low a content of fluorine, chlorine, or hydroxyl, and they assumed that oxygen may also be present: $3Ca_3(PO_4)_2.Ca(F_2, Cl_2, (OH)_2, O)$. The mineral *dahllite*, $3Ca_3(PO_4)_2.CaCO_3$, is a *carbonato-apatite*, or **calcium carbonato-phosphate,** and, also, according to A. F. Rogers, it is isomorphous with apatite. W. Tschirwinsky's *podolite* is, according to W. T. Schaller, identical with dahllite. These minerals have also been studied by W. C. Brögger and H. Bäckström, A. Schwantke, etc. The evidence is not conclusive, but it does indicate that such apatites are possible. According to A. Barillé, when dicalcium phosphate suspended in water is heated with carbon dioxide under press. (13 kgrms. per sq. cm.), 25 to 50 per cent. dissolves according to the duration of the action. The soln., when exposed to air, deposits crystals of dicalcium phosphate. Calcium phosphate similarly treated dissolves to a less extent (10–25 per cent.), and the soln. deposits a mixture of dicalcium phosphate and calcium carbonate (1 mol. P_2O_5 to 3 mols. CaO). It is supposed that an unstable carbonatophosphate of the formula $H_2Ca_2P_2O_8.2CO_2$ is formed, but all attempts to isolate the substance failed. It has been suggested by A. H. Church[5] that the mineral *tirolite* is *calcium cupric oxycarbonatophosphate*, $CaCO_3.2Cu(OH)_2.2Cu_3(PO_4)_2.2H_2O$.

A. Ditte prepared **calcium bromophosphate,** $3Ca_3(PO_4)_2.CaBr_2$, or *bromo-apatite* in hexagonal plates by fusing together sodium bromide and normal calcium phosphate; and he also prepared needle-like crystals of *bromo-wagnerite,* $Ca_3(PO_4)_2.CaBr_2$, in a similar way. The corresponding **calcium iodophosphates, strontium bromophosphates,** and **strontium iodophosphates,** were obtained in an analogous manner. The iodo-apatites could not be obtained by fusing together the iodides and phosphates of the alkaline earths, because the iodides decompose when fused, but if alkali iodides are also present, and access of oxygen to the fused salt be excluded, the iodophosphates are formed.

According to R. J. Haüy,[6] apatite was first synthesized by N. T. de Saussure by the action of gypsum on phosphoric acid, but it is questionable if apatite was here obtained. A. Daubrée, however, prepared microscopic crystals of chloro-apatite by passing the vapour of phosphorus trichloride over red-hot lime. N. S. Manross fused sodium or calcium phosphate with calcium chloride or fluoride, or a mixture of the two, and obtained prismatic crystals resembling natural apatite; and H. Briegleb, and R. Nacken used a slight modification of this process with success. G. Forchhammer prepared chloro-apatite by fusing a mixture of sodium chloride with calcium phosphate or bone-ash, or marl. A. Ditte also obtained prismatic crystals of fluoro-apatite by slowly cooling a molten mixture of calcium phosphate with three times its wt. of calcium fluoride and an excess of potassium chloride. If calcium chloride is used chloro-apatite is formed. According to A. Ditte, chloro-apatite is formed by fusing at 1000° a mixture of calcium phosphate with fifty times its weight of sodium chloride, the sodium phosphate simultaneously formed does not interfere with the result provided no more than 0·11 is present, but if more than this proportion is formed, plates of sodium calcium phosphate, $CaNaPO_4$, free from chloride are produced. H. St. C. Deville and H. Caron fused bone-ash with ammonium chloride, and either calcium fluoride or chloride. H. Debray heated calcium phosphate and calcium chloride with water under press. at 250°; E. Weinschenk similarly heated a mixture of ammonium and calcium chlorides and ammonium phosphate between 150° and 180° in a sealed tube. H. Debray also passed hydrogen chloride over red-hot calcium phosphate, and H. Rosenbusch explained the occurrence of apatite in some eruptive rocks by this reaction. F. K. Cameron and W. J. McCaughey prepared fluoro-apatite by dissolving calcium fluoride in fused disodium hydrophosphate and lixiviating the cooled melt; and chloro-apatite by adding an excess of calcium dihydrophosphate to molten calcium chloride. N. Sheldon, and F. Bainbridge found crystals of fluoro-apatite in fluoriferous Thomas slags.

A. Ditte stated that if the proportion $Ca_3(PO_4)_2 : CaCl_2$ be over 0·2 : 1·0, apatite alone is formed; if over 0·07 : 1·00, a mixture of apatite and *calcium-wagnerite,* $Ca_3(PO_4)_2.CaCl_2$, is formed, and if under 0·07 : 1·00, lime wagnerite is alone produced. A. Sjögren suggests that the mineral *spodiosite,* from Nordmark (Sweden), with a composition $mCa_3(PO_4)_2.nCaF_2$, where $m : n$ approximates 8 : 3, is isomorphous with wagnerite, but this is not in agreement with G. Nordenskjöld's measurements of the rhombic crystals which have the axial ratios $a : b : c = 0·8944 : 1 : 1·5836$. H. V. Tiberg's specimen had a composition corresponding with $Ca_3(PO_4)_2.CaF_2$, or $CaF.CaPO_4$, but there is usually also some evidence of some hydroxyl, and this makes the composition $CaPO_4.Ca(F, OH)$. F. K. Cameron and W. J. McCaughey prepared an artificial chlorospodiosite in rhombic plates.

R. Nacken studied the conditions under which fluoro- and chloro-apatites are obtained from a fused mixture of calcium phosphate with calcium chloride or fluoride. A mixture of calcium phosphate gives a fusion curve, Fig. 68, with a eutectic at about 1205° and about 65 per cent. of calcium fluoride. The data are:

CaF_2	100	90	81	72·8	56·6	40	24 per cent.
Cryst. begins . .	1392°	1356°	1316°	1270°	1255°	1395°	1524°
Eutectic cryst. .	—	1205°	1203°	1205°	1205°	1198°	1180°

There is a maximum melting at about 1650° (extrapolated), corresponding with the formation of fluoro-apatite, $3Ca_3(PO_4)_2.CaF_2$. The corresponding curve with calcium chloride, Fig. 69, shows that two compounds may be formed. The data are:

$CaCl_2$ . . .	97	95	93	92	88	82	70 per cent.
M.p. . . .	786°	861°	900°	958°	1040°	1160°	1280°
	$Ca_3(PO_4)_2.CaCl_2$					$3Ca_3(PO_4)_2.CaCl_2$	

Calcium-wagnerite has an incongruent m.p. at 1040°, and decomposes when heated into chloro-apatite. There is a eutectic at 770°. which is very close to 772°, the m.p. of calcium chloride. Fluoro- and chloro-apatites form a continuous series of mixed crystals.

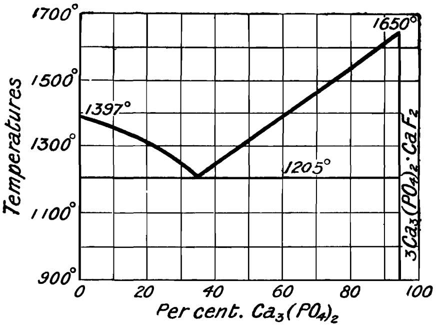


FIG. 68.—Fusion Curve of Mixtures of Calcium Phosphate and Fluoride.

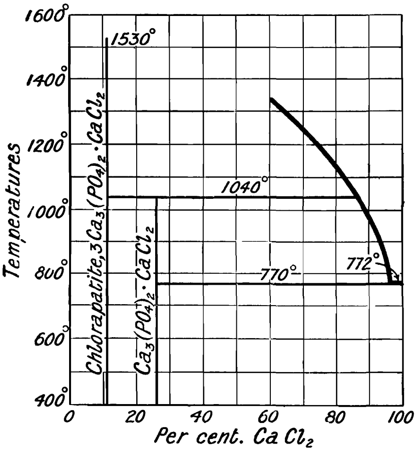

FIG 69.—Fusion Curve of Mixtures of Calcium Phosphate and Chloride.

Apatite forms hexagonal pyramidal **crystals**[7] with axial ratio $a:c=1:0·7346$. The crystals are isomorphous with pyromorphite, vanadinite, and mimetesite; and, according to A. F. Rogers, fluoro-apatite, $3Ca_3(PO_4)_2.CaF_2$, chloro-apatite, $3Ca_3(PO_4)_2.CaCl_2$, dahllite, $3Ca_3(PO_4)_2.CaCO_3$, and völckerite, $3Ca_3(PO_4)_2.CaO$, are isomorphous. F. Rinne and J. Lorenz found the **corrosion figures** corresponded with hexagonal-bipyramidal symmetry; H. Haga and F. M. Jaeger studied the **X-radiogram** of apatite. The reported values for the **specific gravity** of apatite range from G. Forchhammer's[8] 3·069 to S. L. Penfield's 3·39 for a sample from Branchville. H. St. C. Deville and H. Caron gave 3·14 for a sample of chloro-fluoroapatite, and C. Vrba, 3·09 for a sample from Pisek. J. A. Douglas found 3·197 for a sample from St. Gotthard, and for the glass, obtained by fusion and cooling, 2·972, this corresponding with an expansion of 7·57 per cent. K. A. Grönwall gave 3·194 for the sp. gr. of apatite from Nordmarken; and T. Dieckmann and E. Houdremont gave 3·18 for artificial apatite. A. Daubrée gave 2·95 for the sp. gr. of chloro-apatite which had been fused. P. Pusirewsky believed that the sp. gr. of apatite increases proportionally with the content of chloro-apatite. R. Nacken found 3·18 (25°) for the sp. gr. of artificial fluoro-apatite, and 3·17 (20°) for chloro-apatite. F. K. Cameron gave 3·010 for the sp. gr. of chloro-apatite, and for chloro-spodiosite, 3·041 (23°); G. Nördenskjöld gave for natural spodiosite, 2·94. The **hardness** of apatite on Mohs' scale is 5. F. Auerbach found 237 in his scale of absolute hardness; and T. A. Jaggar found with a scratching sclerometer a hardness of 1·23 when that of gypsum is 0·04; calcite, 0·26; fluorspar, 0·75; orthoclase, 25; quartz, 40; topaz, 152; and corundum, 1000. A. Rosiwal discussed the subject. G. Nördenskjöld's value for the hardness of spodiosite is 5. F. Auerbach's value for the **modulus of elasticity** is 13,800 kgrms. per sq. mm.

When heated in the blowpipe flame, apatite melts to a white enamel, without colouring the flame. R. Cusack [9] found the **melting point** of two samples to be respectively 1221° and 1227°; T. Dieckmann and E. Houdremont gave 1630°. C. Doelter found a sample from Renfrew (Canada) began to melt at 1270°, and was quite liquid at 1300°. A. Bran obtained a m.p. 1550°, and R. Nacken gave 1530° for the m.p. of chloro-apatite and 1650° for fluoro-apatite. F.p. curves of binary mixtures with calcium phosphate are shown in Figs. 68 and 69. J. Joly found the **specific heat** of a transparent green sample to be 0·1829, and of a red opaque sample, 0·1920. P. E. W. Oeberg found 0·1903 for a greyish-green sample from Gjerrestadt. F. M. Jäger found the ratio of the **thermal conductivity** in a direction parallel to the principal axis to that in a direction at right angles to this axis is 1·35 : 1. W. Voigt also made measurements of this constant.

Numerous observations of the **index of refraction** have been made.[10] K. Walter's limiting values for samples from Luxullian (Cornwall), and from Malmberget (Sweden); K. Zimanyi's values for samples from Pisek; K. Busz's values for a sample from Gletsch; and M. Seebach's value for a sample from Katzenbuckel (Odenwald), are given in Table XXII. The reported values for the Na-line range from 1·6330 to 1·6482 for μ_a; and from 1·6316 to 1·6431 for μ_γ. The lowest is for apatite from Luxullian, and the highest for apatite from Pisek. K. Walter found the index of refraction, double refraction, and dispersion of apatite increased with increasing proportions of chlorine, but was not able to find any definite relation between the chemical composition and refractive power of apatite. J. E. Wolff and C. Palache examined a number of natural apatites, and were unable to detect any definite relation between the double refraction and the proportion of contained chlorine. K. A. Grönwall obtained the refractive indices 1·638 and 1·635 for a sample of apatite from Woodmarken. R. Nacken found for artificial chloro-apatite, $\mu_a=1·6667 \pm 0·002$; and for fluoro-apatite, $\mu_a=1·6325 \pm 0·001$, and $\mu_\gamma=1·630$, or $\mu_a-\mu_\gamma=0·003$. F. K. Cameron and W. J. McCaughey gave 1·666 for the index of refraction of chloro-apatite with Na-light, and 1·635 for fluoro-apatite. There is a linear increase in the index of refraction with increasing proportions of chloro-apatite, thus, fluoro-apatites with 13, 45, and 74 per cent. of chloro-apatite have the respective indices of refraction 1·638, 1·649, and 1·658. K. Zimanyi

TABLE XXII.—INDEX OF REFRACTION AND DISPERSION OF APATITE.

Origin of apatite.	μ_a			μ_γ			$\mu_a-\mu_\gamma$		
	Li	Na	Tl	Li	Na	Tl	Li	Na	Tl
Luxullian	1·6301	1·6330	1·6352	1·6287	1·6316	1·6337	0·0014	0·0014	0·0015
	1·6389	1·6426	1·6450	1·6372	1·6409	1·6432	0·0017	0·0017	0·0018
Gletsch	1·6341	1·6356	1·6389	1·6319	1·6332	1·6356	0·0022	0·0024	0·0035
Malmberget	1·6328	1·6361	1·6395	1·6294	1·6325	1·6360	0·0034	0·0036	0·0035
	1·6349	1·6381	1·6415	1·6310	1·6343	1·6377	0·0039	0·0038	0·0038
Katzenbuckel	1·6345	1·6379	1·6410	1·3303	1·6336	1·6368	0·0042	0·0043	0·0042
Pisek	1·6445	1·6482	1·6516	1·6396	1·6431	1·6465	0·0049	0·0051	0·0050

found that yellowish-green apatite from Malmberget became colourless after heating to redness, and there was a small decrease in the index of refraction after the sample had been heated—the decrease was greater with the ordinary than with the extraordinary ray.

The coloured varieties of apatite exhibit **dichroism.** H. Rosenbusch,[11] and K. Zimanyi found that the extraordinary ray is more strongly absorbed than the ordinary ray even with colourless crystals. The latter found the ordinary and extraordinary rays to be respectively light yellow and bluish-green with pale green crystals; reddish-yellow and bluish-green with bright green crystals; brownish-yellow and yellowish-green with yellow and brown crystals; and yellowish-brown and dark green with dark yellow crystals. A. K. Coomaraswamy found blue crystals of apatite from Ceylon to have sky-blue and pale wine-red colours respectively parallel and perpendicular to the *c*-axis; and P. Termier found the red crystals from Guillestre (Hautes-Alpes) to be orange or red when viewed along the *a*-axis, and pale yellow or white when viewed along the *c*-axis. A. Karnojitzky found crystals of apatite from Ehrenfriedersdorf to exhibit anomalous **trichroism.** C. Doelter noted that crystals of apatite are optically anomalous H. Becquerel found the extraordinary ray **absorption spectrum** of a didymiferous apatite from Spain gave numerous lines —the most prominent corresponded with $\lambda=583$; with the ordinary ray absorption spectrum, the lines $\lambda=582$ and 575 are prominent.

The **colour** of native apatite may be white, green, blue, red, yellow, grey, or brown. The colour of the mineral changes when heated—thus, K. Zimanyi [12] found greenish-yellow crystals from Malmberget became water-clear after heating to redness; J. E. Wolff and C. Palache found the deep amethyst-coloured apatite from Minot became colourless when heated to about 320°; P. Gaubert obtained a similar result with blue apatite from Priziac; and C. Doelter found the violet apatite from Auburn became paler when heated in chlorine at 500°, and colourless if heated to the same temp. in oxygen. F. Pupke attributed the colouring matter to the presence of manganese. E. von Kraatz-Koschlau and L. Wöhler found up to 0·02 per cent. of carbon and 0·011 per cent. of hydrogen in coloured samples and attributed the coloration to the presence of organic matter; but it must be remembered that many minerals have liquid and gaseous inclusions, and colourless minerals, in consequence, may furnish carbon dioxide and water, hence, the organic nature of the pigment has not yet been established. C. Doelter also showed that many colourless minerals are also coloured by exposure to cathode and other rays. Thus, violet-blue apatite from Auburn becomes paler and more violet by exposure to radium; ultra-violet rays darken the colour, cathode rays were without action. Colourless apatite from Pinzgan was changed to violet after 42 days' exposure to radium; and pale yellow apatite from Sulzbachtal was not changed.

All varieties of apatite so far examined are luminescent. Eupyrochroite and many phosphorites exhibit **thermo-luminescence,** and when heated, glow with a coloured light. E. Newbery and H. Lupton found that a sample of Canadian apatite which has been decolorized by heat, and recoloured brown in two days' exposure to radium, emitted a strong violet thermo-luminescence many times stronger than the original unheated specimen. The brown colour disappeared rapidly in daylight. K. Keilhack [13] found that many apatites glow with a yellow light when exposed to **X-rays.** He found the relative intensity of the light from green apatite from Ehrenfriedersdorf to be 34; that from a red apatite from the same locality, 43; that from yellow apatite from Tyrol, 18, and from Jumilla, 14; a water-clear apatite from Sulzbachtal, 30; from a Norwegian apatite, 21; and from a Canadian apatite, 20. A. Pochettino found no luminescence with X-rays, and with **radium rays** he found a feeble yellowish-green luminescence the light of which was feebly polarized. C. Doelter found that the violet apatite from Auburn luminesced with a greenish-yellow light when exposed to the **cathode rays,** and pale yellow apatite from Sulzbachtal give a yellowish-green luminescence. L. Sohncke, and G. C. Schmidt have studied the yellowish-green **fluorescence** of apatite. The former inferred that the fluorescing particles oscillate vertically to the chief axis, and in this plane, the fluorescence is equally strong in all directions.

According to W. G. Hankel,[14] the crystals of apatite are **thermo-electric.** With most crystals, on cooling, the basal face is positively and the prism face is negatively charged—*e.g.* specimens from Tokawaia, Ehrenfriedersdorf, St. Gotthard, etc.; but more rarely the opposite effect is obtained—*e.g.* specimens from Ehrenfriedersdorf and St. Gotthard. The **dielectric constant** of apatite was found by W. Schmidt to be 7·40 parallel to and 9·50 vertical to the crystal axis, for $\lambda=75$. J. Königsberger found the **magnetic susceptibility** of apatite from Zillertal to be $-1·23\times10^{-6}$. W. Voigt and S. Kinoshuto found no measurable difference in the diamagnetism when measured in directions parallel or vertical to the chief axis. W. Voigt found apatite to exhibit **pyromagnetism,** and also **piezomagnetism**; and the **magnetic moment** to be $0·6\times10^{-6}$ C.G.S. units.

According to H. Rose,[15] boiling *water* extracts a little calcium chloride from apatite, but no phosphoric acid is removed. According to G. Bischof and J. L. Lassaigne, apatite is soluble to a small extent in water sat. with *carbon dioxide.* A litre of water, sat. with carbon dioxide at ordinary temp. and press., dissolves 0·00254 part of apatite; and, after strongly shaking, 0·01034 part; 0·9074 part of artificially prepared undried apatite—and 0·184 part if previously dried, and 0·0321 part if previously dried and calcined. According to F. K. Cameron and J. M. Bell, water dissolved 0·002 grm. of fluoro-apatite per litre, while water sat. with carbon dioxide dissolved 0·014 grm. per litre. R. Müller also examined the action of a soln. of carbon dioxide under a press. of $3\frac{1}{2}$ atm., and after 50 days' treatment he found $1·417P_2O_5$ and 1·696CaO per litre was extracted from moroxite of Hammond, $1·822P_2O_5$ and 2·168CaO from apatite of Katharinenberg; $2·12P_2O_5$ and 1·946CaO from apatite from Chili. The glass was not attacked. Dil. mineral acids—*hydrochloric acid, nitric acid,* and *sulphuric acid*—slowly dissolve apatite in the cold, more rapidly when heated. According to A. Ditte, sulphuric acid in the cold liberates some hydrogen fluoride. T. Petersen found acetic acid dissolves apatite less readily, and A. F. Rogers found that if the mineral contains carbonate, this is dissolved first. T. Dieckmann and E. Houdremont gave 10 per cent. for the solubility of apatite in *citric acid.* H. Baumhauer has studied the *corrosion figures* of apatite.

P. W. Forchhammer[16] found apatite to be readily soluble in molten *sodium chloride,* and on cooling the apatite separates in long needles. P. A. Wagner used molten sodium chloride to separate apatite from kimberlite. B. Vukits melted one part of apatite with 18 parts of *labradorite,* and found apatite crystallizes first, and a little lime felspar (anorthite) is formed; with 9 parts of labradorite, the reaction is greater and anorthite first separates. It is therefore inferred that the apatite forms a complex ion, $[3Ca_3(PO_4)_2.Ca]^{\cdot\cdot}$. With 5 parts of labradorite a calcareous plagioclase is formed. The m.p. of mixtures of one part of apatite with 5, 9, and 18 parts of labradorite are respectively 1210°–1220°, 1220°–1240°, and 1225°–1235°, when apatite melts at 1300° and labradorite at 1210°. Apatite dissolves in fused *microcosmic salt* to a clear glass which freezes to a white enamel. Fused *borax* behaves similarly, and if lead oxide is also present, W. Florence obtained crystals of sodium phosphate. According to C. F. Plattner, fused *sodium carbonate* dissolves and decomposes apatite.

A. Ditte prepared **barium fluorophosphate,** $3Ba_3(PO_4)_2.BaF_2$, or *barium fluoro-apatite,* by a process analogous to that for the corresponding calcium com pound, and C. von Woyczinsky[17] mixed 5·88 grms. of orthophosphoric acid with 26·24 grms. of barium nitrate dissolved in water acidified with nitric acid, and mixed with soln., in a platinum dish, with 0·7 grm. of 57 per cent. hydrofluoric acid. When neutralized with ammonia, a granular precipitate is formed which when recrystallized furnishes crystals resembling apatite. A. Ditte, and C. von Woyczinsky prepared **strontium fluorophosphate,** $3Sr_3(PO_4)_2.SrF_2$, or *strontium fluoro-apatite,* in similar ways. The properties of these compounds resemble those of calcium apatite. H. St. C. Deville and H. Caron prepared hexagonal prisms of **barium chlorophosphate,** $3Ba_3(PO_4)_2.BaCl_2$, *barium chloro-apatite*, by melting barium orthophosphate with an excess of barium chloride. The corresponding **strontium chlorophosphate,** $3Sr_3(PO_4)_2.SrCl_2$, *strontium chloro-apatite*, was obtained in a similar manner.

H. St. C. Deville and H. Caron.[18] prepared *calcium wagnerite*, $Ca_3(PO_4)_2.CaCl_2$, by melting bone-ash with an excess of calcium chloride; A. Ditte prepared it by melting calcium phosphate and chloride. The conditions under which it is formed have been previously indicated, Fig. 69. The monoclinic crystals have a sp. gr. 3·05. According to A. Ditte, when melted with sodium chloride, it is decomposed with the formation of apatite, and mixtures of calcium and sodium chlorides containing over 30 per cent. of the latter behave similarly.

E. Erlenmeyer [19] has prepared a series of hydrated **calcium chloro-dihydrophosphates.** The product, $7Ca(H_2PO_4)_2.CaCl_2.14H_2O$, crystallizes in rhombohedral plates during the spontaneous evaporation of a cold sat. soln. of normal calcium phosphate in hydrochloric acid; if the mother liquid be treated with half as much hydrochloric acid as is already present, and evaporated until crystals separate on cooling to 0°, a crop of crystals, $4Ca(H_2PO_4)_2.CaCl_2.8H_2O$, appear—the filtrate furnishes crystals of $7Ca(H_2PO_4)_2.CaCl_2.14H_2O$. If the mother liquors from the preceding operations be evaporated on the water-bath, crystals of calcium hydrophosphate are first obtained, and then a crop of white talc-like plates of $Ca(H_2PO_4)_2.CaCl_2.2H_2O$ separate out. These crystals are only partially soluble in water with some decomposition. If the last-named crystallization occurs at a temp. below 6°, long needles of $Ca(H_2PO_4)_2.CaCl_2.8H_2O$ appear. E. Erlenmeyer also crystallized **barium chloro-dihydrophosphate,** $4Ba(H_2PO_4)_2.BaCl_2$, from a soln. of normal barium phosphate in hydrochloric acid. R. Ludwig added ammonia to a soln. of barium hydrophosphate in hydrochloric acid (with or without the addition of barium chloride), and obtained a precipitate of variable composition; so too H. Rose extracted the soluble matter from the product obtained by calcining a mixture of phosphorus pentoxide with barium chloride, here again the residue has a variable composition.

F. Wibel [20] prepared what he regarded as a basic phosphate by heating to redness a mixture of calcium carbonate and normal calcium phosphate. The precipitates formed by adding a soln. of sodium phosphate to a hot soln. of calcium chloride were found by F. Wibel to contain some calcium chloride—*e.g.* $4Ca_3(PO_4)_2.CaCl_2$. According to R. Warington, if freshly precipitated normal calcium phosphate be allowed to stand in contact with water for ten to twelve hours, a soln. with an acid reaction is obtained, and the undissolved residue contains an excess of calcium hydroxide which corresponds approximately with $Ca_3(PO_4)_2.Ca(OH)_2$. C. Blarez also found that if a conc. soln. of lime-water be shaken with dil. phosphoric acid, a precipitate is obtained which contains $CaO : P_2O_5$ in the ratio 3·67 : 1, and when washed until the runnings are neutral 3·3 : 1. The mineral *isoclase* was found by F. Sandberger to approximate in composition to $Ca_3(PO_4)_2.Ca(OH)_2.4H_2O$. or tetrahydrated **calcium hydroxyphosphate.** The formula can also be represented $4CaO.P_2O_5.5H_2O$, or, with P. Groth, $CaPO_4(CaOH).2H_2O$. The colourless crystals were considered by F. Sandberger to belong to the monoclinic system; to have the hardness $1\frac{1}{2}$ and sp. gr. 2·92. The water is readily evolved when isoclase is heated, and the crystals melt when heated before the blowpipe. The mineral is readily soluble in nitric or hydrochloric acid.

C. von Woyczinsky prepared plates, belonging to the cubic system, of **strontium hydroxyphosphate,** $Sr_3(PO_4)_2.Sr(OH)_2$, by melting in a silver crucible, protected as far as possible from air, a mixture of 15 grms. of strontium hydroxide, 7 grms. of sodium hydroxide, and 6 grms. of sodium hydrophosphate. The cold mass was extracted with water. He prepared **barium hydroxyphosphate,** $Ba_3(PO_4)_2.Ba(OH)_2$, in a similar manner. C. Blarez also obtained basic phosphates by shaking a dil. soln. of phosphoric acid with a conc. soln. of strontium or barium hydroxide, and washing the precipitate until the runnings were neutral.

Four kinds of crystals have been reported in basic slag: (i) brown plates; (ii) blue rhombohedra; (iii) brown needles; and (iv) blue or green pyramids. A. Carnot and A. Richard obtained blue rhombic crystals of the composition $Ca_3(PO_4)_2.Ca_2SiO_4$ from Thomas slag; V. A. Kroll called the substance *carnotite*, a name likely to lead to confusion with the vanadium ore. J. E. Stead and

C. H. Ridsdale, and H. Bücking and G. Linck isolated monoclinic, pseudo-rhombic colourless or brown plates of anhydrous **calcium oxyorthophosphate**, $Ca_4P_2O_9$, *i.e.* $Ca_3(PO_4)_2.CaO$, also called *tetracalcium phosphate;* V. A. Kroll called it *hilgenstockite*, after its discoverer. According to P. Termier and A. Richard, this compound has axial ratios, $a:b:c=0·5773:1:1·255$ and $\beta=90°$. The sp. gr. is 2·9 to 3·1—H. Bücking and G. Linck gave 3·06; the hardness is about $3\frac{1}{2}$; the m.p. 1870° (H. Blome); and the index of refraction 1·6. The brown plates are feebly pleochroïc; the short prismatic crystals are also pleochroïc, with different shades of blue. G. Hilgenstock prepared hexagonal colourless needles of calcium oxyphosphate by melting together the calculated quantities of lime and normal calcium phosphate, or calcium hydrophosphate, or phosphoric oxide, with fluorspar as a flux. H. Bücking and G. Linck believe that the hexagonal and monoclinic forms are really silicophosphates or phosphatosilicates—*vide supra*, Fig. 65: and their analyses of the uniaxial hexagonal clear or brownish crystals correspond with $4Ca_3(PO_4)_2.Ca_3SiO_5$—V. A. Kroll calls the black crystals *steadite* and represents the composition by the formula $3Ca_3(PO_4)_2.Ca_2SiO_4.2CaO$—and the blue pleochroïc monoclinic crystals, $4Ca_3(PO_4)_2.3Ca_3SiO_5$. J. Ortlieb found brown grains of a mineral species, $4CaO.2P_2O_5.SiO_2$, in the chalk of Ciply (Belgium), and he called it *ciplyte.* J. E. Stead and C. H. Ridsdale also found 1·64 per cent. of vanadium in the blue crystals. H. B. Kosmann believes the constitution of the crystals to be $O\{CaO.PO(O_2Ca)\}_2$; and P. Groth regards them as representing the normal salt of an acid, $H_8P_2O_9$, *i.e.* $(OH)_4P.O.P(OH)_4$. J. E. Stead and C. H. Ridsdale also found in basic slag some feathery crystals with 95 per cent. of base; and two kinds of black needle-like crystals containing calcium oxide, alumina, and ferric oxide. V. A. Kroll described crystals of $6CaO.P_2O_5.Fe_2SiO_4$, which he called *thomasite*, since they were found in Thomas slag. According to D. N. McArthur and A. Scott, there are at least four well-defined silicophosphates in basic slags: (i) J. E. Stead and C. H. Ridsdale's brown crystals with the ratio $SiO_2:P_2O_5=1:4$; (ii) J. E. Stead and C. H. Ridsdale's pleochroïc crystals with the ratio 1 : 1; (iii) V. A. Kroll's octobasic compound with the ratio 1 : 1; and (iv) one which they themselves describe with the ratio 3 : 1. V. A. Kroll, and E. Steinweg found that the slow cooling of the slags favoured the formation of silicophosphates. The nature of basic slags has been discussed by E. Jensch. A. Frank, H. von Jüptner, etc.

A. von Groddeck and K. Broockmann found crystals analogous with $Ca_4P_2O_9$. H. Blome found the crystals of $Ca_4P_2O_9$, or $CaO.Ca_3(PO_4)_2$, to have a m.p. of 1870°. H. Otto stated that the compound is readily soluble in dil. acetic, hydrochloric, or nitric acid; and is decomposed by dil. sulphuric or citric acid. According to R. Hartleb, calcium oxyorthophosphate, $4CaO.P_2O_5$, *i.e.* $Ca_3(PO_4)_2.CaO$, rarely occurs in basic slag, and that even without this, the slag may be very soluble in a soln. of citric acid. Calcium oxyorthophosphate is almost insoluble in a soln. of citric acid, while normal calcium phosphate is completely soluble. E. Dittler has further investigated this subject. Ammonium citrate extracts all the phosphoric acid; and 100 c.c. of water sat. with carbon dioxide dissolves 0·02 grm. According to O. Förster, when calcium oxyorthophosphate is treated with water, it passes first into calcium hydrophosphate, $CaHPO_4$, and calcium hydroxide; and it then forms a compound, $Ca_3(PO_4)_2.Ca(OH)_2$, from which calcium hydroxide extracts no calcium hydroxide, and it is hence supposed to be a true compound and not a mechanical mixture. The compound is soluble in citric acid, but the product obtained by heating calcium oxide and phosphate is not soluble in that menstruum. A soln. of the crystals in very dil. nitric acid gives a precipitate of silver phosphate, Ag_3PO_4, when treated with silver nitrate.

H. Bassett found no evidence of the existence of tetracalcium salt, $Ca_4P_2O_9$, in his study of the ternary system $CaO—P_2O_5—H_2O$; but he obtained what he regarded as *hydroxyapatite*, $3Ca_3(PO_4)_2.Ca(OH)_2$—**calcium hydroxyhexaphosphate.** The region of stability of this compound is fairly extensive, and reaches very nearly to the point representing the solubility of calcium hydroxide; the solubility curve extends from markedly acid, through neutral, to markedly alkaline soln. Of all the calcium phosphates this is the only one not decomposed by water; it can dissolve unchanged in water, but the sat. soln. is extremely dil. The isotherm at 25° is shown in Fig. 70. R. Warington showed that by repeatedly extracting normal calcium phosphate with boiling water, a product is finally obtained with analyses corresponding closely with hydroxyapatite, and K. Buch's experiments on the action of water on calcium hydrophosphate point in the same direction. There is also the Norwegian mineral *võlckerite* with a composition approximating $3Ca_3(PO_4)_2.CaO$, or *oxyapatite*, which A. F. Rogers believes to be isomorphous with apatite. O. Förster obtained this substance as a residue when basic slag is treated with citric acid. T. Dieckmann and E. Houdremont prepared oxyapatite, or **calcium oxyhexaphosphate,** $3Ca_3(PO_4)_2.CaO$, of sp. gr. 2·99; m.p., 1540°; and percentage solubility in citric acid, 67.

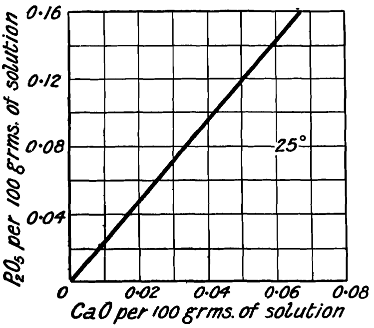

FIG. 70.—Isothermal Solubility Curve for Basic Calcium Phosphate.

The salt $3Ca_3(PO_4)_2.CaO$ is usually regarded as a basic salt in that it contains more base than corresponds with the normal salt. H. Bassett suggests that hydroxy- or oxy-apatite, and possibly normal calcium phosphate, are related to calcium hydro- and dihydro-phosphate, much as an orthophosphate is related to a pyrophosphate, so that hydroxyapatite is the salt of an acid, $H_{11}P_3O_{13}$, in which one acidic hydrogen atom is not neutralized. The great difficulty involved in the expulsion of the water is taken to indicate that it is directly associated with the acid rather than with the base. The halogen of fluoro- or chloro-apatite is then regarded as being directly attached to the phosphorus. The compound $CaO.2POCl_3$ is regarded as a chloro-derivative of calcium dihydrophosphate, **calcium hexahydroxy phosphate,** $CaO.2(OH)_3.P:O$, *i.e.* of $Ca(H_2PO_4)_2.H_2O$. If hydroxyapatite has the formula $3Ca_3(PO_4)_2.Ca(OH)_2.H_2O$, the corresponding acid is $H_{24}P_6O_{27}$, *i.e.* $3H_3P_2O_9$, an acid which has the greatest range of existence of all the phosphoric acids.

The liquid from which bone is deposited in animal tissues is very nearly neutral; and, although complicated by the presence of additional salts, the conditions are probably similar, so far as calcium salts are concerned, to those of the simpler ternary system, $CaO—P_2O_5—H_2O$. Hydroxyapatite is the stable phase in soln. with the degree of acidity characteristic of animal tissues. S. Gabriel[21] has analyzed *bone phosphate* prepared by digesting dry powdered bone with a glycerol soln. of potassium hydroxide at 180°–200°, and obtained the results indicated in Table XXIII.

The alkali in the analyses was not derived from the glycerol soln. The product was a white powder showing the structure of the original bone, and almost free from organic matter. When this product is heated over a small flame in a platinum crucible, carbon dioxide begins to be evolved before the bottom of the crucible is red hot, and he therefore believes that the carbon dioxide is not present as calcium or magnesium carbonate, but rather as a phosphato-carbonate or carbonato-phosphate. H. Bassett has recalculated the data in Table XXIII, and shown that the most probable conclusion is that the mineral constituents of bone consist in the main of hydroxyapatite, $(Ca_3P_2O_8)_3Ca(OH)_2$, mixed with a certain amount of calcium carbonate. In addition to these chief constituents, there are also small amounts of the bicarbonates of magnesium, sodium, and potassium, which appear to be merely adsorbed by the aggregate of phosphate and carbon. The small amount of chloride also present is probably also adsorbed in the form of sodium chloride, although it may be present as chloroapatite. Several other investigators—J. H. Aeby, W. Heintz, R. Müller, E. Erlenmeyer, etc.—have suggested that the inorganic base of bones is a basic calcium phosphate. W. Heintz also suggested that teeth contain a basic calcium phosphate. J. H. Aeby also found the composition of bone phosphate to be $6Ca_3(PO_4)_2.Ca(OH)_2.CaCO_3.4H_2O$, or $3Ca_3(PO_4)_2.Ca(OH)_2.2H_2O$, although F. Wibel held that the composition of bone phosphate is not constant. H. Bassett also added that similar remarks apply to *soil phosphates*. He said:

> The range of acidity or alkalinity in most ordinary soils comes well within the range over which hydroxyapatite is the stable calcium phosphate, and it seems certain that it is the only such phosphate that can exist permanently in the soil. Any other phosphate added to it will be converted into hydroxyapatite with greater or less readiness according to circumstances. It has long been recognized that calcium hydrophosphate added to the soil in superphosphate very quickly ceases to be present as such, although it is generally stated to revert to normal calcium phosphate. By adding the phosphate in the form of superphosphate, the hydroxyapatite is obtained in a finely divided state, which is important owing to its sparing solubility. Finely ground basic slag when added to the soil will also be converted fairly quickly into hydroxyapatite, whether it contains tetracalcium phosphate, or some other compound possibly more closely related to hydroxyapatite. It is highly probable that the earthy phosphorites and coprolites are impure mixtures of hydroxyapatite and calcium carbonate, and it is known that when extremely finely ground they give satisfactory results when used directly as fertilizers. Under the conditions which have led to the accumulation of phosphatic deposits, a certain amount of replacement of the hydroxyl of hydroxyapatite by chlorine or fluorine has occurred, owing no doubt to the action of saline soln.

§ 31. Some Relations between Calcium, Strontium, and Barium

The elements of the alkaline earths—calcium, strontium, and barium—exhibit a close kinship and display a gradation in their properties from member to member as the atomic weight increases in passing from calcium to barium. The elements become more active chemically as their atomic weight increases; the sp. gr. of the elements and compounds increase; the basic properties and solubilities of the hydroxides increase; and the solubilities of the halides, nitrates, sulphates, and chromates decrease. The physical properties of the elements are indicated in Table XXIV.

TABLE XXIV.—PHYSICAL PROPERTIES OF THE ALKALINE EARTH METALS.

—	Calcium.	Strontium.	Barium.
At. wt.	40·09	87·63	137·37
Sp. gr.	1·52	2·55	3·75
At. vol.	26·4	35·15	36·6
M.p.	780°	800°	850°
Sp. ht.	0·152	—	0·068
Flame coloration	Brick-red	Crimson	Green
Heat of formation of monoxide R″O Cals.	131·3	130·98	130·38

The metals are fairly stable in air; they quickly tarnish in ordinary air; and when heated, they burn to the monoxide; they are all bivalent; they combine with water with the evolution of hydrogen at ordinary temperatures; and form soluble oxides of the type $R''O$, hydroxides of the type $R''(OH)_2$, and peroxides of the type $R''O_2$. The salts are discussed under "Chlorides," "Sulphates," "Nitrates," "Sulphides," etc. The normal carbonates are but sparingly soluble in water; the unstable acid carbonates are more soluble. The low solubility of the carbonates, chromates, and sulphates is utilized in analytical work. All three carbonates are precipitated when ammonium carbonate is added to solutions of their salts. Radium, in this family of elements, will be discussed later.
