PREFACE

I HAVE been very pleased with the general reception which the first two volumes have received. The present volume includes copper, silver, gold, and the alkaline earths. The radium and actinium families will appear at the beginning of Volume IV. The history of the atomic theory in the first volume carried the evolution of the atom concept up to, and prepared the way for, the introduction of the developments which followed the interest awakened by the discovery of the X-rays and radioactivity. This subject is also included in the chapters associated with radium.

temp. = temperature(s)
vap. = vapour

The use of **triangular diagrams** for representing the properties of three-component systems was suggested by G. C. Stokes (*Proc. Roy. Soc.*, **49**. 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances *A*, *B*, and *C*, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the triangle represent the single components *A*, *B*, and *C*, the sides of the triangle represent binary mixtures of *A* and *B*, *B* and *C*, or *C* and *A*; and points within the triangle ternary mixture The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure *A* will be represented by a point at the apex marked *A*. If 100 be the

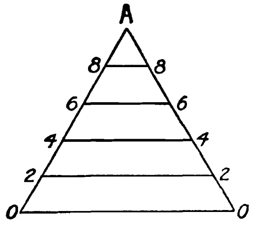

Fig. 1.

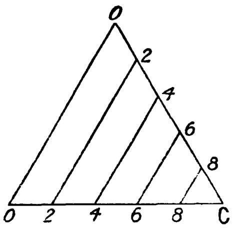

Fig. 2.

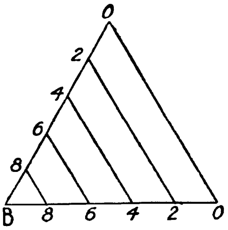

Fig. 3.

standard of reference, the point *A* represents 100 per cent. of *A* and nothing else; mixtures containing 80 per cent. of *A* are represented by a point on the line 88, 60 per cent. of *A* by a point on the line 66, etc. Similarly with *B* and *C*—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig. 4 results. Any point in this

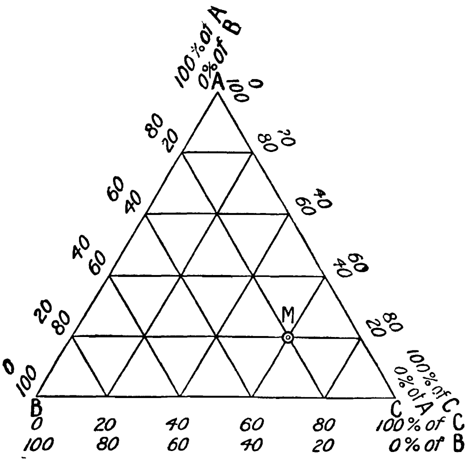

Fig. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point *M* represents a mixture containing 20 per cent. of *A*, 20 per cent. of *B*, and 60 per cent. of *C*.

CHAPTER XXI

COPPER

§ 1. The History of Copper

COPPER was one of the earliest metals discovered by man, and this long before the histories of ancient peoples were inscribed on papyri, or engraved on stone pillars ; Genesis (**4**. 22) states that Tubal-cain—3870 B.C.—was an artificer in brass, although there is some uncertainty whether the original term means copper or bronze. The translators of the Bible did not understand the distinction these terms bear in metallurgy, and they were used synonymously—the translations " brass is molten out of stone " (*Job*, **28**. 2) and " out of the hills thou mayest dig brass " (*Deut.*, **8**. 9), obviously refer to the metal or ore of copper, and not to brass. There is, indeed, nothing to show that what is now understood as brass was known in scriptural times, for zinc, an essential constituent of that alloy, was discovered at a much later period. Bronze, the copper-tin alloy, was known. A button, bead, and piece of wire, all made of copper, are reputed to have been found in the tomb of one of the earlier kings of Egypt—4400 B.C. Excavations among the remains of the ancient Phœnician, Babylonian, Assyrian, and Egyptian civilizations have furnished a multitude of copper and bronze relics—the latter usually containing from 10 to 14 per cent. of tin. The ancient bronze ornaments contain various proportions of copper and tin, and a few show the presence of lead, or of lead and iron. Bronze objects dating back to 3000 B.C. are known.[1] The numbers indicated in Table I represent analyses of some old bronzes :

TABLE I.—ANALYSES OF ANCIENT BRONZES.

Bronze.	Date.	Copper	Tin.	Lead.	Iron.	Arsenic.	Antimony.	Cobalt or Nickel.
Nineveh cup . .	1000 B.C.	80·84	18·37	0·43	0·16	—	—	1·22
Greek vase . .	330 B.C.	81·76	10·07	5·25	0·15	—	—	—
Statuette of Osiris .	300 B.C.	76·83	11·33	11·70	tr	0·11	0·13	—
Assyrian figure .	(?)	85·07	5·33	8·48	0·75	—	—	—

A rod found at Mêdûm in Egypt is claimed to be the earliest specimen of bronze, and it is reputed to date from 3700 B.C. It contains 9·1 per cent. of tin, 89·8 per cent. of copper, and a little arsenic. According to M. Berthelot,[2] some of the old Egyptian relics formerly thought to be bronze, are made of copper, and in Mesopotamia, about 4000 B.C., virtually pure copper was worked, and statuettes dating from about 2600 B.C., consisting of copper or of copper with small amounts of tin, have been found—*e.g.* the bronze statuette of Gude. Analyses of certain relics of the Mycenæan age—that is, the period described in the poems of Hesiod and Homer, perhaps 1000 B.C.—show that they consisted largely of copper unalloyed with tin,[3] as illustrated in Table II. It is stated in the *Iliad*, that Achilles' shield was made of tin, gold, silver, and *chalcos*, which latter may have been copper, but more probably bronze. We are also told that at the Battle of Marathon, 490 B.C., the Persians were armed with bronze swords and spears, and the Greek victors are said to have been more pleased with these captured implements of war than they were with any of their other prizes. According to J. G. Wilkinson, the early bronze tools found in the *débris* of the ancient peoples, show that the bronze they employed was superior for the manufacture of cutting tools, to the bronze produced at the present day.

TABLE II.—ANALYSES OF SO-CALLED ANCIENT BRONZES.

Copper.	Date.	Copper.	Tin.	Lead.	Iron.	Bismuth.	Arsenic.	Cobalt and Nickel.
Egyptian dagger .	4500 B.C.	99·53	nil	tr	0·08	nil	—	nil

Nails (Mycenæan) .	1000 B.C.	99·53	—	0·27	0·20	—	—	—

It has been said that the Chinese book, *Shoo-King*, about 2500 B.C., mentions copper, and later records show that the kings Yu and Chun, who reigned about 2200 B.C., caused nine bronze vases to be cast, and maps of the nine provinces of the Empire to be engraved upon them. However, but little is known of archæological exploration in China because the examination of ancient burial sites is prohibited by the Government, and opposed by the people. M. Chikashigé has analyzed some ancient Chinese and Korean bronze objects, coins, etc. He said that brass articles are not so antique as bronze, and that the former date from the beginning of the Sung dynasty, about the tenth century.

The Sanscrit word *ayas*, the Latin *aes*, the Gothic *aiz*, the German *erz*, and the English *ore*, are all of Aryan origin, and have been taken to show that the Aryans were acquainted with either copper or bronze. The terms were afterwards used to denote copper, brass, or bronze.[4] Even so late as Pliny (*c.* 75 A.D.), these three substances were confused by the one term. From philological and archæological reasons, it is probable that the primitive Aryans had not reached the Iron Age; and there is no Aryan word for tin, an essential constituent of bronze, for the Greek κασσίτερος is said to be derived from the Assyrian *kasazitirra*, which in turn comes from the Accadian *id-kasdura*. Consequently, it is thought that *ayas*, *aes*, or *aiz* is primitive, and originally meant copper. The Greeks, who were among the most advanced of the Aryan nations, seem to have been ignorant of copper when visited by the early Phœnician traders. The Greek term χαλκός for copper or bronze is not of Aryan origin. Just as the Latin *aes cuprium*—the origin of the term cuprium or copper—is derived from the name of Cyprus, having been originally *aes cyprium* (that is, Cyprian copper or bronze), so the Greek χαλκός may be derived from the name of the town Chalcis in Eubœa. In confirmation of the suggestion of the philologists, that a Copper Age preceded that of bronze, some of the oldest relics (celts, etc.) now collected in various museums are of copper, not bronze.[5] These celts are usually chisel-shaped like the celts of the Stone Age. Archæological discoveries in India, Austria, Hungary, France, Italy, and Spain have shown that a Copper Age, about 4000 B.C., came intermediate between the Stone and Bronze Ages. In Britain, however, this is not the case, because the evidence shows that bronze was the first metal known in this island, and that it was introduced by traders from Gaul. In America, too, utensils have been discovered in ancient mounds showing that a prehistoric race prior to the Indians must have been acquainted with copper.[6] A. Helps says that at the time of the Spanish conquest of Peru, copper was considered to be far more valuable than gold or silver. E. Nordenskiöld [7] has discussed the Copper and Bronze Ages in South America; and J. E. Reynolds in North America. According to W. Gowland,[8] there is no evidence of a Copper Age in Japan, but in the early centuries of our era, the Japanese had acquired a skill in the preparation and working of copper far in advance of that attained by any race until many centuries after the beginning of the Iron Age, or even in Roman times.

According to Diodorus (*c.* 30 B.C.), the Nubian and Ethiopian mines kept Egypt so plentifully supplied with copper at the time of the Pharaohs that this metal or bronze was used in making domestic furniture, chariots, swords, arrow tips, etc. According to M. Berthelot,[9] the oldest known copper mine associated with the smelting of copper occurs in the Sinai Peninsula,[10] and workings there have been traced back to 4300 B.C. The remains of a copper foundry dating back to 1300 B.C. have been found at *Tel-el-Sifr* (South Chaldea). The island of Cyprus seems to have produced copper from about 3000 B.C., and its copper mines passed successively under the dominion of the Egyptians, Assyrians, Phœnicians, Greeks, Persians, and the Romans.

The bronze objects found in Cyprus have from 2 to 4 per cent. of tin, but no tin has been found on the island. W. Gowland [11] believes that the early bronze was obtained by smelting stanniferous copper ores, and although this might possibly have been the case in Western Europe, the absence of tin in the copper mines of Asia Minor, Egypt, and India, does not support this view, but rather indicates that the ancient bronzes were made from tin and copper mined or smelted independently. The remains of Roman mines in Egypt, Cyprus, Central Europe, the Spanish Peninsula, and Britain show evidence of the roasting and smelting of sulphide ores. A comparison of C. N. Otin's analyses of various prehistoric articles of copper, and of copper-tin from Rumania, with analyses of various Roman vessels, showed that the Rumanian articles were made from local ores, and that they could smelt copper almost as well as the Romans. In Germany, copper mining began at Rammelsberg (Harz) about 968 A.D., and at Hettstedt in the Mansfeld district (Harz) about 1199. Although the Romans obtained copper from Anglesey during their occupation of Britain, very little copper was mined in England in the Middle Ages. In 1694, copper was imported from Sweden for British coinage, since the Cornish copper was considered of little value. In 1564, Queen Elizabeth granted mining concessions to T. Thurland and D. Hochstetter, who formed companies for mining copper, and German miners worked at Coniston (near Keswick), St. Just (Cornwall), Neath (Wales), Ecton (Staffordshire), and elsewhere. The dates [12] of the opening of smelteries in Wales are Neath (1584), Melincrethyn (1695), Tailbach (1727), Swansea (1717), Penclawdd (1800), Llanelly (1805), Loaghor (1809), Hafod (1810), Cwmavan (1837), and Pembrey (1846). Copper was mined in Connecticut in America in 1709, and later in New Jersey, Pennsylvania, Montana, California, etc. Native copper was discovered in Lake Superior about 1840, but copper mining was not established there until about 1850.

The remains of primitive smelting furnaces show that the copper ore was probably placed on charcoal in shallow pits in the ground, and rude copper cakes 8 to 10 inches in diameter were obtained during the cooling of the metal at the bottom of the pit. Egyptian pictures also show furnaces worked (with forced draught) first by blowpipe (perhaps about 2000 B.C.), and later by bellows (about 1500 B.C.). There are references to copper in Plato's *Timæus* (*c.* 360 B.C.), in Aristotle's *Generation and Corruption* (*c.* 350 B.C.), in the spurious work *On Marvels*, and in numerous other early writings. In the third century B.C., Theophrastus, in his Περὶ Πυρός (*c.* 315 B.C.), first described green and blue copper minerals; and in his *De materia medica* (*c.* 75 A.D.), Dioscorides used the Latinized Greek terms *chalcitis*, *misy*, *sory*, and *melanteria*—*chalcitis* appears to have referred to a partially weathered copper pyrite; and *melanteria* to copper sulphate; while *sory* was a blackish stone impregnated with both copper and iron sulphates; and *misy* appears to have been a yellow earth likewise impregnated with the sulphate. Pliny, in his *Historia naturalis* (*c.* 77 A.D.), gave the same list as Dioscorides, but he seems to have been somewhat confused between chrysocolla and chalcitis. Dioscorides also described a furnace for the smelting of copper.

In the latter half of the eleventh century, Rugerus or Theophilus [13] gave a description of copper smelting and refining:

> The ore employed is of a green colour and mixed with lead. A pile of ore is burned after the manner of lime, whereby the colour is not changed, but the stone loses its hardness

> whereby it can be broken up. Coals are placed in the furnace, then the bruised and roasted ore, again coal, and ore anew until the furnace is charged. The bellows are then applied, and when the stone has commenced to liquefy, the lead flows out through some small cavities, and the copper remains within. When this has been blown on for a very long time, and cooled, it is taken out; and another charge is again placed in the furnace after the same order.

Theophilus also described the construction of the furnace. In 1540, V. Biringuccio outlined the process of roasting, smelting, and pole-refining employed in Saxony; and fourteen years later, G. Agricola gave a description of various copper ores, and of the roasting, smelting, liquation, and refining of copper, which showed clearly the methods employed in the sixteenth century.

The alchemists of the Middle Ages symbolized copper by the looking-glass of Venus—*vide* **1**. 1, 1 and 8. The deposition of copper which occurs when a piece of iron is immersed in a soln. of copper salt was cited by Paracelsus, in his tract *De tinctura physicorum* (*c.* 1520), as a proof of the transmutation of iron into copper, and G. W. Wedel (1715) and J. A. Stiller (1685) seem to have held similar views, although J. B. van Helmont (*c.* 1640) rightly surmised that the copper already existed in the soln., for he stated that when a metal is dissolved in an acid it is not essentially changed, for it can be recovered from the solvent. This hypothesis was established by R. Boyle about 1675,[14] when he showed that this solvent permits the copper to be precipitated in order to take up the precipitating metal iron or zinc.

§ 2. The Occurrence of Copper

An *ore* is a metalliferous mineral or aggregate of metalliferous minerals, mixed with more or less gangue, and contains a metal (or metals) which has found a recognized application in the industries, and which occurs naturally in sufficient abundance to be of commercial importance. The *gangue* is the matrix of minerals associated with the mineral containing the metal to be extracted. The nature and character of the gangue usually determines the details of the ore-dressing and metallurgical treatment to which the ore is subjected in the extraction of the metal.[1]

Copper ores are rather widely distributed, and are found in nearly every country. The occurrence of copper is considered by T. Carnelley [2] to agree with its position in the periodic table. The chief deposits are indicated on the map, Fig. 1. The copper minerals are far more numerous and represent a wider range of composition than those of silver, to be afterwards described. The oxidized ores of copper are very numerous, those of silver are virtually non-existent. Copper occurs as metal, in various forms of sulphide, arsenide, antimonide, halides, etc., and also oxidized, as oxide, silicate, sulphate, phosphate, arsenate, carbonate, nitrate, oxychloride, etc.

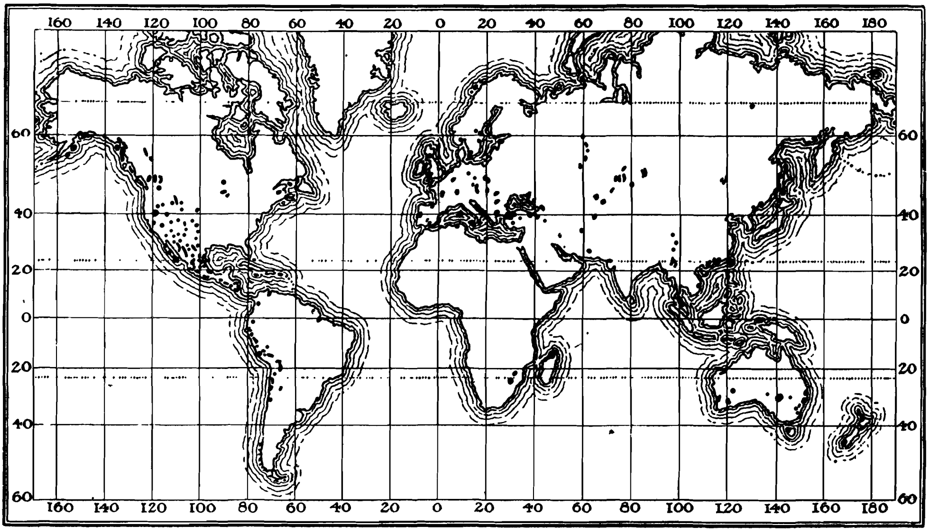

FIG. 1.—The Geographical Distribution of the Chief Deposits of Copper Ores.

The United States of **America** is the largest producer, and the deposits are mainly about the Rocky Mountains and Sierra Nevada; about Lake Superior; and about the Atlantic coast beds—Michigan, Montana, Arizona, California, Utah, Colorado, and Tennessee. The Anaconda mine (Butte, Montana) is said to have been the most productive on record; it is famous for its veins of rich secondary sulphides. The Arizona ores are low-grade porphyries; the Michigan ores are unique deposits of the native metal; the Utah ore is an altered siliceous porphyry containing small grains of copper minerals distributed throughout the mass. The Tennessee deposits are pyritically smelted and the flue gases are used in the manufacture of sulphuric acid. There are important deposits in Mexico, Canada—Sudbury and British Columbia—and Newfoundland. Chile is stated to have probably two thousand mines regularly or intermittently worked. The average yield of each is not stated. The mine at Chuquicamata is very rich, yielding the oxidized mineral, brochantite, $CuSO_4.3Cu(OH)_2$, etc. The deposits were worked by the aborigines before the Spanish conquest. Smaller deposits occur in Peru, Bolivia, Argentina, and Venezuela.

Many of the copper mines of **Europe** have been worked since the days preceding the Roman Empire; several of the old mines are exhausted; others abandoned because unprofitable. Some of the mines most productive to-day are the oldest. The most important mines in Europe occur in the district about Huelva, extending into Spain and

Portugal, where the Rio Tinto Co. alone produced 30,000 tons in 1890. These mines were worked many centuries by the Romans. The German deposits are mainly located about Mansfeld (Rhenish Prussia); they have been worked continuously for a thousand years, and are estimated to have an equally long life ahead of them. The more important Russian deposits occur in the Urals. In Great Britain, the mines of Cornwall have been worked for a long time, but the yield is not very large: there are also deposits at Alderley Edge (Cheshire), Anglesey, etc. In Ireland, copper ore is mined in Cork, Tipperary, and Wicklow. Many districts in **Africa** have important deposits of copper. Some have been worked by the natives for centuries. There are mines in Rhodesia, Cape Colony, Congo Free State, etc. The mines of Namaqualand are the most important. There are large deposits of copper in **Asia**, but they are mainly undeveloped. The mines in Japan are, perhaps, the most important to-day. China has produced copper from shallow pits for thousands of years, but the Chinese mines are quite undeveloped. India has many ancient mines worked in the early centuries, but now mainly idle. The Siberian deposits are undeveloped. In **Australasia**, there are important mines in New South Wales, Tasmania, and South Australia; the mines in Queensland and Western Australia are not so important.

According to W. H. Weed,[3] the World's smelter production in 1920 was:

	Metric Tons.		Metric Tons.
United States of America	548,418	Cuba	6,485
Chile	94,531	Sweden	3,500
Japan	65,554	Norway	1,400
Mexico	50,480	Australasia	1,000
Canada	35,500	Austria-Hungary	1,000
South Africa	32,230	Argentina	..
Peru	31,276	British Isles	..
Spain and Portugal	25,000	Italy	..
Germany	17,255	Russia	..
Bolivia	9,900		

A *metric ton* or *tonne* represents 1000 kilograms or 2205 lbs.; a *short ton* or *net ton* is 2000 lbs.; and a *long ton* or *gross ton* is 2240 lbs. The world's output of copper in metric tons was:

	1880	1890	1900	1910	1913	1917
	156,400	274,065	491,435	877,494	1,002,284	1,435,721
Highest price	£72 10	£61 12 6	£78 7 6	£62 1 3	£77 2 6	£140
Lowest price	£57 0	£46 10 0	£70 15 0	£32 15 0	£61 15 0	£110

The average price in 1801–1810 was £160 per ton; this had fallen to £88 per ton in 1841–1850, and with small fluctuations down to £55 per ton in 1900. There was an abnormally large demand for copper created by the war, and the price soared to £153 per ton in 1916. The World's output in 1920 was 949,015 metric tons, or 1,044,299 short tons; and the price ranged from £70 to £122 5s. per ton.

The minerals forming copper ores are usually associated with a variety of other metallic minerals and earths as gangue. The ores of most industrial importance, and most frequently encountered in mining operations, are, in alphabetical order: azurite, bornite, chalcocite, chalcanthite, chalcopyrite, chrysocolla, covellite, cuprite, enargite, famatinite, malachite, pyrite, tenorite, and tetrahedrite. Others are of less economic value. The ores are generally classified as native copper ores; sulphide ores; and oxidized ores. Small quantities of **native copper** occur in many districts, but large quantities occur in the Lake Superior region, North Michigan. A mass reported to weigh 420 tons was found in the Minnesota mine in 1857. Native copper is usually fairly pure, but it may contain small amounts of silver and bismuth. It has a red colour and crystallizes in the cubic system; the crystals are often twinned to form elongated spear-shaped aggregates. The native copper is considered[4] to be a mineral of secondary origin, and to have been deposited from soln., or formed by the reduction of some solid compound. Pseudomorphs after the oxide, cuprite, and azurite are well known. The soln. have been formed mainly by the oxidation of pyritic ores. R. Pumpelly,[5] G. Fernekes, and R. D. Irving suggest that cases occur where the reducing agent was some compound of iron—oxide or silicate. H. N. Stokes found hornblende and siderite can precipitate the metal from a soln. of copper sulphate, and he showed that other ferruginous minerals can act in a similar manner under suitable conditions. H. C. Biddle studied the reducing action of carbon dioxide under press.; and A. Gautier, that of superheated steam, $Cu_2S+2H_2O=2Cu+SO_2+2H_2$; while H. de Sénarmont, R. Beck, E. Haworth and J. Bennett, and E. J. Schmitz have shown that organic matter found in bones, wood, shales, etc., can effect the reduction.

Among the native sulphide ores is **chalcocite,** also called *redruthite, vitreous copper,* or *copper glance.* In the ideal case, this mineral approaches cuprous sulphide, Cu_2S, with 79·8 per cent. of metal. It crystallizes in the rhombic system, and has a greyish-black colour often with a bluish or greenish tarnish. The sp. gr. ranges from 5·5 to 5·8, and the hardness from 2·5 to 3·0. It is soluble in hot nitric acid, leaving a deposit of sulphur. The corresponding cupric sulphide, CuS, is a rarer mineral called **covellite,** or *indigo copper,* or *blue copper,* on account of its deep blue colour. It occurs in microscopic crystals belonging to the hexagonal system. There is also **chalcanthite** or **cyanosite,** blue copper sulphate, $CuSO_4.5H_2O$, which occurs in deposits, and as incrustations which are oxidation products of minerals containing copper sulphide. There are also some basic sulphates, **brochantite,** $CuSO_4.3Cu(OH)_2$, **langite,** $CuSO_4.3Cu(OH)_2.2H_2O$, and **woodwardite.** These basic salts are probably mixtures. **Chalcopyrite,** also called *copper pyrites, towanite,* and *yellow copper ore,* is the most abundant of all the copper ores. In the ideal case, it approximates to $CuFeS_2$, or $Cu_2S.Fe_2S_3$, with 34 per cent. of copper; but there are sometimes so many impurities present that the ore contains but 2 per cent. of the metal in question; even with this small amount, the ores can be profitably smelted under favourable conditions. In some places auriferous chalcopyrite is worked as an ore of gold. Another variety is called **bornite, erubescite,** *variegated copper ore, purple copper ore, horseflesh ore,* or *peacock ore.* This mineral appears to be related to chalcopyrite much as marcasite is related to pyrite, but there are differences of opinion as to the composition of the ideal mineral: Cu_3FeS_3 is sometimes given. B. J. Harrington [6] gives Cu_5FeS_4. There are also **chalmersite,** $CuFe_2S_3$; and **cubanite,** $CuFe_2S_4$, to be included among the rarer copper-iron sulphides; **carrollite,** $CuS.Co_2S_3$, is also rare. The colour of chalcopyrite is brass or bronze-yellow, sometimes with a bluish iridescence produced by the thin film formed by the tarnishing of the surface; bornite has a bronze colour, and tarnishes much more readily than chalcopyrite—the corresponding iridescent effects are sometimes very pretty. Chalcopyrite crystallizes in the tetragonal system, and the tetrahedral crystals so closely resemble octohedra that they were once thought to belong to the cubic system. A variety of chalcopyrite occurring in botryoidal masses is called *blistered copper ore.* Bornite belongs to the cubic system. Some varieties of marcasite and pyrite contain up to 5 per cent. or even more copper. The arsenides: **domeykite,** Cu_3As, and a variety with cobalt and nickel as well as copper is called *mohawkite* or **algodonite,** Cu_6As; and **whitneyite** or **darurnite,** Cu_9As; the antimonide: **horsfordite,** Cu_6Sb; the selenides: **berzelianite,** Cu_2Se; **umangite,** Cu_3Se_2; **zorgite,** $(Cu_2Pb)Se$, and a variety with copper, silver, and thallium, called **crookesite**; the telluride: **richardite,** Cu_4Te_3, have been reported. **Enargite** or **luzonite** is a mixed copper and arsenic sulphide in some cases approximating $3Cu_2S.As_2S_5$, or Cu_3AsS_4, analogous with the isomorphous **famatinite,** $3Cu_2S.Sb_2S_5$, or Cu_3SbS_4, while **tennantite** corresponds sometimes with $3Cu_2S.As_2S_3$ or with $Cu_8As_2S_7$; and **tetrahedrite,** $3Cu_2S.Sb_2S_3$, or else $Cu_8Sb_2S_7$. Enargite is the source of the arsenic in Manilla copper. Tetrahedrite is also called **fahlerz,** *fahl ore,* or *grey copper ore,* and it can be regarded as cuprous sulphide with more or less copper replaced by iron, zinc, and mercury and mixed with arsenic or antimony sulphide. Gold and silver are also usually present. It is an iron-black or steel-grey mineral occurring in tetrahedral crystals belonging to the cubic system. It is rarely worked for copper alone on account of the difficulty of eliminating arsenic. In addition to these sulpho salts, there are **chalcostibnite,** $CuSbS_2$; **emplectite,** $CuBiS_2$; **stylotypite,** Cu_3SbS_3; **wittichenite,** Cu_3BiS_3; **aikenite,** $CuPbBiS_3$; **klaprotholite,** $Cu_6Bi_4S_9$; **epigenite,** $Cu_7As_2S_{12}$; **cuprobismuthite,** $Cu_6Bi_8S_{15}$; **sulvanite,** Cu_3VS_4. The copper in these minerals is sometimes replaced by other metals—silver, mercury, lead, zinc, thallium, etc.—and the arsenic, antimony, and bismuth may replace one another.

The oxidized ores, like the basic copper sulphates indicated above, usually occur as decomposition products of sulphide ores, and they occur in the upper part of a seam associated with iron oxide, while the sulphide ore is lower down. They do not occur on an extensive scale, and they are not such important sources of copper as the sulphide ores. **Cuprite,** also called *red oxide of copper* or *ruby ore,* in the ideal case approximates to cuprous oxide, Cu_2O, with 88·8 per cent. of copper. It has a red colour, and crystallizes in octahedra and cubes belonging to the cubic system. **Tenorite, melaconite,** or *black oxide of copper,* occurs massive in a few localities. In the ideal case, it corresponds with cupric oxide, CuO, containing 79·85 per cent. of copper. *Green carbonate of copper,* or **malachite,** occurs in green masses or incrustations, and when pure corresponds with $CuCO_3.Cu(OH)_2$, with 57·33 per cent. of copper; the less common *blue carbonate of copper,* also called **azurite,** occurs in blue or greenish-blue masses approximating in the ideal case to $2CuCO_3.Cu(OH)_2$, with 55·3 per cent. of copper. Both carbonates occur in monoclinic crystals. **Dioptase** is a green copper silicate, and is rather scarce. In the ideal case, it corresponds with $CuSiO_3.H_2O$. It occurs in rhombohedral crystals. The more common hydrate, $CuSiO_3.2H_2O$, is called **chrysocolla,** and $CuSiO_3.3H_2O$, **asperolithite.** Chrysocolla is also green, but it does not occur in crystals. The silicates **shattuckite,** $CuH_2Si_2O_7$, and **planchéite,** $Cu_6H_4Si_5O_{18}$, are rare. **Atacamite** is a copper oxychloride, $CuCl_2.3CuO.3H_2O$, or $CuCl_2.3Cu(OH)_2$, approximating to 59 per cent. of copper. It crystallizes in the rhombic system, and occurs massive in Chile and Bolivia. There are several copper arsenates and phosphates which occur as minerals, but they are of no importance as sources of copper. **Olivenite,** $3CuO.As_2O_5.Cu(OH)_2$, occurs in olive-green prisms belonging to the rhombic system; the fibrous aggregates of acicular crystals are called wood copper; it may also occur massive in various shades of green, yellow, or brown. The so-called **liroconite** corresponds with $8CuO.As_2O_5$, and **clinoclare** with $6CuO.As_2O_5.3H_2O$. The hydrated phosphate, **libethenite,** $4CuO.P_2O_5.H_2O$, is olive green; **phosphochalcite,** $6CuO.P_2O_5.3H_2O$, varies in colour from emerald green to almost black. The uranophosphate, **chalcolithite,** $CuO.2UO_3.P_2O_5$, is known; and there is also the tungstate, **cuprotungstite,** $CuWO_4$.

According to C. C. Hutchins,[7] spectroscopic observations indicate that copper is present in the sun, and it has also been found by A. Ward, G. S. Jamieson, W. N. Hartley, and E. E. Howell in meteorites. In the latter case, E. Cohen has reported up to 0·3 per cent. of copper. This metal has also been detected in numerous rocks, and in soils.[8] For example, F. W. Clarke and G. Steiger observed on the average, in oceanic clays, and river silt, 0·0130 per cent. of cupric oxide, and J. D. Robertson found 0·0040 to 0·00880 per cent. in some American limestones. Sea and many mineral waters contain traces of copper.[9] The metal has been found in the ashes of seaweeds. Copper also occurs in numerous plants.[10] This was recognized as early as 1814 by J. F. John. It is also particularly noticeable in plants grown in cupriferous soils. The metal has also been found in different organs of animals; for example, L. van Itallie and J. J. van Eck found copper a normal constituent of the human liver—3·8 to 30·0 mgrm. per kilo. of liver. It was reported by A. H. Church in the blood of herbivora.[11] According to A. H. Church, it occurs in the complex compound *turacine*, $C_{82}H_{81}Cu_2N_9O_{32}$, as a red pigment colouring the plumage of the turacou. W. C. Rose and M. Bodansky found copper in various cœlenterata, mollusca, crustaceæ, elasmobranchii, and teleostomi. R. A. Muttkowsky found the metal in many insects and arthropoda—snails, slugs, garter-snakes, centipedes, spiders, etc. R. S. Hiltner and H. J. Wichmann found 0·12 to 0·362 grms.—or an average of 0·80 grm. per kgrm.—of copper per kilogram in oysters of Atlantic waters. R. A. Muttkowsky believed that copper forms the nucleus of a respiratory protein in mollusca and crustaceæ; and in arthropoda, as a nucelus of hæmocyanine. The copper found in plants is due to mechanical storage, and plays no active *rôle* in the physiology of the plant. It appears also that a very pale blue cupriferous hæmocyanine can play the same *rôle* in the blood of certain crustaceæ and arthropoda that ferruginous hæmoglobin plays in the red blood of animals.

A. Duflos showed that copper may contaminate many food and other products.[12] P. Siedler, J. Milne, T. Bokorny, and L. Vignon reported its presence in water containing carbon dioxide, or in water distilled through copper condenser tubes. Its presence has been reported in bread,[13] jam,[14] pickles,[15] green fruits,[16] cheese,[17] cocoa,[18] bones,[19] sugar,[20] fruit syrups,[21] yeast,[22] beer,[23] wine,[24] vinegar,[25] gin,[26] etc. The copper in many cases is derived from contact with copper vessels in the process of manufacturing these products. It has also been reported in various drugs,[27] geranium oil, olive oil, bergmot oil, etc. Traces are not uncommon in many alloys not usually regarded as cupriferous.[28]

§ 3. The Separation of Copper from its Compounds

The metal can be readily obtained from the various compounds of copper. The processes of reduction illustrate the reduction or decomposition of the copper compounds, and some of them are employed with the object of preparing crystals of the metal. In 1844, C. Watt obtained a patent for the purification of copper by electrically heating the metal. H. Moissan[1] and A. J. P. O'Farrellay distilled all the foreign metals from cupriferous alloys of zinc, cadmium, or lead by heating them for a few minutes in an electric furnace ; C. Féry separated the constituents of brass by fractional distillation; and H. Moissan and T. Watanabe likewise found that all but 3·62 per cent. of silver could be distilled from a 50 per cent. copper-silver alloy.

H. Moissan found that cupric oxide is decomposed when heated in the electric furnace, and A. Guérout also claims to have decomposed the same oxide in a sealed tube at 280°. Several organic salts of copper are decomposed into the metal when heated. For example, P. A. Adet, C. Gehlen, A. Vogel, R. Chenevix, and B. le Roux obtained a mixture of copper and carbon by heating the acetate. According to A. Angel and A. V. Harcourt, the decomposition begins between 150° and 160°; and it is completed at about 330°. C. Gehlen likewise heated the formate, and found the product to be free from carbon. J. W. Döbereiner, P. L. Dulong and J. Pelouze obtained the metal by heating the oxalate; L. A. Planche, and J. B. Trommsdorff by heating the tartrate; J. Pelouze and H. Engelhardt, by heating the lactate; F. Wöhler and J. von Liebig, by heating a mixture of cuprous chloride, ammonium chloride, and sodium carbonate; A. Gautier, by heating its sulphide with water-vapour.

A. Osann obtained the metal by heating to redness cuprous or cupric oxide, or copper carbonate in a stream of *hydrogen, carbon monoxide,* or *coal gas.* The reactions have been studied by W. Müller, F. Glaser, C. R. A. Wright and co-workers, I. L. Bell, E. D. Campbell, and W. Spring. According to L. Pfaundler, a mixture of copper and carbon is formed when coal gas is used; and E. D. Campbell found the reduction of cupric oxide begins between 315°–325° with *ethylene;* between 270°–280° with *propylene;* and between 320° and 340° with *butylene.* G. Gore reduced heated cupric chloride with coal gas; and W. Spring, with hydrogen. P. Sabatier and J. B. Senderens reduced nitrocopper, Cu_2NO_2, with carbon monoxide; W. R. Hodgkinson and C. C. Trench reduced cupric sulphate at 400° with *ammonia;* and D. Stickney, A. Liversidge, and W. M. Hutchings reduced the two sulphides with hydrogen. According to S. U. Pickering, the reaction proceeds at 600° with hydrogen and with carbon monoxide. O. Löw reduced heated copper oxide with *petroleum ether.* G. Bruhns reduced the heated oxide with the vapours of *methyl or ethyl alcohol*—the former acts better than the latter, and, according to L. Pfaundler, the product contains some carbon and hydrogen—A. Guérout used dried *ether;* T. Weyl, *formic acid;* A. Gautier, *water-vapour;* and R. Brauns, *carbon dioxide* or *sulphuric acid*—P. N. Raikow objects that carbon dioxide will not do the work.

E. Beckmann[2] reduced the oxide or sulphide with *calcium;* F. M. Perkin and L. Pratt, with *calcium hydride;* and B. Neumann and A. Frölich, with *calcium carbide.* The reaction with calcium carbide has been studied by F. von Kügelgen, S. Fränkel, H. Schillbach, N. Tarugi, H. N. Warren, L. M. Bullier, H. C. Geelmuyden, etc. B. Neumann reduced with *silicon carbide;* H. Moissan used *boron;* J. P. Schweder, and E. Donath, *iron;* C. R. A. Wright and A. P. Luff, M. Lazowsky, J. Garnier, and A. C. Becquerel, *carbon;* C. Winkler, *magnesium;* G. L. de Chalmot, *zinc;* J. L. Sammis, *lead;* A. G. Betts, *aluminium;* J. N. Pring, *aluminium carbide;* and F. Ephraim, *sodium amide.*

Cuprous oxide is decomposed into copper and cupric sulphate by boiling with dil. sulphuric acid; and cuprous nitrate is decomposed into copper and cupric nitrate. F. Gaud[3] heated Fehling's soln. (*q.v.*) with alcohol in a sealed tube, and P. Cazeneuve heated the formate or oxalate with ammonia under similar conditions for 5 hours at 156°, when microscopic crystals of the metal were obtained. T. Spencer obtained crystals of copper by allowing copper to stand partially immersed in a soln. of cupric sulphate and partially in one of sodium chloride. F. Clément, H. de Sénarmont, J. P. Wagner, and C. Weltz allowed wood to stand for a long time in contact with a dil. soln. of a cupric salt, and obtained cubes, octohedra, and long four-sided columns of the metal. Cupric or cuprous oxides or salts are reduced to the metal by many other agents—*e.g.* F. Wöhler reduced a warm cupric acetate soln. with *sulphur dioxide.* A. Étard, C. Geitner,

L. P. de St. Gilles, P. Berthier and A. Vogel obtained crystals of the metal by heating the sulphite with water in a sealed tube between 180° and 200°. G. Gin and A. Étard reduced a soln. of copper sulphite by heating it in a sealed tube under press.

C. F. Schönbein, P. Schützenberger, J. Meyer, and O. Brunck reduced an acid soln. of cupric chloride with *sodium hyposulphite*, $Na_2S_2O_4$, cuprous chloride was first deposited, then copper—some sulphide is also formed. F. Wöhler, C. F. Rammelsberg, reduced cupric salts with *phosphorous acid*—L. Amat obtained octohedral crystals of the metal from a soln. of cupric hydrophosphite, $CuHPO_3$, in phosphorous acid. According to C. F. Rammelsberg, *phosphites* act but slightly if at all; *barium hydrophosphite*, $BaHPO_3$, acts only in the presence of an acid; and, according to A. Sabanejeff, *ammonium dihydrophosphite*, $(NH_4)H_2PO_3$, does not reduce in alkali soln.; the reducing action of *hypophosphites* and *hypophosphorous* acid has been investigated by C. F. Rammelsberg, E. J. Bartlett and W. Merrill, W. Gibbs, and A. Sabanejeff. T. Curtius and F. Schrader, E. Knövenagel and E. Ebler, and E. Riegler reduced cupric salt soln. with *hydrazine sulphate* in alkaline soln.; in acid soln. a pale blue cupric hydrazine sulphate is formed. H. N. Holmes prepared fine tetrahedra of copper by adding cupric sulphate to silica jelly, and covering the mixture with a soln. of hydroxylamine hydrochloride.

According to E. Lenssen, F. Weil, T. Leykauf, and F. Kessler and J. Löwenthal, *stannous chloride* precipitates cuprous chloride from cupric chloride soln. and an excess of the reagent gives metallic copper as well; but ammoniacal soln. are not reduced. A. Lottermoser obtained crystals of copper by allowing cold soln. of cupric and stannous chlorides to stand in contact with sodium citrate. The reduction of cupric by *ferrous salts* has been symbolized: $FeCl_2+CuCl_2 \rightleftharpoons CuCl+FeCl_3$, followed by: $FeCl_2+CuCl \rightleftharpoons Cu+FeCl_3$. Hence the precipitation of metallic copper by soln. of ferrous salts is a reversible reaction, and the formation of metallic copper is determined by the relative conc. of the four salts: ferric, ferrous, cupric, and cuprous chlorides. This explains some apparently contradictory reports which have been made as to the behaviour of mixed soln. of ferrous and cupric sulphate; some report the formation of metallic copper, others deny this. If the ferric salts have an appreciable conc. they will dissolve metallic copper. The tendency of ferrous salts to reduce cupric salts is shown in the precipitate of cuprous thiocyanate by the action of ammonium thiocyanate on a soln. of ferrous and cupric chlorides; and cuprous chloride is formed when cupric oxide is treated with ferrous chloride. Ferrous salts can reduce alkaline soln. of cupric salts to the metal; for instance, J. M. Eder obtained copper from the cupric acetate or from alkali ferrous oxalate; and A. Müller, and F. Wibel obtained crystalline plates by warming cupric and ferrous sulphates with alkali hydroxide or wollastonite. The reaction has been studied by H. C. Biddle, E. Braun, A. Levol, A. Job, F. Herrmann, E. Müller and F. Kapeller, and H. R. Ellis and W. H. Collier. The last-named find that when ammonia is added to copper sulphate soln., the distinctive blue coloration is not obtained or is rendered indistinct if ferrous sulphate is present. If an excess of ferrous sulphate be present, no coloration is produced, whilst the iron is precipitated as ferrous and ferric hydroxides; the soln. contains cuprous compounds, and a small quantity is present in the precipitate. The production of the ferric hydroxide is brought about by the oxidizing action of the compound $CuSO_4.5NH_4OH$, and the amount of oxidation is proportional to the amount of this substance present. Complete oxidation is brought about when both the copper and ammonia are present in excess. No action takes place between ferrous sulphate and copper sulphate soln. in the cold, but, on boiling, the copper sulphate slowly oxidizes the ferrous hydroxide produced by hydrolysis. Various sugars also reduce the salt soln. to the metal, as in the preparation of cuprous oxide from cupric salts when the reduction is carried to an end (*q.v.*).

Electrolytic copper is usually crystalline. G. Bird[4] obtained crystals of copper by connecting a zinc plate, dipping in a soln. of sodium chloride, with a copper plate, dipping in a soln. of cupric sulphate. The latter was contained in a porous pot dipping in the sodium chloride soln. H. N. Warren obtained cubic crystals of the metal by a similar process. Crystals of copper are also found in some galvanic cells containing a copper element, which have stood for some months.

The electro-refining of copper is based upon the older process of electroplating. As far back as 1801,[5] it was known that if silver be made the negative pole in a soln. of copper sulphate, the silver receives so tenacious a coating of copper that the latter can be burnished; and L. Brugnatelli (1805) gilded silver medals by making them the negative poles in a soln. of gold chloride. E. Davy also stated that in 1830, he gilded, silvered, coppered, and tinned various metals by the voltaic battery. G. R. and H. Elkington, A. Parkes, and O. W. Barratt developed soln. for the electro-deposition of metals, but, prior to 1840, the deposits were thin, with a more or less frosted appearance. The process of electroplating did not meet with commercial success until the use of potassium cyanide had been discovered. The patent by G. R. and H. Elkington (1840) for electroplating copper and its alloys with silver or gold and of iron with copper, by means of an electrolyte containing potassium cyanide, was based on the work of J. Wright, who found in the use of this agent the solution of the problem of electro-depositing bright films of metal. J. Wright, in turn, obtained the hint from C. W. Scheele's memoir, *De materia tingente cœrulei Berolinensis* (1783):

> It is remarkable that our colouring matter (hydrocyanic acid), after it has united with the alkali, or with the lime, forms a menstruum, capable not only of dissolving metallic calxes, but also of constituting a triple salt, which is not decomposed by the aërial acid, as happens with the lixivium sanguinis (aq. soln. potassium cyanide) and the precipitating liquor, when exposed to the free access of air. Iron is not the only metal which has the property of fixing the colouring matter, the same quality belongs likewise to gold, silver, copper, and probably to several other metallic calxes; for if, after these calxes have been precipitated, a sufficient quantity of precipitating liquor be added, in order to redissolve them, the soln. remains clear in the open air, and in this state the aërial acid does not precipitate the metallic calx.

In **electrotyping**, a coating of copper is deposited on suitable objects by making them the cathode in a soln. of copper sulphate with copper plates as anodes, and, as shown by W. de la Rue in 1836, when the copper plate is stripped off, it has the counterpart of every mark or scratch which was on the original. T. Spencer, and M. H. Jacobi applied the idea in 1838 to convert finely engraved designs on copper into relief; and so, they reproduced copper-plate engravings, medals, ornaments, etc. The process was employed for reproducing patterns for wall papers, making rollers for calico printing, etc. The principle has been adopted for reproducing statues, busts, and casts of models in gypsum or guttapercha. The original is first coated with oil and graphite to make the surface electrically conducting, and then made the cathode in an electrolyte of a copper salt. After a sufficient thickness of metal has been deposited, the interior plaster can be removed. Iron can be coated with copper by dipping it in an alkaline soln. of copper cyanide, and, if necessary, continuing the process electrically with copper sulphate as electrolyte. One of the best electrolytes is made by dissolving 3·13 grms. of copper sulphate in water; adding ammonia until the precipitate redissolves, forming a deep blue soln.; adding potassium cyanide until the blue colour of the soln. disappears; and diluting with water to make 500 c.c. of liquid.[6]

According to W. D. Bancroft, in the electroplating of metals, (1) Bad deposits are due to excessive admixture of some compound or to excessively large crystals. (2) Excessive admixture of any compound may be eliminated by changing the conditions so that the compound cannot precipitate. (3) Increase of the current density, or increase of the potential difference at the cathode, or depression of the temp. decreases the size of the crystals. (4) The size of the crystals is diminished when substances adsorbed by the deposited metal are present at the cathode surface. (5) If a given soln. will yield a good deposit at any given current density, it will yield a good deposit at any higher current density provided that the conditions at the cathode surface are kept constant. (6) Treeing is facilitated by a high fall of potential through the soln. and by conditions favourable to the formation of large crystals. W. Blum found that these observations are applicable over a wide range of conditions, and to a variety of metals. W. E. Hughes regards the polished appearance often observed with metallic deposits formed upon rotating cathodes is due to the smallness of the grains composing the deposit. The smallness of the grain appears to be the result of constancy of the concentration of the metal at the surface of the cathode, and this constancy to be the result of the movement of the cathode and not of any burnishing action, as has been suggested.

The metallic precipitation of copper.—Near the beginning of the fourth century, Zosimus mentioned that when iron is immersed in a soln. of a copper salt, the iron acquires a coating of copper. In the sixteenth century, Paracelsus[7] precipitated silver from silver nitrate by inserting a plate of copper in the soln., and he noted that the copper is at the same time attacked by the liquid. To the alchemists of the Middle Ages, the precipitation of copper which occurs when a piece of iron is placed in a soln. of copper in aqua fortis appeared to be a veritable transmutation of iron into copper. T. Bergman, in his *De præcipitatis metallicis*, near the middle of the eighteenth century, noted that " the metals precipitate one another after a certain order . . . which is constant and never inverted . . . zinc prevails over iron, iron over lead, lead over tin, tin over copper, copper over silver, silver over mercury, etc." ; and, in his *De attractionibus electivis* (Upsala, 1775), he added :

> Since, therefore, metallic solutions are of such a nature, that they cannot restore to its metallic splendour what they hold dissolved, without the accession of a new portion of phlogiston, it is self-evident, as well as conformable to experiment, that this cannot be effected by the addition of calces. If, therefore, ochre be put into a solution of vitriol of copper, no copper will be precipitated ; but iron added to the solution is soon observed to be covered with a cupreous pellicle ; for it yields part of its phlogiston, which is necessary to the reduction of the copper, and by this means becomes itself soluble without the emission of any inflammable air.

N. W. Fischer,[8] in his *Das Verhältniss der chemischen Verwandtschaft zur galvanischen Electricität in Versuchen dargestellt* (Berlin, 1830), noted that in cupric nitrate soln. the metal is deposited with decreasing rapidity by zinc, lead, tin, and cadmium. The precipitation of copper by iron was regarded as a simple replacement of the one metal by the other : $Fe+CuSO_4=Cu+FeSO_4$; but, in 1857, W. Odling showed that this is not the case, for an eq. of cadmium will completely extract the copper from a soln. of the neutral chloride containing much more than an eq. of copper. J. B. Senderens examined ninety cases of metal precipitation from salt soln. by aluminium, arsenic, cadmium, iron, lead, magnesium, manganese, molybdenum, nickel, palladium, silver, tin, tungsten, uranium, zinc, and by a number of alloys. The precipitation is not always complete, and only in about eleven per cent. of the cases examined was the quantity of metal precipitated approximately eq. to the amount of metal dissolved, and in only one case was the equivalency exact.

According to F. Hiller,[9] and J. T. A. Mallet, if **copper** sheet be dipped in a soln. of cupric nitrate, some crystals of copper and of cuprous nitrate are formed ; the sulphate does not act so well, although F. Förster and O. Seidel, F. Fischer, F. Wibel, C. Häussermann, and H. Wohlwill obtained crystals of copper by heating the finely divided metal with a feebly acid conc. soln. of the sulphate. G. Quincke, and J. H. Gladstone and A. Tribe also obtained crystals of the metal by dipping copper rods in molten cupric or cuprous chloride. R. M. Caven further observed that in the action of soln. of cupric sulphate on precipitated copper at atm. temp., small quantities of cuprous oxide are produced, and that the conc. of the soln. has little influence on the result. In accord with a suggestion by E. Divers, it is assumed that the cupric sulphate is reduced to cuprous sulphate, which in turn is hydrolyzed to cuprous oxide, $Cu_2SO_4+H_2O \rightleftharpoons Cu_2O+H_2SO_4$, for if much chalk be also present, the acid product of the hydrolysis is neutralized, and is prevented from accumulating [illegible] the system, a comparatively large proportion of cuprous oxide is formed. There [illegible] also the decomposition of the cuprous sulphate: $Cu_2SO_4=Cu+CuSO_4$, which occurs in acid soln. According to M. C. Lea, finely divided **silver** reduces cupric chloride, but not the nitrate.

Copper is rapidly precipitated from soln. of its salts by **magnesium**.[10] According to J. Thomsen, the thermal value of the substitution of copper in an aq. soln. of cupric sulphate by magnesium is 124·22 Cals.; by zinc, 50·13 Cals.; and by iron, 37·24 Cals. J. Thomsen's data for the formation of nitrates and sulphates by the action of an aq. soln. of the acid on the metal are collected in Table III. The data not only enable the heats of soln. of the metal in dil. sulphuric acid with the evolution of hydrogen to be determined, but also the heat of decomposition of a soln. of a salt of one metal by a salt of another metal. For instance, what is the thermal effect of the dissolution of zinc in dil. sulphuric acid? Here, $(Zn, O, SO_3)_{aq.}-(H_2, O)=106{\cdot}09-68{\cdot}36$, or 37·73 Cals. Again, what is the heat of decomposition of a soln. of copper sulphate by metallic iron? Here, $(Fe, O, SO_3)_{aq.}-(Cu, O, SO_3)_{aq.}=93{\cdot}2-55{\cdot}96$; or 37·24 Cals. As J. Thomsen has shown, however, the results in many cases may be illusory because of secondary reactions—*e.g.* the precipitate, A, and precipitant, B, may form a galvanic couple whereby more of B is dissolved than corresponds with A precipitated; insoluble sulphates may be formed as is the case with lead and barium salts, etc. With silver, copper, and gold, reduction by magnesium is the more energetic the greater the at. wt. of the metal—thus cuprous oxide reduces easily, whilst silver oxide is reduced with explosive violence. Aurous oxide breaks down into its constituents below the ignition point of magnesium.

TABLE III.—HEATS OF FORMATION OF SULPHATES AND NITRATES BY THE DISSOLUTION OF THE METAL IN THE ACID.

R	Heats of formation in calories.		R	Heats of formation in calories.	
	$(R, O, SO_3)_{aq.}$	$(R, O, N_2O_5)_{aq.}$		$(R, O, SO_3)_{aq.}$	$(R, O, N_2O_5)_{aq.}$
K_2	195,850	192,100	Co	88,070	84,540
Na_2	186,640	182,620	Ni	86,950	83,420
Li_2	197,810	194,010	Pb	—	68,070
Sr	188,490	185,410	Tl_2	70,290	66,540
Ca	180,409	177,160	Cu	55,960	52,410
Mg	180,180	176,480	Hg_2	—	30,650
Mn	121,250	117,720	Hg	—	28,400
Zn	106,090	102,510	Ag_2	20,390	16,780
Fe	93,200	89,670	$\frac{2}{3}$Al	150,630	—
Cd	89,880	86,000	$\frac{2}{3}$Fe	74,990	—

A. Schmidt noted that magnesium precipitates all the copper as metal from an acid soln. of cupric sulphate; the greatest part of the copper from an acid soln. of cupric chloride; with an ammoniacal soln. of cupric chloride and an excess of magnesium, the blue colour soon disappears, and about 57 per cent. of the copper is precipitated as metal, while the remainder forms cuprous chloride; and with neutral soln. of cupric chloride, a green basic cupric chloride is precipitated and some cuprous hydroxide is formed which passes into cuprous oxide when the soln. is warmed. In 1866, A. Commaille showed that cuprous oxide and chloride are respectively formed during the reduction of soln. of cupric sulphate and chloride, along with basic cupric salts. He attributed the evolution of hydrogen to the decomposition of water by the copper-magnesium couple in which the very electropositive metal magnesium is involved. In 1827, G. Wetzlar suggested that when zinc is used, the precipitated copper forms a *galvanische Kette*. A. Commaille gave an equation which, in modern notation, is $6CuSO_4+5Mg+3H_2O=5MgSO_4+CuSO_4.2CuO+Cu_2O+Cu+3H_2$, and which may be regarded as his attempt t represent the relation between the relative proportions of magnesium and cu sulphate consumed, and the products of the reaction at the temp. and soln. conc employed. W. A. Tilden assumed that the first action of the acid results in the precipitation of copper which formed a couple with the magnesium. Hydrogen is accordingly evolved, and a crust of magnesia formed on the surface of the metal. The former reduces some of the cuprous salt, the magnesia is hydrolyzed, the cuprous salt forming cuprous oxide and a basic cupric salt. E. Divers showed that hydrogen does not reduce soln. of cupric salts, and it is necessary to postulate the existence of an active nascent hydrogen. The latter assumption is unnecessary because zinc reduces chromic to chromous sulphate with the evolution of hydrogen; and with alum soln. also, zinc evolves hydrogen, and precipitates a basic sulphate. It is therefore claimed that the first reaction is more probably that symbolized: $Mg+2CuSO_4=Cu_2SO_4+MgSO_4$. R. M. Caven favours Divers' interpretation that the hydrolysis of the cuprous sulphate is the source of the cuprous oxide and sulphuric acid: $Cu_2SO_4+H_2O=Cu_2O+H_2SO_4$; this agrees with F. Förster's observation that the cuprous oxide formed during the electrolysis of conc. soln. of cupric sulphate is due to the formation and hydrolysis of cuprous sulphate. The small amount of metallic copper which is formed, is probably due to the decomposition of the cuprous sulphate: $Cu_2SO_4=Cu+CuSO_4$, in the action of dil. sulphuric acid on cuprous oxide: $Cu_2O+H_2SO_4=H_2O+Cu+CuSO_4$. With hot soln. (100°) less copper is produced than with cold sat. soln. The copper is mixed with cuprous oxide and imbedded in a mixture of magnesia and basic cupric sulphate. With cold dil. soln., no free acid can be present because the formation of magnesia and basic cupric sulphate is observed from the beginning of the reaction; with conc. soln. hot or cold, the basic products first formed are redissolved by the sulphuric acid. C. Brückner heated magnesium powder with solid cupric sulphate and observed as products of the reaction: copper, cuprous oxide, cupric sulphide, and thiosulphate, sulphur, and sulphur dioxide.

G. Wetzlar found that **zinc** precipitates copper from cupric salts even when they contain a large excess of acid; black copper contaminated with zinc is first precipitated and afterwards red copper, because the precipitate, as it increases, falls away from the zinc, and forms a galvanic couple, which results in the zinc being dissolved. In boiling feebly acid soln., D. M. Levy found the copper is quantitatively precipitated, better with zinc than with aluminium. A. Schmidt obtained similar results with zinc and soln. of cupric salts as with magnesium. L. Meyer attributed the evolution of hydrogen during the reaction with neutral soln. to the formation of a copper-zinc couple. He did not observe the formation of any cuprous oxide. T. Leykauf says that much hydrogen is evolved when the reaction occurs at 90°, and some cupric oxide is formed. From the work of R. M. Caven, it is probable that the mechanism of the reaction is similar to that with magnesium, but with zinc a much smaller quantity of cuprous oxide is produced. A. J. J. van de Velde found that more zinc is dissolved than is eq. to the copper precipitated; that the degree of hydrolysis or ionization has no effect on the substitution of copper by zinc; and that chlorine ions accelerate the reduction while sulphate retards the action; A. J. J. van de Velde and C. E. Wasteels noted that alcohol and cane sugar decrease the speed of the reaction at the beginning.

The reaction has been investigated by N. N. Beketoff, J. C. Shengle and E. F. Smith, J. H. Gladstone and A. Tribe, F. Mylius and O. Fromm, J. J. Sudborough, J. B. Senderens, etc. W. K. J. Schoor says cupric hydride is precipitated from acid soln. of the sulphate; L. Meyer and L. Sostegni, basic zinc sulphate; and R. M. Caven found that in hot soln. cuprous sulphate is formed. N. W. Fischer found cuprous chloride as well as copper is precipitated from soln. of cupric chloride. N. W. Fischer reduced an alcoholic soln. of cupric nitrate with zinc. A. Destrem noted that with the salts with the strong acids, the pulverulent precipitate is chestnut-brown or black, while feebly alkaline salts—*e.g.* ammonium cupric sulphate—give a red coherent mass. O. Sackur did not get a precipitation of copper with soln. of cupric cyanide or thiocyanate, and F. Spitzer measured the differences of potential between copper and soln. of cuprous potassium cyanide with varying amounts of potassium cyanide, and between zinc and soln. of zinc potassium cyanide under similar conditions. The soln. are all positive to the metal. R. Lorenz electrolyzed fused soln. of zinc and cupric chloride, and obtained as products zinc, copper, and cuprous chloride. N. W. Fischer, and H. Pécheux have studied the action of copper-zinc and silver-zinc alloys; they do not reduce cupric salts. N. W. Fischer, J. B. Senderens, and W. Odling have studied the action of **cadmium.** The results are much the same as with zinc.

The reduction with zinc or cadmium is sometimes employed in the analysis of soln. of cupric salts. R. Böttger freed the precipitated copper from the more electropositive metal by washing it with dil. sulphuric acid, then with water, and drying it below 75° in air, or in a stream of hydrogen. Aluminium or iron have also been recommended, but these metals may contaminate the precipitated copper with impurities which do not wash out so readily. O. N. Heidenreich[11] precipitated soln. of copper salts in dil. hydrochloric acid with **aluminium,** and G. E. Perkins found the reaction to be quantitative in soln. acidified with sulphuric acid, and an excess of aluminium. A. Cossa found the reaction with soln. of the chloride occurs immediately; it is slower with the acetate, and it begins immediately with soln. of the sulphate or nitrate only if some alkali chloride is present; if the two last-named soln. are pure, the reaction is very slow. J. B. Senderens and D. Tommasi noted the formation of hydrogen in the reduction and the formation of a basic salt. N. Tarugi studied cuprous sulphite soln. B. Setlik obtained a film of copper on aluminium by the action of the latter on a feebly acid soln. of cupric lactate. C. Göttig, F. Weil and D. M. Levy, M. Lansaigne and M. Leblanc, C. Margot, C. T. J. Oppermann, have studied the plating of aluminium with copper. C. Formenti and M. Levi studied the action of aluminium on molten cupric salts as well as on their aq. soln. A. G. Betts separated copper from the molten chloride by means of aluminium.

As previously indicated, the precipitation of copper from soln. of its salts by **iron** was known in the Middle Ages, and the reaction attracted the attention of T. Bergman, N. W. Fischer, G. Wetzlar, J. B. Senderens, and many others.[12] The reaction in many respects resembles that with zinc. With a cold soln. of cupric sulphate, J. B. Senderens found that hydrogen is evolved, but R. M. Caven obtained no gas with fine iron wire containing an almost imperceptible trace of carbon. The residual copper always contained a trace of cuprous oxide, the soln. was distinctly acid, and the iron in soln. was all in the ferrous condition. Hence it is inferred that the reaction is similar in type to that which occurs with zinc, and that consequently some cuprous sulphate is formed and hydrolyzed. With hot soln. of cupric sulphate of all conc., hydrogen is evolved and the residue consists of cuprous oxide mixed with metallic copper. In the first stage of the latter reaction flecks of orange-coloured hydrated ferric oxide are formed, but these dissolve in the acid and the soln. is reduced to the ferrous state.

G. Wetzlar, J. L. Lassaigne, D. W. Peck, and P. Harting noticed that copper precipitated from neutral soln. may be contaminated with iron; R. M. Caven found a little cuprous oxide and sulphate are formed in cold dil. soln., and no hydrogen is evolved if the iron is well purified. According to J. L. Lassaigne, a soln. of cupric sulphate with one part of copper in 25,000 parts of soln. gives a red deposit on iron in 2 hrs., but with one part of copper in 50,000 to 100,000 parts of soln., no coloration can be detected. C. Paul obtained a precipitate from ammoniacal cupric salts. N. W. Fischer found that with cupric chloride soln., both cuprous chloride and copper are precipitated; and G. Wetzlar noted that alcoholic soln. are also reduced. X. Landerer obtained crystals of copper by boiling steel with a soln. of cupric chloride acidified with hydrochloric acid. C. Paul, and J. B. Senderens studied the action of iron on soln. of cupric nitrate and acetate. G. Wetzlar noted that at 100° copper is rapidly and completely precipitated from soln. of the acetate; according to G. Wetzlar, ammonium cupric oxalate gives a compact precipitate if air be excluded, but if air be present, the precipitation is retarded; and O. Gaudoin studied the precipitation of copper from soln. of potassium cupric oxalate; G. Wetzlar obtained what he called an alloy (mixture ?) of copper and iron by placing iron in a soln. of cupric tartrate; and C. Reiss obtained no reduction with potassium cupric tartrate soln. G. Wetzlar, and N. W. Fischer found that passive iron does not precipitate copper from soln. of the cupric salts. The presence of a little silver nitrate was found to make the iron passive, but, according to W. Heldt, iron made passive with nitric acid of sp. gr. 1·45–1·54, or with platinum in an acid of sp. gr. 1·4, precipitates copper well. W. Heldt also found if the surface of the iron has a film of mercurous nitrate, carbon, or magnetic oxide of iron, its activity is retarded. F. Wöhler obtained no precipitation by treating cupric salts with meteoric iron. O. C. Farrington studied the precipitation with nickel-iron alloys. I. Remsen noticed that copper was deposited on a plate of iron, lying between the poles of a magnet, in such a way that the precipitate forms in lines perpendicular to the lines of magnetic force. C. J. Descharme, F. A. Wolff, and E. Colardeau also studied the effect of a magnetic field on the precipitation, and P. A. M. Janet says that possibly less heat is developed during the precipitation if the iron be magnetized. F. Giolitti studied the etching of polished steel with cupric sulphate soln.

According to M. le Blanc and M. G. Levi,[13] **nickel** does not precipitate any copper from a 2 per cent. soln. of cupric sulphate in 30 hrs., but with a 2 per cent. soln. of cupric chloride some nickel passes into soln., and cuprous chloride is formed. J. B. Senderens made a similar observation with respect to the chloride. According to W. D. Bancroft, "copper does not precipitate nickel to any appreciable extent when immersed in a copper sulphate soln. The nickel becomes passive, and is probably covered with a thin film of oxide." E. Günther obtained a deposition of copper from an acid soln. of cupric sulphate and finely divided copper reduced by hydrogen. N. W. Fischer found that if a copper-nickel alloy be treated with an excess of nitric acid, the undissolved portion remains covered with a film of copper. J. B. Senderens found that **cobalt**, unlike nickel, readily reduces soln. of cupric salts; O. Prelinger, that powdered and purified **manganese** separates copper from aq. soln. of its salts; and A. C. Chapman, that **palladium** reduces cupric salts to the cuprous state, and with a prolonged action, to copper. According to E. F. Smith, copper is also precipitated by **molybdenum** and by **tungsten**; and C. Zimmermann also noted the reducing action of **uranium.**

F. Wöhler [14] and W. Wicke obtained crystals of metallic copper mixed with copper phosphides by allowing sticks of **phosphorus** to stand some months in contact with copper wires under a soln. of copper sulphate. This reaction was studied by L. F. Boeck in 1804. A. Vogel noted that the cupric salt soln. is completely decolorized in a few days. According to R. Böttger, copper is first precipitated from boiling soln. of cupric sulphate, and afterwards transformed into phosphide. M. Sidot noted that when the copper is nearly all precipitated, hydrogen begins to appear, possibly from the decomposition of phosphine formed in the reaction—W. Straub tried to follow the mechanism of the reaction. A stick of yellow phosphorus becomes black when immersed in a soln. of cupric sulphate. The black deposit is copper phosphide, and when removed from the soln. it does not react with atm. oxygen. The black coating is covered by a red film owing to the deposition of copper, and this continues so long as the copper and phosphorus are present. As the reaction proceeds, the phosphoric acid in soln. increases. There is a constant relationship between the quantity of phosphorus which passes into soln. and the amount of reduced metal, provided oxygen is rigorously excluded and the reaction is not carried to an end. At the point where the reaction is just complete, the soln. contains sulphuric acid and phosphoric acid in the proportion

1 : 0·5, and consequently one molecule of phosphorus separates two molecules of copper from the copper sulphate soln. ; the oxygen which oxidizes the phosphorus must come from the water because the amount of sulphuric acid undergoes no diminution. The reduced copper is not acted on by the sulphuric acid, but is oxidized by the atm. oxygen, and the copper oxide dissolves to form copper phosphate, which is then reduced to phosphide. The dark film on the phosphorus is produced in a soln. containing only one mol of crystallized copper sulphate in 100,000 litres of water, and at a dilution 10 times as great, the film is produced in the course of two months.

M. Kohn[15] found that when Fehling's soln., etc. are heated in sealed tubes alkaline soln. of copper salts, they are rapidly reduced by antimony, arsenic, or bismuth. C. Strzyzowsky found Fehling's soln. (*q.v.*) is reduced at 50° by **arsenic,** and according to M. H. Descamps an arsenide is formed. Fehling's soln. is not reduced under similar conditions by **antimony,** and J. B. Senderens found that antimony has virtually no action, although it becomes covered with an unweighably thin film of the metal which acquires an indigo blue colour by oxidation. N. W. Fischer and J. B. Senderens found a boiling soln. of cupric nitrate to be imperfectly reduced by **bismuth ;** cuprous chloride and bismuth oxychloride are formed. H. Pécheux studied the action of bismuth-aluminium alloys. G. Wetzlar[16] found that **tin** precipitates copper from the chloride, nitrate, and sulphate, but not from the acetate. N. W. Fischer noted that with the nitrate, some stannic oxide is formed. J. B. Senderens says that the precipitation from conc. soln. of cupric chloride is slow but complete, and that some stannous hydroxychloride, Sn(OH)Cl, is formed. G. Wetzlar noted that **lead** precipitates copper from soln. of the sulphate ; J. B. Senderens from soln. of the acetate ; dil. soln. of the chloride ; but not from the nitrate. N. W. Fischer said that copper is slightly precipitated from nitrate soln., and he studied the precipitation by the addition of alloys of silver and tin or lead.

§ 4. The Extraction of Copper

Copper is extracted from its ores by pyro-, electro-, or hydro-metallurgical processes. The actual method employed depends upon the character of the ore, and upon the local conditions—cost of labour, fuel, refractory materials, transit, etc. These questions are discussed in special books.[1] If the ore contains no sulphur—as is the case with the carbonates and oxides—the metal can be obtained by simply reducing the ore, mixed with suitable fluxes and coke, in a furnace heated by a blast. The smelting of the oxidized ores furnishes a metal, called *black copper*, which contains iron and other impurities which have to be removed by refining. High grade and medium grade ores are smelted because the cost of this operation is less the richer the ore; but with low grade ores, a large proportion of gangue has to be converted into slag. Low grade ores, copper mattes, and copper containing the noble metals, may be leached by solvents which take little more than the copper into soln. Electrolytic processes are used with mattes, and with copper containing gold or silver. Assuming that the ore to be smelted is a typical chalcopyrite, the operations involved in extracting the copper are somewhat complex, because (1) a large number of impurities are present in the ore; (2) copper of a high degree of purity is needed; and (3) it will probably be profitable to recover gold and silver from the crude metal.

The concentration of ores.—In many cases, the native ore is not rich enough to be smelted profitably for the metal, and in other cases, the smelting may be more remunerative if a certain proportion of the gangue be removed in order to avoid the expense of passing waste or barren rock through the furnaces. The proportion of waste rock—gangue or tailings—in copper ore generally exceeds the valuable portion—the *concentrate*—and the process of separating the concentrate from the gangue is called **concentration.** The more important concentration processes—not necessarily all adapted for the treatment of copper ores—are: (1) *Hand picking.* This is one of the simplest types of concentration. The rough ore is separated into valuable and waste by sorting. The operation may be practised to some extent in the mine itself to avoid sending valueless rock to the surface. (2) *Water concentration.* The ore is crushed with water, and the product or *pulp* is subjected to a shaking, throwing, and flowing motion in suitable machines whereby the gangue, on account of its lower sp. gr., is diverted from the denser ore. One form of the apparatus in which water concentration is performed is called a *jig*, and the operation is called *jigging.* The concentration of material too fine for the jig is performed in other types of machine—concentrating tables, vanners, etc. No machine can separate barren rock completely. On account of the small difference in the sp. gr. of the iron and copper pyrites, it is not practicable to concentrate copper ores by water concentration to the same extent as is possible, say, with lead or tin ores. (3) *Magnetic separation.* Here a stream of the powdered or roasted ore is allowed to fall in a stream past a magnetic field of high intensity. The particles which are more sensitive to the magnetic influence are deflected from the main stream, so as to form two streams—one contains the concentrates, and the other the tailings to be rejected. The process has been specially treated by C. G. Gunther, and D. Korda.[2] (4) *Electrostatic separation.* Here a stream of the powdered or roasted ore is exposed to an electrostatic field. Good conductors—the metal sulphides, magnetite, hæmatite, etc —are separated from poorer conductors—silicates, carbonates, zinc blende, etc.—by electric repulsion. The process has been specially treated by D. Korda. (5) *Flotation.* The selective adhesion of oils for certain minerals is here utilized. Certain minerals, when ground with oil and water, become coated with oils under conditions where other minerals (usually gangue) remain unaffected. The selective action is in some cases materially increased by the use of an acid or other substance. When the froth or pulp of crushed ore, oil and water is exposed to a current of water, the uncoated gangue sinks through the surface of the water and settles rapidly as tailings, while the oiled minerals float on the water and are collected as concentrates quite independently of the fact that the latter have the greater sp. gr. The flotation process is largely employed for the conc. of copper sulphide ores.[3] The theory of the process is discussed by W. H. Coghill and C. O. Anderson.

Roasting sulphide ores.—The sulphur and iron in pyritic or sulphide ores are oxidized by roasting, but sufficient sulphur is left still combined with the copper and iron to form subsequently what is called a *matte*, and sufficient silica must also be present to unite with the iron oxide to form a fusible ferrous silicate slag. In roasting a mixed copper iron sulphide, the copper sulphide oxidizes less rapidly than the iron sulphide; such is the difference that if a mixture of the two sulphides be heated in air, it is commonly stated that "the copper sulphide is not attacked until all the iron sulphide is oxidized." The reaction in the extreme case is represented: $2CuFeS_2+6O_2=Cu_2O+Fe_2O_3+4SO_2$. It may or may not be convenient to use the by-product sulphur dioxide for the manufacture of sulphuric acid. The object of roasting is therefore to oxidize iron and copper sulphides, and to remove as much of the volatile impurities, like arsenic, antimony, and bismuth, as possible. In practice, the crushed ore is roasted in stacks or heaps, in stalls, in kilns, on grids, in muffles, in reverberatory furnaces, in revolving cylinders, or in automatic reverberatory calciners. F. le Play's analyses of samples of the raw and roasted ore are:

Cu_2O.	$CuFeS_2$.	FeS_2. Fe_2S_3.	Other sulphides.	Fe_2O_3.	Various oxides.	SiO_2.	Earthy matters.	H_2O, CO_2, SO_3.
0·47	26·79	26·32	1·18	0·71	0·35	40·47	2·36	0·59
6·91	14·34	14·34	0·79	14·98	0·77	43·90	2·56	1·41

Smelting the roasted ore for copper matte.—There are three methods in general practice for the smelting of copper ores to furnish copper matte: (1) *Reverberatory smelting,* in which the sulphide ores are treated; (2) *Blast furnace smelting,* in which any class of ore is heated with carbonaceous fuel in a reducing atm.; and (3) *Pyritic smelting,* in which sulphide ores are heated alone or with a small amount—say 5 per cent.—of carbonaceous fuel in an oxidizing atm. The partially roasted ore, or a mixture of roasted and unroasted ore, is heated in a reverberatory furnace, or in a blast furnace lined with firebricks—the former is sometimes called the English or the Swansea process, the latter the American or pyrite smelting process. The blast furnace for smelting copper sulphide ore is usually water-jacketed for cooling the furnace walls (Fig. 2). The blast furnace may be used for reducing the roasted ore, $2CuO+C=2Cu+CO_2$, etc., or it may be used for oxidizing pyritic ore in which the heat necessary for the reaction is derived from the oxidation of the pyritic ore. The blast furnace is preferred for the smelting of rough ore, and the reverberatory furnace for fines and concentrates.[4] The ore probably contains some siliceous materials; if not, some must be introduced into the furnace in order that a fusible slag may be formed. The air burns the carbon to carbon monoxide: $2C+O_2=2CO$. Part of the cuprous oxide, formed in the roasting, is reduced to copper by the joint effect of the carbon and carbon monoxide: $Cu_2O+CO=2Cu+CO_2$—the copper oxide is much more readily reduced than iron oxide. The metallic copper reacts with the sulphides in the ore: $3Cu+Fe_2S_3=3CuS+2Fe$; some of the unreduced cuprous oxide forms cuprous sulphide: $3Cu_2O+Fe_2S_3=3Cu_2S+Fe_2O_3$; and some cuprous sulphide and cuprous oxide react to form metallic copper and sulphur dioxide: $Cu_2S+2Cu_2O=6Cu+SO_2$—a curious reaction which is a kind of *self-reduction.* According to F. O. Doeltz and C. A. Graumann,[5] the velocity of the reaction increases with rise of temp. T, such that if W denotes the weight of the sulphur dioxide which is evolved, $\log W=34\times10^{-16}T^5$. The reaction is virtually complete at 1000°. Metallic copper also may react with iron sulphide as just described. Any cupric sulphide present is reduced to cuprous sulphide. The result of the smelting for matte is (i) The transformation of the copper into cuprous sulphide; (ii) The formation of a fusible slag by the union of the iron oxide with the silica; and (iii) The reduction of ferric sulphide to ferrous sulphide which remains in soln. with the cuprous sulphide to form the matte itself. The lighter slag in the furnace rises to the surface and is run into a pit; the matte collecting at the bottom of the furnace is drawn off from time to time.

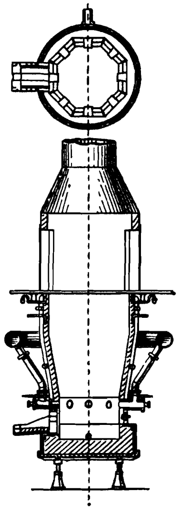

Fig. 2.—Cupola Furnace.

In the so-called *pyritic smelting,* the roasting and smelting of the sulphide ores for matte are conducted in one operation. The high temp. required is derived from the rapid oxidation of sulphur and iron in the blast furnace. Attempts have been made to apply *electro-thermic smelting* of copper ores containing too little sulphur to enable them to be pyritically smelted, and which require the use of carbonaceous fuel to facilitate fusion. Electro-smelting could be applied profitably only where fuel is expensive and electric power cheap. Several experimental plants have given promising results.

Matte or regulus.—A *matte* or *regulus* is an artificial metal sulphide, or a conglomerate of several metal sulphides; it is formed as an intermediate product in the smelting of copper, nickel, or lead ores. Copper matte is a more or less impure mixture of cuprous and ferrous sulphides containing the eq. of 20–75 per cent. of copper; 12–45 per cent. of iron; and 19–25 per cent. of sulphur. F. le Play's analysis of a sample of regulus, matte, or coarse metal is:

Cu.	Fe.	Ni, Co, Mn.	Sn.	As.	S.	Slag.
33·7	33·6	1·0	0·7	0·3	29·2	1·1 per cent.

The impurities or minor constituents of copper matte are arsenic, antimony, bismuth, manganese, nickel, cobalt, zinc, lead, selenium, tellurium, gold, and silver. Matte is an excellent solvent for the precious metals, so that auriferous or argentiferous copper ores containing less than 2 per cent. of copper may be profitably smelted and the precious metals recovered.

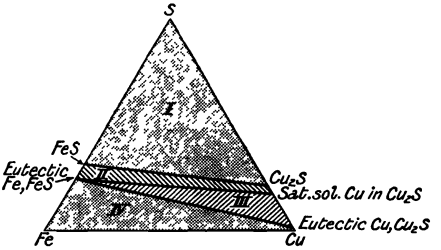

FIG. 3.—Triangular Diagram for Ternary Mixtures of Copper, Iron, and Sulphur.

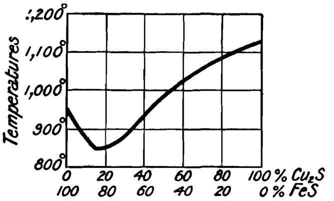

FIG. 4.—Freezing Curve of Mixtures of Ferrous and Cuprous Sulphides.

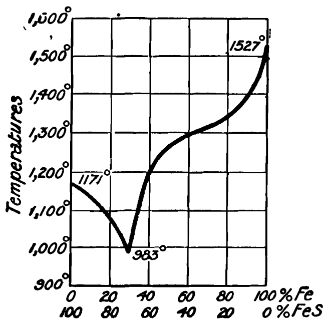

FIG. 5.—Freezing Curve of Mixtures of Iron and Ferrous Sulphide.

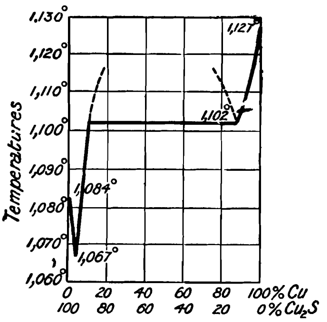

FIG. 6.—Freezing Curve of Mixtures of Copper and Cuprous Sulphide.

According to A. Baykoff and N. Troutneff,[6] the relations between the primary constituents of copper matte are represented diametrically in Fig. 3. The area I represents dissociated mixtures of cuprous and ferrous sulphides; the area II represents solid soln. of the two sulphides; the area IV represents a matte with iron and copper in soln.; and area III, a eutectic mixture of the matte characteristic of area II, and of the solid soln. of area IV. The f.p. curve of mixtures of cuprous and ferrous sulphides is shown in Fig. 4. P. Röntgen[7] obtained a curve with maximal points corresponding with the double sulphides $Cu_2S : FeS = 3 : 2$ melting at about 980°; 1 : 1 melting at about 1025°; and 2 : 5 melting at about 1050°; while H. O. Hofman found no evidence of the formation of definite compounds, but rather obtained a eutectic mixture, with 85 per cent. of ferrous sulphide and 15 per cent. of cuprous sulphide, melting at 850°. The freezing curve of a mixture of iron with ferrous sulphide furnishes a eutectic melting at 983°, as illustrated in Fig. 5;[8] while a mixture of copper with copper sulphide furnishes a freezing curve like that shown in Fig. 6.[9] There is a quick rise in the f.p. with additions of cuprous sulphide until a mixture melting at 1102° is obtained; a further addition of cuprous sulphide produces no further rise of temp. until the mixture contains nearly 86 per cent. of cuprous sulphide, when any further addition produces a rise in the f.p. until 1127°—the f.p. of pure cuprous sulphide. **Speise** is an artificial arsenide or conglomerate of arsenides which is related to a matte in that arsenic and some antimony replace some of the sulphur. The arsenic and antimony are usually eliminated by a series of oxidizing roasts and reducing fusions.

The conversion of matte into blister copper in the reverberatory furnace.—The matte is converted into metallic copper by roasting and further smelting either in a (i) reverberatory furnace—*blister roasting* or *roaster smelting*, or (ii) in a converter—*bessemerizing*. The richer mattes with from 87·5 of Cu_2S and 12·5 of FeS to 100 per cent. Cu_2S, are called *white metal*. F. le Play's analysis of white metal is:

Cu.	Fe.	Sn, As, etc.	S.	Slag.	
77·4	0·7	0·1	21·0	0·3	per cent.

When the conversion is effected in a reverberatory furnace, Fig. 7, the lumps of matte on the hearth of the furnace are slowly oxidized, and the oxidation is continued until the sulphur is nearly all removed, and a bath of metallic copper, sat. with more or less cuprous oxide and sulphide, remains. The reactions are supposed to be those represented by the equations: $Cu_2S+O_2=2Cu+SO_2$; and $2Cu_2S+3O_2=2Cu_2O+2SO_2$. The copper oxide and sulphide react to form metallic copper and sulphur dioxide: $2Cu_2O+Cu_2S=SO_2+6Cu$. The metal is called *coarse copper* or *blister copper*, from the blister produced on its upper surface by the escape of sulphur dioxide during solidification. The blister copper contains iron, sulphur, arsenic, etc., as impurities. F. le Play's analysis of blister copper is:

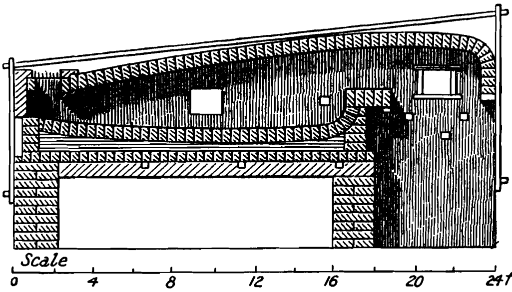

Fig. 7.—Reverberatory Furnace.

Cu.	Fe.	Ni, Co, etc.	Sn, As, etc.	S.	
98·4	0·7	0·3	0·4	0·2	per cent.

The copper can be further refined by an oxidizing fusion followed by a reducing fusion in a reverberatory furnace, or it can be refined electrolytically.

The conversion of matte into blister copper in the converter.—Much of the copper produced to-day is made in a modified form of Bessemer's converter, Fig. 8. The matte is bessemerized by blowing air through the molten metal contained in a converter analogous to that employed in the manufacture of steel. The converter may be lined with siliceous material—*acid converter*—or with magnesite—*basic converter*.

In 1866, A. Rath patented a process of oxidizing the iron and sulphur in matte by blowing air through the molten mass; in 1867, A. von Jossa and N. Latetin reported that white metal (72–80 per cent. Cu) was made in a converter, but blister copper could not be produced. The process of oxidizing copper matte to metallic copper in a Bessemer's converter was patented by J. Holloway[10] in 1878, and between 1880 and 1884 P. Manhès established the technical and commercial success of the process for the treatment of copper mattes. In bessemerizing pig iron, the oxidation of the 6 to 7 per cent. of impurity generates enough heat to keep the iron molten, and the oxidation of a much larger proportion of impurity in the case of copper furnishes an ample amount of heat to keep the charge molten, but a more voluminous slag results. The time occupied by the copper "blow" is five to fifteen times as long as is needed for steel; with steel, too, the iron itself is oxidized towards the end of the blow, but this is not the case with copper, and accordingly, molten copper is only chilled by the blast. In consequence, P. Manhès placed the tuyères in the copper converter, not at the bottom, as is the case with iron, but laterally at some distance from the bottom above the pool of molten metal which accumulates at the bottom of the converter. Matte converters are side blown, and not bottom blown as is the case of large steel converters. The tuyères are directed below the surface of the matte in a position where, if choked, they can be easily "punched" clear by the attendant. In the converter, the iron sulphide is oxidized to iron oxide, and this unites with the silica present to form a slag; the sulphur is oxidized to sulphur dioxide. The operator can tell from the appearance of the flame issuing from the converter when it is time to stop the blast. The converter is tilted and the slag run off; white metal remains. The white metal formed in the first stage of the process is further oxidized, and the cuprous oxide and sulphide react as in the reverberatory furnace process. The product obtained from the second blow in the converter is the so-called blister copper containing about 99 per cent. of copper. As the copper cools, the sulphur dioxide dissolved by the metal is liberated and the resulting blisters give the copper its characteristic appearance. The copper is then refined on the hearth of a reverberatory furnace and poled as indicated previously.

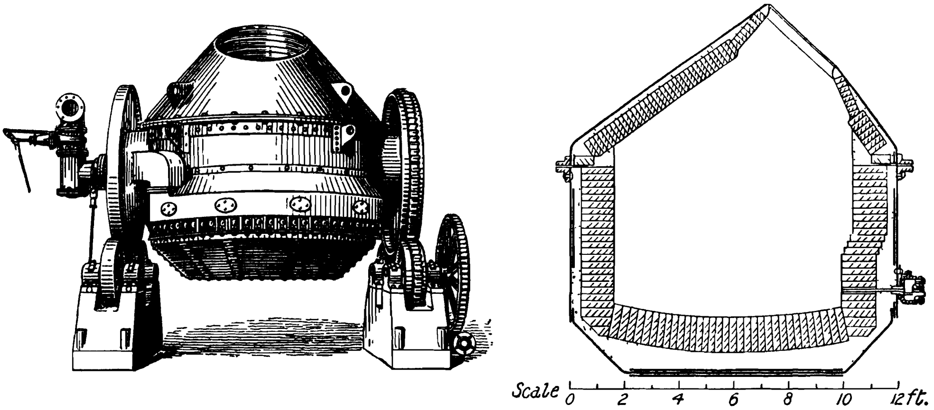

Fig. 8.—Converter.

Refining copper by fusion in the reverberatory furnace.—The metal to be refined is first heated on the hearth of a reverberatory furnace in an oxidizing atm.—the *oxidizing fusion*—and the molten metal agitated to assist the oxidation of the iron, lead, etc. The impurities form a slag with the siliceous matters of the lining of the furnace, etc. The cuprous oxide simultaneously formed dissolves in the copper and facilitates the oxidation of the dissolved cuprous sulphide and ensures that the other impurities are converted into oxides; the cuprous oxide also reduces the tendency of the metal to dissolve gases, and generally improves the quality of the metal. The refiner tries to make a metal, called *dry copper*, containing 6 to 7 per cent. of cuprous oxide. The slag is skimmed off. Refinery slag contains from 20 to 50 per cent. of copper as silicate, and it is mixed with the charge for the furnace in an earlier stage of the smelting. If much arsenic or antimony is to be removed, caustic soda and lime are repeatedly added towards the end of the oxidizing fusion, and continued until a sample of the metal shows that the purification has gone far enough.

The molten metal is now subjected to a *reducing fusion*. The surface of the metal is covered with charcoal or anthracite, and a pole of green wood is introduced below the surface of the molten metal. Vigorous ebullition occurs owing to the evolution of gas from the wood, and sulphur dioxide is also liberated. When the reduction has proceeded far enough, the metal is called *tough pitch copper*, and it contains up to about one per cent. of cuprous oxide in soln. W. Stahl[11] gives the following analyses of the refining of blister copper at Mansfeld:

	Cu.	Ag	Pb.	Ni.	As.	O.
Blister copper . .	98·140	0·011	1·060	0·610	0·058	0·121
After melting . .	98·950	0·010	0·330	0·350	0·058	0·302
After fining . .	98·550	0·010	0·160	0·350	0·055	0·875
After dense poling .	99·060	0·009	0·190	0·360	0·057	0·324
After tough poling .	99·300	0·009	0·170	0·360	0·054	0·107

A test bar of tough pitch copper can be bent through 180° without cracking, and when broken, the fractured surface is salmon-red in colour, with a fibrous texture, and silky lustre. During the operation, samples are removed at intervals from the furnace so that the progress of the operation can be determined; the man in charge has learned to judge this from the appearance of the sample. Over-poled copper is brittle, and it must be oxidized back to dry copper either by flapping—that is, by vigorously striking the surface of the molten metal with an iron rabble so that the metal is splashed about—or else by forcing compressed air on or beneath the surface of the molten metal. The re-oxidized metal is then re-poled. Under-poled copper is brittle, and the fractured surface is brick-red in colour.

Refining copper by electrolysis.—A great deal of the copper in commerce—at least a third, perhaps one half—passes through an electrolytic refining process. The metal refined in the furnace is not pure enough for many commercial purposes for it contains base metal impurities which interfere with its electrical conductivity—*e.g.* arsenic and antimony—or which make the metal brittle—*e.g.* lead and tellurium—the metal may also contain some gold and silver which can be profitably extracted. M. von Leuchtenberg proved in 1847 that impure copper can be refined electrolytically, and J. B. Elkington[12] applied the process successfully on a large scale in 1865, at Pembrey (Wales). The modern process is described in L. Addicks' *Copper Refining* (New York, 1921). The metal to be refined—blister copper, or copper from the refining furnace—is cast into plates—say 36 ins. sq., and 2 or 3 ins. thick. These plates are provided with lugs, and used as anodes with sheets of refined copper as cathodes or "starting sheets." The electrolyte is a soln. containing 12 to 14 per cent. of copper sulphate with 5 to 10 per cent. of sulphuric acid. In the so-called *multiple* or *parallel system*, the cathodes are all connected with one pole of the circuit, so also all the anodes are connected with the other pole; in the so-called *series system* the anodes and cathodes are connected in pairs. The electrolyzing vats are wooden tanks, lead-lined. In some cases, 20 or 30 anodes about 3 ins. apart, and with the same number of intermediate cathode plates, form a working unit. During the electrolysis, the electrolyte is agitated, say, by arranging the vats in terraces so that the outflow from the vat on the top row passes into that in the next row below, and so on until finally the outflow runs into a well whence it is pumped into the distributing box, to pass again in a cascade through the electrolysis vats. During the electrolysis, with a current between 4 and 15 amperes per sq. ft. and 0·1 to 0·3 volts, the copper is continuously dissolved from the anode, and re-deposited in a purified condition on the cathode sheet. The zinc, iron, nickel, and cobalt accumulate in the soln., but are not deposited on the cathode; part of the arsenic, antimony, bismuth, and tin is also deposited, and part remains in soln.; while the copper sulphide, gold, silver, tellurium, and most other impurities remain undissolved, and fall as *anode mud* or *anode slime* at the bottom of the electrolyzing vat.

It is stated that the anode mud contains from 15 to 55 per cent. of copper; 5 to 50, silver; 0·02 to 0·70, gold; 0·5 to 6·0, lead; 2 to 8, antimony; 1·5 to 6, arsenic; 0·2 to 8·0, bismuth; 0·5 to 1·5, iron; 0·1 to 2·5, selenium; 0·1 to 3·5, tellurium; and 0·5 to 12 per cent. of SO_3. The mud is screened to separate particles of copper which have fallen from the anodes, and the slime may be (1) fused on a dolomitic clay bed in a reverberatory furnace ; the slag removed and the resulting metal cupelled for silver and gold ; or (2) the dried slime may be oxidized and scorified on the lead bath of a cupelling furnace ; or (3) leached with sulphuric acid and afterwards fused with nitre in a reverberatory furnace ; or (4) the slime may be roasted, pulverized, leached with sulphuric acid, and afterwards fused in a reverberatory furnace with nitre as a flux. The nitre slag may contain up to 20 per cent. tellurium. The silver alloy is afterwards parted to recover the gold.

The more important main and secondary reactions which occur at the cathode during electrolysis may now be indicated.[13] When copper electrodes are dipped in a soln. of copper sulphate or copper chloride, say the latter, the reaction symbolized : $CuCl_2+Cu=2CuCl$, takes place. Thus, if an acid soln. of cupric sulphate be boiled with powdered copper, metallic copper will be deposited from the filtered soln. on cooling—presumably owing to the reoxidation of the cuprous sulphate. The equilibrium constant K at room temp. is $K[CuCl_2]=[CuCl]^2$, where the bracketed symbols represent the conc. of the salts in question. When a current is passing through a soln., the possible cathodic reactions are therefore $2CuCl_2=2CuCl+Cl_2$; $2CuCl=2Cu+Cl_2$; and $2CuCl_2=2Cu+Cl_2$. The relative magnitudes of these different reactions is determined by (1) the temp. ; (2) the current density. A low current density favours the oxidation and hydrolysis of the cuprous salt, and allows time for the reaction to occur. If the current density be too high, the precipitated copper will have a spongey appearance :

Temp.	Current density amps. per sq. metre.			
	0·3	30	100	300
20° . .	80	—	100	100
70° . .	—	96	98	100
100° . .	—	47	83	99

(3) The conc. of the soln. If the conc. of the copper salt in soln. be high, a correspondingly large conc. of the cuprous salt must be maintained to satisfy the equilibrium constant. With normal sulphuric acid soln., and a current density of 0·135 amp. per sq. cm. :

$CuSO_4$ normality.	Cu_2O.	Cu.
0·05	—	0·121
0·25	—	0·083
2·00	—	0·0086

(4) The presence of dissolved oxygen ; and (5) the acidity or conc. of the $H^{\cdot}$-ions. A high conc. of the acid is favourable to the oxidation of cuprous chloride, and a low acid conc. favours hydrolysis and the consequent precipitation of cuprous oxide. According to A. Sieverts and W. Wippelmann,[14] copper deposited electrolytically from acid soln. of the sulphate is crystalline ; neutral soln. give a mixture of cuprous oxide and crystallites of copper ; and alkaline soln.. a mixture of complex copper salts give structureless (colloidal) copper. With $0·25N$-$CuSO_4$, and a current density 0·135 amp. per sq. cm. :

H_2SO_4 normality.	Cu_2O.	Cu.
0	0·368	—
0·01	0·413	trace
0·025	0·061	trace
0·1	—	0·071
1·0	—	0·083

If the conc. of the cuprous salt at the cathode falls below the equilibrium value, the yield of precipitated copper per unit quantity of electricity during electrolysis will be low. This may occur owing to (i) a rise of temp. which favours the formation of cuprous chloride and increases the value of K; (ii) the hydrolysis of cuprous chloride: $CuCl+H_2O=Cu(OH)+HCl$, which leads to the precipitation of cuprous oxide; and (iii) the oxidation of cuprous chloride back to cupric chloride by the dissolved atm. oxygen: $4CuCl+4HCl+O_2=2H_2O+4CuCl_2$. Although copper is deposited as a bivalent element in accord with Faraday's law—two farads of electricity transform one eq. of bivalent copper $Cu^{\cdot\cdot}$ to the metallic state—yet the actual cathodic yield of the metal may appear to fall below the theoretical requirements. The above discussion shows the conditions which favour high yields: (1) Low temp.; (2) Fairly high current density; (3) Moderately conc. soln. of the cupric salt; (4) Absence of oxidizing agents; (5) Fairly high acid conc. These favourable conditions are also necessary for the successful working of a copper voltameter. G. Grube and co-workers have made a metallographic study of electro-deposited copper.

Attempts to use copper ore or copper matte as anode in an acidulated soln. of copper sulphate, with sheet copper as cathode, have not been very successful commercially; although the electrolysis of soln. with anodes of copper mattes containing little more than cuprous sulphide, have given very fair results—*e.g.* in E. Marchese's process [15] an electrolyte containing copper and ferrous sulphates and dil. sulphuric acid is used with anodes of copper iron matte.

Hydrometallurgical or wet processes for extracting copper from its ores.—A comparatively small proportion of the world's output of copper is extracted from its ores by leaching the ore [16] with suitable solvents—dil. sulphuric, hydrochloric, or sulphurous acid,[17] ferric sulphate, ferrous chloride, ferric chloride,[18] cuprous chloride,[19] ammonia or its salts [20]—and subsequently precipitating the metal by iron, ferrous sulphide, hydrogen sulphide, sulphur dioxide, sodium or calcium polysulphide, lime water, or by electrolysis. The more important hydrometallurgical processes can be classified [21] as:

> *I. Chemical processes.*—The copper is dissolved and precipitated by chemical agents involving (1) Alkali processes (*e.g.* leaching with ammoniacal soln.); (2) Sulphate processes (*e.g.* the Rio Tinto process); (3) Sulphite process (*e.g.* J. M. Neil's); (4) Chloride processes (*e.g.* C. Dötsch's, O. Frölich's, T. S. Hunt and J. Douglas', and W. Longmaid and W. Henderson's processes).
>
> *II. Electrolytic processes.*—The copper is dissolved chemically and precipitated electrolytically. The electrolysis is usually accompanied by the regeneration of the solvent. These processes include the so-called (i) Sulphate processes (*e.g.* E. W. von Siemens and J. G. Halske's process); Chloride processes (*e.g.* C. Höpfner's process).

The wet processes may be profitably used in some cases where the proportion of copper, or the precious metals—gold and silver—in the ore is not sufficient to pay for bringing fuel and fluxes to the mine, or taking the mined ore to a locality where fuel and fluxes are cheaper. The wet processes are applicable to low grade ores with finely disseminated copper minerals and a gangue which is not attacked by the solvent. As a rule, the wet processes do not recover the precious metals owing to the insolubility of these elements in ordinary solvents. With the poorer ores, the commercial success of a copper extracting proposition may be determined by the possibility of recovering gold and silver with a comparatively small additional cost; ores which carry small quantities of copper, but relatively large amounts of silver and gold, may be treated by wet processes, but this merely as a preliminary treatment in a process mainly devised for the extraction of the two precious metals. In the ideal case, the ore for treatment by wet processes contains the greater part of its copper as oxide or carbonate, since these substances are relatively easily dissolved by dil. acids; copper silicate or copper sulphide ores do not so readily yield their copper to solvents.

The cupriferous pyrites of Rio Tinto (Spain) contains about 3 per cent. of copper. The ore is built in large heaps arranged with channels so that there is as free a circulation of air as possible in the interior. The heaps are sprayed with water at suitable intervals. As a result, according to C. H. Jones,[22] the pyrites, FeS_2, is first oxidized to ferrous sulphate, and then to ferric sulphate. The latter converts copper oxide or sulphide into soluble copper sulphate: $Cu+Fe_2(SO_4)_3=CuSO_4+2FeSO_4$; $3CuO+Fe_2(SO_4)_3=3CuSO_4+Fe_2O_3$; and $Cu_2S+2Fe_2(SO_4)_3=4FeSO_4+2CuSO_4+S$. Some cupric sulphide is simultaneously formed as an intermediate product of the oxidation. According to A. N. Winchell, cuprous sulphide is more readily oxidized than pyrites, FeS_2, and he suggests that the cuprous sulphide is oxidized first, and hastens the oxidation of the iron pyrites. The sulphides of nickel, lead, zinc, arsenic, antimony, and bismuth are simultaneously oxidized and dissolved. The soln. which drains from the heaps of pyrites contains both ferric and cupric sulphates; the former is converted to ferrous sulphate by passing the soln. through a layer of fresh ore, and the liquid is then led through troughs in which scrap iron, or lumps of spongy iron (reduced from roasted pyrites), or pigs of iron have been laid. Copper is precipitated upon the iron as a brownish-red powder. The precipitation of copper on iron is sometimes called *cementation*, and the product, *cement copper*. The copper is removed from time to time, fused, and refined in the usual manner. The refining is commonly needed because cement copper usually contains iron oxide, sand, and other extraneous matters. In some places, the ore is converted into sulphate by roasting with or without the addition of other sulphates—ferrous sulphate, aluminium sulphate, sodium hydrogen sulphate, etc. The operation is called *sulphatizing roast*. In E. W. von Siemens and J. G. Halske's process,[23] the roasted ore is treated directly with an acidified soln. of ferric sulphate.

In some mines, and dumps, the air has already oxidized the sulphide to water soluble sulphate, and the water percolating from the mine, or dump, is charged with sufficient copper sulphate to pay for the recovery of the copper—*e.g.* at Wicklow (Ireland), Schmoellnitz (Hungary), Rammelsberg (Germany), Ashio (Japan), Wallaroo (Australia), Gumeshavsky (Russia), Butte (Montana), Bisbee (Arizona), Iron Mountains (California), etc.

T. S. Hunt and J. Douglas' process[24] depends on the fact that ferrous chloride in the presence of hot brine (at 70°) converts copper oxide into soluble cuprous chloride. The copper in the ore must therefore be first converted into oxide by heating the carbonates, or roasting the sulphides. The ore is treated with a soln. of ferrous sulphate containing an excess of sodium chloride with or without calcium chloride. The reaction with cuprous oxide is represented: $3Cu_2O+2FeCl_2=2Cu+4CuCl+Fe_2O_3$, and the cuprous chloride is held in soln. by the other chlorides which are present; with cupric oxide the reaction is represented: $3CuO+2FeCl_2=2CuCl+CuCl_2+Fe_2O_3$. The copper is then precipitated by iron. In a later modification of the process, the copper oxide is extracted by dil. sulphuric acid, and ferrous or calcium chloride is added to the soln. to convert sulphates to chlorides. Cuprous chloride is then precipitated by blowing sulphur dioxide through the soln.: $CuCl_2+SO_2+CuSO_4+2H_2O=2CuCl+2H_2SO_4$. The precipitate is converted into cuprous oxide by treatment with milk of lime, and the washed oxide is smelted with carbon for copper. Part of the sulphur dioxide is recovered from the soln. by blowing hot air through the liquid; and the calcium chloride, left after treating the cuprous chloride with milk of lime, is used for chloridizing the copper in the sulphate soln.

W. Longmaid and W. Henderson's process was invented by W. Longmaid in 1842, and improved by W. Henderson in 1860.[25] The process is suited for the treatment of burnt pyrites or *blue billy*—the residue obtained when cupriferous pyrites has been roasted for sulphur dioxide in the manufacture of sulphuric acid. The roasted ore contains from 1 to 5 per cent. of copper—partly as cupric sulphate, cupric oxide, cuprous sulphide, and copper iron sulphide, $FeCuS_2$. The crushed and burnt ore is mixed with 12 to 15 per cent. of rock salt and roasted in a reverberatory furnace whereby the copper is converted into soluble chloride—*chloridizing roast.* The mass is then lixiviated with water, and the copper precipitated from the soln. by scrap iron. If much gold and silver are present, these elements may be precipitated before the copper by the addition of sodium iodide (F. Mayer), zinc iodide (F. Claudet), treatment with hydrogen sulphide (T. Gibb), or by dilution with water (W. Jardine and H. Chadwick).

Instead of precipitating the copper by cementation, electrolysis with insoluble electrodes may be used—lead anodes stand well in sulphate soln.; carbon anodes stand well with chloride but not sulphate soln. H. Carmichael[26] used an acidified soln. of cupric sulphate impregnated with sulphur dioxide as electrolyte, and insoluble lead anodes. S. von Laszczynsky used an acidified soln. of copper sulphate as electrolyte, and the lead anodes were enclosed in tight-fitting cotton bags in order to hinder the oxidation of the ferrous sulphate into ferric sulphate at the anode.

Numerous analyses of commercial copper are recorded in literature. In the United States, the three important brands are casting copper, lake copper, and electrolytic copper. In casting copper, the amount of precious metals is too small to justify their extraction, and the impurities are too small to make them objectionable for many purposes. The following[27] is a selection :

	Casting.	Lake.	Electrolytic Copper.
Cu	99·44	99·890	99·953

A. Eilers found selenium in all the varieties of copper he examined, but a few contained no tellurium. Copper from Garfield (Utah) contained :

Gold.	Silver.	Platinum.	Palladium.	Selenium.	Tellurium.	Bismuth.	Nickel.
14,400	174,000	17	59	44,800	4432	4880	32,000

ounces per 5000 tons. O. Nielsen discusses the standardization of copper in grades according to its degree of purity.

The preparation of highly purified copper by Richards' process.[28]—Commercially pure copper was dissolved in sulphuric acid mixed with a little nitric acid, and evaporated to dryness. The mass was heated in a porcelain dish on an asbestos plate until the fumes of sulphuric acid were no longer evolved. The copper sulphate was then dissolved in water, and twice re-crystallized. A dil. soln. of the crystals was boiled and shaken for three hours with water containing a little potassium hydroxide. The soln. was filtered, and copper sulphate crystallized from the hot soln. a number of times. An aq. soln. of the crystals was strongly acidified with sulphuric acid and a little nitric acid, and electrolyzed in a cell with platinum plates. The electrolytic copper was then washed with a dil. soln. of potassium hydroxide, dil. sulphuric acid, and then boiled for half an hour with water, washed, dried, and heated red-hot in a stream of hydrogen. The metal was allowed to cool in the stream of hydrogen.

Sometimes copper is used in organic chemistry as a condensing agent, for which purpose it must be in a fine state of subdivision. For **colloidal copper** *vide* gold. Finely divided copper is obtained by the action of zinc dust on copper sulphate soln.

L. Cohn's process for preparing finely divided copper.[29]—Zinc dust is shaken through a fine sieve into a cold sat. soln. of copper sulphate in a porcelain dish while the liquid is being thoroughly stirred so as to prevent the formation of clots; the zinc dust is added so long as the liquid has any but the faintest trace of a blue colour. The temp. will probably have risen to about 80° during the addition. The finely divided copper settles to the bottom of the vessel; and the dark red mass is well washed with water. In order to remove any zinc which may be present, dil. hydrochloric acid is added so long as any effervescence is observable. The mass is then washed by decantation, and then on a filter until the washings are free from acid. The metal is easily oxidized, even if dried, and it is best preserved in closely stoppered bottles. O. Ohmann prepared what he called *copper wool;* and J. Piccard, *catalytic copper.*

§ 5. The Physical Properties of Copper

The **colour** of copper in compact masses is yellowish-red by reflected light, the tint ranging from orange-red to a rose colour dependent upon the temp. at which the metal was quenched from the liquid condition. The deep red colour of metallic copper is best seen when the light has been reflected many times from the surface of the metal, *e.g.* when a sheet of the metal is bent to an acute angle (about 45°), and viewed with the eye directed to the point where the two inner surfaces of the copper approach one another. The metal precipitated from soln. is brownish-red, and the colloidal metal ranges in colour from crimson or scarlet to various shades of blue and brown. Thin films of copper appear greenish-blue by transmitted light. According to W. I. Baragiola,[1] copper distilled ten times or more in a high vacuum has a pale rose colour. According to C. Bischof [2] molten copper has a bluish-green colour. Thin layers of copper, said M. Faraday, are green; G. B. Rizzo said bluish-green; E. Braun, blue; and C. Bischof, reddish-violet. According to G. T. Beilby, the red colour of copper in reflected light is conditioned by a glassy variety of the metal. W. L. Dudley says that copper vapour is green. The compact metal has a bright metallic lustre, and takes a bright polish which is soon tarnished when exposed to the air.

J. G. Wallerius [3] first described the crystalline form of copper in 1772; he said *cuprum est figura octaedrica vel cubica.* J. B. L. Romé de l'Isle, J. D. Dana, G. Rose, J. W. Mallet, etc., have since described the crystals. The **crystals** of copper belong to the cubic system—hexakis-octahedra (ἑξάκις, six times)—whether the metal occurs naturally or is reduced from its soln., or congeals from a molten condition. Twin crystals are common; an example of *dendritic copper* is illustrated by Fig. 12 in the chapter on crystals. G. W. A. Kahlbaum and co-workers obtained small octahedra when the metal was sublimed in vacuo, and similar crystals have been obtained by slow deposition from dil. soln. W. L. Bragg's **X-radiogram** of a crystal of copper shows that the atoms are arranged in the pattern of the simple face-centred cubic lattice with side 3·60 A. and closest approach of the atoms, 2·54 A. P. Scherrer gave $3·61 \times 10^{-8}$ cms. for the length of the edge of the elementary cube. H. Bohlin also studied the X-radiogram of copper. S. Nishikawa and G. Asahara, and M. Ettisch and co-workers, found that rolled copper gives an ill-defined X-radiogram with a symmetry related to the direction of rolling; on annealing definite spots replace ill-defined patches, but the copper still shows the direction of rolling after annealing 2 hrs. at 800°. K. F. Slotte estimated the edge of the molecular cube of liquid and solid copper to be $5{\cdot}8\times10^{-9}$ cm. W. L. Bragg computed the radius of the atomic spheres of the crystals to be $0{\cdot}137\mu\mu$, or 137 A. M. N. Saha also made estimates of this magnitude.

J. Percy said that the term **moss copper** is employed in copper-works to designate accumulations of filamentous or moss-like copper which is formed in cavities on ingots of certain kinds of regulus. Under the microscope, he added, the filaments present numerous minute parallel and longitudinal lines or grooves, as though they consisted of bundles of extremely delicate fibres. Moss copper is also said to be remarkable for its purity. F. le Play found at the junction of the regulus and slag of a copper furnace a geode filled with extremely delicate threads of metallic copper, containing Cu, 98·2 per cent.; Fe, 0·4 per cent.; Ni, 0·6 per cent.; and admixed sand and carbon, 0·2 per cent. The so-called **filiform or hair copper** was obtained by A. Liversidge by heating native cupric sulphide in hydrogen at a temp. below the m.p. of copper. Moss silver has been discussed by W. Hampe, W. Hittorf, E. Murmann, H. Moissan, J. Margottet, and E. Weinschenk. A. Beutell has made some observations on this subject—*vide* moss silver.

The surface of cast copper, under the microscope, appears to be composed of large primary and small secondary polygonal granules definitely oriented; a sheet of electro-deposited copper appears to consist of primary granules only, without definite orientation. The crystalline structure of electrolytic copper has been described by O. Faust, G. Grube and co-workers, M. von Schwarz, Z. Jeffries, A. Sieverts and W. Wippelmann, H. S. Rawdon, etc. A low current density gives large well-formed crystals, and a high current density gives crystals which grow at right angles to the surface of deposition, and which have a columnar appearance; with a still higher current density, the structure is broken up, and twinned crystals are common—the twinning is at right angles to the direction of crystal growth. The production of idiomorphic crystals of copper was found by W. E. Hughes to follow the same general laws as those involved in the formation of well-shaped crystals in salt soln.

The metal is an aggregate of crystals so that each grain has a definite orientation which is different from that of its neighbours. The external shape is polyhedral. The grains may grow in the solid metal: (1) When heated below the crystallizing temp. after cold plastic deformation; (2) when a hot-worked or annealed metal is heated to a higher temp. than was previously used, or for a longer time at a lower temp.; (3) when the compressed powder is heated to a high temp. below the m.p.; and (4) when the metal is heated or cooled through certain transition temps. When just crystallized after cold-drawing or rolling, the grains of copper approximate 0·0002 to 0·0012 cm., and after annealing, 0·002 to 0·006 cm. in diameter. G. Tammann has studied the regrouping of the atoms during annealing whereby new crystals are formed. H. Baucke clamped the polished surfaces of two pieces of copper, one piece hammered and the other annealed, and found that, at 105°, the hammered surface became considerably recrystallized, but when the surfaces were separated, or insulated with an oil film, there was practically no modification even after 48 hrs. heating at 180°. This confirms the general observation that forged or drawn metals are in a less stable condition with respect to crystallization than the same metal in the soft state—*e.g.* if plates of forged and soft metals be made the poles of a galvanic cell in a soln. of a salt of the same metal, the forged metal becomes charged negatively and passes into soln. The presence of all but very minute proportions of cuprous oxide, bismuth, and lead is evidenced as discrete particles under the microscope; whereas silver, gold, nickel, manganese, antimony, arsenic, zinc, phosphorus, etc., dissolve to a greater or less extent in the solid metal, and may leave no trace of their presence except possibly in the appearance of the crystals. During rolling, the primary granules are elongated in the direction of the rolling, and this gives the metal its characteristic fibrous structure. M. Ettisch and co-workers say that the crystallites in soft wires are arranged irregularly, while those in hard wires are regularly arranged. E. Rassow and L. Velde have plotted on a triaxial diagram the degree of cold working, the annealing temp. (time constant), and the mean diameter of the grains of copper. Copper is etched for microscopic examination by aqua ammonia, or ammonium persulphate, or an ammoniacal soln. of hydrogen peroxide.[4]

The production and properties of thin films of copper have been discussed by A. W. Wright,[5] W. Betz, L. Houllevigue, W. Spring, A. Knop, M. Faraday, O. Brunck, T. Curtius and F. Schrader, F. D. Chattaway, G. T. Beilby, and P. Neogi.

As previously indicated, in the Arabian, *The Book of the Best Things for the Knowledge of Mineral Substances*, by Abu-r-Raihan,[6] written towards the end of the tenth century, the **specific gravity** of copper is stated to be 8·70, which is not far removed from the value accepted to-day. He also gave 8·82 for the sp. gr. of bronze, and 8·57 for that of brass. Another Arabian writer, Al-Khazini, in his *Book on the Balance of Wisdom*, written in the twelfth century, gave 8·66 for the sp. gr. of copper. An early determination of the sp. gr. of this element by R. Boyle (1690) gave 9; and one by D. G. Fahrenheit (1725) gave 8·834 for Swedish copper, and another 8·799 for Japanese copper. C. Hatchett (1803) gave 8·895; A. T. Kupffer (1824), 8·78; C. J. B. Karsten (1832), 8·721; T. Herapath (1824), 8·900; R. Mallet, 8·667; and H. Schiff, 8·902 (12°). According to W. Stahl, the sp. gr. of copper at different temp. is:

	15°	1100°	1125°	1150°	1175°	1200°	1250°
Sp. gr. .	8·8604	8·3601	8·3492	8·3384	8·3276	8·3168	8·2953

The sp. grs. of the pure metal, measured by different observers, do not agree. The sp. gr. is greatly influenced by the thermal history of the metal, and the presence of impurities. The sp. gr. of ordinary commercial copper usually ranges from 8·6 to 8·9; the standard value is 8·89 at 20°; M. J. Brisson (1787) reported that the sp. gr. of the cast metal is 8·788, and that of the rolled metal 8·878; A. Baudrimont found that slowly-cooled cast copper had a sp. gr. 8·4525; and wire prepared in several different ways had a sp. gr. varying from 8·3912 to 8·8893. Similar observations were made by R. Böttger, and C. O'Neill, while R. F. Marchand and T. Scheerer found for electrolytic copper, 8·914; A. Dick, 8·937; and L. Playfair and J. P. Joule, 8·920; and for finely divided copper, the latter also gave 8·931 (4°), and A. Dick, 8·938. For copper plate at 0°, G. Quincke gave 8·902. The cold working of copper affects the mechanical and the physical properties—elasticity, sp. gr., e.m.f., thermal and electrical conductivities, etc.—of the metal. F. C. A. H. Lantsberry found that the sp. gr. of the cold-worked metal is 8·8313 and of the annealed metal 8·8317. G. W. A. Kahlbaum and E. Sturm [7] state that the sp. gr. of native crystalline copper is 8·94; electrolytic copper, 8·914; cast copper, 8·921; drawn copper, not annealed, 8·939 to 8·949; drawn annealed copper, 8·930; hammered copper, 8·951; copper reduced by hydrogen, 8·367 to 8·416; copper cast in an atm. of coal gas, 8·95. According to W. Hampe (1872), the sp. gr. of pure electrolytic copper at 0° is 8·945; and 8·952 according to H. Schröder (1859). After hammering, the sp. gr. changes from 8·952 to 8·958; and according to G. W. A. Kahlbaum and co-workers (1902), the sp. gr. of the distilled metal is 8·93258 at 20°, and 8·93764 after being subjected to a press. of 10,000 atm. After being subjected to a still higher press., the sp. gr. begins to diminish. According to T. Scheerer and R. F. Marchand, the low sp. gr. of cast copper is due to the **porosity** of the metal, which is supposed to be caused by the absorption of gases at a high temp., and their subsequent evolution during cooling. T. M. Lowry and R. G. Parker say that the sp. gr. of copper increases when the metal is annealed at 100°, and that while the sp. gr. of the metal *en masse* is 8·9153, that of the filings is 8·8900. P. Pascal and J. Jouniaux found the sp. gr. of liquid copper at its m.p. 1083°, in an atm. of an inert gas, is 8·40, and at 1200°, 8·32; L. Playfair and J. P. Joule gave 7·272; and W. C. Roberts-Austen and T. Wrightson, 8·217.

W. Spring has shown that many substances after compression have a lower sp. gr. than before. For example, lead, tin, cadmium, and silver, after being forced through small apertures under press., also show a slight diminution in sp. gr., while with bismuth there is a slight increase. When two plates of a metal—one of which has been compressed, and the other not compressed—are used as plates of a cell in a soln. of one of the salts of the metal, an electric current is generated such that the metal which has been compressed by hammering, etc., is negative to the annealed metal. The current is in the opposite direction with bismuth—which contracts on liquefaction—to what it is with lead, tin, cadmium, and silver—which expand on liquefaction. W. Spring supposed that the metals change under compression to the mol. condition characteristic of liquids; otherwise expressed, metals under great compression assume an allotropic form corresponding with the liquid or amorphous condition which P. Duhem calls *métal flué*, as distinct from the crystalline state—*métal recuit*—obtained by slowly cooling the molten metal.

G. T. Beilby [8] also considers that the metals can exist in two distinct solid phases: (i) the hardened or amorphous state; and (ii) the annealed or crystalline state; and he gives evidence to show that the former is converted into the latter by annealing; and that the latter is converted into the former when work is done on the crystalline metal—*e.g.* polishing the surface of a metal produces what he assumes to be an amorphous film which can be removed by suitable solvents so as to show the underlying crystalline phase; similarly, when a piece of metal is strained by, say, wire-drawing, the friction of the crystals produces an encircling net-work of the amorphous hardened phase between the crystals which increases the tensile strength of the metal. According to G. T. Beilby, the transition temp. between the two phases of gold lies between 250° and 280°; copper, between 250° and 290°; silver, between 230° and 265°; and magnesium, between 300° and 360°.

W. Rosenhain [9] also has given much indirect evidence of the existence of an intercrystalline amorphous film in normally crystalline metals. As a rule, an amorphous substance is more susceptible to attack by chemical agents than the same substance in a crystalline state. According to S. W. Smith, if two buttons of silver—one slowly and the other rapidly cooled—be treated with nitric acid, the one which has been cooled most rapidly will be most quickly dissolved; and according to W. Rosenhain, the loss by volatilization of rapidly chilled castings of silver is greater than with slowly cooled castings. With slow cooling, the crystals are larger and the intercrystalline amorphous cement is less abundant than with sudden chilling where the crystals are smaller. It is inferred that the volatilization is mainly from the amorphous cement, and that the amorphous cement is likewise attacked most rapidly by acids. In the latter case, too, the faster the amorphous cement is dissolved, the greater the surface exposed to the action of the acid, and the more quickly will the metal be dissolved.

O. W. Ellis,[10] therefore, infers that the cold-working of metals favours the production of the amorphous at the expense of the crystalline metal in the balanced reaction: $Cu_{crystalline} \rightleftharpoons Cu_{amorphous}$, and that the amorphous matter produced by the strain undergoes recrystallization when the stress is relieved. The crystallization of deformed metals has been studied by D. Hanson and many others. As a result, it is inferred by D. Hanson that for every degree of deformation in strained metals, there is a critical recrystallization temp. at which crystal growth is extremely rapid, and the size of the crystals produced by this growth is greater, the smaller the amount of deformation preceding such annealing. According to Z. Jeffries and R. S. Archer, 200° is the lowest temp. at which the recrystallization of the cold-worked metal has been observed.

The pure metal is highly ductile and malleable, for it can be rolled into sheets, hammered into foil, or drawn into wire. When subjected to mechanical treatment of this kind, the metal becomes hard; the hardness can be removed by annealing between 500° and 700° in an atm. free from sulphur. When the metal is mechanically worked, it must be frequently annealed to avoid fracture. This is illustrated by the curve, Fig. 9, showing the effect of annealing at different temp. on the elastic limit; the tensile strength curve changes with temp. in an analogous manner. According to E. Heyn,[11] by annealing the metal at 500°, the crystal granules increase in size until they become visible to the naked eye.

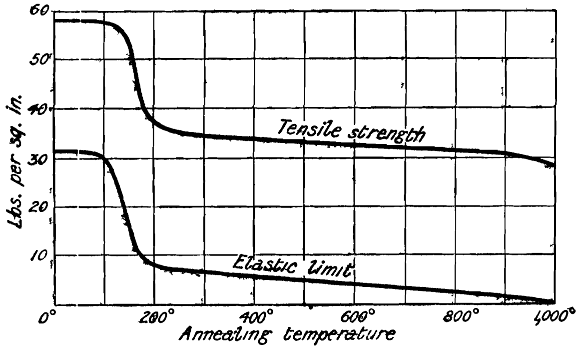

FIG. 9.—The Effect of Annealing at different Temperatures on the Tensile Strength and Elastic Limit of Electrolytic Copper (C. Grard).

According to G. Tammann, cold-work increases the energy content of a metal because the formation of gliding planes, and the translation of particles, leads to a decomposition and an increase in the potential energy; and further, processes take place within the atom which lead to a similar increase. A cold-worked metal is less noble, *i.e.* more chemically active, in the hard than in the soft state. Since, however, the surface layers are alone affected, a superficially hardened piece, still soft in the interior, may behave less nobly than a thoroughly hardened piece. The change in the chemical activity of a metal by working is ascribed to an alteration in the properties of the particles of the metal which, once displaced, are held less firmly in the lattice than before.

The **fracture** of cast copper is more or less granular; that of rolled or drawn copper is fibrous. The **malleability** of a metal refers to its property of permanently extending in all directions without rupture when a stress—pressure (rolling) or impact (hammering)—is applied. The **ductility** refers to the property which enables metals to be drawn into wires. The malleability of copper [12] is equal to that of gold and silver; it has been hammered into sheets 0·0026 mm. thick. The ductility of copper is also high. E. S. Shepherd and G. B. Upton found the ductility expressed in *percentage elongation* during the application of a tensile stress to vary from 12·0 to 22·5 per cent. for cast copper, and from 18·5 to 28·0 per cent. for copper kept a week at 540° and then quenched in water. G. D. Bengough and D. Hanson found that there is a range of low ductility for copper between 250° and 450°; and that the presence of oxygen and arsenic increase the high temp. ductility of the metal.

The ductility of copper is increased by annealing, and G. V. Cæsar and G. C. Gerner, and B. E. Curry have shown that the temp. range within which this softening takes place most rapidly is from 200° to 350° for pure copper; but this is affected by (i) the extent of the previous cold reduction; and (ii) the impurities. Arsenic and silver raise the annealing temp. range of copper. The properties of copper are not affected like those of steel after annealing or rolling. From the work of A. Martens, and F. Johnson. it is generally believed that quenching copper in water after annealing produces a softer metal than if it be slowly cooled, although there is some evidence for and against this view. B. Hopkinson, and J. E. Sears have studied the momentary expansion which occurs on percussion. C. J. B. Karsten pointed out that the greater the purity of copper the greater its malleability and softness, and the less heat required to render the brittle metal malleable. The effects of various foreign metals on the physical properties of copper have been much investigated

Copper is malleable when cold, and at a red-heat; a metal malleable at a red-heat, and not so when cold, is said to be *cold-short;* and a metal malleable when cold, but not so at a red-heat, *red-short.* According to E. Cohen, the Greek Theophrastus, about 371 B.C., stated that he had noticed the disintegration of copper during a severe winter.

Pure copper is comparatively soft. As indicated in the general remarks on hardness, in connection with the alkali metals, this property can be expressed in several different ways, many of them quite arbitrary. On F. Mohs' or the mineralogical scale, the **hardness**[13] of copper is about 3, when that of iron is 4·5, and silver 2·7. O. Faust and G. Tammann's values for the sclerometric hardness measured by the width of a scratch made with a load of 10 grms., is 0·014–0·016 mm. for soft and 0·016 for the hard metal; and with a load of 17 grms., 0·022–0·027 mm. for the soft and hard metals. J. A. Brinell's test for hardness measures the diameter of an impression made by the application of a load applied for a definite time—say 15 seconds. J. A. Brinell's hardness number of copper cast and slowly cooled is 52·8; C. A. Edwards gave 53·0. The numbers for rolled sheet copper unannealed range from 65 to 75, when the value for mild steel is about 104. J. A. Brinell's hardness test can also be represented as a press. in kgrms. exerted per sq. mm. of the ball segment. Copper then gives a hardness of 35·3 kgrms. per sq. mm. A kilogram, under standard conditions, is eq. to 981,000 dynes, or a dyne is eq. to 0·00000101937 kgrm. The curve showing the decrease in the hardness of copper with temp. is slightly concave towards the temp. axis. A. Kürth gave for a load of 400 kgrms.:

	−83°	−50°	18°	100°	200°	300°	390°	523°
Hardness .	41·3	40·1	37·4	35·2	30·8	26·7	23·4	17·6

L. Guillet has shown that the ratio of the tensile strength to Brinell's hardness varies with the hardness of the metal. E. H. Pierce found that in the hard-drawing of copper wire the effect is the same throughout the whole section, and no hard or exterior skin is formed. While M. Hanriot, and Z. Jeffries detected no change in the microstructure of compressed metals, the Brinell's hardness of copper was raised by compression at 10,000 kgrms. per sq. mm. from 27·0 to 46·1. C. Calvert and R. Johnson give the relative hardnesses of gold, silver, and copper as 4 : 5 : 7·2; J. R. Rydberg gives 2·5 : 2·7 : 3·0; S. Bottone, 979 : 990 : 1360; and F. Auerbach, 97 : 91 : 95.

According to G. Quincke, the **surface tension** of copper at its m.p. is 581 dynes per cm., and the **capillary constant,** a^2, is 14·44 sq. mm.; and for solid copper he gives for the capillary constant in grms. $\alpha\, 2r\pi + \beta\, r^2\pi$ for wires r mm. diameter, where $\alpha=0$ for soft copper and 2388 for hard-drawn copper. S. W. Smith found the surface tension at 1150° to be 1178 dynes per cm., and $a^2=28·85$ sq. mm. According to I. Traube, the **internal pressure** of the solid metal is 236,100 megabars. A. Johnsen found the **plastic flow** of copper is not diminished by cooling the metal in liquid air. C. A. Edwards, and W. E. Dalby, and E. C. Bain and Z. Jeffries, also studied the plastic flow of copper. According to H. E. Diller, when a bar of steel was packed in cupric oxide and carbon and heated for some time at 1000°, metallic copper penetrated the steel to the extent of 21·4 per cent., thus demonstrating the **diffusion** of copper into iron. R. J. Anderson measured the rate of diffusion of solid copper in molten aluminium and found it to increase rapidly with rise of temp.; G. Sirovich and A. Cartoceti demonstrated the diffusion of manganese from ferro-manganese into copper at 900°; and H. Weiss studied the diffusion of copper into molten zinc. The **velocity of sound** in copper is $39·7 \times 10^4$ cms. per second. According to J. Kleber, the velocity V of sound in solid metals is proportional to the square root of the quotient of the sp. ht. C and the coeff. of linear expansion α such that $V=57·698\sqrt{C/\alpha}-637$. This applies to copper, silver, gold, magnesium, aluminium, tin, lead, iron, nickel, and platinum, but with tantalum there is a difference, presumably because the constants have not been determined with sufficient accuracy. The velocity of sound is also proportional to the square root of the quotient of the modulus of elasticity, E, by the density, D, such that $V=99\cdot04\sqrt{E/D}$. Consequently, $99\cdot04\sqrt{E/D}=57\cdot698\sqrt{C/a}-637$, and if any three of these constants be known, the fourth can be computed to within five per cent. of its value. The internal **viscosity** of copper has been investigated by M. Ishimoto by the use of tuning-forks and torsion pendulums. K. Honda and S. Konno found the viscosity of rolled copper to be $4\cdot83\times10^8$ at 15°; and that of the metal annealed at 300°, to be $5\cdot13\times10^8$ at 15°.

It must be emphasized that the data for the mechanical properties of the metals are more or less dependent upon the methods employed in the measurements. The values for the elastic qualities, for example, are more or less dependent upon the size and shape of the test-pieces, and on the rate at which the stress is applied, as well as on the previous mechanical and thermal treatment of the material, this quite apart from the influence of traces of impurities on the results. It is therefore usually safer to give ranges of values for pure material treated in different ways rather than to assign definite values for an arbitrarily selected mode of testing these characteristics. It is generally considered that copper may be normalized—*normalized copper*—for tensile strength determinations by casting, rolling, and drawing, followed by annealing for 30–60 min. at 500° with slow or quick cooling, because when prepared under these conditions there is less variation between different samples than in any other condition.[14]

Copper does not break down by fracture; when compressed, it yields indefinitely and becomes flattened out. According to R. H. Thurston,[15] if c denotes the resistance to compression in lbs. per sq. in., e the fractional compression, $c=145000e^{\frac{1}{3}}$ for compressions up to 50 per cent. The **compressibility** of a substance is the change in volume dv which unit volume v undergoes per unit change of press. p (say, a kilogram per sq. cm.), or the ratio of the compression dv/v, to the press. dp applied, that is, dv/vdp. The compressibility of copper is $0\cdot75\times10^{-6}$ (20°), meaning the fractional change of the original volume caused by a press. of a megabar, that is, 10^6 dynes per sq. cm., between 100 and 500 megabars. L. H. Adams, E. D. Williamson, and J. Johnston give $0\cdot75\times10^{-6}$; and they represent the change in volume between the press. p_0 and p by $0\cdot00001+0\cdot000000749(p-p_0)$. E. H. Amagat gave 0·857 per atm.; H. V. Regnault, 1·23; J. Y. Buchanan, 0·864; S. Lussana, 1·0 to 1·1 for press. from 100 to 3000 atm. E. Madelung and R. Fuchs gave $3\cdot101(\pm0\cdot004)\times10^{-12}$ dynes per sq. cm. According to B. Lera, the relation between the compressibility β, the coeff. of expansion α, the at. wt. w, and sp. gr. D, is represented by $(\alpha/\beta)(D/w)^{\frac{4}{3}}=0\cdot048$. Unit volume of copper at 0° is estimated to change 0·0089 vol. when the press. is raised to 12,000 kgrms. per sq. cm. H. Grüneisen found that the compressibility of copper, β, increases rapidly with rise of temp., and that the greater the expansion with rise of temp., the greater the change of compressibility. Thus the value of β for copper at −191° is $0\cdot718\times10^{-6}$; at 17·5, $0\cdot773\times10^{-6}$; at 133°, $0\cdot815\times10^{-6}$; and at 165°, $0\cdot828\times10^{-6}$. A. Mallock found at −190°, $0\cdot718\times10^{-6}$; at 17°, $0\cdot778\times10^{-6}$; and at 100°, $0\cdot801\times10^{-6}$.

Copper is considered to be a very elastic metal. If a strain of ω kilograms exerted on a cylinder of s sq. mm. sectional area, and length l, produces an increase in length, dl, the **modulus of elasticity,** or the **longitudinal elasticity, Young's modulus,** or the **coefficient of resistance to extension,** is $(l/dl)(\omega/s)$ kilograms per sq. mm. The modulus of elasticity is therefore the product of the longitudinal stress by the longitudinal extension or compression; and the value for highly purified copper is between 10,000 and 13,000 kilograms per sq. cm., or about $12\cdot20\times10^{11}$ dynes per sq. cm., or 1220×10^6 dynes per sq. mm., or 17·3 lbs. per sq. in. The observed maximum and minimum values are 1323 and 1052 dynes per sq. mm. A. Gray, V. J. Blyth, and J. S. Dunlop found for electrolytic hard-drawn copper an elastic modulus of 13,220 kgrms. per sq. mm. (19·5°), and for commercial copper, 11,354 (17·4°); G. Wertheim gave 10,519 (15°); and for wire drawn, 12,513; K. Zöppritz gave 12,646; E. H. Amagat, 12,145; K. F. Slotte, 12,550; G. Angenheister, 12,240; W. Voigt, 10,850; J. Kiewiet, 10,800; C. Benedicks, 12,300; F. Kohlrausch and F E. Loomis, 12,140; H. Buff, 12,270; G. F. C. Searle, 12,400 kgrms. per sq. mm., and $17\cdot6\times10^6$ lbs. per sq. in. for drawn and $18\cdot3\times10^6$ lbs. per sq. in. for annealed copper. The best representative value may be taken as 12,200 kgrms. per sq. mm. with maximum and minimum values 13,230 and 10,520 kgrms. per sq. mm. B. Welbourn measured the elastic modulus of a number of stranded cables of hard-drawn copper wire. P. Galy-Aché has measured the elastic deformation which copper possesses in the amorphous intercrystalline medium and in the crystalline part; and F. Rehkuh, the effect of temp. on the restoration of the elastic deformation. M. Rudeloff's values for the effect of temp. on Young's modulus for different samples of copper were:

20°	100°	200°	300°	400°
$17\cdot8-18\cdot1\times10^6$	$18\cdot1\times10^6$	$14\cdot3-15\cdot6\times10^6$	$11\cdot8-13\cdot5\times10^6$	$10\cdot1\times10^6$ lbs per sq. in.

The steady and gradual fall of the modulus of elasticity of copper as the temp. rises[16] to 1000° is illustrated by Fig. 10, due to K. R. Koch and C. Dannecker. According to F. Kohlrausch and F. E. Loomis, the elastic modulus at θ is $E=E_0(1-0\cdot000572\theta-0\cdot00000028\theta^2)$. A. Wassmuth gives for the temp. coeff. of the elasticity $E=E_0(1-0\cdot000359\theta)$. According to C. Bischof, copper becomes very brittle just below its m.p. F. Streintz, M. C. Noyes, H. Walker, H. L. Dodge, G. A. Shakespeare, etc., have made observations on the effect of temp. on this modulus. Heating by an electric current shows no other than a temp. effect According to W. Sutherland, the observed variations of Young's modulus with temp. are linear, and approximately in accord with the empirical relation $E/E_0=1-0\cdot823(\theta/\theta_m)$, where E denotes the value of Young's modulus at $\theta°$, and E_0 its value at absolute zero; and θ_m denotes the m.p. of the solid. The relation was found to hold good for a number of metals between atm. temp. and 102°, but it is imperfect in that it gives a finite value for the modulus at the m.p. when it ought to give a zero value. C. Schäfer gave 3·627 for the temp. coeff., or the percentage increase in Young's modulus in passing from 20° to −182°. E. A. Lewis noted the elasticity is increased by alloying the metal with arsenic, and A. Riche found the same thing with iron.

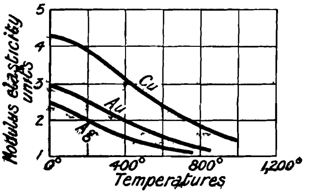

FIG. 10.—Effect of Temperature on the Modulus of Elasticity.

The ratio of the contraction in a lateral direction to the longitudinal extension of a body stretched by a longitudinal stress is called **Poisson's ratio**: the value of this constant for copper ranges from 0·338 to 0·378; E. H. Amagat gave 0·327. The best representative value is 0·34, with a temp. coeff. of about 0·00023 per degree between 0° and 150°. Investigations on Poisson's ratio have also been made by G. Angenheister, who found 0·382; P. Cardani, 0·374; J. Morrow, 0·327; J. R. Benton, 0·322; C. E. Stromeyer and W. Kennedy, 0·322; A. Mallock, 0.348; and W. Voigt, 0·350 for electrolytic copper. A. Bock found Poisson's ratio to be 0·340 at 20°; 0·355 at 60°; 0·352 at 100°; and 0·370 at 150°.

If a uniform press. p kilograms per sq. cm. changes the volume v by dv, the ratio dv/v is called the compression, and the quotient of p by the compression, pv/dv, is called the **volume elasticity** of the substance; the value of this constant for copper is from $13\cdot1\times10^{11}$ to $16\cdot8\times10^{11}$ dynes per sq. cm. The resistance to shearing, or the quotient of the shearing stress by the shear, is called the **rigidity** of the substance to transverse distortion—that is, the **torsion or shear modulus.** The value of this constant for copper is $4\cdot47\times10^{11}$ to $4\cdot55\times10^{11}$ dynes per sq. cm. W. Voigt gave 4780 kgrms. per sq. mm.; N. Savart, 4213; S. Katzenelsohn, 3587; A. Gray, 4199; C. Schäfer, 3967; G. Angenheister, 3587; M. Baumeister, 4450; and J. Kiewiet, 4664 kgrms. per sq. mm. G. Pisati's value for the rigidity n at $\theta°$, when the value at 0° is 3972 kgrms. per sq. mm., is $n=3972(1-0\cdot002716\theta+0\cdot0_623\theta^2$

$-0{\cdot}0_8 47\theta^3$); F. Kohlrausch and F. E Loomis give $n=3900(1-0{\cdot}000572\theta+0{\cdot}0_6 28\theta^2)$ kgrms. per sq. mm. F. Horton gives $4{\cdot}37\times10^{11}$ dynes per sq. cm. at 15° for purified copper, and at 0° the value is $n=4{\cdot}37\times10^{11}\{1-0{\cdot}00039(\theta-15)\}$ dynes per sq. cm. For commercial copper, he gives $n=3{\cdot}80\times10^{11}\{1-0{\cdot}00038(\theta-15)\}$ dynes per sq. cm. K. R. Koch and C. Dannecker give 4240 kgrms. per sq. mm. or $6{\cdot}15\times10^6$ lbs. per sq. in., and for the values at different temp :

20°	100°	200°	300°	500°	800°	1000°
$6\ 02\times10^6$	$5{\cdot}82\times10^6$	$5{\cdot}58\times10^6$	$4{\cdot}85\times10^6$	$3{\cdot}96\times10^6$	$2{\cdot}72\times10^6$	$2{\cdot}10\times10^6$

W. Sutherland[17] gives 4300 kgrms. per sq. mm. for the rigidity at 15°, and estimates that at −273°, the rigidity is 4530 kgrms. per sq. mm. According to H. Tomlinson, the torsion of a wire is increased by raising the temp. to 100°.

The **tensile strength** or **tenacity** of a substance is the greatest longitudinal stress which it can suffer without rupture; the tensile strength of cast copper is 1·2 to $1{\cdot}9\times10^9$ dynes per sq. cm., and of rolled copper 2·0 to $2{\cdot}5\times10^9$ dynes per sq. cm. The tensile strength of cast copper has been almost doubled by mechanical working. E. H. Pierce found the tensile strength of copper wire to be equally affected throughout its whole section by hard drawing. The observed skin effects are due to the rolling of oxide scale into the wire. T. Bolton, D. R. Pye, and W. E. Alkins have studied the effect of cold work on copper. In general, the work of P. Goerens, W. R. Webster, and others has shown that cold work changes the elastic limit, the yield point, the tensile strength, the hardness, sp. gr., magnetic permeability, electrical conductivity, solubility in acids, etc. W. E. Alkins has shown that the effect of progressive cold-drawing is to change the tenacity T of the wire with the sectional area S as illustrated in Fig. 11. The portion AB of the curve corresponds with the equation $T=31{\cdot}6-67S$; the portion CD with $T=30{\cdot}83-82{\cdot}66S$; and the portion BC with $T=23{\cdot}2-(S-0{\cdot}107)^{\frac{1}{3}}$. The results are explained by assuming that the first change which occurs when copper is drawn through the dies is allotropic; when this change is complete, a second change occurs, forming either an allotropic or an amorphous variety of the metal. F. Johnson showed that the presence of cuprous oxide is not responsible for the abrupt change which occurs. O. W. Ellis studied the phenomenon in connection with a zinc-copper alloy Annealing reduces the tensile strength of cast copper from 40 to 21 kgrms. per sq. mm., or, according to C. W. Bennett,[18] from 60,000 or 70,000 to 30,000 or 40,000 lbs. per sq. inch. The tensile strength of electrolytic copper annealed for 2 hrs. at 750° in an atm. of carbon dioxide, decreases as the temp. is raised, passing from 13 tons per sq. in. at 22° to 2·0 tons per sq. in. at 975° as illustrated by the curve, Fig. 9. G. Charpy gave for rolled copper with a tensile strength of 30 kgrms. per sq. mm., the following values when annealed at different temp.:

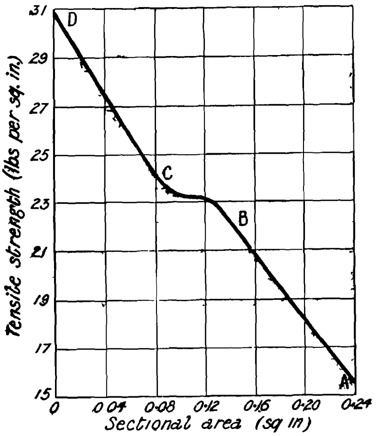

FIG. 11.—Effect of Sectional Area on the Tensile Strength of Copper Wire.

Annealing temp. .	200°	280°	420°	500°	730°	850°
Tensile strength .	30·8	30·5	22·1	22·2	22·2	22·0

Any stress within the elastic limit results in an elastic deformation from which the metal recovers on releasing the stress; if the stress exceeds the elastic limit, plastic deformation or permanent set results. In this overstrained state, the material stretches at an enormously greater rate than before, and the yield is mainly plastic. Under the action of small loads the strains increase at a still greater rate and deviate further from the law of proportionality to stress ; as the load is applied, the material exhibits a strain which is increased by creeping more or less slowly. A. Morley and G. A. Tomlinson showed that copper gives practically the same results immediately after overstrain as before it, showing that if the properties are altered by overstrain, recovery is very rapid.

According to J. Dewar, the breaking stress of copper wires 0·098 in. in diameter is 200 lbs. at 15°, and 300 lbs. at —182°. F. A. and C. A. Lindemann found for the tensile strength of copper 60·10 kgrms. per sq. mm. at —252·6° ; 48·8 kgrms. per sq. mm. at —192° ; and 35·8 kgrms. per sq. mm. at 17°. A. Mallock obtained 1·37 for the ratio of Young's modulus at 0° K. to that at 273° K. E. S. Shepherd and G. B. Upton found the tensile strength of cast copper to lie between 17,990 and 23,740 lbs. per sq. in., and after annealing one week at 540° and then quenching in water, 22,600–24,540 lbs. per sq. in. The lowering of the ultimate tensile strength of copper with rise of temp. is indicated in Fig. 12. F. Johnson studied the effect of impurities on the annealing temp. of copper. P. D. Merica gives for the ultimate tensile strength of normalized copper 35,000 ± 5000 lbs. per sq. in., elongation in 2 in., 40–60 per cent., and reduction in area, 40–60 per cent. The determination of the **elastic or proportional limit** does not yield a measurable value because annealed copper yields slightly with the slightest loads applied in the testing machine ; with hot-rolled copper, there is a small value with very small loads. The elongation with annealing follows just the opposite course to the tenacity. C. Grard's experiments, Fig. 9, give 150°–200° as the transition range, but E. S. Bardwell gives 300°–430°, and the difference is said to be due to the greater oxygen content of C. Grard's test-pieces.

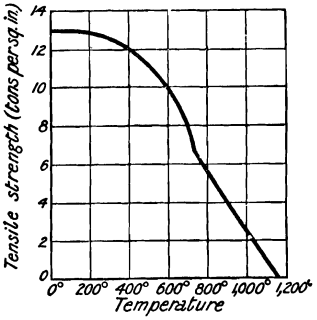

FIG. 12.—The Tensile Strength of Copper at different Temperatures.

A. Martens has studied the effect of variations in the size and shape of the test-pieces on the measurement of tensile strength. A. Martens measured the effect of time in testing and found that with a variation of 0·5 to 40 per cent. in the elongation per min,. the observed difference in the ultimate tensile strength is less than 2 per cent. ; while P. Ludwik found that a wire of electrolytic copper, 0·5 mm. diameter, sustained a load of 4958 grms. for 5 min., one of 4500 grms. for 90 hrs., and one of 3950 grms. for one and a half years. M. von Hübl studied the effect of varying current density on the mechanical properties of electro-deposited copper ; and C. W. Bennett obtained electrolytic copper with a tensile strength approaching that of hard-drawn copper—*viz.* 68,000 lbs. per sq. in.—by varying the current density and using a rapidly rotating cathode. G. D. Bengough and D. Hanson found that the nature of the atm. has a marked influence on the tensile strength of copper at a high temp. An oxidizing atm. gives a high ductility at a high temp. L. Dufour has studied the influence of an electric current on the breaking stress of a wire. Traces of impurities like lead and tellurium make copper brittle, while phosphorus, arsenic, or antimony make the metal tougher. For example, according to G. D. Bengough and B. P. Hill :

Amount of arsenic .	0·04	0·05	0·75	0·94	1·91 per cent.
Maximum stress .	15·55	15·75	15·65	16·55	16·90 tons per sq. in.

R H. Thurston[19] has measured what he calls the *torsion test*, the *shear test*, and the *transverse bending test* of copper. F. Johnson, and A. K. Huntington have studied the effect of the so-called *fatigue test*, or the *alternating stress test*, on copper up to 500°. H. Baucke has investigated the so-called *impact test* on copper at ordinary temp. L. Guillet and V. Bernard carried the impact tests up to 1000°, and found that there is a linear decrease in the specific impact work needed to bend the specimens examined

The coeff. of thermal expansion of copper between 0° and 100° was measured by A. L. Lavoisier and P. S. Laplace in 1782, and they found 0·00001722 and 0·00001712. The *Physikalisch-Technische Reichsanstalt* gives 0·002917 for the linear expansion of unit length between —191° and 16°; and P. Glatzel, 0·001705 mm. for the expansion of a dcm. rod per degree. According to H. Fizeau,[20] the **coefficient of thermal expansion** (linear) at 20° is 0·00001669; at 46°, 0·0000170; W. Voigt gives 0·00001669 at 20°; and H. le Chatelier, 0·0000170, and at 1000°, 0·000020. For the mean coeff. of expansion between 0° and 100°, H. Fizeau gives $0{\cdot}0_4 1596+0{\cdot}0_9 1025\theta$; and A. Matthiessen, $0{\cdot}0_4 1481+0{\cdot}0_7 185\theta$. The linear expansion of copper is not a linear function of temp.; but is well expressed between —40° and 300° by a quadratic equation. W. Dittenberger gives for $dl/l_0 \times 10^6 = 16{\cdot}07\theta + 0{\cdot}00403\theta^2$. F. Henning found a contraction between 0° and —191° of 2·917 mm. per 100 cms. This does not fit Dittenberger's formula. P. D. Merica has quoted a sample, 99·956 per cent. purity, of hot-rolled and cold-drawn electrolytic copper which, between —24° and 64°, had a unit linear expansion (within 0·000003) of $dl/l_0 \times 10^6 = 16{\cdot}48\theta + 0{\cdot}00382\theta^2$; and another sample of 99·968 per cent. copper hot-rolled, drawn and annealed, had (within 0·000009) between —49° and 305°, $dl/l_0 \times 10^6 = 16{\cdot}34\theta + 0{\cdot}00413\theta^2$; F. A. Lindemann from 85° K. to 292° K., $dl/ldt = 124 \times 10^{-6}$; from 20° K. to 80° K., 49×10^{-6}; and from 80° K. to 90° K., 75×10^{-6}. W. E. Dorsey found the coeff. to be lowered by reducing the temp. Thus:

Abs. temp. .	283°	243°	223°	203°	183°	163°	143°	123°	103°
$\alpha \times 10^8$ . .	1635	1610	1595	1500	1468	1437	1305	1206	1039

F. A. Lindemann verified for copper E. Grüneisen's relation: coeff. of expansion ÷sp. ht.=a constant independent of temp. According to I. Zakrezewsky, the coeff. between —103° and —78° is 0·00001516; between —78° and 0°, 0·00001602; between 0° and 25°, 0·00001699; and between 25° and 100°, 0·00001753. The coeff. with hammered copper is rather less than with cast copper. According to A. Matthiessen, if the volume of copper is unity at 0°, it is 1·004998 at 100°. The coeff. of cubical expansion is $5{\cdot}0 \times 10^{-5}$. L. Holborn and E. Grüneisen found 0·0000532 for the mean coeff. of cubical expansion between 0° and 100°, and 0·0000598 between 0° and 300°. E. Grüneisen found the coeff. of expansion, between —190° and 17°, was decreased from $14{\cdot}18 \times 10^{-6}$ to $14{\cdot}09 \times 10^{-6}$ by raising the press. from one to 1000 atm.; and between 17° and 100°, from $16{\cdot}36 \times 10^{-6}$ to $16{\cdot}25 \times 10^{-6}$. F. Wehrenfennig found that by heating and rapidly cooling a copper rod 1·8 metres long and 55 mm. thick, it expanded 3·3 mm. permanently in length. W. Stahl gives for the coeff. of cubical expansion of purified molten copper 0·000054; and for copper after refining by poling 0·0000436. The difference is attributed to the absorption of gases.

The **thermal conductivity** of copper is rather less than that of silver or of gold. According to G. Poloni,[21] if the conductivity of gold is 1000, that of copper is 888; G. Wiedemann and R. Franz give that of commercial copper 732 when silver is 1000, and L. Lorenz gives 0·7198 absolute units for the conductivity of copper at 0°, and 0·7226 at 100°. These numbers represent the amount of heat in cals. which is conducted per second across a plane one cm. thick and one sq. cm. sectional area, when the difference of temp. on the two surfaces of the plane is 1°. H. F. Weber gives 0·8190; W. Schaufelberger, 0·9382. According to C. H. Lees (1908), the thermal conductivity at —160° is 1·079; and according to W. Jäger and H. Diesselhorst (1900), at 18°, 0·918; and at 100°, 0·908 cal. per second per degree per sq. cm. E. Schott found for copper crystals at 0°, $4{\cdot}1 \times 1{\cdot}0$ C.G.S. units; and at —252·6°, $4{\cdot}1 \times 31{\cdot}0$ C.G.S. units; for commercial copper at 0° and —251°, the numbers are respectively $3{\cdot}93 \times 1{\cdot}0$, and $3{\cdot}93 \times 33{\cdot}4$. A. C. Mitchell, E. H. Hall, G. Glage, A. Berget, and others have also studied this property of copper. If K be the thermal conductivity; D the sp. gr.; and C, the sp. ht., then $K/DC = a^2$ represents the thermal conducting capacity at 0°. K. Angström found $a^2=1\cdot163$; at 18°, E. Grüneisen found 1·144, and W. Jäger and H. Diesselhorst, 1·13 ; at 75°, G. Glage obtained 1·15 ; and at 100°, W. Jäger and H. Diesselhorst found 1·09. For a phosphor-copper G. Kirchhoff and G. Hansemann obtained $a^2=0\cdot5059$ at 15°. A. Rietzsch found that the presence of phosphorus and arsenic as impurities diminish the heat conductivity more than they do the electrical conductivity. L. Lorenz found the thermal conductivity to be proportional to the absolute temp. ; R. W. Stewart found at $\theta°$, the thermal conductivity of copper is $1\cdot10(1-0\cdot000530\theta)$. W. Jäger and H. Diesselhorst gave 0·00026 for the temp. coeff. of the thermal conductivity ; K. L. Hagström gave 0·00064 ; O. Chwolson, $0\cdot0_4389$; and L. Lorenz, $0\cdot0_4389$. P. W. Bridgman found the thermal conductivity of copper decreases linearly with press.

The **specific heat** of copper was measured by P. L. Dulong and A. T. Petit,[22] and they found 0·0949 between 0° and 100°, and 0·1013 between 0° and 300°. The sp. ht. increases with rise of temp., and the metal thus offers an increasing resistance to a rise of temp. the higher the temp. Numerous determinations have been made since then by H. Kopp, H. V. Regnault, H. Buff, H. Tomlinson, A. Bartoli and E. Stracciati, W. A. Tilden, P. Galy-Aché, U. Behn, etc. According to G. W. A. Kahlbaum, K. Roth, and P. Siedler (1902), the sp. ht. of pure distilled copper is 0·09272, and after compression at 6000 atm., 0·09266. The sp. ht. increases with rise of *temperature*. H. E. Schmitz (1903) found that the sp. ht. between —192° and 20° to be 0·0798 ; between 20° and 100°, 0·0936 ; and U. J. J. le Verrier obtained the value 0·104 between 0° and 360° ; 0·125 between 360° and 580° ; 0·09 between 580° and 780° ; and 1·118 between 780° and 1000°. J. Dewar obtained 0·0245 for the sp. ht. of copper at 50° K. or —223°. W. Nernst and F. Koref have determined the sp. ht. of copper at low temp. showing that the sp. ht., and hence also the at. ht., approach zero at absolute zero :

	−258°	−223°	−173°	−123°	−73°	−23°	0°
Sp. ht.	0·00077	0·0208	0·0620	0·0794	0 0854	0·0895	0·0909

at temp. above 0°, the values for solid copper are :

	50°	100°	200°	400°	500°	800°	1000°	1083°
Sp. ht. .	0·0931	0·0952	0·0985	0·1050	0·1115	0·1180	0·1245	0·1272

The sp. ht. of 99·87 per cent. copper, at $\theta°$, between 0° and 50°, may be regarded as a linear function of the temp., and may be represented by $0\cdot0917+0\cdot000048(\theta-25°)$. F. Wüst, A. Meuthen, and R. Durrer give $0\cdot10079+0\cdot0000061\theta$, between 0° and 1084° ; and $-0\cdot4150+0\cdot0001312\theta$ between 1084° and 1300°. E. Bède gives 0·09680 for the mean value of the sp. ht. between 17° and 247° ; F. Glaser, 0·1172 for the sp. ht. at the m.p. ; and A. Naccari, $0\cdot092455+0\cdot0_421258(\theta-17)$ at the temp. θ between 0° and 300°, and H. Schimpff, $0\cdot091996+0\cdot0000228545(\theta-17)-0\cdot0000002022(\theta-17)^2$. E. Grüneisen found that the change in the sp. ht. of copper with pressure is $-dC_p/C_p.dp=0\cdot35\times10^{-6}$ kgrm. per sq. cm. The sp. ht. and the density suffer changes of about the same order of magnitude with changes of press. The coeff. of expansion and sp. ht. undergo changes of approximately the same magnitude down to about —190°. W. H. Keesom and H. K. Onnes have carried the measurements of the sp. ht. of copper down to 14·5° K. or —258·5°. F. Glaser gives 0·15563 for the sp. ht. of molten copper at 1084°. The corresponding **atomic heat** rises from 0·0396 at —258° to 5·78 at 0°, to 8·08 at 1083° ; J. Dewar's value at —223° is 1·56. P. L. Dulong and A. T. Petit's constant is 6·02 ; H. V. Regnault found 5 93 for hammered copper and 6·04 for annealed copper.

L. B. Guyton de Morveau (1799) [23] gave 1207° for the **melting point** of copper ; J. F. Daniell gave 1398° ; and J. Violle, 1054°. A. von Riemsdyk said that the m.p. of copper is higher than that of silver, and lower than that of gold. The early determinations are erroneous. According to C. J. B. Karsten, a number of dull stellate spots quickly form on the mirror-like surface of molten copper, and as quickly disappear; these phenomena probably represent the formation and dissolution of cuprous oxide. He added that copper with cuprous oxide in soln. fuses more readily than purer copper, but it does not form so mobile a liquid, and it does not solidify so quickly. Accordingly, if the metal be melted in air, cuprous oxide is formed and dissolved by the metal, and the m.p. is accordingly lowered down to the eutectic indicated in E. Heyn's diagram, Fig. 24. In harmony with this L. Holborn and A. L. Day reported that the m.p. rises from 1064·9° when melted in air to 1084° when air is excluded. The m.p. is also altered by the presence of other metals. J. K. Clement gives 1080·2° ± 1·5°; and A. L. Day, R. B. Sosman, and E. T. Allen give 1082·6° ± 0·8° for m.p. of the pure metal; E. Rudolfi found 1083°; E. Tiede and E. Birnbräuer, 1085°; F. Wüst and co-workers, and T. W. Richards, 1084°; and C. T. Heycock and F. H. Neville, 1081°. The best representative value is 1083°; this is in agreement with the lists of L. I. Dana and P. D. Foote, and K. Scheel; W. Guertler and M. Pirani give 1084° for the best representative value. J. Johnston has shown that the relation between the press. p and the m.p. of the metal at the temp. θ is $p=95{\cdot}1\lambda D \log (T/\theta)$, where λ denotes the heat of fusion per gram. T, the m.p. at ordinary press. on the absolute scale. For copper, $p=95{\cdot}1\times43\times8{\cdot}93 \log (1356/\theta)$; at ordinary temp. copper will therefore melt when the press. is about 24,000 atm.; and the m.p. of copper is depressed $1355/(41{\cdot}3\times43\times8{\cdot}93)=0{\cdot}086°$ per additional atm. R. Wright and R. C. Smith showed that very finely divided copper shows signs of sintering considerably below its m.p.

According to G. J. Meyer, a copper wire 4 mm. thick melts in 130 secs. by the passage of 500 amps., and a 3·5 mm. thick wire in 48 secs., and L. Lincoln found that if the current strength be represented by C, a copper wire of diameter d melts when $C=0{\cdot}14d^{1{\cdot}7}+2{\cdot}3$; and W. H. Preece gives $C=ad^{\frac{3}{2}}$, where a depends on the length of the wire, being 80 if the length is 3 mm., and 70 if it be 150 mm. C. Matignon and R. Trannoy found the melting of copper wires in ammonia or alkyl-amine vapours is probably preceded by the formation of nitrides. Plane clean surfaces of two cylinders of copper were found by W. Spring to be welded together after heating for 8 days at 403°, and the metal can be readily brazed under microcosmic salt, borax, salt, etc. C. J. B. Karsten noted that molten copper expands on solidification, but if the metal has a large proportion of the oxide in soln., the expansion does not occur; and the addition of 0·1 per cent. of potassium, zinc, or lead is likewise sufficient to prevent expansion on solidification. C. T. Heycock and F. H. Neville studied the lowering of the f.p. of cadmium, tin, lead, and bismuth by copper.

C. M. Despretz noticed the **volatility** of copper in a stream of hydrogen, at a white heat; and copper may be boiled in the oxy-hydrogen flame. A. von Riemsdyk could detect no volatilization of the metal below its m.p., but C. Zenghelis detected signs of volatilization at ordinary temp.; E. Tiede and E. Birnbräuer, at 960° in vacuo; and W. Spring, at 400°. R. Blondlot suggested that the volatilization at a bright red heat is due to the formation of a nitride. C. A. Mahoney found that if sodium chloride is present the volatility of copper is augmented; and J. Roskell found a loss in assaying due to the formation of volatile products when copper ore is fused with fluorspar and borax. H. Moissan and A. J. P. O'Farrelley found that when alloys of lead or zinc with copper are heated in the electric furnace, the more volatile lead or zinc is rapidly distilled off leaving comparatively pure copper; tin is not eliminated from a tin and copper alloy so readily. H. Moissan distilled 50 grms. copper from an electric furnace running at 300 amps. and 110 volts; in 6 min., 16·0 grms. were distilled; and in 8 min., 23·3 grms.. C. R. Groves and T. Turner, W. E. Thorneycroft, G. D. Bengough and D. E. Hill, J. Johnston, T. K. Rose, and W. H. Bassett have studied this question in more detail. A. Butts found the volatilization of copper in wire-bar furnaces to be quite appreciable at 1120°. H. Moissan and T. Watanabe found the **boiling point** of copper is above that of silver. Owing to experimental difficulties, it has not been found possible to determine the b.p. very accurately; O. Ruff and B. Bergdahl gave 2305° at atm. press.; J. A. M. van Lempt, 2282°; C. Féry, about 2100°; E. Tiede and E. Birnbräuer, 2000°; and H. von Wartenberg, over 2200°. H. C. Greenwood found the b.p. of copper to be 2310° (760 mm.), and the effect of press. on the b.p. of copper is similar to that of mercury such that if T_1 and T_1' are respectively the b.p. of copper and mercury at 1 atm. press., and T_2 and T_2' their b.p. at some other press., these four magnitudes are so related that $T_1/T_2=T_1'/T_2'$.

H. C. Greenwood found the **vapour pressure** to be 1 atm. at 2310°; 0·34 atm. at 2180°; and 0·13 atm. at 1980°; or, the vap. press. p mm. of mercury at T° K., is given by $\log p=14-16400T^{-1}$. Hence, the vap. press. at the m.p. is near 0·001 mm. O. Ruff and co-workers observed the vap. press. 124 mm. at 2105°; 209 mm. at 2175°; 300 mm. at 2215°; 404 mm. at 2245°; and 752 mm. at 2300°. J. A. M. van Liempt represented the vap. press. $\log_{10} p=-23600T^{-1}+9·20$ for p in atm.; this gives Trouton's constant 42·12. J. W. Richards gave $\log_{10}p=-24180T^{-1}+9·64$. A. Henglein compared the vap. press. formula for copper. The vap. press. of mercury at 115° (388° K.) is approximately 1 mm., and hence copper at 1300° (1573° K.) will have the same vap. press. since the b.p. of copper and mercury are respectively 2583° K. and 630° K. J. H. Hildebrand gives $\log p=-14600T^{-1}+7·85+\log 4·65$ for the vap. press. p in mm. of mercury; and J. Johnston $\log p=-16400T^{-1}+9·14$; and for the temp. at which the vapour is 10^{-3} mm., 1080°; 1 mm., 1520°; 10 mm., 1740°; 100 mm., 2030°; and 760 mm., 2350°. According to F. Kraft, with cathode rays in vacuo, vaporization begins at 1090°, and it is quite fast at 1315°; F. Kraft and E. Bergfeld say that under these conditions vaporization begins at 960° and the metal boils at 1600°. E. Tiede and E. Birnbräuer distilled 3 grms. of copper in 10 min. in a high vacuum. According to L. Hamburger, the thin film of copper deposited on the walls of the vessel in which the metal is heated, is a network of ultramicrons. M. Knudsen has studied the condensation of the vapour of copper on clean glass and mica surfaces; below 350°–575° all the vapour is condensed, and above that temp. an appreciable fraction of vapour is not condensed on the surface.

The **latent heat of fusion** L can be calculated from E. Heyn's data, and J. H. van't Hoff's formula $L=0·02wT^2/fM$ cals. per gram, where f denotes the lowering of the m.p., when w grms. of the solute of mol. wt. M are present in 100 grms. of the metal; and T denotes the absolute temp. of fusion. The result is 38 cals. F. Glaser found experimentally 41·4 cals., F. Wüst and co-workers found 40·97 cals., J. W. Richards, 43·3 cals.; J. Johnston gave 75 Cals. per mol.; and T. W. Richards 8 kilojoules per gram atom, or 30 cals. per gram. J. W. Richards' estimate of the **latent heat of vaporization** is 858 cals. per gram. J. A. M. van Liempt calculated from O. Ruff and B. Bergdahl's data, 120000 cals. for the latent heat of vaporization at the b.p.

According to E. Priwoznik,[24] if copper dips in a neutral soln. of cupric chloride it is blackened by exposure to light, and G. le Bon adds that the metal is sensitive only to rays of shorter wave-length than $0·252\mu$. J. Waterhouse believes that the effect is conditioned by the formation of a film of allotropic copper. Copper, free from radium, was found by N. R. Campbell to emit a peculiar radiation carrying a positive charge, W. J. Russell and A. Colson detected a very slight action of the metal on a photographic plate such that the sensitive surface is darkened when the plate is developed. A. Colson found also that air in the vicinity of some metals acts in a similar way, and he attributed the **photographic activity** of metals to the action of their vapours. W. J. Russell supposed the active agent to be hydrogen peroxide because of the perfect analogy between the effect, and the action of hydrogen peroxide; B. von Lengyel looked upon hydrogen as the active agent; and J. H. Vincent showed that some inactive bodies become active when treated with small quantities of ozone. F. Streintz and O. Strohschneider could detect no action of copper on silver bromide photographic paper, or on potassium iodide paper. R. Emden found a dark grey radiation begins at 415°. C. B. Thwing found that the radiation from molten copper is half as great as that of molten iron, and about 0·14 of that emitted by a black body. P. Desains and P. Curie found the **heat radiation** from copper at 150° and at 300° to have a maximum intensity for wave-length 0·00400. The respective intensities for an incandescent platinum lamp, copper at 300° and 150°, were 5785, 33, and 2 for a wave-length of 0·00186 ; 2123, 60, and 9 for a wave-length of 0·00400 ; and 225, 26, and 6 for a wave-length of 0·00700. The heat radiation has also been studied by D. McFarlane, and H. Knoblauch.

Copper takes a fairly high polish, and reflects well. P. Drude [25] found that copper is the most transparent of the metals for sodium light. H. Rubens found the reflecting power of copper to be stronger than that of nickel or iron, and changes quickly with changes of the wave-length of the incident light.

According to P. Drude, there are two constants which characterize a metal optically—the **refractive index** μ, and the **absorption index** k. The latter is defined in the following manner: The amplitude of a wave, after travelling one wave-length, λ_1, measured in the metal, is reduced in the ratio $1 : e^{-2\pi k/\lambda_1}$, or, for any distance l, $1 : e^{-2\pi l\mu k/\lambda_1}$, where μk is called the **extinction coefficient.** Again, plane polarized light reflected from a polished metal surface is in general elliptically polarized because of the relative change in the difference of phase between the two rectangular components vibrating in and perpendicular to the place of incidence. For a certain angle, ϕ, the **angle of principal incidence,** the change is 90°, and if the plane polarized incident beam of light has a certain azimuth, ψ, the angle of principal azimuth, circularly polarized light results. A selection of these constants for copper is shown in Table IV, which also includes the percentage **reflecting power** R of copper in air, that is, the ratio of the intensity of the reflected ray to that of the incident ray, for light of wave-length λ. P. Drude and L. P. Wheeler studied the reflecting power of copper in water, alcohol, cassia oil, and carbon disulphide. I. C. Gardner measured the reflection coeff. in Schumann's region of the spectrum. A. Kundt gives 0·65 for the index of refraction for white light; for red light, 0·75; and for blue light, 0·95; P. Drude gives for yellow sodium light, 0·54; and 0·58 for red light; and E. van Aubel gives for the A-line of the solar spectrum 2·63. J. H. Gladstone gave for the **refraction equivalent** $(\mu-1)/D=0·184$, and $A(\mu-1)/D=11·7$, where A is the at. wt. of the metal. W. J. Pope gave 13·52. A. Schrauf found the refraction eq. for molten copper to be 0·03876. The above scheme also contains a selection or interpolations from E. Hagen and H. Ruben's values for reflecting power R of the metals expressed in per cent. of the rays vertically incident on the reflecting surface. The relative **emissivities** of copper at 20° by J. T. Tate and at 1090°, 1127°, and 1174° by C. M. Stubbs, for different wave-lengths, λ in microns, are :

TABLE IV.—OPTICAL CONSTANTS OF COPPER.

λ	ϕ	ψ	μ	k	μk	R per cent.

20° . .	—	0·51	—	0·42	0·29	—	0·22	0·210μ
1090° . .	0·374	0 374	0·340	—	0·210	0·148	—	0·106μ
1127° . .	0 473	0 381	0·340	—	0·210	0·152	—	0·130μ
1174° . .	—	0·402	0·349	—	0·197	0·136	—	1·124μ

According to G. K. Burgess and R. G. Waltenburg, the emissivity of a mass of copper 0·01 mgrm., area 0·25 mm., and thickness 0·005 mm., is 0·33 for red light $\lambda=0{\cdot}65\mu$; and 0·38 for $\lambda=0{\cdot}55\mu$; and it is for light of wave-length 0·65μ, 0·10 for solid copper, and 0·15 for the liquid; similarly, for light of wave-length 0·55μ, the emissivity of solid copper is 0·38, and of the liquid 0·36. According to C. C. Bidwell, C. M. Stubbs, and G. K. Burgess and R. G. Waltenburg, there is practically no temp. variation of the emissivity between 20° and 1500°. The selective emissivity is evident from the strong absorption and emissivity at the blue end of the spectrum. H. Lubowsky and F. Henning also measured the emissivity of copper. M. Faraday noted the polarization of thin films of copper prepared by electrically deflagrating the wire in hydrogen. B. Pogany measured the **Faraday effect,** that is, the **rotation of the plane of polarization** of thin films of copper.

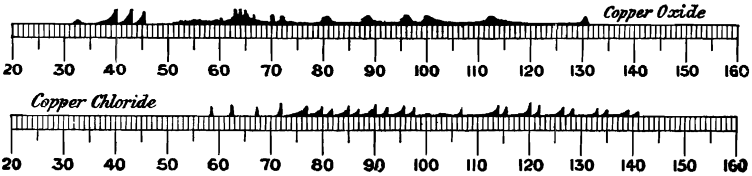
The **photo-electric action** in which the metal loses a negative and acquires a positive charge when exposed to light, was found by W. Hallwachs [26] to be the same with a copper plate polished with fine and with coarse emery. The attempts which have been made to arrange the metals in the order of their photo-electric activity have given very different results in different hands—E. Ladenburg, W. Ramsay and J. F. Spencer, K. Herrmann, and R. A. Millikan and G. Winchester. The latter also measured the positive potential assumed by the metals in vacuo under the influence of ultra-violet light, and found:

Ag.	Fe.	Au.	Cu.	Ni.	Mg.	Al.	Sb.	Zn.	Pb.
1·340	1·225	1·215	1·135	1·126	0·839	0·738	0 394	1·197	0 0 ?

O. Stuhlmann found the photo-electric effect of a beam of ultra-violet light is 1·08 times greater after it has passed through a thin film of copper. W. Frese found the photoelectric sensitiveness of copper is not affected by treatment with water or alcohol; but oxidizing agents generally increase the sensitiveness, and reducing agents decrease it. The absorption and reflection of **cathode rays** by thin plates of copper has been studied by E. Warburg and S. Williams. The X-ray spectrum has been studied by A. Duvallier, F. K. Richtmyer, E. Hjalmar, E H. Kurth, etc. The action of **X-rays** by J. H. Gladstone and W. Hibbert, W. Duane and F. Shimizu, A. Hébert and G Reynaud, D. Hurmuzescu, A. Voller and B. Walter, and T. Cooksey; of **radium radiations** has been investigated by J. A. McClelland; and of **Hertz waves** by J. R. von Geitler. G. W. C. Kaye, and C. S. Brainin have studied the X-radiations from copper. J. Chadwick measured the nuclear charge of the atom.

According to W. H. Bragg, the stopping power s of substances for the **α-rays** is approximately proportional to the sq. root of the at. wt. A, and for copper, $s=2{\cdot}43$ and $\sqrt{A}=7{\cdot}97$. H. R. von Traubenberg found the range of the α-particles in copper to be $18{\cdot}3\times10^{-4}$ cm. J. Crowther found the coeff. of absorption μ for the **β-rays** is approximately proportional to the sp. gr. D, and for copper, $\mu/D=6{\cdot}8$. According to A. S. Russell and F. Soddy, for copper up to 7·6 cm. in thickness, and brass up to 5·86 cm. in thickness, the coeff. of absorption of copper for the **radium rays** is $\mu=0{\cdot}351$; and of brass, $\mu=0{\cdot}325$; for the **uranium rays,** μ is respectively 0·416 and 0·392 for copper and brass; for the **thorium-D rays,** μ is respectively 0·294 and 0·271 for copper and brass; and for **mesothorium rays,** μ is respectively 0·375 and 0·355 for copper and brass. I. G. Barber studied the emission of electrons from copper surfaces. E. Rutherford and J. Chadwick obtained little if any evidence of the emission of long-range α-particles, or charged hydrogen atoms, when copper is exposed to α-rays from radium C.

R. Boyle (1685) [27] noticed that a flame is coloured blue or green by a soln. of cupric nitrate. C. L. Bourdelin (1755) also mentioned the coloration of the alcohol flame by copper. A. S. Marggraf (1765) used copper salts for making green fire; and B. Higgins (1773) made observations in the same direction. According to J. Formanek,[28] the **flame spectrum** of cupric chloride has green lines $\lambda=5507$ and 5386, and blue lines $\lambda=4437$, 4413, 4332, and 4354. According to W. Lanzrath, the strongest lines in the oxy-coal gas flame are λ=3274 and 3247. When a bead of cupric chloride is introduced into the Bunsen flame, a yellow patch of light with a reddish fringe appears; this in turn is bordered with a blue colour, which is surrounded by a green colour. As soon as the cupric chloride is all converted into oxide, the blue colour disappears while the green persists. If hydrogen chloride be introduced into the flame, the blue colour is restored. Copper and cupric oxide give the spectrum of the chloride when hydrogen chloride is introduced into the flame. The spectra of the oxide and chloride of copper, due to W. M. Watts, are shown in Figs. 13 and 14. They are usually superposed one on the other in the same spectrum.



FIGS. 13 and 14.—Flame Spectra of Copper Oxide and Chloride.

Hence, argued A. Smithells, the green colour is produced by copper oxide, the blue by copper chloride, and the yellowish-red colour by metallic copper, at a temp. not high enough to produce its characteristic spectrum. A. Smithells and W. D. Bancroft and H. B. Weiser obtained a deposit of copper by holding in the flame glass or porcelain basins cooled with water. The last-named concluded:

> Copper chloride introduced into the Bunsen flame by a platinum wire gives light blue fringed with grass green. There is a diffuse red coloration through the flame and especially at the tip. The bromide and iodide of copper give a similar coloration except that there is a tendency toward greenish-blue in the inner portion. Cooling a flame coloured green by cupric chloride gives a blue in the cooled region. A flame coloured with an excess of copper chloride gives a spectrum that differs from that obtained with the nitrate, sulphate or oxide. A part of this difference is due to the coloured vapours of the chloride itself. Copper salts dissociate in the flame, and the subsequent oxidation is most important in producing the luminescence. Cupric oxide is stable under the conditions of the Bunsen flame. Copper vapours impart to a gas flame or a hydrogen flame an intense grass-green colour. Copper powder sprinkled into the gas flame, the hydrogen flame, or the carbon monoxide flame, colours it an intense grass green. Copper burns in chlorine with a red glow. When chlorine is impinged on molten copper, the cupric chloride vapours above it are violet-red in colour. An excess of copper chloride in a carbon monoxide flame colours it blue. A jet of hydrogen impinged on it gives green at the point of contact. Copper in the hydrogen flame burning in chlorine gives chiefly blue with an edge of reddish-brown. Copper in the chlorine flame burning in excess of hydrogen gives chiefly green. Copper chloride in the flame of air burning in hydrogen gives green. There is a ruddy colour in the interior of the copper flame, particularly marked when the flame is made strongly reducing.

They also suggest that the green luminescence is due to the copper→cuprous ion reaction; the red luminescence to the cuprous ion→cuprous salt reaction; and the blue luminescence to the cuprous ion→cupric ion or salt reaction. W. N. Hartley found that cupric oxide in the oxy-hydrogen flame gives two copper lines, and a fine band spectrum, Fig. 13. C. Fredenhagen obtained the cuprous chloride or bromide spectrum by warming the compound in a Geissler's tube and passing an electric discharge. A. Gouy obtained the spectrum of copper by spraying cuprous chloride into the Bunsen flame. According to E. Cappel, the sensitiveness of the spark spectrum is seventy times that of Bunsen's flame. B. de la Roche studied the effect of reducing gases on the spectrum of copper.

The emission spectrum in the electric arc in vacuo gives prominent lines of wave-length 3248 and 3274 in the ultra-violet; 4023 and 4063 in the violet; 5105·543, 5153·251, and 5218·202 in the green; and 5700·000, 5782·090, and 5782·159 in the yellow. W. G. Duffield studied the effect of press. on the arc spectrum of copper. The spectrum in the ultra-violet is characteristic. There is a large number of lines in the spectrum of copper. 444 lines between λ=4704·8 and 2105 have been recorded by W. N. Hartley, G. D. Liveing and J. Dewar, A. de Gramont, F. Exner and E. Haschek, L. and E. Bloch, etc. The arc spectrum of copper though so much richer in lines than the spectra of silver and gold, appears to be built on the same general plan. This has been studied by H. Kayser and C. Runge, W. Huppers, K. Hasbach, W. Randall, M. A. Catalan, J. R. Rydberg, etc. The spectra all show a strong pair of doublets in the ultra-violet; a series of lines in the red which are proved to belong to the same system by their Zeemann patterns; and a series in the immediate ultra-red. With copper and silver a few other lines have been assigned to these two series, but with gold none have been so allocated. F. Handke has studied the spark spectrum in Schumann's region. H. Kayser and C. Runge pick out two triplets and six pairs of doublets, and suggest that the pair of lines λ=3274·06 and 3247·65, which forms the strongest in the spectrum of copper, be regarded as the first member of the principal series, and that the other components of the series have not yet been found, but they probably occur far in the ultra-violet in Schumann's region. The pair of lines for λ=5782·30 and 5700·39 belong to no known series. There is an associated series with the two pairs of lines:

$$\lambda^{-1} \times 10^8 = 31591{\cdot}6 - 131150n^{-2} - 1085060n^{-4}; \quad 31840{\cdot}1 - 131150n^{-2} - 1085060n^{-4}$$

when $n=4$, 5, and 6, Fig. 15, and another line λ=3654·6, which does not fit this series for $n=3$ or $n=7$. A second associated series with two pairs of lines:

$$\lambda^{-1} \times 10^8 = 31591{\cdot}6 - 124809n^{-2} - 440582n^{-4}; \quad 31840{\cdot}1 - 124809n^{-2} - 440582n^{-4}$$

with $n=4$ and 5, as in Fig. 15. W. M. Hicks has made a more elaborate study of the series spectral lines of copper, silver, and gold. A. Fowler has summarized the available data on this subject. R. A. Millikan followed the ultra-violet spectrum to λ=149·5 A.; J. C. McLennan studied the vacuum arc spectrum. The effect of the magnetic field has been studied by J. R. Rydberg, and by C. Runge and F. Paschen.

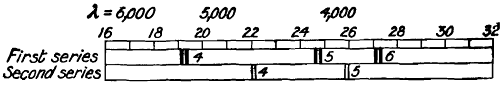


FIG. 15.—Series Spectra of Copper.

N. Lockyer and W. C. Roberts-Austen found that copper vapour gives a continuous absorption in the blue. Thin sheets of glass coloured with cuprous oxide give a small absorption near λ=5702; and glass coloured with cupric oxide gives an absorption in the orange-yellow and the red part of the spectrum. G. A. Hemsalech found the spectral lines due to thermoelectric and chemical excitation are of the same type. M. N. Saha made observations on the **ionizing potential** of copper; and B. E. Moore, on the excitation stages in the arc spectrum of copper.

The **electrical conductivity** of copper is rather less than that of silver, and greater than that of platinum; and on account of the technical importance of copper wires or cables as conductors of electricity, the subject has attracted a great deal of attention.[29] Remembering that the electrical conductivity is the reciprocal of the electrical resistance of a cm. cube, expressed in ohms, when mercury at 0° has the value $1{\cdot}063 \times 10^{-4}$ ohms, copper has a conductivity of $58{\cdot}83 \times 10^{-4}$ at 25°, and $44{\cdot}23 \times 10^{-4}$ at 100°; and a **specific resistance** of $1{\cdot}700 \times 10^{6}$ ohms per cm. cube at 25°, and $2{\cdot}261 \times 10^{6}$ at 100°. The International Electrical Commission of 1913 recommended the adoption of the following values for the electrical resistance of annealed copper at 20°: 0·017241 ohm (metre, sq. mm.); 0·15328 ohm (metre, gram); and 0·67879 microhm (cubic inch). The conductivity diminishes or the resistance increases as the temp. rises such that, according to A. Matthiessen and M. von Bose, the resistance R at θ° when the resistance at 0° is R_0 is given by $R=R_0(1-0{\cdot}0036701\theta+0{\cdot}000009009\theta^2)$; J. Dewar and J. A. Fleming gave $R=R_0(1+0{\cdot}004280\theta)$; the standard of the *Verbandes deutscher*

Elektrotechniker is $R=R_0(1+0{\cdot}004\theta)$; and L. Benoist gives $R(1+0{\cdot}003637\theta+0{\cdot}000000587\theta^2)$. E. F. Northrup's values for the electrical resistance of copper in microhms per cm. cube at high temp. are :

	20°	1000°	1082·6°	1082·6°	1100°	1340°	1443°
Resistance . .	1·7347	9·42	10·20	21·30	21·43	23·39	24·22
	Solid.			Liquid.			

G. W. O. Howe has studied the electrical resistance of multiple-stranded wires. According to E. S. Bardwell, the electrical conductivity of copper wires increases slowly with the temp. of annealing up to 300°, and a rapid rise then occurs as the annealing temp. reaches 430°, after that there is very little change up to 650° when the conductivity falls very considerably owing to the deterioration of the metal. A. L. Feild calculated the resistance of *amorphous copper* at 20° to be 12·67 micro-ohms per c.c. The resistance diminishes rapidly as the *temperature* falls and approaches zero below −200°, as illustrated in Fig. 16. J. Dewar, J. A. Fleming, and H. Dickson have given data for the resistance of copper down to −206°, and G. Niccolai values for the resistance of a cm. cube in ohms.

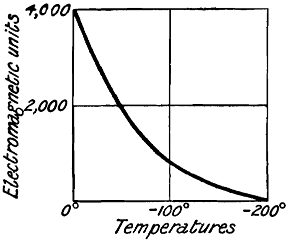

FIG. 16.—Effect of Low Temperature on Electrical Resistance of Copper.

	0°	−50°	−100°	−150°	−192·9°	−206·6°	−251·1°	−252·8°	−258·6°
Ohms .	1·578	1·240	0·904	0·567	0·249	0·163	0·028	0·016	0·014

The temp. resistance curve for silver cuts that of copper below —70°, when copper has a greater resistance than silver. L. Holborn gave 0·00433 for the mean coeff. per degree between 0° and 100°. R. Schott gave for the electrical conductivity of crystals of copper at 0° and —252·6°, respectively $62{\cdot}1\times10^4$, and $62{\cdot}1\times834\times10^4$ C.G.S. units ; and for commercial copper, respectively $63{\cdot}0\times10^4$, and $63\times48\times10^4$ C.G.S. units.

E. Wartmann and O. D. Chwolson found that the resistance of copper is increased by *pressure*. P. W. Bridgman found the electrical resistance of copper to be influenced by the press. such that

	0°	25°	50°	75°	100°
Resistance . . .	1·000	1·1073	1·2146	1·3219	1·4293
Press. coeff. 0 kgrm. .	$-0{\cdot}0_5201$	$-0{\cdot}0_5196$	$-0{\cdot}0_5192$	$-0{\cdot}0_5188$	$-0{\cdot}0_5184$
Press. coeff. 12,000 kgrms.	$-0{\cdot}0_5175$	$-0{\cdot}0_5174$	$-0{\cdot}0_5173$	$-0{\cdot}0_5172$	$-0{\cdot}0_5171$

This gives a temp. coeff. 0·004293 for 99·995 per cent. copper ; the result is a shade higher than 0·00428 of W. Jäger and H. Diesselhorst for copper with 0·05 per cent. of zinc. The press. coeff. at 0° was $-0{\cdot}0_52008$, while E. Lisell's value is $-0{\cdot}0_5187$. A. Matthiessen found that the resistance does not change by the passage of feeble currents, but W. H. Preece and F. Larroque found it is increased by strong currents. E. Lax studied the effect of *mechanical stresses* on the resistance of copper. According to J. Bergmann, the resistance of copper depends on the *structure*, and H. P. Brown showed that it is influenced by working the metal. Hard-drawn copper was found by G. W. A. Kahlbaum and E. Sturm to have a greater resistance than annealed copper since the resistance of a wire 4·25 m. long and 0·27 mm. diameter was 1·00953 ohm in the first case and 1·00321 ohm in the second. For electrolytic copper at 0°, the specific resistance of hard wire is $1{\cdot}603\times10^{-6}$ with a temp. coeff. of 0·00408 between 18° and 48° ; and of soft wire, $1{\cdot}563\times10^{-6}$ with a temp. coeff. 0·00416 between 18° and 48°. L. de Marchi, H. Tomlinson, J. Hopps, and

A. Mousson found that the resistance of copper wire is increased by stretching. J. and A. Bidwell reported that vertical wire conducts better downwards than upwards; G. Ercolini, that the twisting and untwisting of copper wire increases the resistance; L. L. Grunmach, that the resistance increases by transverse magnetization; and B. Sabat, that the resistance is increased by exposure to radium radiations.

The influence of impurities on the electrical conductivity is so marked that quantities almost inappreciable by chemical analysis raise considerably the electrical resistance. Lord Kelvin and P. Drude investigated the decrease in the conductivity of copper by melting the purified metal in air. According to A. Matthiessen, this phenomenon does not occur if lead, silver, or tin be present, because these metals retard the formation of cuprous oxide. Generally, the presence of impurities lowers the conductivity of the metal, and that, as J. Dewar and J. A. Fleming showed, particularly at low temp. G. Kamensky found the conductivity of copper is reduced if antimony be present; A. Matthiessen and M. Holzmann that phosphorus, arsenic, or iron acts in the same way; and L. Addicks, that the presence of 0·0013 per cent. of arsenic, or 0·0071 per cent. of antimony, lowers the electrical conductivity of copper 1 per cent. as illustrated in Fig. 17. He also noted that oxygen is inclined to raise the electrical conductivity as indicated by the dotted line, Fig. 17; in this case, the oxygen possibly acts by oxidizing the impurities. W. H. Mordey studied the effect of arsenic; and J. O. Arnold and J. Jefferson that of bismuth. According to the latter, bismuth acts by forming small crystals which offer a greater resistance to the passage of the current. J. Dewar and J. A. Fleming studied the effect of aluminium; K. Feussner and S. Lindeck, that of manganese; and E. Branly, that of zinc. The presence of one-eighth per cent. of magnesium is said to improve the conductivity of cast copper. A. L. Williams and J. C. McLennan found that when fused with mica there is a marked fall in the resistance with a rise of temp.

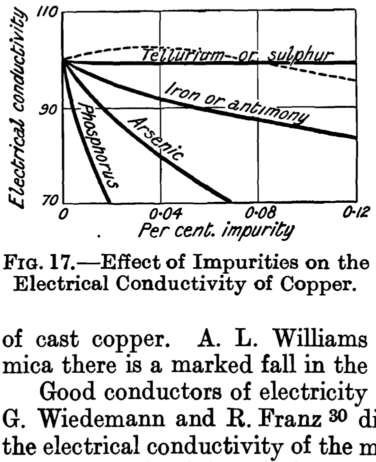

FIG. 17.—Effect of Impurities on the Electrical Conductivity of Copper.

Good conductors of electricity are in general good conductors of heat. In 1852, G. Wiedemann and R. Franz [30] discovered empirically the interesting relation that the electrical conductivity of the metals at 20° is approximately proportional to their thermal conductivity; otherwise expressed, **the ratio of the thermal to the electrical conductivity of good conducting metals has always the same value when the temperature is constant—Wiedemann and Franz's law ;** meaning that the ratio of the thermal to the electrical conductivity is a universal constant and independent of the nature of the metal. This rule has been found to be valid for silver, copper, gold, zinc, tin, lead, platinum, bismuth, and for a number of alloys. A. W. Porter and F. Simeon showed that with sodium and mercury the ratio holds quite well when carried through a change of state, for while the thermal conductivities change abruptly in passing from the solid to the liquid state, their electrical resistivities likewise increase abruptly on fusion. Similarly, E. F. Northrup and F. R. Pratt compared bismuth and tin under like conditions; the electrical resistances of these two metals change abruptly in opposite directions on fusion, and they found, in agreement with G. Wiedemann and R. Franz's rule, that the thermal resistivities likewise change abruptly in the opposite direction. The results with iron are not so satisfactory. G. Kirchhoff and G. Hansemann consider that the disturbance is connected with the magnetic properties of iron, but E. Grüneisen showed that the exceptional behaviour of iron is due to the impurities present in the metal. The law holds exceedingly well for pure metals, less accurately for alloys, and not at all for poor conductors. How well may be gathered from the comparisons of the thermal and electrical conductivities of the metals shown in Table V.

TABLE V.—THERMAL AND ELECTRICAL CONDUCTIVITIES OF SOME METALS.

Metal.	Thermal conductivity — cals. per cm. per sec. at 0° (*K*).	Electrical conductivity — reciprocal ohms per cm. at 0° (κ).	Ratio.	
			0°	18°
Copper . .	0·7198	457,400	$6{\cdot}35\times10^{-11}$	$7{\cdot}38\times10^{-11}$
Magnesium . .	0·3760	244,700	6·51	—
Aluminium . .	0·3435	244,600	6·54	7·06
Cadmium . .	0·2200	144,100	6·55	7·84
Iron . . .	0·1665	103,700	6·23	8·90
Tin . . .	0·1528	93,500	6·12	8·16
Lead . . .	0·0836	51,400	6·15	7·94
Antimony . .	0·0443	22,000	4·97	—
Bismuth . .	0·0177	9,200	5·26	10·68

In 1872, L. Lorenz showed experimentally that in many cases **the temperature variation of Wiedemann and Franz's ratio between 0° and 100° is proportional to the absolute temperature :** or G. Wiedemann and R. Franz's ratio is equal to $1{\cdot}367T$; or, if K denotes the thermal conductivity, and κ the electrical conductivity, $k_{100}=\kappa_0/\kappa_{100}K_0=1{\cdot}367$. The observed values for the constants are :

Copper.	Magnesium.	Aluminium.	Cadmium.	Iron.	Tin.	Lead.
1·358	1·398	1·367	1·315	1·530	1·334	1·304

More, generally, for the metals copper, silver, gold, nickel, zinc, cadmium, lead, tin, L. Lorenz's temp. coeff. is appreciably constant within the limits of experimental error. W. Meissner showed that the divergences of copper from the G. Wiedemann, R. Franz, and L. Lorenz's law increase as the temp. is reduced. With platinum and palladium, both G. Wiedemann and R. Franz's ratios and the temp. coeff. are rather large ; with aluminium, G. Wiedemann's and R. Franz's ratio is rather low, and the temp. coeff. rather large ; and with bismuth, the converse obtains. C. H. Lees found that the deviation from L. Lorenz's 1·367 is rather larger at the temp. of liquid air than at ordinary temp. In a general way it may be said that alloys show considerable deviations from both G. Wiedemann and R. Franz's and L. Lorenz's laws, although with some alloys the two laws apply very well. The increase in the electrical resistance of some metals, say silver, with the addition of a trace of impurity has not been explained by a decrease in the number of mobile ions. Lord Rayleigh has pointed out that since the flow of an electric current from one metal to another produces an absorption or development of heat at the junction—the Peltier effect—the observed resistance of heterogeneous alloys will be affected by the local thermoelectric junctions in the interior of the metal.

Table V seems to show that the two effects are somehow related, and it has been assumed that both heat and electricity are conducted by the same agent, namely, rapidly-moving electrons assumed to be normally present in the metal. With good conductors, the amount of heat distributed by radiation and the dynamical action of the molecules is assumed to be small in comparison with that distributed by the rapidly-moving electrons ; and with poor conductors, the amount of heat distributed by radiation and mol. motion is appreciably greater than with good conductors. Accordingly, G. Wiedemann and R. Franz's ratio will be greater with poor than with good conductors.

The mathematical investigation of the assumption that the conduction of both heat and electricity in good conducting metals is effected mainly by the agency of free electrons, leads to the conclusion that the ratio of the thermal and electrical conductivities is a constant which is independent of the nature of the metal, and proportional to the absolute temp. If k denotes the thermal conductivity ; κ, the electrical conductivity ; R, the gas constant ; c, the electrical charge carried by a univalent electrolytic ion; and T, the absolute temp., then N. R. Campbell has shown from the electron theory of conduction that, at 18°, G. Wiedemann and R. Franz's ratio, will be:

$$\frac{k}{\kappa}=\frac{4}{3}\left(\frac{R}{e}\right)^2 T\text{; or } \frac{k}{\kappa}=7{\cdot}15\times10^{-11}$$

This is in close agreement with the observed results; and with the assumption that the deviation with poor thermal or electrical conductors is due to an appreciable contribution to the thermal conductivity by atomic or mol. motions. Substances like quartz or paraffin wax, which are exceedingly poor electrical conductors, have an appreciable thermal conductivity—*e.g.* the thermal conductivity of quartz, 0·029, exceeds that of some of the metals.

According to H. Davy,[31] two pieces of the same polished copper introduced at the same time into an aq. soln. of potassium sulphide, exhibit no electrical effect, but if introduced in succession, there is sometimes a marked electrical effect—the piece of metal first immersed in the liquid is negative, the other positive. Again, copper hardened by hammering is negative to rolled copper; a specimen of brittle copper, in which no impurity could be detected, was negative with respect to soft copper; and over-poled or under-poled copper, containing in the one case probably a little carbon, and in the other a little oxide, are negative to pure copper. The **Volta difference of potential** of two metals in contact, in air at about 18°, varies with the condition of the metal surface, and the nature of the surrounding atm. The following results in volts for copper and brass are therefore more or less of an approximation:

	C.	Cu.	Fe.	Pb.	Pt.	Sn.	Zn.	Zn amalgam.	Brass.
Copper . .	−0·370	—	0·146	0·542	−0·238	0·456	0·750	0·894	0·087
Brass . .	−0·414	−0·087	0·064	0·472	−0·287	0·372	0·679	0·822	—

These results must not be confused with the e.m.f. at the junction of two metals in metallic contact.

A. Walker found that copper filings are positive towards a copper plate if the two be separated with paper moistened with sodium sulphate or chloride; and negative, if the paper be moistened with ammonia or dil. sulphuric acid. S. Marianini found that a polished plate of copper is positive when opposed in a soln. of sodium chloride to a similar plate which has been made brown by heat; and A. Gouy and H. Rigollot found the potential difference is augmented when the browned plate is illuminated; hence, H. Rigollot proposed to utilize the phenomenon to make an *electrochemical actinometer*. A. Pacinotti, W. Hankel, and H. Pellat found that an illuminated plate of copper is electronegative towards a similar plate in darkness, and if the illuminated plate has been oxidized, it is electropositive. W. Ramsay and J. F. Spencer obtained an e.m.f. of 10 millivolts by illuminating one of two such copper plates with ultra-violet light.

E. Abel placed copper next to silver in the electrochemical series, and according to G. de Overbeck, a film of copper 0·000001 mm. thick suffices to show these electrochemical effects. According to H. Buff, W. Hankel, W. Skey, R. B. Clifton, B. W. Gerland, J. C. Poggendorff, and W. Ostwald, copper is *negative* in aq. potassium hydroxide, conc. soln. zinc sulphate (indifferent in a dil. soln.), aq. potassium hydrosulphide, aq. potassium cyanide, *positive* towards cupric sulphate soln., the haloid acids, and towards nitric, sulphuric, phosphoric, formic, acetic, propionic, oxalic, and benzene sulphonic acids. H. Buff says it is negative towards water, W. Skey says positive.

The e.m.f., E, of a metal in contact with a soln. of a salt of this metal is, according to W. Nernst's theory, described in the first volume:

$$E=\frac{RT}{nF}\log\frac{P}{p}\text{; or, } E=\frac{RT}{nF}\log P-\frac{RT}{nF}\log p$$

where n represents the valency of the cation; p the osmotic press. of the metal cation; $F=96,540$ coulombs; and P is a magnitude which is called the soln. press. of the metal. For copper, at 18°, $E=0·0577n^{-1}\log_{10}(P/p)$. If E_0 be the potential of a metal at 18° against a soln. of a salt of the metal with a gram-ion of the metal per litre, and p_0 the corresponding osmotic press. of the ions, in the above expression $(RT/nF)\log P=E_0$ when $p=p_0$. If C and c denote the conc. of the ions in gram-ions per litre,

$$E=\frac{RT}{nF}\log\frac{C}{c};\quad \text{or,}\ E=\frac{RT}{nF}\log C-\frac{RT}{nF}\log c$$

The **electrolytic solution potential** of an N-soln. of copper (ous), $Cu^{\cdot}$-ions against the hydrogen electrode is reported to be —0·43 volt by G. Bodländer;[32] —0·465 volt by C. Immerwahr; —0·470 volt by G. Bodländer and O. Storbeck; and —0·487 volt by R. Luther; for an N-soln. of copper (ic), $Cu^{\cdot\cdot}$-ions against the hydrogen electrode, N. T. M. Wilsmore gives —0·329 volt; W. Nernst, and G. Bodländer give —0·34 volt; G. Bodländer and O. Storbeck, —0·344 volt. G. Magnanini found the difference of potential in volts between zinc in a normal soln. of sulphuric acid and copper immersed in the given soln. containing M mols per litre, $\frac{1}{2}M$-H_2SO_4, 1·007 volt; M-NaOH, 0·802 volt; M-KOH, 0·770 volt; $\frac{1}{2}M$-Na_2SO_4, 1·013 volt; M-$Na_2S_2O_3$, 0·388 volt; $\frac{1}{2}M$-K_2CrO_4, 0·946 volt; $\frac{1}{2}M$-$K_2Cr_2O_7$, 1·236 volt; $\frac{1}{2}M$-K_2SO_4, 0·957 volt; $\frac{1}{2}M$-$(NH_4)_2SO_4$, 1·015 volt; $\frac{1}{4}M$-K_4FeCy_6, not constant; $0·167M$-K_3FeCy_6, 1·107 volt; M-KCNS, 0·525 volt; M-$NaNO_3$, 1·036 volt; $\frac{1}{2}M$-$Sr(NO_3)_2$, 1·030 volt; $\frac{1}{8}M$-$Ba(NO_3)_2$, 1·096 volt; M-KNO_3, 1·048 volt; $\frac{1}{5}M$-$KClO_3$, 1·053 volt; $0·167M$-$KBrO_3$, 1·113 volt; M-NH_4Cl, 0·812 volt; M-KF, 0·613 volt; M-NaCl, 0·809 volt; M-KBr, 0·736 volt; M-KCl, 0·816 volt; $\frac{1}{2}M$-Na_2SO_3, 0·899 volt; M-NaOBr, with a quantity of bromine was used corresponding to NaOH, 1·0 volt; M-tartaric acid, 1·046 volt; $\frac{1}{2}M$-tartaric acid, 1·109 volt; $\frac{1}{2}M$-potassium sodium tartrate, 1·008 volt.

The potential of a normal calomel electrode is —0·56 volt. N. T. M. Wilsmore hence calculates that at 18° the potential of a soln. of a copper salt, containing a gram-ion per litre, against a copper electrode, is —0·606 volt; it follows that the electrode potential is $-0·606=0·0289\log_{10}P$, if the unit of press. be 23·9 atm., for this is the osmotic or soln. press. of the metal at 18°; and therefore $\log p=\log 1=0$. Hence the soln. press. of copper in its passage from $Cu\rightarrow Cu^{\cdot\cdot}$ at 18° is 3×10^{-20} atm. This small magnitude means that metallic copper has but a small tendency to form cupric ions. Similarly, for a normal soln. of cuprous ions $Cu\rightarrow Cu^{\cdot}$, at 18°, $-0·731=0·058\log(P/23·9)$, or $P=24\times10^{-11}$ atm. Hence, also, cuprous copper is more electro-positive than cupric copper. If the potential of the normal hydrogen electrode be conventionally regarded as zero, what has been called the absolute potential, under the assumption that the true potential of the normal calomel electrode is —0·56 volt, must have 0·277 volt added to it to give the electrolytic potential. Thus, the electrolytic potential of copper, $Cu\rightarrow Cu^{\cdot\cdot}$, is $-0·606+0·277=-0·329$ volt, where the sign denotes the charge of the soln. against that of the electrode. Usually, however, the potential of the electrode is under discussion, and since in a voltaic combination, the electrode metal with the higher potential is said to be its positive pole, and the charge of the electrode against that of the soln. is to be understood. S. Labendzinsky found for the potential of copper against the hydrogen electrode with soln. containing N gram-eq. of the salt per litre:

N.	1·0	0·1	0·01
$CuSO_4$	0·304	0·284	0·262 volt
$Cu(NO_3)_2$	0·331	0·294	0·266 „
$Cu(C_2H_3O_2)_2$	0·278	0·264	0·242 „

For the absolute potentials add 0·277 to these values. The soln. of copper acetate marked 1·0N was sat., approximately 0·8N. In addition, many other determinations of the potential of the copper electrode against different soln., have been made; the potential of copper against aq. soln. of sulphuric, hydrochloric, and nitric acids, by F. Exner and J. Tuma; cupric sulphate, by H. Pellat, J. Miesler, N. T. M. Wilsmore, B. Neumann, M. le Blanc, W. E. Ayrton and J. Perry, F. Paschen, C. Immerwahr and F. Braun; cupric nitrate, by B. Neumann, and F. Exner and J. Tuma; cupric acetate, by B. Neumann and C. Immerwahr; copper anodes in alkaline soln., by F. Jirsa; cupric chloride, by F. Exner and J. Tuma; and cupric tartrate and cupric ammino-compounds, by C. Immerwahr. The latest-named also has studied soln. with suspensions of cupric carbonate, hydroxide, oxide and sulphide, and of cuprous chloride, bromide, iodide, and thiocyanate; and R. Luther has dealt with soln. of cuprous sulphate. G. Thompson, F. Spitzer, A. von Oettingen, S. B. Christy, and F. Kunschert have studied the potential of copper against cupric salts in soln. of potassium cyanide. S. B. Christy found

Per cent. KCy	6·5	0·65	0·065	0·0065	0·00065	0·000065	0·0000065
Potential .	+0·930	+0·680	+0·430	−0·050	−0·250	−0·270	−0·280 volt

F. Spitzer found the potential increases with the proportion of cupric salt and of cyanide which are present. F. Kunschert found that in normal soln. with free Cy'-ions, the potential is 0·157 volt, or, $1{\cdot}130-0{\cdot}0575 \log ([CuCy''_4]/[Cy']^4)$. U. Sborgi and A. Donati, G. Magnanini, and N. R. Dhar, studied the potential of copper in various salt soln.

L. W. Oholm studied the e.m.f. of the cell with copper or copper amalgam in cupric sulphate soln. against mercurous sulphate and mercury. A. Voller found that the potential of copper in soln. of cupric sulphate at 91° is 0·43 of its value at 22°; and in soln. of zinc sulphate at 80°, 0·33 of its value at 25°. The potential in soln. of sodium chloride is raised at 78° to 0·17 of its value at 21°. G. N. Lewis and W. N. Lacey found the normal potential of the copper electrode against cupric ions at 25°, to be −0·3469 volt. P. Chroustchoff and A. Sitnikoff found the temp. coeff. between 0° and 50° is 0·00066 volt per degree. From E. Bouty's, and A. Gockel's measurements $dE/dT=0{\cdot}000756$, F. Exner also found copper at 92° to be less negative in sulphuric acid (1 per cent.), nitric acid (0·6 per cent.), and acetic acid (0·6 per cent.) than at ordinary temp., and more negative in acetic acid (7 per cent.), potassium hydroxide (5 per cent.), and sodium hydroxide (0·3 per cent.); he also found that the potential of a copper tube is not affected if one of the gases hydrogen, oxygen, carbon dioxide, coal gas, carbon disulphide, or the four hydrogen halides, is streaming through the tube. According to A. Fischer, and G. Coffetti and F. Förster, the decomposition potential falls with increasing current density.

G. Carrara and L. d'Agostini found the potential of copper towards soln. of cupric sulphate, chlorate, or nitrate in methyl alcohol; N. P. Kazankin, in amyl alcohol; and L. Kahlenberg, in pyridine soln. J. Brown investigated the potential of copper against fused chlorides; J. H. Gladstone and A. Tribe fused cupric chloride; J. L. Hoorweg used a copper-iron couple in fused waxes, sulphur, etc.

G. Bodländer[33] found the **ionization constant** for $Cu^{\cdot\cdot} \rightarrow Cu^{\cdot}$, $K=[Cu^{\cdot\cdot}]/[Cu^{\cdot}]^2$, to be $1{\cdot}4\times10^{-6}$; R. Luther gave $1{\cdot}5\times10^{-6}$; for $Cu^{\cdot}+Cl'=CuCl$, G. Bodländer gave 2×10^{-6}, and R. Luther, $2{\cdot}2\times10^{-7}$; the latter also gave for $Cu^{\cdot}+Br'=CuBr$, $8{\cdot}2\times10^{-9}$. J. Traube found the **atomic solution volume** of 63·6 parts of $Cu^{\cdot}$ to be the same as $H^{\cdot}$, and $Cu^{\cdot\cdot}$, the same as zinc and nickel. W. R. Bousfield and T. M. Lowry found the **heat of formation** of $Cu^{\cdot}$ is −8·57 Cals. According to W. Ostwald and H. Jahn, the decrease of free energy which occurs in the ionization of a gram-atom of copper in a soln. of copper sulphate $Cu \rightleftharpoons Cu^{\cdot\cdot}$ is equal to the electrical energy developed $2FE$, where E is the electro-potential of copper against an N-soln. of copper sulphate at 18°; the heat absorbed from the surroundings in an isothermal reversible process is $2FT.dE/dT$ per gram-atom of copper; and Q represents the decrease in the total energy in cals. per gram-atom of copper. From H. von Helmholtz's equation, $2FR=Q+2FTdE/dT$; and, from S. Labendzinsky's measurements, $2FE=-2\times96{,}540\times0{\cdot}58$ joules, or −26,800 cals.; while $2FTdE/dT$

$=2\times96{,}540\times291\times0{\cdot}000756$ joules, or —10,200 cals. Hence, $Q=-26{,}800+10{,}200=-16{,}600$ cals. Hence, the heat of ionization of metallic copper in an eq. soln. of cupric sulphate at 18° is attended by an increase of energy eq. to 16,600 cals. per gram-atom; the consumption of electrical energy is 26,800 cals., and the heat absorbed from the surroundings is 10,200 cals. W. Ostwald's value for the **heat of ionization** is —175 cals.; and W. Vaubel gave —144 cals. for $Cu_2=2Cu^{\cdot}$ A. Coehn and Y. Osaka found the **oxidation potential** of copper in potassium hydroxide soln. to be 0·46 volt; and oxygen is given off from the metal or oxide at 1·48 volts. W. P. Davey gave 0·63 A. for the **atomic radius** of copper in cuprous iodide, and 0·76 A. for cuprous chloride and bromide. The effects of telluric acid on the depolarization of copper anodes was studied by F. Jirsa; and the anodic behaviour of copper in soln. of sodium sulphide by V. Kohlschütter and H. Stäger.

The separation of a gram-atom of copper from an *N*-cupric soln. requires work eq. to $0{\cdot}606\times2F$ volt-coulombs, and from an *N*-cuprous soln. $0{\cdot}731F$ volt-coulombs. In order that one can be compared with the other, it is necessary that chemically or electrochemically eq. amounts be employed. Hence, the free energies of normal soln. of cupric and cuprous salts are respectively $0{\cdot}606F$ and $0{\cdot}731F$, so that cuprous salts have a smaller electro-affinity than cupric salts. This is in agreement with the lower solubility of cuprous salts, and their greater tendency to form complexes. The electro-affinity of cuprous ions is related with the electro-affinity of mercury and silver, while that of the cuprous ions is related more to the iron group.

A. Volta,[34] J. W. Ritter, J. C. Poggendorff, and C. H. Pfaff placed copper near the electro-negative end of the electrochemical series:

K, Ba, Mg, Al, Mn, Zn, Cd, Fe, Co, Ni, Sn, Pb, H, **Cu,** Bi, Sb, Hg, Ag, Pd, Pt, Au,

and A. MacFarlane did the same thing for the series with frictional electricity. S. Kyropoulos showed that different parts of a piece of metal may exhibit different electric potentials, and have different degrees of "nobility."

The relative position of copper in the electro-chemical series changes with different kinds of soln. Thus, J. B. Biot noted that it alters its position with respect to iron in soln. of potassium sulphide; J. Brown found the same thing applies in an atm. of hydrogen sulphide; and J. C. K. Schrader, in fused liver of sulphur. M. Faraday found that copper retains the same relative position with fused salts as it has in acids. G. McP. Smith and Mc. A. Johnson noted that cadmium and zinc are precipitated by copper from conc. KCy soln. of their salts, although zinc or cadmium precipitate copper from aq. soln. of its salts. T. Andrews studied the e.m.f. of cells with copper and platinum in fused potassium carbonate, chloride, chlorate, and nitrate. According to A. de la Rive, copper is negative towards iron in salt soln. and in potash-lye; and it is positive towards iron in ammoniacal soln. W. E. Ayrton and J. Perry noted that at 18° commercial copper against carbon gave 0·370 volt; platinum, 0·238 volt; brass, —0·087 volt; iron, —0·146 volt; tin, —0·456 volt; lead, —0·542 volt; zinc, —0·750 volt; and amalgamated zinc, —0·894 volt. H. Götz and A. Kurz found for copper and graphite a difference of potential of 0·61 volt; F. Exner for Cu : Pt, 0·367 volt; and with radio-tellurium in air to make it conducting, H. Greinacher found, at room temp., Mg : Cu, —1·974 volt; Zn : Cu, —1·344 volt; Al : Cu, 1·055 volt, and the latter at —180°, 1·03 volt. Other combinations have been studied by G. C. Simpson, B. Gaede, F. Kohlrausch, B. W. Gerland, R. B. Clifton, W. Hallwachs, G. T. Fechner, W. Hankel, etc. G. Trümpler studied the e.m.f. of copper against the normal calomel electrode.

The hardness or softness of the metal and the surface impurities were shown by H. Pellat to have an influence on the position of the metal in the series, and he also noted that a rise of temp. made the metal more positive, while a fall of temp. made it more negative. G. Carrara and L. d'Agostini found that methyl alcohol did not alter the relative position of Volta's series from that obtained with other salts, although it altered the difference of potential. The difference of potential of copper with various metals in sulphuric, hydrochloric, nitric acids, soln. of sodium carbonate, and chloride; potassium bromide, iodide, and cyanide; has been studied by B. C. Damien, W. Wolff, C. R. A. Wright and C. Thompson, T. Erhard, A. Naccari and M. Bellati, S. P. Thompson, J. and A. Bidwell, etc. Copper and cadmium in an *N*-soln. of cupric nitrate were found by F. M. G. Johnson and N. T. M. Wilsmore to give —0·68 volt; in $\frac{1}{10}N$-soln., —0·70 volt; and in $\frac{1}{100}N$-soln., —0·58 volt. *Daniell's cell*, Cap. 16, has been investigated by F. Streintz, C. R. A. Wright and C. Thompson, E. Cohen, F D. Chattaway, and W. Tombrock, etc. The direction of the current is reversed if an excess of potassium cyanide is added to the cupric soln. The reducing action of the *copper-zinc couple* of J. H. Gladstone and A. Tribe[35] has been indicated in connection with hydrogen.

W. R. Grove,[36] G. Planté, and H. Buff electrolyzed dil. sulphuric acid with a copper plate as anode and observed much gas was evolved at first, but later, the anode was covered with a film of what they regarded as cupric oxide, and this interrupted the passage of the current owing to polarization. The deposit gradually cleared off when the circuit was broken. The polarized plate is negative towards platinum, and if warmed with dil. sulphuric acid, the liquid becomes turbid as the film is loosened from the plate; only a little copper passes into soln. E. Wohlwill regarded the film as due to copper formed by the decomposition of primarily formed cuprous sulphate, Cu_2SO_4. F. Fischer made a cell with an anode of purified copper, 2 mm. thick, immersed to a depth of 10 mm. in sulphuric acid of maximum conductivity, and a copper plate as cathode; when an e.m.f. of 20 volts was applied, the pulverization of the anode was accompanied by a singing sound; a cloud of copper-coloured dust was formed; and copper sulphate was found in the soln. When a gradually increasing e.m.f. is applied, a coating forms on the anode, and this is suddenly pulverized when the e.m.f. has reached about 20 volts. The pulverization is accompanied by a sudden increase in the current to more than fifty times its initial value. The temp. of the cathode rises to between 106° and 108° during the pulverization. It is supposed that the coating which forms on the anode consists of cuprous sulphate, which, owing to its high resistance, becomes heated, until finally the liquid contained in its pores boils and disperses suddenly into the surrounding cold soln., where it decomposes into cupric sulphate and finely-divided metallic copper. By cooling a hollow cathode internally, pulverization occurs at a much higher voltage. The resistance of the anode coating diminishes as the temp. rises, and disappears at about 80°. In a more dil. soln. of sulphuric acid, or in a soln. of sodium sulphate, cuprous hydroxide is formed instead of finely-divided copper. The behaviour of aluminium in sulphuric acid is quite similar in many ways to that of copper; by cooling an aluminium anode internally, the non-conducting layer will withstand 220 volts, whilst under ordinary circumstances 20 volts suffice to break it down. The pulverized copper reduces potassium permanganate, chromic anhydride, ferric sulphate, etc. W. Holtz prepared electrolytic-valve cells of copper in cupric chloride or sulphate, which resembled the aluminium cell for moderate e.m.f.

In 1821, A. Seebeck[37] discovered that if two metal wires be in contact at one of their ends, and a low resistance galvanometer be in circuit with the free ends of the wires, an electric current is generated when the wires are heated and flows from copper to iron through the hot junction—**Seebeck's effect.** With some metals the e.m.f. *E* of the current is nearly proportional to the difference of temp. between the hot and cold junctions, and the principle is therefore applied in the construction of thermo-electric pyrometers, and in the construction of thermopiles, etc. Again, if a galvanic battery replaces the galvanometer in A. Seebeck's experiment, A. Peltier (1834) found that heat is absorbed at what was previously the hot junction, and generated at what was previously the cold junction. This phenomenon is called **Peltier's effect.** F. Rziha, and P. Czermak have studied Peltier's effect with a copper-nickel couple; F. F. le Roux, with the copper-iron couple; H. Jahn, with copper coupled with zinc, cadmium, iron, nickel, silver, or platinum; and E. Sedström, with copper coupled with zinc or nickel.

The **thermoelectric properties** of copper are discussed in F. Peter's *Thermoelemente und Thermosäulen* (Halle, 1908). Copper is rather strongly negative, and this the more, the purer the metal. Between 0° and 100°, K. Noll[38] found a *mercury-copper* thermocouple of mercury and iron-free hard-drawn copper gave an e.m.f. of 725·58 microvolts; and with annealed copper, 725·64 microvolts; the *copper-lead* thermocouple gave an e.m.f. of 3·22 microvolts, and with commercial copper, 1·376 microvolt. J. Dewar and J. A. Fleming found the e.m.f. of a copper-lead thermocouple diminished as the temp. fell from 100° to —205·1°. Expressing the e.m.f. in C.G.S. units:

	100·1°	51·6°	8·8°	—9·1°	—3·52°	—53·6°	—104·7°	—205·1°
E.m.f. .	+31590	+14320	+1985	—2630	—8830	—13130	—24180	—41350

At atm. press.. and $\theta°$, the e.m.f. of the copper-lead thermocouple is $E=(2{\cdot}777\theta+0{\cdot}00483\theta^{2})\times10^{-6}$ volts; the Peltier effect $P=(2{\cdot}777+0{\cdot}00966\theta)(\theta+273)\times10^{-6}$ volts; and the **Thomson effect** $\sigma=0{\cdot}00966(\theta+273)\times10^{-6}$ volts per degree. E. Lecher measured the Thomson effect of copper between 252° and 678° and found $+(3{\cdot}28+0{\cdot}003400\theta)10^{-7}$ gram-cals. per coulomb. P. W. Bridgman's observations on the effect of press., in kgrms. per sq. cm., on the Seebeck, Peltier, and Thomson effects are indicated in Table VI; where the heat effects are with couples with the compressed and uncompressed metals. The Seebeck and Peltier effects are positive and rise regularly with temp. and press.; Thomson's effect is zero at low press., becoming positive at higher press., and passing through a minimum with rising temp. and constant press. E. Wagner made some observations on the effect of press. on the Seebeck effect. The e.m.f. of couples with a copper wire under ordinary conditions and one with tension up to 700 kgrms. per sq. cm. were found to vary linearly with tension, so that at 95°, the e.m.f.$=(0{\cdot}00056T)10^{-6}$ volts. The direction of the e.m.f. is from the unstretched to the stretched wire at the hot junction; this corresponds to a current from the compressed to the uncompressed metal at the hot junction, and is opposite in sign from the pure press. effect. G. Borelius and F. Gunneson found the Thomson effect, in microvolts per degree, to be 2·36 at 400° K., 1·63 at 300° K., 0·76 at 200° K., 0·06 at 140° K., —0·08 at 120° K., and —0·16 at 100° K. A. Cöhn and A. Lotz studied the **contact electricity** of copper against glass in vacuo.

TABLE VI.—THE EFFECT OF PRESSURE ON THE SEEBECK, PELTIER, AND THOMSON EFFECTS.

Temp.	Seebeck effect. Volts ×10⁶.			Peltier effect. Joules per coulomb ×10⁶.			Thomson effect. Joules per coulomb ×10⁶.		
	Press., kgrms. per sq. cm.			Press., kgrms. per sq. cm.			Press., kgrms. per sq. cm.		
	2000	6000	12,000	2000	6000	12,000	2000	6000	12,000
10°	+0·058	+0·154	+0·288	+1·6	+4.1	+ 7·6	0	+3·7	+6·3
40°	0·234	0·668	1·256	1·8	5·7	10·8	0	1·3	3·5
60°	0·350	1·038	1·976	2·1	6·3	12·2	0	1·0	3·4
100°	0·584	1·828	3·546	2·2	7·8	15·9	0	3 8	7·5

A. Heil measured the thermoelectric force of the *copper-constantan* (an alloy of 60 per cent. copper, 40 per cent. nickel) thermocouple; E. Lecher, and F. F. le Roux, the *copper-iron* thermocouple; F. Rziha, and P. Czermak, the *copper-nickel* thermocouple. G. Gore found that hot copper is positive to cold copper in many soln., and in others negative. If the two copper-iron junctions be initially at 10°, the maximum current obtains at 270°, and there is no current at 530°, above that temp. the direction of the current is reversed. Let the two junctions of the couple be initially at $T°$, and let one be raised in temp. dT when the e.m.f. dE is generated—the ratio dE/dT is called the **thermoelectric power** of the two metals at $T°$. From W. Jäger and H. Diesselhorst's, J. Dewar and J. A. Fleming's, K. Noll's, and W. H. Steele's measurements, the thermoelectric power of *copper-platinum* thermocouple at 100° is +0·74 millivolt; for *copper-constantan* couple at —190°, F. G. Wick gives +5·20 millivolts; +3·10 millivolts at —100°; —4·00 millivolts at 100°; —8·80 millivolts at 200°; and —14·9 millivolts at 300°. G. Reichard obtained similar results at 100°–200°. G. Reichard also obtained for *copper-cobalt* and *copper-nickel* couples at 100° respectively —2·74 and —2·69 millivolts, and at 200°, respectively —6·30 and —5·55 millivolts. H. Péchaux measured the Cu : Co-couple up to 900° when —28·4 millivolts were obtained. W. W. Coblentz found that with the *tungsten-copper* couple at —190°, an e.m.f. of +0·58 millivolt was obtained; at —100°, +0·24; at 100°, +0·04; and at 200°, +0·34 millivolt. L. H. Adams' value for copper-platinum at $\theta°$, is $aE/d\theta=5{\cdot}85+0{\cdot}0406\theta-7{\cdot}46\times10^{-5}\theta^2+1{\cdot}096\times10^{-7}\theta^3$; and for the copper-lead couple, $dE/d\theta$ is $2{\cdot}84+0{\cdot}0082\theta-0{\cdot}84\times10^{-5}\theta^2+0{\cdot}236\times10^{-7}\theta^3$. The thermal e.m.f. E obtained by integrating $\int(dE/d\theta)d\theta$ between 0° and $\theta°$ is $E=5{\cdot}85\theta+0{\cdot}0203\theta^2-2{\cdot}48\times10^{-5}\theta^3+0{\cdot}274\times10^{-7}\theta^4$ for the Cu-Pt couple, and $E=2{\cdot}84+0{\cdot}0041\theta+0{\cdot}0041\theta^2-0{\cdot}28\times10^{-5}\theta^3+0{\cdot}0565\times10^{-7}\theta^4$ for the Cu-Pb couple. For the copper-constantan couple, L. H. Adams and J. Johnston, and R. B. Sosman give $E=38{\cdot}105\theta+0{\cdot}0442\theta^2-0{\cdot}0000285\theta^3$. K. Noll obtained for the *copper-mercury* couple between 0° and 100°, 725 microvolts both for hardened and annealed copper; and +443 and +435 microvolts respectively for hardened and annealed brass. P. W. Bridgman gave for a thermocouple of commercial and electrolytic copper $E=(0{\cdot}03468\theta+0{\cdot}0000133\theta^2)\times10^{-6}$ volts. W. G. Duffield, T. H. Burnham, and A. H. Davis studied the electric arc between copper electrodes.

In 1879, E. H. Hall [39] discovered that when a powerful magnet is made to act on a current flowing in a very thin strip of metal, the equipotential lines are deflected from their original position at right angles to the lines of flow of the current in the strip. This is the so-called **Hall effect.** If a magnetic field of strength H, carrying a current I in a plate of thickness t, the difference of potential e produced by the deflection of the equipotential lines is $e=RIH/t$, where R is a **Hall constant.** For copper, $R=-0{\cdot}00052$. The attendant thermomagnetic and thermoelectric phenomena have been studied by A. von Ettinghausen and W. Nernst, A. Leduc, H. Zahn, and F. Unwin. M. Faraday [40] found copper to be feebly diamagnetic. The **magnetic susceptibility,** or the intensity of magnetization of electrolytic copper per unit field, is $-0{\cdot}82\times10^{-6}$ vol. units, according to J. Königsberger, and according to S. Meyer, $-0{\cdot}66\times10^{-6}$ at 15°. O. C. Clifford gave $-1{\cdot}22\times10^{-6}$ mass units for native copper; and G. Chéneveau, $-0{\cdot}90\times10^{-6}$. The magnetic behaviour is profoundly altered by traces of iron; as little as 0·04 per cent. of iron makes the metal paramagnetic. M. Owen found for electrolytic copper with 0·0004 per cent. of iron, $-0{\cdot}085\times10^{-6}$, and for electrolytic copper with 0·008 per cent. of iron, K. Honda found $-0{\cdot}86\times10^{-6}$ mass units. J. Königsberger found for the temp. coeff. —0·0015, so that the magnetic susceptibility decreases with rise of temp. S. Meyer gave $0{\cdot}0044\times10^{-6}$ for the atomic magnetism. A. Günther-Schulze [41] studied the **electrolytic valve-action** of copper in sulphuric acid. V. L. Chrisler [42] studied the potential gradient in the arc with copper electrodes.

§ 6. The Chemical Properties of Copper

According to R. Fink,[1] the affinity of copper for oxygen is greater than that of magnesium, manganese, zinc, cobalt, or nickel. While purified electrolytic copper has no catalytic activity on certain reactions—say, $C_2H_5OH=H_2+CH_3CHO$—copper prepared by reducing the oxide is active. The activity was found by W. G. Palmer to be greater the lower the temp. of reduction; and it also depends on the reducing agent. The difference may be due (i) to the presence of an oxide in solid soln. in the copper; (ii) to the presence of one or more labile forms of copper which slowly pass into a stable inactive form; or (iii) to different degrees of fineness of the particles. Copper is so readily attacked by various reagents that the old alchemists called it *meretrix metallorum*—the harlot among metals.

P. A. von Bonsdorff showed that the surface of a piece of copper does not oxidize at ordinary temp. in dry air, or even in moist air unless carbon dioxide be present. According to C. R. A. Wright and A. P. Luff, copper obtained by the reduction of cupric oxide by carbon monoxide at 100° is *pyrophoric;* and J. J. Berzelius found that copper reduced by hydrogen below a red-heat is readily transformed into cuprous oxide under conditions where the metal reduced at a red-heat in hydrogen is stable. A. Smits, A. Kettner, and A. L. W. Gee believe that the pyrophoric condition of a metal is not only due to the fine state of subdivision, but also to the initial formation of the metal in a metastable state; the metal loses its pyrophoric character when heated.

C. R. A. Wright and A. E. Menke observed that no change occurs when the metal is heated in air for many hours at 100°; at 130° a slight action was noticed after two hours; and at higher temp., the action was more vigorous. According to H. Debray and A. Joannis, copper begins to oxidize at about 350° when the vap. press. of cupric oxide, CuO, is about 0·2 atm.; at about 500°, finely-divided copper forms cuprous oxide, Cu_2O. According to F. Emich, finely-divided copper and wire-gauze are rapidly and quantitatively converted into cuprous oxide at 500°; while E. F. Anthon found that when copper plate is heated in a muffle to bright redness, cuprous oxide is the main product so long as any metal is present, after that a larger proportion of cupric oxide appears. Copper burns with a blue flame when heated to a high temp., and cupric oxide is formed as *flores cupri* or *flowers of copper.*

According to R. Schwirkus, and F. von Leichtenstein, when the temp. of a piece of copper is gradually raised to redness, the surface of the metal appears to acquire a brownish-orange colour at about 200°, and it then passes through a gradation of colours—rose-red, violet, steel-blue, brass-yellow, red, greenish-grey, grey, and finally black. The red coloration is probably due to the formation of cuprous oxide, the black to cupric oxide, so that the surface of a plate of copper, after heating to redness in air, is covered with a film of cupric oxide, CuO, and below this is a layer of cuprous oxide, Cu_2O. If the hot metal be now quenched in water, the oxide falls off in scales furnishing the so-called *scale copper oxide.* L. Maumené assumed a series of intermediate oxides are formed, but this is probably wrong. W. Elkan obtained what he called a *red patina* by polishing the outer black film so as to leave the red exposed. Some of the oxidation colours are produced as a special effect on ornamental vessels, although usually the metals are coloured by "pickling" in suitable reagents as described in G. Buchner's *Die Metallfärbung* (Berlin, 1910) and other special works—*vide infra* for patina effects.

W. J. Russell and A. Matthiessen [2] detected no absorption of gas when **oxygen** is passed into molten copper, but W. Stahl found that an absorption of gas does occur, and E. Heyn further showed that cuprous oxide is formed and dissolved by the molten metal. When copper is heated in oxygen gas, the results resemble those obtained with air. C. H. Mathewson and G. V. Cæsar have studied the action of cuprous oxide on copper. In manufacturing commercial copper, a little oxygen is allowed to remain combined with the metal in order that it may retain the desirable qualities of malleability and ductility, and in order to prevent the spitting or spewing of the metal during the cooling of a casting. The ease with which copper takes up oxygen during the smelting renders "poling" necessary until the small amount of oxygen required to produce tough pitch copper remains. This oxygen is present as cuprous oxide in all copper not specially deoxidized, and it forms a matrix around the primary grains of copper. According to F. Dezeine, the difference in the chemical reactions of colloidal and compact copper with acids and salt soln. in which copper ions or basic copper precipitates are formed without evidence of any reducing action, may be explained by the action of the dissolved oxygen on the very extensive surface of copper. W. Manchot showed that copper reacts with **ozone** at a temp. rather lower than that at which it reacts with oxygen. According to A. Berliner, finely divided copper begins to act catalytically on electrolytic gas at about 280°; and according to M. Traube, finely divided copper acts catalytically on **hydrogen peroxide** without forming cupric hydroxide as supposed by F. Cintolesi.

According to E. Mitscherlich,[3] when copper is melted in air, comparatively large crystals of cuprous oxide are sometimes formed. The cuprous oxide formed on the surface of molten copper is immediately dissolved, but it is rejected as the metal solidifies; as a result, a polished surface of the metal, when magnified, shows the presence of this oxide. According to S. Lucas, as the metal, which has been melted while exposed to the air, solidifies, some oxygen may escape and make the metal porous, or the gas may force its way through the skin of solid which first forms on the surface, and produce a kind of spitting or spewing—*das Spritzen oder Spratzen des Kupfers.* L. W. Gilbert records the projection of particles of copper to a height of 8 ins. during the spitting. C. M. Marx stated that a hissing noise attends the escape of gases from spitting copper. The spitting produces the so-called *blister copper—Blasenkupfer.* Copper which spits after refining is brittle owing to the presence of cuprous oxide, whereas that which does not spit is ductile. E. Abel found that if copper be melted in a graphite crucible and allowed to cool while exposed to the air, spitting occurs just before the metal solidifies. H. Caron melted the metal in glazed porcelain crucibles in an atm. of hydrogen or carbon monoxide, and noticed that the cooling liquid remains at rest until, just before solidification, it sets up internal movements as the evolution of gas begins. Some carbon dioxide was present in the evolvèd gases; it was formed by the oxidation of carbon monoxide during the reduction of the dissolved cuprous oxide. It is doubtful if the gas which escapes from the solidifying metal is really oxygen as S. Lucas, O. L. Erdmann and R. F. Marchand, and T. Scheerer supposed; W. J. Russell and A. Matthiessen say the gas is a mixture of carbon monoxide and sulphur dioxide. T. Graham extracted both hydrogen and carbon monoxide by heating copper in vacuo; M. Guichard says that the gas so extracted is mainly carbon dioxide. A. Caron, S. Stein, W. Stahl and W. Hampe also attribute the spitting to the escape of these gases. T. R. Merton proposed to utilize the ready absorption of gases by finely-divided copper to produce high vacua.

According to W. Hampe, spongy copper does not adsorb **hydrogen** at ordinary temp.; but, according to A. Sieverts, copper prepared by reducing the oxide at a red-heat in a stream of hydrogen, contains 0·79 to 0·49 vol. of hydrogen, and there are no signs of the formation of a hydride. H. Meslens showed that the hydrogen absorbed by spongy copper reduced from the oxide affects the weight of the metal to the extent of about 3 parts in 100,000, or 0·0029 grm. of hydrogen (at a red-heat) per 100 grms. of metal reduced from oxide; and in another experiment (at 175°) he obtained 0·0200 grm. of hydrogen. T. Graham obtained 0·0006 grm. of hydrogen per 100 grms. of reduced oxide; 0·0003 grm. per 100 grms. of wire; G. S. Johnson, 0·0074 grm. for rolled wire; and O. Leitzenmeyer 0·0061 for wire-gauze. Otherwise expressed, H. Meslens, and O. L. Erdmann and R. F. Marchand found 3 vols. of hydrogen were occluded by copper at a red-heat; T. Graham, 0·6 vol.; G. Neumann and F. Streintz, 4·81 vols.; C. P. Baxter, 1·4 to 2·1 vols.; A. Leduc, 1·8 vols.; G. S. Johnson, 1·2 to 3 vols.; and O. Leitzenmeyer, 5 to 6 vols. The older reports of the amount of hydrogen occluded or adsorbed by copper are stated by A. Sieverts to be too high in consequence of inadequate methods of analysis. According to A. Sieverts, a piece of copper wire begins to adsorb hydrogen at 400°, the amount adsorbed increases with temp. E. Jurisch found the amounts of hydrogen absorbed—expressed in mgrms. per 100 grms. of copper—to be

Temp.	416°	518°	620°	724°	827°	930°	981°	1033°
Gas absorbed	0·006	0·016	0·030	0·048	0·072	0·108	0·132	0·159

vol. of gas per vol. of copper; and the metal retains 0·05 vol. on cooling. A. Sieverts found that the hydrogen adsorbed between 20° and 920°, and atm. press., has scarcely any effect on the electrical conductivity. R. Lenz found that electrolytic copper contained the eq. of 3·4 vols. of hydrogen; 0·37 vol. of carbon monoxide; carbon eq. to 0·49 vol. of carbon dioxide; and 1·14 vols. of water vapour per volume of copper. The metal is supposed to have been cooled in an atm. of hydrogen. According to J. L. W. Thudichum and H. W. Hake, new wire adsorbs six times as much hydrogen as wire which has been re-oxidized and re-reduced. G. S. Johnson pointed out the importance of the adsorption of hydrogen by the copper wire used in organic analyses. The occluded hydrogen is given off when heated in vacuo. J. L. W. Thudichum and H. W. Hake say that the hydrogen can be completely expelled by carbon dioxide, but G. Neumann says that this is not the case at 220°; and A. Leduc found that the hydrogen is not expelled by passing air over the red-hot metal. E. Heyn found that the sp. gr. of the metal, heated in hydrogen at 600°, falls from 8·9 to 8·4, and L. Archbutt also found that an expansion of the metal occurs during the adsorption of hydrogen. According to W. E. Ruder, the brittleness due to the so-called *burning* of copper, and the alleged expansion of the metal during the adsorption of hydrogen or reducing gases, is essentially due to the reduction of cuprous oxide about the primary grains of metal (solid) leaving a more or less spongy mass of little mechanical strength. The brittleness begins to appear with dry hydrogen at about 400°, at 600° in wet hydrogen, at 800° in carbon monoxide, and at 700° in steam. Copper, completely deoxidized while fused, remains unaffected by the reduction. N. B. Pilling also showed that the deterioration in the mechanical strength of copper which contains disseminated oxide, and which has been exposed to reducing gases, is due to a reaction with the cuprous oxide which is attended by the formation of steam at a press. great enough to cause lack of mechanical cohesion in the puffed copper. At 700°, the rates of diffusion of hydrogen, steam, carbon monoxide, and carbon dioxide in copper, were respectively as 1000, 65, 17, and 0·6. The diffusion with hydrogen was considerable between 400° and 500°. W. C. Hothersall and E. L. Rhead found evidence that solid copper retains a little hydrogen permanently in soln., and studied the effect of occluded hydrogen on the casting of molten copper; H. Moore and S. Beckinsale, W. C. Hothersall and E. L. Rhead, and N. B. Pilling investigated the action of reducing gases; and G. Tammann, the evolution of gas during the annealing or recrystallization of copper. H. S. Taylor and R. M. Burns studied the absorption of hydrogen, carbon dioxide and monoxide, and ethylene by finely divided copper.

E. G. Bartlett and W. Merrill[4] obtained what they supposed to be a cupric hydride, CuH_2, by passing hydrogen over heated cupric oxide until the weight is constant. A. Leduc reported the formation of *copper hydride* by passing a stream of hydrogen for about two hours over a quantity of copper, contained in a combustion tube, heated to cherry-redness at the middle and to 300° at the ends, a solid of a hyacinth-red colour was formed at those parts which had reached, but not exceeded, dull redness, and when these parts were subsequently heated to bright redness in a stream of carbonic anhydride, the escaping gas was found to contain hydrogen, together with a little carbon monoxide. He argued that a definite compound is formed because the dissociation press. of hydrogen in copper attains a definite lower limit—between 0·5 and 0·8 mm. of mercury—but A. Sieverts and W. Krumbhaar show that the alleged hydride probably does not exist, but a solid soln. is formed; but A. Sieverts did obtain what he regarded as **cuprous hydride**, CuH, by the action of sodium hypophosphite on cuprous chloride. W. K. J. Schoor also believed that a copper hydride is formed when a soln. of cupric sulphate acidified with sulphuric acid is treated with zinc, and, according to F. Mylius and O. Fromm, a copper-zinc alloy is precipitated as a black amorphous powder. The black powder—*black copper*—obtained by J. C. Poggendorff, H. Buff, C. Ullmann, and M. Colletas in the electrolysis of a dil. 7 per cent. soln. cupric sulphate, with 10 per cent. of free sulphuric acid with copper electrodes at 2·5 to 3·5 volts, and current density over unity, was shown by A. Soret to contain an amount of occluded hydrogen dependent on the temp. and acidity of the soln. F. Mylius and O. Fromm found that the black product has only a few vols. of occluded hydrogen. F. Förster and O. Seidel, and F. Mylius and O. Fromm believe the so-called black copper to be a kind of hydrogen alloy. The electrolysis of a very dil., slightly acid, $\frac{1}{20}N$-soln. of copper sulphate with a high current density at the cathode furnishes a deposit of black copper if the soln. be not stirred, and of red copper if the soln. be stirred. With a $\frac{1}{100}N$-soln. as electrolyte, the black deposit is obtained in either case. The electrolysis of a $\frac{1}{100}N$-soln. of copper nitrate also furnishes black copper, but if ammonium nitrate is added to the electrolyte, red copper is deposited, and hydrogen is evolved.

So far there is no adequate evidence of the formation of a definite copper hydride. A. Wurtz, however, treated an aq. soln. of cupric sulphate below 70° with hypophosphorous acid, and obtained a yellow precipitate which soon changed to a reddish-brown colour. The experiment has been repeated by F. Mawrow and W. Muthmann, C. F. Rammelsberg, and H. Rose. D. Vorländer and F. Meyer recommend adding 100 grms. of sodium hypophosphite, NaH_2PO_2, in 310 grms. of sulphuric acid of sp. gr. 1·13 to a soln. of 75 grms. of crystallized cupric sulphate in 300 c.c. of water. If an excess of hypophosphorous acid is used, some copper remains in soln. E. A. van der Burg said the precipitate contains some copper, and copper phosphate, and develops less hydrogen than corresponds with CuH. A. Wurtz's analyses gave 1·22 per cent. of hydrogen, whereas the theoretical value for CuH is 1·55 per cent. E. J. Bartlett and W. Merrill claim that *cupric hydride*, CuH_2, is the product of the action of hypophosphorous acid or of the hypophosphites on cupric sulphate or oxide. M. Berthelot has stated that the alleged hydride is formed with an absorption of heat, and always contains water, phosphorus, and oxygen, probably present as a very basic cuprous phosphate. P. Schützenberger claimed that hyposulphurous acid and its salts precipitate cuprous hydride admixed with metal from soln. of cupric sulphate, but J. Meyer and O. Brunck could not obtain satisfactory evidence of the formation of the alleged hydride on repeating P. Schützenberger's experiments.

R. Nasini and F. Anderlini say that the hydrogen line is not present in the spark spectrum or the oxyhydrogen flame spectrum of copper hydride. A. Wurtz found that his product in moist air readily forms yellow cupric hydroxide, and in dry air it blackens in about a day. According to H. Moissan, fluorine in the cold gives a green flame with copper hydride, and forms a black mass; it was also found by A. Wurtz to inflame in chlorine and bromine. W. K. J. Schoor found that it develops hydrogen when treated with water, and more energetically when treated with hydrochloric acid; O. Brunck found that sulphurous acid decomposes the product with the evolution of gas. J. H. Gladstone and A. Tribe found it converts chlorates into chlorides, and nitrates into nitrites and ammonia; and ferricyanides to ferrocyanides. According to E. J. Bartlett and W. Merrill, arsenic trioxide is not changed, but if a drop of hypophosphorous acid is added, arsine is developed. D. Vorländer and F. Meyer, and L. Chiozza have studied the reduction of organic compounds by the alleged copper hydride; A. A. Pollitt, the hydrogenation of oils with copper as the catalytic agent. F. Mylius and O. Fromm say that copper hydride dissolves rapidly in a soln. of potassium cyanide with the evolution of hydrogen; with a soln. of cupric sulphate it slowly forms sulphuric acid and crystalline copper; it dissolves in soln. of ferric chloride; and with auric chloride it gives a black mixture of copper and gold.

Violent explosions have been reported as a result of pouring water on the surface of molten copper, and also as a result of a workman spitting in a large crucible of the molten metal. This, however, is largely an effect of the sudden change in the state of aggregation of water, rather than of a chemical action between the heated metal and the water. In 1800, J. L. Proust reported that **water** is decomposed by copper. H. V. Regnault[5] found that the water is slowly decomposed at a white-heat forming cupric oxide. S. Kern noted the formation of oxides of copper when steam is superheated in copper tubes; and G. K. Elliott found that under these conditions, the copper becomes crystalline and brittle; the cause of the disturbance is indicated above. L. Wöhler and O. Bale studied the equilibrium of steam in contact with copper at 450°, and observed no other than cuprous and cupric oxides are formed.

Water alone acts very slowly on copper; this is shown when water is distilled through a copper tube condenser, but M. E. Chevreul[6] reported that such water is slightly contaminated by copper. According to M. T. Mengarini and A. Scala, copper in contact with distilled water gradually yields a colloidal soln. in which the particles of copper can be detected ultramicroscopically. According to M. C. Schuyten, copper reduced by hydrogen does not decompose water even if potassium permanganate be present, nor could W. van Rijn or M. M. P. Muir detect any action of distilled water on copper. H. T. Barnes and G. W. Shearer could detect no signs of the formation of hydrogen peroxide when air is passed through water in the presence of copper.

T. Carnelley showed that distilled water dissolves a distinct amount of copper on standing in contact with the metal for an hour. The amount dissolved is increased by the time of exposure, and by the extent of metal surface in contact with the water. 100 c.c. of water at ordinary temp. when in contact with 2 sq. decm. of copper, dissolved:

Time exposed	1	2	3	4	6	24	48	54	72 hrs.
Cu dissolved .	0·035	0·050	0·070	0·085	0·155	0·168	0·210	0·290	0·280 mgrms.

The presence of solder diminishes the solvent action of water on copper, but is probably itself readily attacked, since the solder functions as the electropositive or sacrificial element in the solder-copper couple. The copper is always discoloured if exposed alone, but with solder, the copper remains quite bright. The action is less marked between 90° and 100° than it is at ordinary temp.

In view of G. T. Moody's and J. N. Friend's experiments on the rusting of iron, and of B. Lambert's experiments on the corrosion of lead, it is probable that in the *absence* of air (dissolved oxygen), highly purified water would have no action on purified copper. Indeed, G. D. Bengough and O. F. Hudson removed all but about 1 c.c. of air per litre from distilled water, and they could detect no corrosive action on copper during the first 24 hrs. ; a very slight tarnish then appeared ; and subsequently no further action could be detected. According to J. Aston, when two strips of iron in electrical contact are placed in an electrolyte, and a stream of air is allowed to bubble about one of them an e.m.f. is established between the two strips—the aerated strip acts as cathode. If one of the strips is covered with a colloid, it becomes the anode. J. Aston also noted that the iron beneath a spot of rust is anodic to the neighbouring clear metal. G. D. Bengough and O. F. Hudson made analogous observations with strips of copper and cupriferous alloys.

G. D. Bengough and O. F. Hudson thus described the ionic hypothesis of corrosion : Metals pass into soln. by electrolytic action whenever a clean metallic surface is in contact with a liquid which contains ions less electropositive than the metal itself. The nature and conc. of these ions determine the corrosiveness of the liquid as regards the electrolytic type of attack ; and :

> When an atom of copper passes into soln. it must obtain one or two positive charges, according as it passes into soln. as cuprous or cupric ion. Alternatively one or two negative charges may appear, which comes to the same thing. Now in salt soln., such as sea-water, the cations with the least soln. press. are the hydrogen ions ; hence if copper is to pass into soln. it must displace hydrogen. From quite pure salt soln. copper cannot displace hydrogen ; but if there is present in the soln. some depolarizer which will remove the hydrogen by oxidation sufficiently quickly at the moment it is about to be discharged, then the copper can replace hydrogen. The depolarizer in the case of sea-water is oxygen.

On this hypothesis, the copper is assumed to pass into soln. displacing hydrogen, and to be reprecipitated back on the copper as cuprous oxide. In the exchange of copper and hydrogen ions, N. K. Chaney believes that each point on the surface of copper can act as anode and cathode ; the alternative view is that the surface is made up of anodic and cathodic areas, and that the copper passes into soln. only on the anodic areas. W. R. Dunstan and J. R. Hill maintain that there is no evidence to show that dissolved oxygen can directly oxidize hydrogen at the cathode surface at ordinary temp., or that oxygen can act as a depolarizer, while reagents like potassium dichromate, etc., known to act as depolarizers under certain circumstances, may render metals passive and delay corrosion. G. D. Bengough and O. F. Hudson were never able to detect the direct displacement of hydrogen by copper from distilled water or dil. acids. According to W. Ostwald and N. T. M. Wilsmore, the electrode potentials of hydrogen and copper at 0° are respectively —0·277 and —0·606 volt, so that although the values are close together, the former is the more electropositive, while O. P. Watts and N. D. Whipple say that the position of hydrogen in the electrochemical series is below that of copper. In any case, G. D. Bengough and O. F. Hudson found that the effects of slight variations in the physical conditions are of more importance than small variations in the e.m.f. ; and that differences in the rate of oxidation have a greater effect on the speed of corrosion than small differences of potential. For example, if strips of copper and brass be electrically connected while immersed in 1 per cent. hydrochloric acid, the brass becomes anodic, yet the cathodic copper is also attacked. Hence, it is assumed that the copper is directly oxidized ; that the oxide is dissolved by the acid ; and that the most important factor in determining the rate of corrosion is the rate of direct oxidation by oxygen in soln.

G. D. Bengough and O. F. Hudson found that the action of distilled water on copper in the presence of air is attended by the immediate formation of a layer of tarnish over the surface of the metal. This tarnish consists of the lower oxide of copper. Under certain conditions the tarnish may be formed uniformly over the whole specimen, and be very resistant to further oxidation. The tarnish appears to be formed directly on the metal and resembles and reinforces that formed by air oxidation. The tarnish is readily soluble in dil. acids, such as hydrochloric acid (1 : 10,000), and even in distilled water to a minute extent; it undergoes ultimately a further chemical change, becoming darker in colour and porous. This change is probably due to further oxidation, and perhaps hydration. Carbon dioxide probably also plays a part.

Some time after the formation of the tarnish its further oxidation may take place at certain spots, and increased action occurs at such spots with the formation of shallow pits. This increased attack may be due to (*a*) electrolytic action, *i.e.* ionic exchange between copper and hydrogen ions in the water, or (*b*) increased oxidation of the copper due to the porous character of the oxide scale at these points. The centres of increased action on the metal are definitely associated with the dark oxidized areas of the copper. These areas are covered with porous material, and the result is that oxidation becomes conc. on the underlying metal, a loose amorphous and probably readily soluble oxide being formed by the rapid attack. The increase in the rate of oxidation may possibly cause the metal to become anodic, and electrolytic action may take place to some extent. Later, the dark oxide tends to become detached and flake off, leaving the loose, porous, and non-protective oxide exposed. The action is thus localized. Part of the copper which passes into soln. by electrolytic action or by soln. of amorphous cuprous oxide may be reprecipitated as a crystalline form of cuprous oxide. This substance is quite easily distinguishable from the amorphous or subcrystalline oxide which forms the original tarnish. It may be called the secondary oxide.

Both the primary and secondary oxides may undergo slow changes with time, and may eventually form black cupric oxide and blue-green hydroxide, possibly associated with traces of basic carbonate. The secondary oxide, however, frequently persists for long periods of time. The hydroxide or carbonate is not infrequently seen at the bottom of the pits. After three months of immersion the surface condition of cast copper was found to be as follows: (*a*) Certain areas still exhibit the original tarnish in an unchanged condition. Such areas will usually form but a very small portion of the whole, not more than 1 or 2 per cent., but may amount to nearly 40 per cent. (*b*) The greater part of the surface is covered with oxidized and porous primary and secondary oxides and hydroxide. (*c*) Beneath this layer are present a number of shallow pits formed by electrolytic action, or by increased local oxidation. The latter view is the more probable. The net result of the whole action, at the end of several months' immersion, is to cover nearly the whole surface of the metal with a layer of oxide of varying degrees of thickness, oxidation, and physical condition.

Copper soon becomes covered with a greenish film when exposed to the joint action of carbon dioxide and moist air, as demonstrated by P. A. von Bonsdorff.[7] A. W. Carpenter exposed sheets of copper (99·5–99·76 per cent.), aluminium, iron, and steel to corrosion in different places, and measured the rate of corrosion in loss of thickness per surface inch per year:

	On roof of office building.	In railway tunnel.	In smoke-stack plates.
Copper	0·0000	0·004	0·014
Aluminium	0·0011	0·013	—
Iron	0·001–0·004	0·15	0·018
Steel	—	0·12	0·020

According to F. B. Ahrens, the attack is more rapid in the air of towns; and more rapid in countries with hygroscopic atm. than in dry climates like that of Egypt. The greyish-green basic carbonate formed under these conditions is called *verdigris*—from *vert de gris*, greyish-green—although the latter term is more correctly applied to the basic acetate. Ancient bronzes preserved in museums, are liable to develop a light green colour at one or more points upon their surfaces, and this spreads by degrees over the whole surface of the *métaux malades*. The disease is called *rogna* or *caries* of bronze, and it is regarded as a pest or plague in archæological museums.

The copper and bronze antiquities found in the earth or in graves are also usually covered with a green or blue crust—called *patina* or *ærugo nobilis*—varying in thickness from a very thin film to one several mm. thick. The outer green crust is mainly basic copper carbonate, and below this, next to the metal, is a reddish layer mainly composed of cuprous oxide. The patina may contain malachite, $CuCO_3.Cu(OH)_2$; azurite, $2CuCO_3.Cu(OH)_2$; atacamite, $CuCl_2.3Cu(OH)_2$; admixed with covellite, CuS, tin oxide, silver oxide, iron oxide, lead carbonate or chloride, and ammoniacal salts are sometimes present.[8] The composition naturally depends on the composition of the alloy, the texture of the metal, the nature of the soil, and the length of time the metal has been exposed to particular conditions. Chlorides are common in the patina of Egyptian bronze antiquities, and this is to be anticipated when it is remembered that Egypt was once the bottom of a sea, and that the soil water is brackish with sea-salt.

Many natural waters can take copper into soln. when passing through pipes of this metal. According to E. Reichardt, ordinary water which had passed through copper pipes contained 7·24 mgrms. of copper per litre when the pipes were first laid in 1859, but, in 1872, thirteen years later, 0·8 mgrm. per litre was dissolved, and even this small quantity gave a perceptibly green soap. B. Roux also reported that an epidemic in a village was supposed to be due to the presence of this metal in the water which had passed through copper pumps and pipes. G. Wetzlar found that copper is readily attacked by saline soln., and less readily when potassium carbonate is present. A. Vogel could detect no effect by exposing copper to the action of lime-water, diluted with twice its own volume of water. Water containing carbon dioxide in soln. has an appreciable action on copper, and, according to M. M. P. Muir, the attack is hastened if the water contains chlorides or nitrates in soln. but not so much if carbonates are present; indeed, if much carbonate is present, the water does not attack the copper. P. D. Merica and R. W. Woodward noticed that the corrosion of manganese bronze in water and moist air did not appear to be affected if the metals were exposed while subjected to a stress.

T. Carnelley found that a 48 hrs. exposure of a sq. dcm. of copper to salt soln. of different conc. dissolved the amounts of copper expressed in mgrms. indicated in Table VI. With the exception of the ammonium salts, the nature of the base appears to have but little influence on the result, the action depends principally on

TABLE VIA.—EFFECT OF DIFFERENT SALT SOLUTIONS ON COPPER.

Grms. of salt in soln.	0·001	0·01	0·05	0·50	5·06
Potassium nitrate	0·13	0·07	0·13	0·14	0·16
Sodium nitrate	—	—	0·18	—	0·19
Ammonium nitrate	0·08	0·19	0·68	3·33	60·00
Calcium sulphate	—	—	0·10	—	—
Potassium sulphate	0·11	0·09	0·12	0·16	0·28
Magnesium sulphate	—	—	0·16	—	0·34
Ammonium sulphate	0·17	0·17	0·66	2·35	28·50
Sodium carbonate	0·06	0·06	0·11	0·29	2·80
Potassium carbonate	—	—	0·14	—	2·35
Sodium chloride	0·07	0·07	0·14	1·63	7·50
Potassium chloride	—	—	—	—	8·17
Ammonium chloride	—	—	0·92	—	158·75

the acid radicle, and this increases in passing from nitrates to sulphates, carbonates, and chlorides. The chlorides are the most active. The action of ammonium salts is far in excess of that of any of the other salts tried. The solvent action increases with the time of exposure, and with the surface area of the metal exposed. The action with potassium nitrate and sulphate was decreased by raising the temp. to between 90° and 100°, but with sodium carbonate and chloride, and ammonium sulphate, the action was increased. G. D. Bengough and O. F. Hudson attribute the greater solvent action of soln. of ammonium chloride to the removal of the protective film of oxide as fast as it is formed owing to the solubility of the oxide in ammonium chloride soln.

According to W. A. Tilden, the action of soln. of sodium chloride is greater than that of soln. of magnesium or calcium chloride. The air is of great importance in hastening the action. W. A. Tilden says that "brass may be boiled with a soln. of salt for any length of time without alteration, provided air is excluded;" and that the action of sea-water on the copper sheathing of ships is generally much the worst near the water-line. Although T. Carnelley found that the speed of attack increased with the conc. of the soln., W. A. Tilden, in agreement with H. Davy, found that very conc. salt soln. did not act so vigorously as more dil. soln.—presumably because conc. soln. absorb oxygen less rapidly than dil. soln. The subject has also been studied by G. Lunge and L. Weibel, H. Keil, X. Rocques, H. Fleck, H. Ost, A. Wagner, etc. T. Carnelley reported that the action of sodium chloride is augmented by sodium nitrate and more so by potassium sulphate; the action of ammonium sulphate is slightly increased by the presence of potassium nitrate, while that of ammonium nitrate is scarcely affected; the activity of ammonium chloride is lessened by sodium chloride, less so by potassium nitrate, and sulphate. O. P. Watts and N. D. Whipple studied the corrosion of copper by hydrochloric, perchloric, phosphoric, nitric, chromic, sulphuric, and acetic acids; by sodium hydroxide, and by a number of oxidizing agents—hydrogen peroxide; sodium arsenate and nitrite; ferric sulphate and chloride; potassium dichromate, chlorate, permanganate, nitrate, bromide, and iodide; and mercuric chloride. A. J. Hale and H. S. Foster studied the action of soln. of sodium, magnesium, and calcium chlorides, sodium hydroxide and carbonate, and aq. ammonia.

The general conclusion is that waters contaminated by sewage and nitrogenous products have a greater action on copper vessels, brass taps, and machinery fittings than water free from these impurities. According to A. Daubrée, waters containing sulphates and organic matter deposit a film of cupric sulphide on the surface of copper. F. W. Shaw and T. Carnelley say that a thin layer of cupric sulphide, obtained by washing the surface of the metal with ammonium sulphide, facilitates the attack by water, but reduces that of salt soln. F. Utehmann puts a spiral of iron or steel wire inside copper tubes to protect them from attack by salt soln. H. Davy also protected copper from salt soln. by joining it to a piece of zinc.

If salty water charged with air and carbon dioxide is allowed to act on copper or copper alloys, an oxychloride, analogous with the mineral atacamite, $3CuO.CuCl_2.3H_2O$, is said to be formed. M. Berthelot has given an elaborate series of equations to represent the formation of patina on copper or bronze vessels buried in soils containing salty water. He supposed that the simultaneous action of water and the oxygen and carbon dioxide of the air and the sodium chloride upon the copper furnishes copper oxychloride: $4Cu+2O_2+CO_2+2NaCl+3H_2O=3CuO.CuCl_2.3H_2O+Na_2CO_3$. A little of the oxychloride dissolves in the salt soln., and this in contact with the copper forms cuprous oxide and a double salt of cuprous and sodium chlorides: $3CuO.CuCl_2.3H_2O+4Cu+2NaCl=2CuNaCl_2+3Cu_2O+3H_2O$. The double salt is oxidized by air, $6CuNaCl_2+3O+3H_2O=2CuCl_2+3CuO.CuCl_2.3H_2O+6NaCl$. The cupric chloride so formed, in contact with air and copper, may form cuprous oxide, or be converted into the oxychloride: $CuCl_2+3Cu+3O+3H_2O=3CuO.CuCl_2.3H_2O$. The cycle constantly recurs under the influence of moist air. The patina crust may vary from a very thin film to a crust several millimetres in thickness. Some patinas are free from chlorides and were probably formed out of contact with soluble chlorides. Some patinas are comparatively stable, and do not change under normal conditions; others, principally those containing chlorides, are unstable, and are liable to spread and deepen. The former type of patina is not prejudicial to the preservation of bronzes, and has accordingly been called *noble patina* or *Edelpatina*.

If the green crust of a typical patina be removed by washing in dil. sulphuric acid, there remains a reddish crust of cuprous oxide which may be removed by washing with aqua ammonia so as to expose the underlying metal. The layer of cuprous oxide has been remarked by B. G. Sage (1778), J. Davy (1825), etc. It has been suggested that the presence of cuprous oxide shows that the formation of this oxide is the first stage in the patinization of copper objects, and the carbonates represent the later completed stage. F. Wibel, on the contrary, assumed that the cuprous oxide is formed by the reduction of the copper carbonate formed by the action of moist air and carbon dioxide on copper. When such a film is moistened, a layer of a soluble copper salt is in contact with the metal, the metal reduces the soln. to cuprous oxide or even to copper itself; this is exemplified by the occurrence of copper crystals in some patinas; and by an experiment due to C. F. Bucholz when the lower half of a strip of copper is immersed in a conc. neutral soln. of copper nitrate, and the upper half of the strip is immersed in a layer of distilled water superposed on the copper nitrate soln. The lower half of the strip becomes coated with crystals of copper and of cuprous oxide.

Copper is rapidly corroded by **sea-water.** When a piece of copper is immersed in sea-water, the liquid soon exhibits a bluish-white cloudiness, and, after a time, if the metal be exposed to the air, it becomes covered with a green crust. F. C. Calvert and R. Johnson[9] found that the following numbers represent the relative action of sea-water on a number of metals; the results are expressed in grams of metal dissolved by 100 litres of sea-water per sq. metre of surface, in a month, at ordinary temp.:

Steel.	Iron.	Cu (best).	Cu (cake).	Zn.	Iron (galv.).	Tin.	Lead.
29·16	27·37	12·96	13·85	5·60	1·12	1·45	trace

A green deposit is formed on the copper, and this is readily washed from the surface of the metal if the water is in motion. Hence, if the water be in motion, but little of the green deposit is seen; the copper is rapidly corroded; and the surface of the metal often becomes dark red owing to the formation of cuprous oxide. F. C. Calvert and R. Johnson hence stated that the mechanical action of sea-water accelerates the attack. The composition of the crust was investigated by H. Davy. A. H. Sexton's analysis (1906) of a sample of the green deposit furnished:

Copper carbonate.	Copper chloride.	Copper oxide.	Water.
29·77	8·39	59·38	2·46

The action thus appears to be a chemical attack by the oxygen, carbon dioxide, and chlorides in soln. in the sea-water. If air and carbon dioxide are removed from sea-water, the action is rather slight. The attack may be uniform over the whole surface, more usually it is irregular, if not erratic, so that portions may be in holes while the remainder is quite sound. When brass or copper tubes are used in marine engines with salt waters, the metal may be rapidly pitted or the tube perforated. The cause of the pitting is not known; it has been attributed to the local voltaic action set up by contact with particles of metal or oxides less electropositive than copper. W. A. Tilden found that the portions of metal which have been bent or distorted in any way, are more rapidly attacked than the undisturbed metal by hydrochloric acid or chlorides; etc. E. L. Rhead found hard copper to be much more readily corrodible than soft copper. T. A. Eastick attributed local corrosion to the presence of hard and soft areas in the metal. Corrosion was found by A. Philip to be accelerated locally by contact with electronegative substances like carbon or coke. G. D. Bengough and O. F. Hudson also found particles of string, clinker, anthracite, sand, glass, and ferric hydroxide may accelerate local action, while calcium carbonate generally exerts a protective action, and red lead is harmless. Much, however, depends on the physical condition of the particles.

H. Davy argued that "since chemical attractions may be exalted, modified, or destroyed by changes in the electrical state of bodies, and since copper is only weakly positive in the electrochemical scale, if it could be rendered slightly negative, the corroding action of sea-water on it would be nil." H. Davy demonstrated that the attack by ordinary sea-water is retarded if the copper be in contact with the electropositive metals—zinc, iron, etc.—but the protective action extends over a small area in the vicinity of the protective metal, and the remedy failed in practice because the sheathing thus protected became quickly covered with an earthy deposit on which sea-weeds and barnacles gathered more abundantly than when protectors were not used. M. Diegel has studied the protective action of metals in relation to their contact difference of potential in sea-water. Tinning the condenser tubes may protect the copper so long as the coating of tin remains intact, but directly the underlying brass or copper is exposed, the action of sea-water is increased.

It has long been assumed that the rapid decay of the copper sheathing of ships could be hindered by alloying copper with other metals. Thus, J. Keir (1779), W. Collins (1817), R. Mushet (1823), J. Revere (1830), M. Uzielli (1830), G. G. Bompas (1830), G. F. Muntz (1832), etc., have patented alloys of copper, zinc, tin, or iron. The brasses containing over 70 per cent. of copper are attacked by sea-water, but not so rapidly as copper. The zinc may be preferentially removed from these brasses much more rapidly than the copper, so that the brass is dezincified; in some cases the copper is dissolved and partly redeposited on the corroding metal. Brasses containing less than 70 per cent. of copper are much more readily attacked than the more cupriferous brasses. The first attack of sea-water on a brass, with Cu : Zn =1 : 1, is almost wholly confined to the zinc. Acid, mine, and other waters rapidly attack the zinc in brass alloys.

According to G. D. Bengough and O. F. Hudson, the action of distilled water on brass in the presence of air may be regarded as taking place in three stages: (1) The formation of a translucent tarnish consisting of oxide. It is nearly uniform and not very porous to water or oxygen. A part of the zinc passes into soln., probably after being first oxidized; most of the copper oxide is found on the metal, but a trace is found in soln. (2) The further oxidation of the tarnish, beginning at widely scattered patches and areas, to form a dark purple or black oxide and a basic salt of an amorphous nature. (3) The commencement of local pitting. The positions at which this action begins are definitely related to the oxide areas characteristic of the second stage.

A. Philip[10] explains the corrosion of brass by assuming that the alloy is an agglomeration of minute metallic couples of zinc and copper, but he says that the couples may also be formed of the different phases of the copper zinc-alloys. C. A. Edwards suggests that in the case of ordinary brass, the metallic couples are of copper and Cu_2Zn_3, where the latter is slightly electropositive to copper. W. E. Gibbs believes that in brass, the characteristics of the component metals are to some extent altered, the zinc more than the copper; as a result, instead of a 70 : 30 brass being rapidly dezincified in aerated water, as is the case with a copper-zinc couple, copper is lost rather more rapidly than zinc. He also stated that the corrosive action of sea-water results in the dissolution of the copper by the dissolved salts, and in the dissolution of the zinc by the dissolved gases. G. D. Bengough and O. F. Hudson say that the normal action of neutral or nearly neutral sea-water is predominantly one of oxidation, and that the action of couples, if such exist, is too seriously hampered to be effective. Under some conditions, such as occur beneath certain deposits of basic salts of a semi-permeable nature, and in other conditions where the rate of oxidation is slow, zinc may be removed in its entirety from the brass together with part of the copper, and some copper is left behind. This suggests that part at least of the copper is not directly associated with the zinc in any form of aggregate. The rest of the copper may be so associated, perhaps in the way suggested by W. E. Gibbs; there is therefore the possibility of couple action under non-oxidizing conditions. It does not appear certain, however, that any copper is left *in situ* when zinc passes into soln.; what appears to be left may really be redeposited. There is, however, a little evidence that the oxidation of the zinc does actually get slightly ahead of the oxidation of the copper.

The bronzes resist attack by sea-water and other corrosive agents better than copper or brass. If much zinc be present, the bronze may be attacked as readily as if it were brass itself. According to A. Carnot, manganese bronze resists the action of mine and acid waters better than the other cupriferous alloys.

According to A. Chodneff,[11] if **potassium hydroxide** be fused in copper vessels, without access of air, cuprous oxide is formed and the mass is coloured blue. The aq. extract of the fused cake contains both cuprous and cupric oxide in soln., but G. N. Antonoff and B. V. Malyscheff found evidence of the formation of a peroxide. In 1833, A. Payen observed that copper is oxidized in a dil. soln. of potassium hydroxide in which iron remains bright, and the action is more particularly marked where the metal is in contact with air and water at the same time. Copper wetted with a conc. soln. of alkali hydroxide is coloured brownish-black in a few hours by exposure to air. The action is slower in dil. soln. The solubility of copper in alkali hydroxide soln. has been investigated by E. Murmann, G. Lunge and L. Weibel, A. Wagner, etc. According to M. Honigmann, copper vessels are much attacked when used for the evaporation of soln. of alkali hydroxide; the action is lessened if a piece of iron wire be present. R. G. van Name and L. Gräfenberg found copper electrodes are oxidized energetically when used with a current alternating 110 times per second.

According to H. Moissan,[12] **fluorine** attacks copper superficially at ordinary temp. and, just over 500°, it forms the white fluoride; at ordinary temp. J. Davy found that **chlorine** forms cuprous and cupric chlorides. The metal reduced by hydrogen was found by A. Osann and S. B. Christy to burn in a stream of chlorine at ordinary temp. with a white or bluish-white flame and to furnish cupric chloride. In 1889, T. Andrews pointed out that if the chlorine be thoroughly dried, there is no appreciable action. H. Gautier and G. Charpy found that a piece of copper wire sealed in a tube with liquid chlorine increased 3·241 per cent. in weight after standing four months at 15°. According to A. Colson, **bromine** acts at ordinary temp. on copper reduced below 280°; at 500°, it forms copper bromide. H. Gautier and G. Charpy found a piece of copper wire 2 mm. thick at 15°, lost 0·371 per cent. in weight in 8 days in darkness with dry bromine, and 1·740 per cent. in 4 months; at 100°, it lost 6·62 per cent. in 8 days; a piece of similar wire 5 cms. long dissolved in bromine water with an excess of bromine in over 7 days. **Iodine** vapour or **iodine monochloride,** ICl, reacts with finely divided copper; a plate of copper immersed in an aq. soln. of iodine is soon covered with crystals of copper iodide, CuI. According to J. B. Hannay, the reaction with liquid iodine chloride is very slow for the first few minutes; cuprous iodide and chloride are formed as well as a little cupric chloride. G. Tammann studied the surface coloration of copper by exposing the metal to iodine vapour at ordinary temp. There are three different types of action according as (i) the metal has been rolled and cleaned; (ii) the metal has been melted and thus covered with large crystallites; or (iii) the metal has been left unworked and thus covered with multitudinous small dendritic crystals. C. Poulenc found **hydrogen fluoride** to have scarcely any action on copper at ordinary temp. According to M. Berthelot, dry **hydrogen chloride** has but little action on copper at ordinary temp., but if oxygen be present, some cuprous chloride is formed, and the presence of water retards the action. J. Thomsen says the reaction with copper begins at 200°, and, according to P. Jannasch and H. Heimann, a mixture of both chlorides is obtained. According to M. Ribalkin, dry hydrogen chloride begins to react with copper slowly between 92° and 100°, forming cuprous chloride: $2Cu+2HCl\rightleftharpoons 2CuCl+H_2$, and the action is rapid at 230°—see cuprous chloride. H. E. Patten also showed that in the absence of moisture, soln. of hydrogen chloride in many organic and inorganic solvents—chloroform, carbon tetrachloride, ethyl chloride, benzene, silicon tetrachloride, stannic tetrachloride, phosphorus trichloride, arsenic trichloride, antimony pentachloride, sulphur monochloride, and thionyl chloride—have no appreciable action on copper. According to R. S. Norris and F. G. Cottril, liquid hydrogen chloride does not attack copper, while liquid hydrogen iodide forms cuprous iodide at ordinary temp. The action of liquid hydrogen iodide on brass was noticed by M. Faraday in 1844.

According to C. Poulenc, aq. **hydrofluoric acid** has scarcely any action on copper. M. Berthelot[13] noted that **hydrochloric acid** in contact with copper is in air rapidly coloured greenish-blue, but I. Kupferschläger says that if air be excluded, hydrochloric acid alone does not attack the metal. According to W. Odling, copper slowly dissolves in hydrochloric acid, forming cuprous chloride and liberating hydrogen. The same result was recorded by J. L. Proust in 1799. The action, says T. Charlton, is quite rapid if the copper be finely divided. W. A. Tilden confirmed W. Odling's observation with finely-divided copper, and found that rolled sheet copper is slowly dissolved in boiling conc. hydrochloric acid. This explains how "brass is capable of being dissolved entirely in hot hydrochloric acid; the zinc is for the most part attacked, and the residual spongy copper is then dissolved quite readily." F. C. Calvert and R. Johnson showed that an alloy of about equal weights of copper and zinc, immersed in conc. hydrochloric acid, gives up in a few days nearly the whole of the zinc, leaving the copper behind in a spongy state. According to J. Löwe, cold hydrochloric acid (sp. gr. 1·12) has scarcely any action on sheet copper at ordinary temp.; a more dil. acid (sp. gr. 1·083) acts slowly, and the hot acid forms cuprous chloride and liberates hydrogen. According to R. Engel, the action begins between 15° and 19° with an acid of sp. gr. 1·083 (16·5 per cent. HCl), and is very slow when the liquid is sat. with cuprous chloride. C. Weltzien, A. Vogel and C. Reischauer, A. J. Hale and H. S. Foster, and H. Vogel have investigated the reaction. S. Dushman found that air-free hydrochloric acid sat. with carbon dioxide dissolves copper anodically. H. Hager studied the action of copper on arseniferous acid, and of hydrochloric acid on arseniferous copper. According to J. E. Gerock, seleniferous hydrochloric acid attacks copper more rapidly than the ordinary acid. W. F. Brugman observed no evolution of hydrogen sulphide from copper containing some ferrous sulphide. The action of soln. of **sodium chloride, potassium chloride,** and **ammonium chloride** has already been discussed, *vide* Table V; and G. Quincke found that copper dissolves in molten **cupric chloride.** M. Berthelot observed that both **hydrobromic acid** and **hydriodic acid** dissolve copper more readily than hydrochloric acid. H. Rose reported that hydrogen is given off with the latter, and J. Thomsen, with the former provided platinum is present. Copper is also stated to resist dil. hydriodic acid.

In 1834, A. J. Balard,[14] and, in 1903, A. D. White found that copper filings are partly dissolved by **hypochlorous acid,** forming cupric chloride, and partly converted into a green powder of a copper oxychloride. Chlorine gas mixed with a little oxygen is at the same time evolved. A. J. Balard also added that copper is readily converted into the oxychloride by soln. of hypochlorites, and there is a slight disengagement of chlorine mixed with oxygen. E. Soubeiran (1831) stated that when a sheet of copper is immersed in an aq. **solution of bleaching powder,** a blue layer of the oxychloride is gradually formed on its surface; small bubbles of oxygen are at the same time evolved. The reaction is faster with powdered copper, and the oxychloride is green. The evolution of oxygen is said to be a remarkable fact first attributed to the spontaneous decomposition of the hypochlorite. A. D. White found that with copper turnings, and an aq. soln. of bleaching powder, a green oxychloride is formed, and 60 c.c. of 94·3 per cent. oxygen were formed in the first 12 hrs.; 70 c.c. of 96·86 per cent. oxygen were formed in the second 12 hrs.; and

55 c.c. of 98·85 per cent. oxygen in the third 12 hrs. W. S. Hendrixson found that 2*N*-**chloric acid**, at 50°, acts rapidly on copper; the metal simply disappears, forming a clear blue soln. In no case is any hydrogen evolved. When a normal soln. of chloric acid is electrolyzed in the cold, using a copper anode, the latter is attacked regularly over its whole surface and becomes coated with a layer of cuprous chloride which, however, disappears on warming. Similarly, when copper is dissolved in a cold normal soln. of chloric acid, the metal becomes covered with a layer of hydrated cuprous oxide. It appears, therefore, that the metal passes into soln. in the cuprous form, the cuprous compound first produced being dissolved, if there is an excess of chloric acid present, forming cupric chloride and chlorate. With the conc. acid, the reaction is complicated by the formation of oxygenated compounds of chlorine, and in the absence of an excess of free chloric acid, complex basic salts are precipitated. A. L. Voege found that copper, though but slightly attacked by sulphuric acid alone, is readily dissolved in the presence of **potassium chlorate**, and an almost quantitative yield of potassium chloride results. This reduction by copper without electrolysis is about four times that by zinc for eq. quantities dissolved, though zinc dissolves much more slowly than does copper. With copper electrodes the electrolytic reduction is probably less than with zinc electrodes. According to W. D. Bancroft, a hot aq. soln. of potassium chlorate is not appreciably affected by copper, but G. H. Burrows showed that reduction is complete at 93°. L. Rossi has also studied the reduction of sulphuric acid soln. of potassium chlorate between copper electrodes. O. P. Watts and N. D. Whipple have studied the action of **perchloric acid** on copper. A. Ditte found that copper is attacked by soln. of **hydriodic acid**.

The members of the family: **sulphur, selenium,** and **tellurium,** all attack copper, forming respectively sulphide, selenide, and telluride—*q.v.*[15] C. R. Hayward measured the rate of penetration of copper by sulphur vapour by placing copper rods a definite time in boiling sulphur; when cold, the specimen was broken open, and the copper core removed from the shell of sulphide, and weighed. The percentage loss in weight represented the copper converted to sulphide:

Time	5	10	15	30	60	120	180	240 mins.
Loss .	1·95	2·86	3·39	4·58	6·0	8·59	9·90	9·73 per cent.

E. Obach found that copper acts on impure **carbon disulphide,** but not on the pure liquid; and A. Cavazzi, that at a high temp., copper reacts with the vapour of carbon disulphide, forming graphite and cuprous sulphide. In a study of absorbents for the vapour of carbon disulphide, A. Eiloart found that when a mixture of carbon dioxide and carbon disulphide vapour is passed over copper heated to redness, almost pure carbon monoxide is abundantly evolved with simultaneous formation of copper sulphide, Cu_2S. Carbon disulphide alone is decomposed when passed over copper heated below redness, and if copper, coated with carbon from the decomposition of carbon disulphide, is heated in a stream of carbon dioxide, only a limited and small quantity of carbon monoxide is slowly produced. Hence, the mixture of gases is necessary for the above reaction, and decomposition and combination evidently go on at the same time. Without copper, the mixture of gas is not decomposed in this manner, for instance, when passed over heated pumice. Sulphur dioxide and carbon disulphide, when passed over copper or pumice heated even below redness, give rise to carbon dioxide, and as a secondary product carbonic monoxide. J. Thomsen obtained what he regarded as carbon monosulphide by passing a mixture of nitrogen and carbon disulphide vapour over heated copper. V. Merz and W. Weith found that **hydrogen sulphide** has virtually no action at ordinary temp. on finely-divided copper, but if air be present, a vigorous reaction occurs. If copper (precipitated from a soln. of the sulphate by metallic zinc) is brought into a cylinder containing 2 vols. of oxygen and 1 of sulphuretted hydrogen, it immediately turns black, then grows red hot, and ignites the sulphuretted hydrogen. According to A. Ditte, a soln. of **potassium monosulphide** does not act on the metal if air be excluded, but if air be admitted, cuprous sulphide

and potassium cuprous sulphide are formed. A soln. of **ammonium hydrosulphide** **was** found by G. Lunge and L. Weibel to dissolve appreciable quantities of the metal. According to E. Priwoznik, the ammonium and the alkali polysulphides are converted into the monosulphides. The reaction has also been studied by V. Merz and W. Weith, and K. Heumann. C. Strüver found that at ordinary temp. several natural sulphides are reduced by copper, forming cupric sulphide—*e.g. arsenical pyrites* and *cobaltite* are not reduced; *hauerite* is reduced in 3 days; *pyrite* acts more slowly, *marcasite* rapidly, *magnetic pyrites* very rapidly. The reduction of **aluminium sulphide** and **magnesium sulphide** has been investigated by F. G. Reichel; of **cadmium sulphide** by A. Colson; of **ferrous sulphide** by A. Colson, and E. Schütz; and of **nickel sulphide** by G. P. Schweder. **Zinc sulphide** and **lead sulphide** are desulphurized by heating with copper. K. Heumann found that **mercuric sulphide** is rapidly reduced when boiled with finely-divided copper and water.

When copper is heated in a stream of **sulphur dioxide**, J. Uhl[16] found that cuprous sulphide, sulphate, and a little sublimate are formed. E. Heyn and O. Bauer found that the sulphide begins to form at 900° if reducing agents be present, but not if they are absent. According to W. Hampe, molten copper absorbs sulphur dioxide, and part is retained when the metal solidifies, which is not removed, except perhaps superficially, and very slowly, by heating the metal in a stream of an indifferent gas. J. Uhl found that a mixture of dry sulphur dioxide and air is not transformed into sulphur trioxide when heated in presence of copper, but the surface of the metal is blackened owing to the formation of a compound which gives hydrogen sulphide when heated in a stream of hydrogen. A. Sieverts and E. Bergner found the solubility of sulphur dioxide in copper increases with the temp., and the amount w dissolved varies with the sq. root of the press. p up to conc. of about 7 per cent., so that $w=kp^{\frac{1}{2}}$, where k is constant. The observed results are in part explained by assuming that the sulphur dioxide is decomposed in soln., forming cuprous sulphide and oxide: $SO_2+6Cu\rightleftharpoons Cu_2S+2Cu_2O$, and the corresponding equilibrium holds only in a qualitative manner.

According to S. U. Pickering, while **sulphurous acid** under some circumstances may dissolve some copper, yet if that metal be heated in sulphurous acid while a stream of sulphur dioxide is drawn through the liquid, the copper remains untarnished and unattacked. G. Barruel left some copper and sulphurous acid in a sealed tube for six months, and found copper sulphate and a black body were formed; the latter was probably copper sulphide: $2Cu+2H_2SO_3=CuS+CuSO_4+2H_2O$. H. Causse found that an aq. soln. of sulphur dioxide acts slowly on metallic copper, forming cupric sulphite and hyposulphurous acid; if, however, a large excess of sulphurous acid is present, hydrogen sulphide is formed, precipitating the sulphide from the soln. of cupric sulphite, and coating the metallic copper with a film of sulphide; a precipitate of sulphur is also produced. These reactions appear to take place more rapidly when the copper is exposed to an atm. of moist sulphur dioxide. L. P. de St. Gilles noticed that when copper filings wetted with hydrochloric acid are treated with sulphurous acid, copper sulphide is formed; C. Geitner also obtained cupric sulphide by heating copper with sulphurous acid to 200°; H. Reinsch and J. Uhl found that copper is converted, by an aq. sulphuric acid or hydrochloric acid soln. of sulphur dioxide, into cuprous sulphide. M. Berthelot also noted that when copper is heated with sulphurous acid, the colour becomes dark red or reddish-brown owing to the formation of an oxysulphide or cuprous sulphite, and cupric sulphide slowly appears. G. Bredig studied the catalytic action of copper on the oxidation of sulphites, and noted the retardation of the action by mannite or glycerol; and H. Rössler also noted the catalytic oxidation of sulphurous acid at 100° in the presence of copper.

According to E. Divers and T. Shimidzu,[17] copper is not acted upon by **sulphur trioxide** provided moisture be rigorously excluded; and when spongy copper, reduced in hydrogen, is treated with **pyrosulphuric acid**—fuming sulphuric acid—there is a slight effervescence, the copper soon blackens, and then further action proceeds with extreme slowness. Only traces of copper are present in the acid liquid. Water dissolves a little sulphate from the blackened copper, but leaves the black coating of cuprous sulphide. It therefore appears that, in the cold, the first reaction is: $5Cu+4H_2SO_4=3CuSO_4+Cu_2S+4H_2O$, but further progress is quickly arrested by the insolubility of the products. G. Barruel found that the reaction between copper and **sulphuric acid** occurs at ordinary temp. if sufficient time be allowed. C. Baskerville said the action began at 0°. E. Salkowsky showed that in the presence of hydrogen peroxide, sulphuric acid readily attacks copper. Under these conditions, however, the action is so slow that F. C. Calvert and R. Johnson failed to note any action below 130° and supposed that none takes place; and L. W. Andrews says that the reduction of 98·4 per cent. sulphuric acid by copper does not begin below 86°, that is, not until the acid has become partially dissociated into sulphur trioxide and water—the dissociation of the acid begins just below 70°.

According to M. Berthelot, if air be excluded, cold conc. sulphuric acid acts slowly on copper, giving, in about 8 days, considerable amounts of sulphur dioxide, and forming a layer of cupric sulphide and sulphate; the unattacked copper has a reddish tint—possibly due to the formation of a basic sulphite. According to F. Cintolesi, if air be excluded, the solubility of copper in sulphuric acid is less the more dil. the acid; cold dil. sulphuric acid attacks copper only in the presence of air. According to S. U. Pickering, at 100° the amount of copper dissolved in half an hour by sulphuric acid of different conc. is as follows:

	H_2SO_4	$H_2SO_4+\frac{1}{2}H_2O$	$H_2SO_4+H_2O$	$H_2SO_4+2H_2O$
Sp. gr.	1·843	1·8295	1·780	1·62
Per cent. of Cu dissolved .	2·380	0·585	0	0

S. U. Pickering also gave Table VII in illustration of the influence of temp. on the products of the reaction, between copper foil and sulphuric acid of sp. gr. 1·843. J. J. Berzelius mentioned the formation of a black insoluble powder, oxidizable by nitric acid; and he assumed this product is "copper subsulphate." J. Davy noted the formation of cupric sulphate and sulphide; and G. Barruel thus describes the reaction between copper turnings and sulphuric acid in a closed vessel, completely filled with liquid, at ordinary temp.:

TABLE VII.—EFFECT OF TEMPERATURE ON THE SOLUBILITY OF COPPER IN SULPHURIC ACID.

Temp.	Time. d=days m=mins.	Proportion of copper converted into		Percentage composition of insoluble residue.			Percentage amount of copper dissolved.	Percentage amount of copper dissolved per minute.
		Cu_2S	$CuSO_4$	Cu_2S	CuS	S

> At the end of one week, the liquid has a pale rose colour; at the end of three weeks, the liquid is decolorized, and the metal is bright; at the end of eight weeks, a small quantity of brownish powder is deposited at the bottom of the vessel; this powder increases in quantity up to the fifth month, and finally, transparent colourless crystals of anhydrous cupric

sulphate are deposited on the sides of the vessel. After the elapse of six months, the colourless liquid emits a strong odour of sulphur dioxide, and turns blue when mixed with water, showing that it contains anhydrous cupric sulphate dissolved in the sulphuric acid. Hence, it follows that sulphuric acid is slowly decomposed by copper yielding cupric sulphate and sulphur dioxide : $Cu+2H_2SO_4=CuSO_4+SO_2+2H_2O$, and that the latter is wholly consumed in forming cupric sulphide and sulphate : $2Cu+2H_2SO_3=CuS+CuSO_4+2H_2O$.

E. G. Maumené analyzed the black body and assumed that it contained cuprous sulphide, Cu_2S ; copper oxysulphides, $CuO.2Cu_2S$; $CuO.2CuS$; and $CuO.CuS$. C. Baskerville also said that in the absence of air an oxysulphide, $CuO.2CuS$, is formed at about 250°. The black film has been studied by J. Laubheimer, and many others ; S. U. Pickering found that it contains copper and sulphur but never oxygen. Cuprous sulphide is best formed between 100° and 130° ; at a lower temp. less is produced, and at 270° none appears. T. Kliche found that the relative amounts of cuprous and cupric sulphides, and of sulphur which are produced in the reaction, depend on the duration of the action ; at 125° or 130°, sulphur slowly unites with cuprous sulphide to form cupric sulphide.

The action of hot sulphuric acid on copper is thus described by S. U. Pickering : Sulphuric acid attacks copper at all temp. from 19° (and probably even still lower) upwards, to an extent increasing rapidly with the increase of temp. ; with the exception of a few minute and occasional bubbles of sulphur dioxide, no gas is evolved from the liquid till about 130° : as soon as the copper begins to be attacked, its surface becomes dull and covered with a film of black cuprous sulphide ; when the amount of cuprous sulphide floating in the liquid is small it exhibits a brownish colour, similar to that exhibited by small quantities of the cupric sulphide when suspended in a liquid ; but as the quantity of cuprous sulphide increases, the colour deepens and soon appears perfectly black. If the temp. be allowed to rise, the liquid generally begins to boil below 300°, the b.p. of pure conc. sulphuric acid being 327° ; when the source of heat is withdrawn, the suspended sulphide subsides, leaving a bluish-green soln. containing copper sulphate, which, on cooling, crystallizes out from the acid in white acicular anhydrous crystals, leaving the sulphuric acid free from dissolved copper, and, when the proportion of metal and acid above mentioned is used, but little diminished in density. After the copper is entirely dissolved, and sometimes even before this, a deposit of sulphur appears in the neck of the flask. No gas insoluble in water, such as oxygen or hydrogen, is given off during the action.

S. U. Pickering showed that the reaction between sulphuric acid and copper may be supposed to involve two primary actions: (i) $Cu+2H_2SO_4=CuSO_4+SO_2+2H_2O$, which in turn is compounded of a reaction in which cupric sulphate and nascent hydrogen are formed : $Cu+H_2SO_4=CuSO_4+2H$; and the reduction of the sulphuric acid by the nascent hydrogen : $2H+H_2SO_4=SO_2+2H_2O$. The other primary reaction is (ii) $5Cu+4H_2SO_4=Cu_2S+3CuSO_4+4H_2O$, which does not involve nascent hydrogen. Both reactions may take place together, or either may occur alone. The first reaction predominates between 0° and 270°, and above that temp. it occurs alone ; the second reaction increases between 0° and 100°, and decreases between 100° and 270°. The several other products which occur may be regarded as being formed by the decomposition of cuprous sulphide by the sulphuric acid : $Cu_2S+2H_2SO_4=CuS+CuSO_4+O_2+2H_2O$, and of the cupric sulphide by the same acid : $CuS+2H_2SO_4=S+CuSO_4+SO_2+2H_2O$. According to this interpretation of the reaction, cuprous sulphide is a direct product of the action of the acid on copper, and cupric sulphide is the result of a secondary reaction. H. Causse found some cuprous sulphite is formed.

T. Andrews, and C. M. van Deventer favour an *oxidation theory* in which cupric oxide, sulphur dioxide, and water are supposed to be the primary products of the reaction rather than the formation of sulphate and hydrogen ; in both theories the acid is reduced and acts as an oxidizing agent. No direct proof of the formation of hydrogen has been adduced. He also prefers the assumption that water plays an important part in first forming cupric oxide and hydrogen: $Cu+H_2O=CuO+2H$; followed by $CuO+H_2SO_4=CuSO_4+H_2O$ and by $2H+H_2SO_4=2H_2O+SO_2$. According to C. H. Sluiter, the only rational explanation of the formation of copper sulphide is the assumption that hydrogen is liberated, and reduces the sulphur dioxide to hydrogen sulphide. The hypothetical reduction of sulphur dioxide by copper is not supported by evidence. This *reduction theory* is confirmed by the reduction of nitrobenzene, $C_6H_5NO_2$, to aniline, $C_6H_5NH_2$, when heated with copper and sulphuric acid at 130°; when, however, sulphuric acid containing 12 per cent. of trioxide is heated with copper and nitrobenzene at 140°, sulphur dioxide is formed but no aniline is evolved. S. U. Pickering argued that the copper sulphide is not formed by nascent hydrogen; nor by the action of hydrogen sulphide on copper sulphate; nor by the union of metallic copper with free sulphur as assumed by F. C. Calvert and R. Johnson. He believes that the sulphuric acid is decomposed directly by the copper, forming cuprous sulphide, etc. The sulphur is formed by the action of sulphuric acid on the sulphides of copper in the liquid, and not by a reaction between sulphur dioxide and hydrogen sulphide. The sulphide volatilizes from the liquid and is arrested by the simultaneous escape of gas or vapour.

According to J. T. Cundall, when copper is heated with conc. sulphuric acid, and portions of the dark reddish-brown liquid are drawn off at successive stages of the reaction until the copper is nearly all dissolved, and poured into a large volume of water, a bright red precipitate of metallic copper is produced, and not a black precipitate of copper sulphide. It is, therefore, inferred that cuprous sulphate is the first product of the reaction of dil. or conc. sulphuric acid on copper, and this compound is decomposed by water as indicated by A. Recoura: $Cu_2SO_4=CuSO_4+Cu$. If the reddish-brown liquid obtained by the action of sulphuric acid on copper is allowed to remain, or is heated, it becomes dark and deposits a greyish-black precipitate of cuprous sulphide, and if more strongly heated, a greenish-black precipitate of cupric sulphide is formed which re-dissolves if the heating be continued: $CuS+4H_2SO_4=CuSO_4+4SO_2+4H_2O$. The primary action is therefore $2Cu+2H_2SO_4=Cu_2SO_4+2H_2O+SO_2$, or possibly at low temp., $8Cu+4H_2SO_4=3Cu_2SO_4+Cu_2S+4H_2O$; and the secondary products are $5Cu_2SO_4+4H_2SO_4=Cu_2S+8CuSO_4+4H_2O$; and $Cu_2S+2H_2SO_4=CuS+CuSO_4+2H_2O+SO_2$; and $CuS+4H_2SO_4=CuSO_4+4SO_2+4H_2O$. A combination of five times the first equation with three times the third gives one of S. U. Pickering's fundamental equations.

S. U. Pickering found that the reaction is faster with impure than with pure copper. With acid of sp. gr. 1·843, and 30 mins. action at 100°, he found that the percentage of copper dissolved with the purest electrolytic copper wire was 2·412; with electrolytic copper foil, 3·123; with a less pure electrolytic copper foil, 4·068; with ordinary copper wire, 4·897; with commercial sheet copper, 11·5; and with a bronze coin, 14·8. He also tried the effect of sulphuric acid on copper while under the influence of an electric current, by connecting a copper plate with one pole of a small Daniell's cell, while another plate was connected with another pole of the cell, and with a piece of platinum foil dipping in the acid. In another series of experiments, a piece of copper was made electropositive by attaching it to a coil of platinum wire. The more electropositive the copper was made the greater was the speed of dissolution in the acid, so that as much metal was dissolved in 15 mins. as was dissolved in one hour when the metal was neutral or electronegative. Again, when the copper was electropositive, the proportion of sulphide to sulphate formed was increased, and decreased when the copper was made electronegative. The explanation is connected with the speed of dissolution—when fast, more cuprous sulphide is produced and decomposed by the acid in a given time. A. J. Hale and H. S. Foster have also studied the action of sulphuric acid on copper.

W. Ostwald interprets the action of dil. sulphuric acid on copper by saying that in consequence of the slow reaction of the dissolved oxygen with the hydrogen ions of the acid, cupric ions are formed; J. Sěbor says that the dissolution of the metal in the presence of *hydrogen dioxide* is an ionic reaction involving $Cu+H_2SO_4=CuSO_4+H_2$, and the hydrogen is depolarized by the dioxide without a primary oxidation of the copper. According to M. Traube, hydrogen peroxide is formed during the slow oxidation of copper in the presence of dil. sulphuric acid. He says that neither moist air nor dil. sulphuric acid alone reacts with copper at ordinary temp., and it appears as if the affinity of copper for the acid SO_4-group and of oxygen for hydrogen suffice for the decomposition, which probably proceeds, $Cu+H_2SO_4+O_2=H_2O_2+CuSO_4$, followed by the consecutive reaction $H_2O_2+H_2SO_4+Cu=CuSO_4+2H_2O$. No active oxygen is liberated in the reaction. According to V. Lenher, copper is attacked by warm **selenic acid.**

If conc. sulphuric acid is mixed with **sodium nitrite,** a purple coloration is produced which slowly disappears on standing, or rapidly on warming, or on diluting the mixture with water—cuprous oxide and salts are formed. G. J. Burch and J. W. Dodgson found that copper in contact with *silver* in a mixture of 5 parts of sulphuric acid (sp. gr. 1·84) and one of nitric acid (sp. gr. 1·436) is scarcely attacked at all; but the action increases as the mixture is diluted with water. W. R. E. Hodgkinson and N. E. Bellairs say that molten **ammonium sulphate** does not appear to attack copper, but W. Smith showed that ammonium sulphate does not melt, but rather decomposes, forming ammonium hydrosulphate. The solubility of copper in soln. of ammonium sulphate has been investigated by T. Carnelley, J. W. Turrentine, and G. Lunge and L. Weibel—*vide* Table V, and also for the solubility of copper in soln. of **potassium sulphate, calcium sulphate,** and **magnesium sulphate.** During the alternating current electrolysis of soln. of **sodium hydrosulphate,** with copper electrodes, M. le Blanc and K. Schick say that copper is not dissolved because no complex salts are formed. The conversion of **cupric sulphate** in feebly acid conc. aq. soln. into cuprous sulphate was noted by J. J. Berzelius, and the equilibrium conditions: $Cu+CuSO_4\rightleftharpoons Cu_2SO_4$, have been studied by F. Förster and O. Seidell, by T. W. Richards, E. Collins and G. W. Heimrod, and by E. Abel; while R. Namais and J. W. Turrentine have studied the dissolution of copper in an ammoniacal soln. of a **persulphate.** G. Scagliarini and G. Torelli showed that copper acts as a catalytic agent in the oxidation of ammonia by persulphates. H. Ditz observed no formation of activated oxygen or of sulphur dioxide during the action; but M. G. Levi, E. Migliorini, and G. Ercolini found that a gas is slowly evolved, and a layer of cupric oxide is formed on the metal. Potassium persulphate acts more rapidly than the ammonium salt. E. Priwoznik, and F. J. Faktor found that a boiling soln. of **sodium thiosulphate** rapidly converts copper into cuprous sulphide. V. Merz and W. Weith noted the reaction between copper and the molten thiosulphate; and J. Girard studied the production of iridescent films on the metal by the action of double thiosulphates and by the electrolysis of a mixed soln. of sodium and lead thiosulphates and cupric sulphate with copper electrodes.

According to F. Raschig, a soln. of **nitrosulphonic acid** in conc. sulphuric acid is reduced to nitrososulphuric acid, $HO.NO.SO_3H$, by copper; the blue colour disappears with a more prolonged action, forming nitric oxide and sulphuric acid. E. Fromm found that a soln. of **sulphuryl chloride,** SO_2Cl_2, in absolute ether, does not dissolve copper. The action of **sulphur monochloride,** S_2Cl_2, according to P. Nicolardot, is similar to that of hydrogen chloride; the action occurs only at a high temp. F. Wöhler said copper is but slowly attacked by sulphur chloride.

P. L. Aslanoglou [18] heated powdered copper in open air and obtained no evidence of the formation of a nitride such as occurs with magnesium or aluminium under similar conditions. W. R. Grove electrolyzed a soln. of ammonium chloride with a copper plate as cathode, and a platinum plate as anode, and stated that copper nitride is formed; J. F. Daniell, and H. Pauli obtained confirmatory results, but P. L. Aslanoglou, repeating the experiment, obtained only a mixture of cupric oxide and metallic copper. A. Rossel, however, did obtain evidence of the formation of cupric nitride by heating a mixture of finely-powdered copper with calcium carbide in a crucible in the open air; and L. Arons says that the efflorescence on copper electrodes formed about an electric arc in an atm. of **nitrogen** consists of copper nitride—*q.v.* If a piece of copper wire be heated in a porcelain tube in a stream of **ammonia** gas, L. J. Thénard found that the metal becomes brittle and yellow or yellowish-white; but he could detect no increase in weight; F. Savart, however, did find an increase of $\frac{1}{300}$th and $\frac{1}{273}$rd in the weight of the metal, and a decrease in sp. gr. to 7·792 in the latter case and 8·866 in the former. C. Despretz also recorded a fall in sp. gr. to 5·5, and he stated that the metal became porous and crystalline and assumed various tints of grey, yellow, green, orange, and rose-red or purple-red. Although the amount of foreign matter in the copper so treated is very small, the metal probably takes up a large quantity of nitrogen during the operation, and gives it up again. C. H. Pfaff analyzed the gas which had passed over the heated metal, and instead of obtaining hydrogen and nitrogen in the ratio of 3 : 1, he obtained a ratio more nearly 3 : $\frac{1}{2}$, showing that some nitrogen must have been taken up by the copper. A. Schrötter and C. W. J. Kastner contradict these reports, and claim that on repeating these experiments they found rather a deficiency in the hydrogen than in the nitrogen, and that if ammonia gas is passed into molten copper, the metal retains its characteristic properties. H. N. Warren also reported the formation of a nitride by heating copper or copper oxide to bright redness in ammonia gas. C. Matignon and R. Trannoy also believed copper nitride is formed when a red-hot copper spiral is introduced into ammonia or a volatile amine. G. T. Beilby and G. G. Henderson repeated the experiments, and showed that the results are consistent with the assumption that a nitride is formed and decomposed in the reaction because the nitride can exist only within a comparatively narrow range of temp. The evidence turns on (i) the ammonia is decomposed into its elements; (ii) the copper suffers a marked change in its physical properties—*e.g.* it loses its metallic lustre, it acquires a pink colour, it develops a spongy structure, and it becomes brittle; and (iii) the maximum quantity of nitrogen fixed by the copper was 4·5 per cent.—the nitride Cu_3N requires 6·86 per cent. Ammonia was found to penetrate the metal quickly, for a copper rod, $\frac{1}{2}$ in. in diam., was attacked through the centre when heated 30 mins. in a stream of ammonia; copper at 800° for seven days was reduced to a fine spongy powder. R. Blondlot heated a disc of copper and a disc of platinum about 3 or 4 mm. apart in an atm. of nitrogen contained in a porcelain globe, the surface of the copper remained bright, that of platinum was much corroded and covered with a black deposit. Since no such result is obtained in an atm. of hydrogen, it is suggested that a nitride of copper is formed and volatilized.

In a well-known process for preparing nitrogen (*q.v.*) a mixture of ammonia and air is passed over heated copper, the hydrogen is oxidized to water, and free nitrogen remains. A soln. of ammonia dissolves copper if air be present. E. Yamasaki studied the rate of dissolution of copper in aq. ammonia, and he represented the reaction by the equation $Cu+nNH_3+\frac{1}{2}O_2+H_2O=Cu(NH_3)_n(OH)_2$, where n is probably 4. W. R. E. Hodgkinson and H. E. Bellairs detected the formation of nitrous acid a few minutes after the reaction had commenced; in time, the ammonia is completely oxidized. M. Prud'homme made some observations on this subject. The phenomenon was noted by T. Bergmann and by L. J. Proust. According to C. F. Schönbein, and N. A. E. Millon, the copper is oxidized to cupric oxide and the ammonia to ammonium nitrite; and M. Berthelot and L. P. de St. Gilles said that the copper takes up twice as much oxygen as the ammonia. E. M. Péligot noted that heat is developed during the reaction, while S. Kappel found that the reaction progresses more quickly as the temp. rises. M. E. Schweizer says that the action is favoured by some drops of aq. ammonium chloride; W. Knop, by a little platinum chloride; S. Kappel, by carbon dioxide; and C. R. A. Wright, by iron. C. R. A. Wright and C. Thompson believe that the primary reaction which occurs when metallic copper, immersed in aq. ammonia, is exposed to a limited supply of air, is the dissolution of the metal as **cuprous oxide**; this reaction is very slow if the liquid be at rest. They said:

> The reaction can be greatly accelerated by arranging horizontally, near the surface of the liquid, a plate, termed the "aeration" plate, of platinum or other conductor not acted on under the circumstances, and joining this to the copper by a wire. The voltaic element thus formed polarizes rapidly unless the external resistance is very high. Its electromotive force varies from 0·5 to 0·6 volt, and increases with the conc. of the ammonia soln., or when sodium or ammonium chloride is added thereto, or when spongy platinum is substituted for the platinum plate. In the latter case, and with strong ammoniacal brine, it may amount to 0·8 volt, nearly equalling that due to the heat of formation of cuprous oxide (40·810 Cals.), or 0·88 volt.

W. Traube and A. Biltz[19] found the oxidation of the ammonia to nitrite is favoured by the electrolysis of the ammoniacal soln., containing a little copper hydroxide in soln. The cathode was spongy copper and the anode a strip of iron or platinum; a certain amount of free alkali should be present. If an excess of ammonia be present, about eleven per cent. of nitrite can be formed before it begins to oxidize to nitrate. E. Müller and F. Spitzer add that the oxidation to nitrate does not cease when a certain conc. has been reached, but proceeds quite independently of the nitrite conc. If no alkali hydroxide is present, the oxidation of nitrite to nitrate proceeds more rapidly than the oxidation of ammonia to nitrite, and the conc. of the latter tends to decrease; nitrogen is said to be formed during the oxidation. The presence of hydrogen peroxide was found by W. R. E. Hodgkinson and A. H. Coote to favour the action of ammonia on copper. C. Häussermann found that if alcohol be present, some acetaldehyde is formed.

G. Gore found that liquid ammonia gives a blue soln. with copper; E. C. Franklin and C. A. Kraus also found that copper is attacked by liquid ammonia if air be present; but C. A. Seely, and F. M. G. Johnson and N. T. M. Wilsmore say that copper is insoluble in liquid ammonia free from water, and even if water be present, it is insoluble provided no free oxygen be present. According to T. Weyl and J. Bronn, a colloidal soln. of copper in liquid ammonia is obtained by dissolving cupric chloride in the liquid, and treating the soln. with one of sodio-ammonium. G. Arth and E. Divers found copper is not dissolved by Divers' fluid if air be excluded.

The solubility of copper in soln. of **ammonium chloride** or **ammonium cupric chloride** was studied by T. Carnelley and J. Schlerschmann, W. R. E. Hodgkinson and A. H. Coote, *vide* Table V. Hammered copper, and copper reduced in hydrogen were found by F. Osmond to give the same rise of temp. when dissolved in ammonium cupric chloride. For the electrolysis of ammonium chloride soln. *vide supra.* The solubility in ammonium nitrate soln. is indicated in Table V. According to M. Prud'homme, a cold **ammonium nitrate** soln. gives nitric oxide, and an ammoniacal soln. of ammonium nitrate gives nitrogen. W. R. E. Hodgkinson, N. E. Bellairs, and A. H. Coote found that molten ammonium nitrate attacks copper with the evolution of ammonia and a little hydrogen; M. Traube has studied the formation of ammonium cupric carbonate by the action of a soln. of **ammonium carbonate** on copper in the presence of hydrogen peroxide; he likens the reaction to that which occurs with dil. sulphuric acid: $Cu+(NH_3)_2CO_3H_2+O_2=H_2O_2+Cu(NH_3)_2CO_3$; followed by $H_2O_2+Cu+H_2CO_3(NH_3)_2=Cu(NH_3)_2CO_3+2H_2O$. If any active oxygen were here formed, ammonium nitrate would be produced; but none has been observed. J. Tafel found a soln. of **hydroxylamine sulphate** in sulphuric acid does not act on copper sponge or on a copper cathode; A. Flaschner says reduction occurs, but, add J. Tafel and H. Hahl, only when the soln. about the cathode is too feebly acid.

According to P. Sabatier and J. B. Senderens,[20] **nitrous oxide** does not act on reduced copper at 200°, but the gas is oxidized above 250° with the formation of nitrogen and cuprous oxide. With a mixture of hydrogen and nitrous oxide, P. Sabatier and J. B. Senderens found that reduced copper at 180° gave nitrogen, but no ammonia, where the hydrogen is in excess; and if the oxide be in excess, higher nitrogen oxides and a little ammonia are formed, and a slight inflammation. F. Emich found **nitric oxide** is quantitatively reduced by red hot copper; and P. Sabatier and J. B. Senderens found that with compact copper there is only a superficial film of oxide formed at a dull red heat, while with reduced copper the gas is slowly reduced even at 200°—cuprous oxide is formed. T. Gray removed nitric oxide from gases by passing the mixture over heated copper. A mixture of nitric oxide and hydrogen over 180° was found by P. Sabatier and J. B. Senderens to give a mixture of ammonia, water, and nitrogen. The same investigators found that **nitrogen peroxide,** NO_2, forms a brown copper nitroxyl, Cu_2NO_2, when in contact with freshly reduced copper warmed to 30°; and at 250° cupric oxide and nitrogen are formed, and the reaction is attended by a feeble glow. A mixture of nitrogen peroxide and hydrogen behaves like a mixture of hydrogen with nitric oxide, and if the proportion of peroxide is increased, ammonium nitrate and nitrite are formed, and when the proportion exceeds a certain limit, the metal becomes incandescent and an explosion occurs. The action of nitrogen peroxide on copper was studied by H. V. Tarton and W. L. Semon. E. Divers and T. Shimidzu found that spongy copper sealed up with liquid nitrogen peroxide in a tube at first gives a brisk effervescence owing to the escape of nitric oxide, the action soon subsides and the copper turns grey with a greenish or bluish tinge. The excess of nitrogen peroxide becomes an intense deep green which is not due to dissolved copper, because the colour disappears when the liquid is partially evaporated. It was believed that the product of the action was insoluble cuprous nitrate mixed with little cupric nitrate. P. T. Austin says copper does not burn in **nitric acid vapour.** P. Sabatier and J. B. Senderens found mixtures of nitric acid vapour and hydrogen behave like mixtures of hydrogen and nitrogen peroxide when treated with reduced copper at 180°. J. J. Sudborough found that **nitrosyl chloride,** NOCl, is not attacked by copper in the cold, but at 100° it forms a black deliquescent powder: CuCl.NOCl, which decomposes when heated to 100°, or, when allowed to stand over sulphuric acid for several hours, giving off nitric oxide, and leaving a residue of anhydrous cupric chloride: $CuCl.NOCl = NO + CuCl_2$.

The rate of corrosion and soln. of metals by different acids—hydrochloric, sulphuric, perchloric, phosphoric, and acetic acids—in the presence of oxidizing agents, led O. P. Watts and N. D. Whipple to class the metals: (1) Metals whose potentials exceed the discharge potential of hydrogen; and (2) Metals whose potentials are less than the discharge potential of hydrogen. The former are above hydrogen in the electrochemical series, and, excepting such as form insoluble salts, they dissolve readily in the acid; the latter occur below hydrogen in the electrochemical series, and dissolve in acids only in the presence of oxidizing agents —*e.g.* copper and silver. The superiority of nitric acid as a solvent for the metals is due to its acting at the same time as an acid and as an oxidizing agent; this enables it to dissolve metals of the second class which non-oxidizing acids are unable to do.

V. H. Veley[21] has shown that copper rapidly dissolves in **nitrous acid,** less rapidly in a mixture of nitrous and nitric acid, and still less rapidly in nitric acid alone. The metal also readily dissolves in one per cent. nitrous acid. According to E. Divers and T. Haga, hydroxylamine is formed when copper is left in contact with the green soln. of copper sulphate and potassium nitrate. O. Flaschner found that nitrous acid is completely reduced by low cathode potentials—*e.g.* with a copper cathode, nitrous and nitric acid are reduced to ammonia, no hydroxylamine is formed. W. Peters found a 5 per cent. aq. soln. of **sodium nitrite,** in the absence of air, is decomposed, with the evolution of nitrous and nitric oxides and the formation of sodium nitrate, when warmed at 60° with metallic copper. The reaction is chemical, not catalytic, and involves simultaneous oxidation and reduction.

Chemistry, said V. H. Veley, presents few problems at once of such technical importance and of such almost infinite complexity as the transformations of nitric acid. Ordinary dil. **nitric acid** is regarded as one of the best solvents for copper, but V. H. Veley showed that when a sphere of copper is rotated in dil. nitric acid, there is a period of inertness during which no bubbles of gas are evolved from the metallic surface for some minutes; this period of inertness is followed by a period of acceleration during which the dissolution proceeds with a gradually increasing velocity until a steady stage is attained. The metal then dissolves readily in 27·5 per cent. nitric acid with the evolution of nitric oxide, and gives a soln. of cupric nitrate: $3Cu+8HNO_3=3Cu(NO_3)_2+2NO+4H_2O$. Nevertheless, nitric oxide, NO, is not the only gaseous product of the reaction between nitric acid and copper; for example, P. C. Rây found that a considerable quantity of *nitrous oxide*, N_2O, is formed when copper dissolves in nitric acid under ordinary conditions employed in preparing nitric oxide; he also said that some *nitrogen* is formed. The green colour of the soln. in the vicinity of the copper appears deep green, indicating that possibly some *copper nitrite*, as well as nitrate, is formed. According to C. Montemartini, dil. nitric acid, below 30 per cent. conc., yields only nitric oxide and nitrous acid; with a more conc. acid, *nitrogen trioxide* and peroxide are formed, so that with 50 per cent. acid only about half the gaseous product is nitric oxide.

J. H. Stansbie found the volume of gas (calculated dry at n.p.t.) generated from a gram of purified copper in 15 c.c. of nitric acid of sp. gr. 1·2 increased with temp. and the contained nitric oxide also increased a little at the expense of the other gases. The speed of the reaction increased 25-fold as the temp. rose from 25° to 95°.

Temp. . . .	25°	35°	45°	55°	65°	75°	85°	95°

J. J. Acworth and H. E. Armstrong investigated the influence of temp. and the conc. of the nitric acid on the composition of the gases, and a selection from their results is indicated in Table VIII.

TABLE VIII.—GASEOUS PRODUCTS OF THE ACTION OF NITRIC ACID ON COPPER.

Temp.	Concentration of acid. Acid : water.	Vol. of gas per unit wt. of metal.	Percentage composition of gas.		
			NO	N_2O	N
15°	1 : 0	434	54·00	10·30	35·70
15°	1 : 1	8574	98·26	1·15	0·67
13°	1 : 2	15272	97·86	1·47	0·74
12°	1 : 4	12192	94·28	3·57	2·15
16°	1 : 8	12845	71·89	20·74	7·37
8°	1 : 2	8584	96·89	0·30	2·81
11°	1 : 2	13879	97·33	1·55	1·12
50°	1 : 2	9683	96·98	2·27	0·75
90°	1 : 2	14261	97·23	1·82	0·95

There is not much difference in the results with the 1 : 1 and the 1 : 2 acids; the amounts of nitrous oxide and nitrogen increase, while the amount of nitric oxide decreases as conc. of the acid decreases. The metal dissolves in acid more quickly at an elevated temp., but the composition of the gas is not much different from that obtained at ordinary temp. With conc. soln. of cupric nitrate and acid, J. J. Acworth obtained a gas with 85 per cent. of nitrous oxide with some nitric oxide, nitrogen, and he also detected the formation of ammonium nitrate. J. H. Stansbie reported the formation of ammonia, but G. O. Higley could detect no signs of the production of ammonia in the action of nitric acid on copper; and

C. Montemartini could find no ammonia when using between 3·0 and 27·5 per cent. acid. He also found that *nitrogen peroxide* only is obtained from 70 per cent. nitric acid. L. S. Bagster found that gas evolved with 14·5*N*-nitric acid, contains 85–90 per cent. of nitrogen peroxide, and the residue is nitrogen trioxide; with 10*N*-acid there is about 15–20 per cent. of nitrogen peroxide. P. C. Freer and G. O. Higley also said that the sole products of the action of nitric acid of sp. gr. 1·40, on copper, are nitrogen trioxide and peroxide approximately in the proportion 1 : 9; and as the sp. gr. of the acid is reduced by dilution, G. O. Higley found the proportion of nitrogen peroxide decreases and that of nitrogen trioxide rapidly increases until, when the sp. gr. falls below 1·25, nitrogen trioxide is alone produced. The nitric oxide is supposed to be a product of the decomposition of nitrogen trioxide and peroxide. This has been confirmed by L. S. Bagster.

According to G. P. Baxter and C. H. Hickey, if platinum be mixed with the copper, a steady stream of nitric oxide is obtained by dropping nitric acid of sp. gr. 1·2 on the metal; and O. Brunck noted the accelerated action of the acid on copper in contact with platinum. J. H. Stansbie examined the effect of mixing and of alloying the copper with arsenic, antimony, and bismuth on the reaction of the metal with nitric acid of sp. gr. 1·2 at 65°, and found that the results are modified "out of all proportion with the quantity of impurity present." With arsenic, the amounts of gas and of nitric oxide formed with alloys rapidly fall to a minimum with alloys containing 0·25 per cent. of arsenic, or 0·5 per cent. of antimony, and then steadily increase as the proportion of impurity increases up to 10 per cent.; with bismuth, there is a steady fall in the proportions of each gas for alloys ranging up to 10 per cent. impurity. The production of nitrous acid during the reaction was also measured. A. J. Hale and H. S. Foster also studied the action of nitric acid on copper.

In accord with A. de la Rive's view that the dissolution of a metal in an acid depends on the formation of local elements between an impurity in the metal, the metal, and the acid, say $Cu \mid HNO_3 \mid M$, T. Ericson-Aurén and W. Palmaer claim that the addition of anything which increases the e.m.f. of the combination—(i) the addition of certain metal salts, depolarizers, etc.; and (ii) variations in the nature of the negative element *M*—increases the rate of dissolution, and conversely. H. E. Armstrong has adopted a modification of this hypothesis for chemical reactions in general.

The various gaseous products are the result of complex changes taking place both between the nitric acid and its reduction products, and between these products *inter se*. If the nitric acid be freed from all traces of nitrous acid by passing a rapid current of air into nitric acid, sp. gr. 1·41, sheltered from direct sunlight, and at 35°, and diluted to the given conc., the metal remains unacted upon until nitrous acid is formed, when a brisk evolution of gas occurs; if some agent—say, urea, hydrogen peroxide, potassium chlorate, potassium permanganate, etc.—be introduced into the acid so as to destroy any nitrous acid, the metal is not dissolved at 27°, provided it and the acid be kept agitated. Hence it is inferred that nitric acid free from nitrous acid does not dissolve copper. The presence of nitrous acid is necessary for the dissolution of the metal. N. A. E. Millon had previously emphasized the fact that the reaction between nitric acid and the metals is promoted by the presence of nitrous acid which is produced by passing a few bubbles of nitric oxide into the acid: $2NO+HNO_3+H_2O \rightleftharpoons 3HNO_2$, or adding a few drops of a soln. of a nitrite. The reaction was also shown to be hindered by the presence of such substances as ferrous sulphate which removes the nitrous acid as fast as it is formed. He showed that the oxidation of copper by nitric acid is conditioned by (i) the conc. of the acid; (ii) the temp.; (iii) the presence of nitric oxide; and (iv) the solubility of the products of the reaction in the acid. He thus explained the course of the reaction:

> La marche générale des oxydations s'explique sans peine; l'acide nitreux forme des nitrites de cuivre, de mercure, d'argent qui sont détruits par l'acide nitrique à mesure

qu'ils se forment ; cette destruction donne naissance au deutoxide d'azote qui, retrouvant de l'acide nitrique refait de l'acide nitreux ; d'où résulte une nouvelle attaque et une nouvelle destruction.

The nitrous acid is thus regenerated, $2NO+HNO_3+H_2O=3HNO_2$, as fast as it is destroyed : $3HNO_2=2NO+HNO_3+H_2O$. This makes it appear as if a metallic nitrite and nitric oxide are among the first products of the reaction, the nitrite is decomposed by the excess of nitric acid to form nitrous acid, and the nitric oxide reduces some nitric acid to form nitrous acid. E. Divers also found that nitrogen trioxide, N_2O_3, acted as a stimulant—possibly owing to its forming nitrous acid. C. Montemartini represented the first stage of the reaction between dil. nitric acid and copper by the equation: $Cu+3HNO_3=Cu(NO_3)_2+HNO_2+H_2O$, and nitric oxide is a result of the decomposition of the nitrous acid : $3HNO_2=HNO_3+2NO+H_2O$. In the period of inertness, nitrous acid is being formed, and during the period of acceleration, the rate of production of nitrous acid is greater than its rate of destruction, and in the steady state, the rates of production and destruction are the same. A revolving ball of copper was immersed in 29·86 per cent. nitric acid, at 27° to 27·2°, and V. H. Veley found that the amounts of nitrous acid expressed in mgrms. per c.c. at different periods of time were :

Time (min.)	0	2	11	30	60	90	105	120
Mgrms. HNO_2	0·0042	0·015	0·064	0·111	0·124	0·166	0·195	0·195

If copper be introduced into nitric acid which already contains sufficient nitrous acid, there is no period of inertness ; the reaction starts immediately. The speed of the dissolution of the metal by nitric acid is proportional, not to the quantity of nitric acid, but rather to the amount of nitrous acid which may be present, the two magnitudes vary concomitantly provided a large excess of nitric acid is present. R. Ihle showed that nitric acid just under 8*N*-conc., or 35 per cent. nitric acid by vol. attacks copper without nitrous acid being present. According to M. Drapier, for nitric acid of a given conc., the amount of copper dissolved in a given time is very considerably reduced by shaking or rotating the copper, and if the velocity of rotation is increased sufficiently, may be reduced practically to zero. This is not due to the destruction of local heating effects, since the flow of cold water through a copper tube has no effect on its rate of soln. in nitric acid. The effect is supposed to be due to the distribution of the nitrous acid primarily produced at the surface of the metal, and to the consequent inhibition of its catalyzing effect on the soln. The addition of increasing quantities of sodium nitrite to the nitric acid gradually nullifies the shaking effect.

L. Gmelin explained the reaction by assuming that the nitric acid first oxidizes the metal. The resulting oxide then combines with undecomposed acid to form a salt, and the portion of the acid which oxidizes the metal may be converted into nitrogen peroxide, nitric oxide, nitrous oxide, or nitrogen. If the metal at the same time decomposes water, the resulting hydrogen may produce ammonia. The nature of the products thus depends partly on the affinity of the metal for oxygen, and partly on the temp. and conc. of the acid. J. J. Acworth and H. E. Armstrong hold that the reduction of the acid is due to the displacement of hydrogen from the acid, by the metal, the successive stages in the reduction of nitric acid being →nitrogen peroxide→nitrous acid→nitrous oxide→hyponitrous acid→hydroxylamine →and ammonia. H. E. Armstrong adds that " the primary product of the reduction of nitric acid is nitrous acid, whatever be the nature of the reducing agent, be it hydrogen, or metal, or arsenious acid." E. Divers divides the metals into two classes, according to their behaviour with nitric acid : (1) Those which furnish a nitrite or nitrate but exert no further action, forming neither ammonia nor hydroxylamine. This class is typified by silver, mercury, bismuth, copper, etc. The second class includes (2) Those which form ammonia and generally also hydroxylamine, but do not yield nitrite or nitrous acid ; on the other hand, they readily form nitrite by acting on their own nitrate. The members of this class are typified by tin, zinc, and other metals with strongly marked basic properties. V. H. Veley does not believe the distinction is valid because when the members of both classes enter into reaction with nitric acid, nitrous acid is formed immediately after chemical change, and that too in the presence of considerable amounts of nitric acid; but he adds that "it is probable that the *amount* of reaction between the metal and the nitric acid is dependent on the proportion of nitrous acid in the case of members of the first class but not of those of the second class." G. N. Lewis and A. Edgar studied the equilibrium between nitric acid, nitrous acid, and nitric oxide. J. J. Acworth and H. E. Armstrong attribute the production of nitrous oxide and nitrogen to secondary reactions, and E. Divers agrees with this, and added:

> *Nitrous acid* is actually formed as a secondary product when some of the nitrite actually produced, that is, produced in the primary action, is decomposed by nitric acid. This decomposition occurs (*a*) when, as at first, there is not the requisite proportion of nitrous acid already present, and (*b*) when there is not enough water present to preserve the nitrite from the action of the nitric acid. *Nitric peroxide* appears as a secondary product when the proportion of water is so low that nitrous acid interacts with nitric acid. Lastly, *nitric oxide* results as a secondary product when the proportion of water to nitric acid is so large that the nitric acid fails to prevent the nitrous acid decomposing into this substance and nitric acid: $3HNO_2=HNO_3+2NO+H_2O$. The accordance of these assertions with well-known facts is incontrovertible.

J. J. Acworth and H. E. Armstrong found the reduction of nitric acid to be more complete the more dil. the soln. This is in harmony with the observation that the e.m.f. of copper against platinum in conc. nitric acid, sp. gr. 1·5, is greatest, 0·98 volt; and it falls to 0·57 volt with an acid of sp. gr. 1·42; the addition of an equal volume of water raises the e.m.f. to 0·75 volt; and with 3 to 7 volumes of water, the e.m.f. is raised to 0·81 volt. M. Faraday showed that nitric acid is not a good conductor when pure, but the presence of nitrous acid (conjointly with water) gives it this power in a very high degree amongst electrolytes. G. J. Burch and V. H. Veley have also shown that the e.m.f. of a $Cu \mid HNO_3 \mid Pt$ cell is dependent on the conversion of nitric to nitrous acid. The e.m.f. is at first very small; it then rises slowly; then more or less rapidly; and finally very slowly to a maximum value. The effects of the conc. of the acid, temp., and presence of nitrous acid were also investigated.

During electrolysis, a dil. soln. of nitric acid is quantitatively reduced to ammonia at the cathode, and this fact has been utilized in the quantitative determination of the nitrates. The conditions for successful work have been studied by C. Luckow, G. Vortmann, K. Ulsch, A. Becker, W. H. Easton, and L. H. Ingham. The action is eq. to a nascent hydrogen reduction: $4H_2+HNO_3=NH_3+3H_2O$. On the other hand, copper reduces nitric acid chemically, not to ammonia, but to nitric oxide, yet it does reduce nitrobenzene to aniline. J. Girard found that a mixture of commercial nitric acid with 7 to 12 times its volume of commercial sulphuric acid dissolves silver from silver-plated copper without attacking the copper. According to J. Tafel, a mixture of nitric and sulphuric acids reacts with copper, forms nitric oxide: $2HNO_3+3Cu+3H_2SO_4=3CuSO_4+2NO+4H_2O$, and neither ammonia nor hydroxylamine is produced; whereas in the electrolytic reduction, hydroxylamine is formed—if the sulphuric acid be omitted, ammonia is produced. J. Tafel's general conclusion from these and other reactions is that electrolytic reduction is distinct in nature from chemical reduction. W. D. Bancroft takes the opposite view; he argues that the peculiarity of an electrolytic reduction is that the process occurs in two places, at the anode and at the cathode, and this peculiarity is less marked by bringing the electrodes closer together until, at the limit, the electrolytic and chemical processes are the same. In illustration, when copper is dissolved in sulphuric acid, the formation of copper sulphate is the anode reaction, and the reduction of sulphuric acid the cathode process. J. W. Turrentine concluded from his study: *Copper cathodes in nitric acid,* that the apparent discrepancy between the electrochemical and chemical reduction of nitric acid by copper is entirely due to the different conditions under which the two sets of reactions are performed. In the electrolytic reduction of nitric acid with a copper cathode, the reaction occurs in a soln. practically free from a copper salt; while in the chemical reduction by copper in nitric acid, the copper nitrate is formed at the same place that the reduction occurs. He showed that ammonia is formed in the reaction between copper and nitric acid when the conc. of the copper salt is kept sufficiently low. The reduction of nitrates to nitrites in neutral or feebly alkaline soln. depends on the nature of the cathode—*e.g.* gold, platinum, lead, or iron cathodes give ammonia as the main product; and E. Müller and J. Weber found that spongy copper, spongy silver, or an amalgamated copper cathode give nitrites. E. Müller and F. Spitzer further showed that the chemical behaviour runs parallel with the depolarization values, even though E. Müller, J. Tafel, and R. Russ have shown that these values are not always trustworthy because of catalytic effects due to the metals. F. Pearce and C. Couchet found that alkali nitrates are not reduced with an alternating current and copper, iron, or carbon electrodes, but with cadmium and zinc electrodes the reduction to nitrites is quantitative. J. H. Gladstone and A. Tribe's copper-zinc couple reduces a soln. of potassium nitrate to nitrite and then to ammonia—a process analogous with E. Müller and F. Spitzer's electrolytic reduction with a copper cathode. T. E. Thorpe developed a quantitative method for the reduction of nitrites to ammonia by working in hot soln., and he showed that small quantities of ammonia are produced in the reduction of nitrates by finely divided copper. J. F. Persoz, H. Müller and C. Pauli, and H. Kunheim found that finely divided copper reduces molten alkali nitrates quantitatively to nitrites. E. Divers showed that *cupric nitrate* is reduced by copper to cuprous nitrate. For the effect of alkali nitrate or *ammonium nitrate* soln. on copper, *vide* Table V. T. Fairley showed that copper and, indeed, many other metals dissolve with increased facility in acids containing hydrogen peroxide, and that no gaseous products are evolved in those cases where they would otherwise be obtained, and the metal dissolves quietly without losing its metallic brilliancy. This enables many of the non-ferrous metals to be dissolved in nitric acid without being troubled with the escape of nitrous fumes.

The passivity of copper.—In 1837 T. Andrews[22] found that copper rod in nitric acid of sp. gr. 1·4 is rapidly attacked, but if the rod be touched by platinum under the liquid, the soln. in the acid is checked, although the surface remains bright so long as contact with the platinum is maintained. If the platinum be removed, the metal remains in the "peculiar state" which enables it to resist chemical action, and it becomes covered by a black film which is very slowly removed by the acid. M. Faraday pointed out that this action is the reverse of that which would be anticipated from an application of the theory of galvanic couples, for the platinum would be expected to make the copper more electropositive and so dissolve quicker. If the copper, while covered with the film be raised from the liquid, the adherent acid immediately dissolves away the film of what T. Andrews supposed to be oxide, and the copper is now in its ordinary state. T. Andrews found that the peculiar state of the metal is developed in nitric acid of sp. gr. 1·5. When alone in acid of sp. gr. 1·47, there is at first a violent action, and the copper then acquires the peculiar state whereby it is but slowly soluble in the acid. If a strip of passive copper and a strip of ordinary metal be suspended in distilled water, the former remains bright for three or four weeks, the latter is covered by a film of oxide in three days, and is completely oxidized in three weeks. If a piece of passive copper immersed in distilled water is scratched with a glass rod, the scratched part begins to oxidize in a couple of days, the rest of the surface remains bright. Ordinary copper treated in the same way shows no difference between the scratched and unscratched parts. Again, if pieces of active and passive copper be dipped in a 0·1 per cent. soln. of silver nitrate, the former is at once coated with a furry grey deposit of silver, while the latter remains unchanged for three or four minutes.

W. Heldt attributes the protective action to a film of cupric nitrate, E. Jordis to the passage of the metal into a metalloidal state; W. R. Dunstan and J. R. Hill to the formation of a non-metallic film, probably oxide; C. W. Bennet and W. S. Burnham to the coating of the metal by adsorption with a film of higher oxide which, being more noble than the metal, protects it from the soln.; G. D. Bengough and O. F. Hudson believe the film is a lower oxide, possibly Cu_4O, which is stabilized by the copper—*vide* the passivity of iron. Copper can be rendered passive by immersion in a one per cent. soln. of chromic acid, potassium dichromate, or chromate for 12 hrs., and washing in distilled water. According to W. A. Hollis, the copper loses its passivity in nitric acid if the temp. exceeds 10°, and the critical temp. is affected by the degree of purity of the metal. G. Wiedemann, G. Berson and A. Destrem, and E. Duter found that a copper anode is rendered passive during the electrolysis of a 50 per cent. soln. of potassium or sodium hydroxide; E. Müller thus describes the behaviour of a copper anode in a conc. soln. of sodium hydroxide:

> When a clean copper plate is immersed in a $14N$-soln. of sodium hydroxide which is free from dissolved oxygen, the copper is negative compared with the soln.; measured against the $\frac{1}{10}N$-calomel electrode its potential is $-0·66$ volt. When a very small current, 2×10^{-6} amp. per sq. cm., is passed, the potential rises at first slowly, then rapidly to about $-0·54$ volt. If electrolysis is continued with a larger current density, a blue soln. of cupric hydroxide is formed, and the potential rises again, at first slowly, then rapidly to $+0·76$ volt, at which point oxygen is evolved and copper ceases to be dissolved. The first rise is accompanied by the formation of a skin of cuprous oxide, the second by the formation of a skin of cupric oxide. During the last period, a little copper peroxide is always formed. In the earliest period, the change $Cu+F\rightleftharpoons Cu^{\cdot}$ takes place; when the soln. is sat. with cuprous ions, which very soon occurs, a skin of cuprous oxide forms, and the potential rises to the point at which the reaction $Cu^{\cdot}+F\rightleftharpoons Cu^{\cdot\cdot}$ can occur; this goes on until the soln. (in contact with the anode) is sat. with cupric hydroxide; owing to the greater solubility of this substance, this stage lasts longer or requires a larger current; when the skin of solid cupric oxide is formed, the potential again rises until the reaction $Cu^{\cdot\cdot}+F=Cu^{\cdot\cdot\cdot}$ occurs. The peroxide is, however, unstable, and decomposes spontaneously, giving off oxygen.

O. W. Brown and F. C. Mathers found that the copper anode may become passive during the electrolysis of potassium sodium tartrate, and instead of dissolving "becomes covered with a thin coating probably of cuprous oxide"; R. Lorenz, that the passive state is induced by molten alkali hydroxides; and M. le Blanc, that a copper electrode which has been heated in the flame of a blowpipe until fusion begins, and then quenched in alcohol, has a smooth even surface; it is in a noble or passive condition in a soln. of cupric sulphate; and it gives a difference of potential of 13 millivolts against ordinary copper. The passive state is removed by treatment with nitric acid. M. le Blanc and K. Schick found that when an alternating current, of current density 4·6 amp. per sq. decm., is passed through a $4N$-soln. of potassium cyanide between copper electrodes, the amount of copper which dissolves depends on the frequency of the current alternations, the conc. of the soln., the current density, etc. With a frequency 700 per min. the copper went quantitatively into soln., with 3400 per min., 91 per cent. of the theoretical; with 17,600 per min., 58 per cent.; and with 38,600 per min., 33 per cent. With a $\frac{1}{10}N$-soln., current density 2·3, and frequency 40,000 per min., no copper passes into soln. A. Brochet and J. Petit obtained similar results. The diminution in the amount of copper which passes into soln has been ascribed to a passive condition of the metal; A. Löb explains the phenomenon as a result of over-voltage—as the over-voltage increases, the amount of hydrogen liberated by the current decreases, and, as a consequence, the amount of copper liberated will increase. The phenomenon is more pronounced with a zinc electrode and less pronounced with a nickel electrode than with one of copper; this corresponds with the higher over-voltage of the zinc electrode and the lower over-voltage of the nickel electrode over one of copper.

From the heat of the reaction, and the contraction which occurs during combination, W. Müller-Erzbach[23] deduced that the affinity of copper for **phosphorus** is smaller than that of palladium, platinum, or iron, and greater than that of manganese, nickel, cobalt, zinc, silver, or gold. According to W. Straub, phosphorus can react slowly with copper at ordinary temp. A. Granger did not obtain any marked reaction at 360°, but over 400° the copper assumed a grey colour and became very brittle, but the transformation into a definite phosphide is incomplete. O. Emmerling obtained combination by heating the two components in a sealed tube. Many of the metallic phosphides, when heated, react with copper—*e.g.* E. Defacqz found that tungsten phosphide, WP_2, at 1200°, was completely decomposed by copper. The commercial alloy *phosphor-copper* is made by the action of phosphorus vapour on fused copper, and it contains 9–15 per cent. of phosphorus. Alloys with over 14 or perhaps 15 per cent. of phosphorus cannot be made by the fusion process, although E. Heyn claims to have made alloys with as much as 20 per cent. of phosphorus by mixing copper filings and red phosphorus in crucibles connected together in series like a train of wash-bottles, and heating them one at a time to 300° or 400°—not over 700°—the vapour from the crucible being heated is condensed by the others. Phosphor-copper was made by A. S. Marggraf (1740), and B. Pelletier (1789), from phosphorus and the metal; by B. Pelletier (1789), B. G. Sage (1792), C. Künzel (1888), H. Schwarz (1875), P. Berthier (1826), and P. Mellmann (1888) from copper, carbon, and phosphoric acid or a phosphate—*e.g.* bone ash; from the reduction of phosphoric acid with copper electrodes, by H. Davy (1807); from copper oxide, carbon, and phosphorus, by H. N. Warren (1887), P. Burckhard (1870), and T. Dill (1897); by G. Seyboth, from the electrolysis of molten phosphates with copper electrodes; from the reduction of cupric phosphate with carbon, by P. Berthier (1826), L. Gnétat and J. Chavanne (1883), and C. Matignon and R. Trannoy (1905); from the reduction of aq. soln. of cupric salts either by electrolysis or by treating them with phosphorus, by D. S. Ashbrook, E. Goerke, A. Oppenheim, A. Joannis, O. N. Heidenreich, and R. Böttger. Phosphor-copper is steel-grey in colour, fine-grained, and brittle; it is so hard that it is filed with difficulty. It is used in making phosphor bronze; and for adding phosphorus to copper which is to be rolled, for the metal then works more uniformly. It probably acts by deoxidizing the cuprous oxide. The addition of a little phosphor-copper to brass mixtures cleans the metal and increases its fluidity. Small proportions of phosphorus make copper hard, copper with 0·05 to 0·10 per cent., and not over 0·04 per cent. oxygen, can be rolled. J. L. Jones gives Brinell's hardness, the tensile strength (lbs. per sq. in.), and the elongation in 2 ins. of copper with different proportions of phosphorus:

P per cent.	2·5	4·5	6·5	8·5	10	12
Hardness	92	136·0	197·0	229·0	212·0	223·0
Tenacity	52,800	69,500	79,000	34,250	26,500	—
Elongation	28·2	15·2	2·8	0	0	—

F. A. Abel, A. H. Hiorns, E. Münker, H. de Ruolz-Montchal and H. de Fontenay, etc., have studied the properties of these alloys. E. Heyn and O. Bauer's equilibrium diagram for the binary system, and the *copper phosphides*, are discussed in connection with phosphorus.

According to E. Rubénovitch,[24] between 180° and 200° copper is attacked by **phosphine**, forming copper phosphide. H. Moissan also obtained copper phosphide by heating copper with **phosphorus trifluoride**; A. Granger, with all three **phosphorus halides** at a dull red heat; H. Goldschmidt, with **phosphorus pentachloride**; and B. Reinitzer and H. Goldschmidt, with **phosphorus oxychloride.** According to H. Rose, finely-divided copper dissolves slowly in molten **phosphoric acid.** As indicated above, O. P. Watts and N. D. Whipple have studied the action of phosphoric acid on copper. D. Wilson found a conc. soln. of **sodium phosphate** dissolves no copper.

Copper forms an alloy with **arsenic** when arsenic is dropped into molten copper or when a compound of arsenic is melted with copper under charcoal. T. Bergman,[25] in the eighteenth century, reported that copper takes up five-sixths of its weight under these conditions. K. Friedrich found that 44 per cent. is the greatest amount of arsenic which can be alloyed with copper by fusion. The mechanical properties of copper are not harmed by small amounts of arsenic; according to W. C. Roberts-Austin, copper with 0·8 per cent. of arsenic can be drawn into the finest wire, but with one per cent. of arsenic, red-shortness appears; as noted by C. J. B. Karsten, much arsenic is injurious, making the metal brittle and hard. P. Jolibois and P. Thomas studied the effect of arsenic on the oxygen content of copper. W. Stahl, E. A. Lewis, G. D. Bengough and B. P. Hill, F. Johnson, R. H. Greaves, L. Archbutt, W. C. Roberts-Austen, P. Oberhoffer, H. D. Law, H. Baucke, etc., have studied the tensile strength, the elongation, and the elastic limit of copper with up to 1·8 per cent. of arsenic. G. D. Bengough and B. P. Hill find:

(1) Arsenic in small quantities tends to increase the maximum stress without affecting appreciably the ductility of these alloys. (2) It increases their resistance to reducing gases at high temp. (3) Alloys with low percentages of arsenic tend to be unhomogeneous, but with increase in the arsenic this ceases to be apparent. (4) In ordinary oxidizing atm. no heat treatment (for three hours or less) short of an approximation to fusion seriously affects the properties of these alloys. The only result of annealing is to render the bars slightly more homogeneous and to lower the yield-point somewhat. This statement, however, does not apply to annealing temp. in the neighbourhood of 1000° C. (5) Alloys containing less than 1 per cent. of arsenic are ruined by the action of reducing gases for three hours at 700° C. or above it; in some cases the action is apparent at 600° C. (6) The yield-points of these alloys are somewhat variable and unsatisfactory.

A. Mathiessen and C. Vogt studied the electrical conductivity, and J. H. Stansbie, the solubility of copper-arsenic alloys in dil. nitric acid. The f.p. curves of mixtures of copper and arsenic have been studied by K. Friedrich and G. D. Bengough and B. P. Hill. K. Friedrich's curve is shown in Fig. 18.

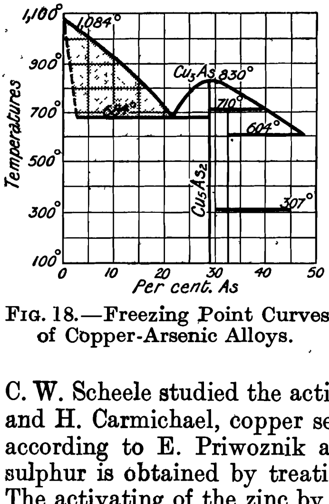

FIG. 18.—Freezing Point Curves of Copper-Arsenic Alloys.

A solid soln. is formed which attains a maximum at 684° with 4 per cent. of arsenic at the terminus of the eutectic line. The eutectic at 684° with 21·5 per cent. arsenic is made up of the solid soln. with 4 per cent. As, and the compound Cu_3As. There is a maximum in the curve for cupric arsenide Cu_3As, at 830°. At 710° there is evidence of the formation of an unstable compound Cu_5As_2 with 32·1 per cent. of arsenic. The eutectic at 604° and the transformation line at 307° have not been definitely settled. G. D. Bengough and B. P. Hill believe there is a series of solid soln. between the two compounds Cu_3As and Cu_5As_2.

C. W. Scheele studied the action of copper on **arsenic acid.** According to H. Hager, and H. Carmichael, copper separates arsenic from acid soln. of **arsenic salts**; and, according to E. Priwoznik and K. Heumann, a mixture of arsenic, copper, and sulphur is obtained by treating ammoniacal soln. of arsenic sulphide with copper. The activating of the zinc by introducing a little copper, in Marsh's test for arsenic, has been studied by C. Mai and H. Hurt, A. Gautier, G. Lockemann, Z. de Vamossy, M. Vizern and L. Guillet, E. T. Allen, etc., and A. C. Chapman and H. D. Law found that the reduction of arsenious or arsenic oxide by copper cathodes is not quantitative; H. J. S. Sand and J. E. Hackford obtained no reduction in dil. soln. N. Puschin and E. Dischler have studied the electrical conductivity of these alloys.

Alloys of copper with **antimony** are prepared in a manner similar to those with arsenic. G. Kamensky prepared a series of alloys and showed that with increasing proportions of antimony, the colour passes from that of copper to violet or purple when between 45 and 75 per cent. of antimony has been added; the colour then becomes grey. The alchemists called the violet alloys *regula veneris*. The effect of antimony on the mechanical properties of copper resembles that with arsenic. P. Jolibois and P. Thomas found that antimony did not reduce the proportion of copper oxide. The tensile strength of the metal is increased with up to half per cent. of antimony, but when other metals are present, the effects of this small amount of antimony are not necessarily advantageous. As noted by C. J. B. Karsten, much antimony makes the copper brittle when hot and when cold. Over one per cent. of antimony makes the fracture appear dull yellowish-grey, and its injurious effects are more marked than with arsenic. The tenacity of the copper-antimony alloys has been studied by W. Hampe, E. A. Lewis, R. H. Greaves, L. Archbutt, F. Johnson, H. D. Law, L. Guillet, G. Kamensky, etc. F. Johnson concluded:

> (1) Antimony up to 0·5 per cent. has no detrimental influence on the hot-forging qualities of tough-pitch copper free from other impurities. It is even possible to forge copper containing 1 per cent. antimony if sufficient oxygen be present. (2) In copper which has been over-poled, antimony tends to mitigate the phenomenon of spewing during solidification. (3) Tough-pitch arsenical copper (0·4 per cent. arsenic) is slightly hardened after hot-rolling by the presence of antimony (0·2 per cent.), but otherwise its mechanical properties are slightly improved. (4) The mechanical properties of tough-pitch pure copper after rolling and annealing are but slightly altered by small additions of antimony. The tensile strength is slightly raised (5 per cent.), and the elongation lowered (10 per cent.). The slight gain in toughness is probably traceable to the greater soundness of the ingot. (5) With regard to the structural condition of antimony in tough-pitch copper, it exists in two forms: (*a*) partly in solid soln. (as Cu_3Sb); (*b*) partly as an insoluble compound with oxygen (slate-coloured oxidules). Oxygen in excess exists as Cu_2O. The latter together with the antimony oxides form a ternary eutectic with the solid soln.

P. Braesco found the mean coeff. of expansion of copper-antimony alloys between 100° and 300° to be a maximum 0·0000234 for alloys with 38·6 per cent. of antimony. The electrical conductivity has been studied by G. Kamensky, E. J. Ball, etc.; the sp. gr. and specific volume by G. Kamensky, E. Maey, etc.; the hardness by A. A. Baikoff; the thermal expansion by H. le Chatelier, and P. Braesco; and the action of dil. nitric acid by J. H. Stansbie. The f.p. curves and the microstructure of the alloys have been studied by J. E. Stead, A. A. Baikoff, G. Charpy, J. A. Mathews, W. Campbell, A. H. Hiorns, W. Guertler, etc. A. A. Baikoff's diagram is shown in Fig. 19.

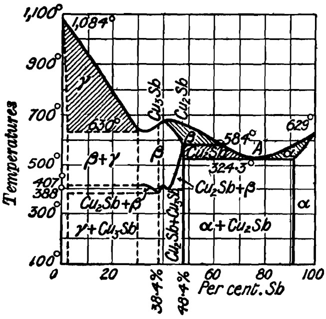

FIG. 19.—Freezing Point Curves of Copper-Antimony Alloys.

Starting from antimony melting at 629°, a solid soln., α, is formed which reaches a maximum with 10 per cent. of copper. The eutectic *A*, at 524° and 25 per cent. of antimony, is a mixture of the solid soln. α and copper antimonide, Cu_2Sb; the eutectic line extends to 49 per cent. of antimony. This compound has a purple colour and it is formed at 584° by the union of the grey compound Cu_3Sb with antimony. The latter compound, Cu_3Sb, solidifies at 681°; and between 681° and 584° the solid soln. β of Cu_3Sb and antimony separates, and at 584° is, in part, transformed into β and Cu_2Sb. The solid soln. β separates unchanged between 46·5 and 31 per cent. of antimony; and above 630° with between 31 and 0·4 per cent. of antimony, there separates out a solid soln. of Cu_3Sb, and a solid soln. γ of copper with 2·5 per cent. of antimony. Below 630°, the solid soln. of Cu_3Sb is transformed into the solid soln. β and γ. Another transformation occurs below 407°, leaving on the antimony side of the ordinate—39 per cent. of antimony—and a mixture of Cu_2Sb and Cu_3Sb, and on the copper side, a mixture of γ and Cu_3Sb.

Alloys of copper with **bismuth** were prepared by C. M. Marx[26] by heating the two metals at a temp. below the m.p. of copper. The f.p. curves have been investigated by H. Gautier, A. H. Hiorns, K. Jeriomin, C. T. Heycock and F. H. Neville, and A. Portevin. The general conclusion is that there are neither compounds nor solid soln. There is a V-shaped curve with a eutectic at 0·25 per cent.

of bismuth—Fig. 20—where the scale is too small to show the eutectic. H. Gautier's curve, with two eutectics and a maximum corresponding with copper bismuthide, CuBi, is probably wrong. The eutectic is prone to undercooling. As indicated by C. J. B. Karsten, a small proportion of bismuth in copper makes the metal hot-short and cold-short. W. Hampe, for instance, found as little as 0·02 per cent. of bismuth makes copper red-short; and 0·1 per cent. makes it very brittle. H. N. Lawrie's correction of H. Baucke's data show that 0·05 per cent. of bismuth makes copper brittle at a red heat, and 0·025 makes it cold-short; H. N. Lawrie says that the presence of 0·0005 per cent. of bismuth prevents copper being drawn into wire. F. Johnson found that arsenic counteracts to some extent the evil effects of bismuth; and N. Parravano says that antimony acts in the same direction. F. Johnson concluded:

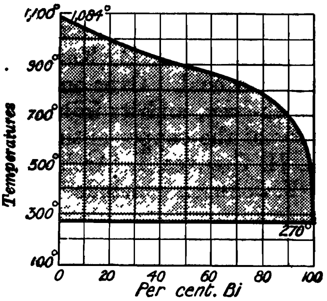

Fig. 20.—Freezing Point Curves of Copper-Bismuth Alloys.

> The effect of bismuth on the mechanical properties of tough arsenical copper which has been rolled is not serious up to 0·1 per cent.; but no commercial arsenical copper could be regarded as fit for working at a red heat which contained so much bismuth. With 0·02 per cent., although the hot-working properties would be noticeably worse than if no bismuth were present, the copper would not be ruined. Any crude copper containing over 0·01 per cent. bismuth should be regarded with suspicion, since the copper might contain traces of other impurities, *e.g.* nickel, which, while intensifying the injurious effect of bismuth, would hinder the corrective action of arsenic.

According to P. Jolibois and P. Thomas, bismuth oxide is less injurious than bismuth. C. M. Marx noted that an alloy of copper with twice its weight of bismuth expands a considerable time after solidification; and W. C. Roberts-Austen explains the injurious effects of bismuth by assuming that the bismuth with perhaps a little copper remains fluid until the temp. of the mass has fallen to at least 268°, the m.p. of bismuth.

According to G. J. L. de Chalmot,[27] the affinity of **silicon** and copper for one another is smaller than that of silicon for iron, manganese, or chromium, and about the same as it is for silver and zinc. A. L. Williams could detect no sign of combination. M. Philips found the two elements begin to unite at about 775°. E. Rudolfi's fusion curve shows the existence of two silicides (*q.v.*). According to O. Ruff and B. Bergdahl, molten copper can dissolve a little **carbon.** J. H. Vivian[28] was of the opinion that a compound of copper and carbon was present in over-poled copper; C. J. B. Karsten believed a compound is formed when copper plate and powdered carbon are heated in alternate layers for several hours at a red heat when the copper takes up 0·2 per cent. of carbon; and W. Hampe thought a compound is formed when cupric succinate is reduced by hydrogen. There is, however, no trustworthy evidence here of chemical combination, and C. J. B. Karsten showed that even if a little carbon is absorbed by the copper, the metal readily gives up its carbon when fused in air. H. Moissan found that carbon is dissolved by copper at its b.p., and rejected as the metal solidifies.

According to W. Hampe,[29] **carbon monoxide** behaves like hydrogen towards molten copper; E. Jurisch did not detect any absorption of carbon monoxide by copper between 620° and 930°; and I. L. Bell found that spongy copper is not changed by heating it with carbon monoxide. P. Sabatier and J. B. Senderens found carbon monoxide is not affected by heating it with copper to 450°, but M. Berthelot heated copper with carbon monoxide in a sealed tube at 550° and obtained some carbon and carbon dioxide. W. Hampe found no **carbon dioxide** is absorbed by molten copper, although both G. Neumann and K. Heydenreich reported that copper, reduced in hydrogen, occludes carbon dioxide at a red heat. According to L. Pfaundler some carbon dioxide is decomposed by copper at 220°, and a little carbon is retained by the metal; and H. Limpricht also reported a slight reduction of carbon dioxide to the monoxide by spongy, not sheet, copper. According to F. von Bacho, copper turnings free from hydrogen do not react with carbon dioxide at a full red heat, but at 1070° there is a slight action with the formation of cuprous oxide and carbon monoxide; the reaction is quicker at the m.p. of the metal. P. Sabatier and J. B. Senderens found that carbon dioxide, mixed with hydrogen, is reduced to carbon monoxide, not methane, when passed over heated copper. For the occlusion of carbon monoxide and dioxide *vide supra.*

W. Hampe[30] found copper, at a temp. a little above its m.p., decomposes **methane,** and J. C. Bull patented a process for removing oxygen, phosphorus, arsenic, and antimony from copper by melting the metal in an atm. of hydrocarbon vapour. P. Sabatier and J. B. Senderens found that **ethylene** is not attacked by finely divided copper at 400°. W. R. Hodgkinson found copper heated up to its m.p. is not affected by **acetylene.** For the occlusion of this gas *vide supra.* Ordinary acetylene, contaminated with ammonia, attacks brass, and, according to N. Caro, forms an explosive acetylide. A. Denaeyer found that the purified gas does not act on copper turnings; and N. Caro also noted that dry acetylene has no action on copper, on brass, or on bronze, but there is a slow reaction with the moist gas resulting in the formation of a trace of acetylide in about six months; if ammonia be also present, the action is fairly rapid, and the explosive acetylide is formed. According to H. Erdmann and P. Köthner, and H. Alexander, finely divided copper begins to react with acetylene between 225° and 260°, producing graphite. P. Sabatier and J. B. Senderens say that the reaction begins at 180° with reduced copper, and between 200°–250° with copper wire or foil. More or less of a condensation product, *cuprene,* $(C_2H_2)_n$, is obtained, which can be freed from copper by washing it with hot hydrochloric acid; cuprene is not attacked by sulphuric acid, but it reacts with nitric acid. It is decomposed over 400°, and when prepared with the acetylene under press., J. Fuchs patented its use as a cork *Ersatz.* A. Mailhe, and P. Sabatier and J. B. Senderens also found that acetylene begins to be hydrogenized when it is mixed with hydrogen, and passed over finely-divided reduced copper at 130°—if compact copper is used, the action begins at 180°. Ethane is formed at 200°. P. Sabatier and J. B. Senderens observed no change with **benzene** between 350° and 400°. According to F. Bellamy, when a mixture of air and acetylene is passed over red-hot copper, the metal becomes incandescent, and an explosion occurs; and N. Caro found copper-asbestos becomes incandescent in an explosive mixture of acetylene and air.

According to M. Berthelot,[31] copper at 300° has no action on **cyanogen,** but between 500° and 550°, it forms a little cyanide, some carbonaceous matter, and nitrogen. An aq. soln. of **potassium cyanide** dissolves copper with the evolution of hydrogen; the action takes place if air be excluded. G. A. Goyder found that allowing for the presence of a little cyanate, and for the solubility of the gas, the reaction corresponds with the equation: $2Cu+4KCy+2H_2O=2KCuCy_2+2KOH+H_2$; and W. Nernst says the action is turbulent if the copper be in contact with a platinum wire. F. Kunschert has investigated the free energy and potential of copper towards potassium cyanide soln.—*vide* passive copper. A. Brochet and J. Petit found that hydrogen is evolved in the reaction which they represent: $2Cu+8KCy+2H_2O=2(CuCy.3KCy)+2KOH+H_2$. Amalgamated copper dissolves about ten times as fast as the ordinary metal.

In the presence of copper, **hydrocarbon oils** are oxidized by air, and, according to C. Engler and E. Kneis,[32] the copper at the same time dissolves as oxide; if air or oxygen be excluded, the mineral oils have no action on metals. A. Gawalowsky also says crude petroleum is not attacked. S. Macadam found the paraffin burning-oils act on metals and that the different effects by different samples could not be traced to impurities. The **fatty oils** and **fats** also attack copper slowly. The action does not bear any simple relation to the acid content of the oil. C. W. Volney found with olive oil, cotton-seed oil, and lard oil, the first had the greatest action on brass, and the last had the least action. W. Thomson found that *olive oil, palm oil, neatsfoot oil, tallow oil, palm-nut oil, ground-nut oil,* and *lard oil* form a green coating on the copper, but a very small quantity if any copper passes into soln.; refined *rape oil, linseed oil, sperm oil, cod-liver oil,* and *seal oil* left the surface of the copper bright, but dissolved large proportions of copper; *castor oil, brown rape oil, raw linseed oil,* and English *neatsfoot oil* tarnished the metal and dissolved a large proportion of copper; and *seal oil, whale oil, cod oil, shark oil,* and East Indian *fish oil* left the copper bright but dissolved moderate quantities of metal; W. H. Watson found that after ten days' exposure in contact with 8 sq. ins. of a surface of copper, the amounts in grains dissolved by 500 water grain measures of oil were: linseed oil, 0·3000; olive oil, 0·2200; *colza oil,* 0·0170; *almond oil,* 0·1030; seal oil, 0·0485; sperm oil, 0·0030; castor oil, 0·0065; English neatsfoot oil, 0·1100; *sesame oil,* 0·1700; and *paraffin oil,* 0·0015. I. J. Redwood also experimented on the same subject. N. J. B. G. Guibourt found copper to be soluble in *cajeput oil.* A. Livache, and W. Lippert found copper accelerates the oxidation of oils in air. C. A. Fodin also recommends copper cathodes in the electrolytic reduction of the fatty acids because of the activity of the occluded hydrogen. A. Carpené found the solubility of copper in **wine** to be greater than nickel and less than iron. According to J. Golding and E. Feilmann, copper is acted upon by **milk**, especially in the presence of air, and from one to a hundred parts go into soln. per 10^6 parts of milk. D. Klein and A. Berg found copper is not attacked by a soln. of **sugar** between 115° and 120°, but J. H. Gladstone found aq. soln. dissolve appreciable quantities of copper in a few days. A. Lidow found alkaline soln. of **gelatine** also dissolve copper.

H. Fleck [33] states that dil. **acetic acid** acts slowly on copper in the absence of air; the reaction is quicker if air has access. Cold glacial acetic acid in the presence of hydrogen peroxide dissolves copper. P. Sabatier and J. B. Senderens found that acetic acid is slowly decomposed when heated with finely divided copper at 260°, the action is rapid between 390° and 410°, carbon dioxide, methane, and acetone are formed. T. Bergman noted the gradual formation of copper oxalate in aq. soln. of **oxalic acid**. H. C. Bolton found a boiling sat. soln. of **citric acid** in presence of sodium nitrate dissolves copper. K. B. Lehmann, T. Schwarz, and A. Gawalowsky found that the attack of copper by organic acids is retarded in the presence of sugar, etc.

Copper or copper oxide dissolves in glasses and glazes producing a blue or a green colour—the former when the alkalies predominate. A red colour is produced when about 0·1 per cent. of copper is dissolved in the silicate.[34] This colour is exemplified by the copper ruby glass, and in the *sang de bœuf* or *rouge flammé* Chinese porcelain glazes, and the modern imitations. It was assumed by P. Hautefeuille that the green colour is due to the formation of a soln. of cupric silicate; and the blue colour, of a soln. of an alkali cupric silicate. When heated in a reducing atm., the cupric silicate was assumed to decompose into cuprous oxide and silicate, and the former was supposed to colour the glaze or glass red. It is now believed that the red colour is due to the formation of red colloidal copper (*q.v.*).

Reactions of analytical interest.—Cupric sulphate (*q.v.*) is usually regarded as a typical salt. The addition of **potassium hydroxide** in a cold soln. of cupric sulphate gives a blue precipitate of cupric hydroxide, $Cu(OH)_2$; with cuprous chloride a yellow precipitate of cuprous hydroxide, CuOH, is formed. On boiling, the former changes to brownish-black cupric oxide, the latter to red cupric oxide. T. G. Wormley [35] detected one part of copper (ic) in 12,500 of liquid by means of a soln. of sodium hydroxide; and F. Jackson, 1 in 16,000. The presence of alkali tartrates—*e.g.* Rochelle salt—prevents the precipitation by alkalies. With a mixed soln. of silver and cupric nitrates, P. Jolibois and co-workers showed that all the silver is precipitated as hydroxide before the copper hydroxide begins to separate. The **alkali carbonates** precipitate a pale-green basic carbonate, $Cu_2(OH)_2CO_3$, with cupric salts, and a yellow precipitate with cuprous salts. T. G. Wormley detected one part of copper (ic) in 12,500 parts of liquid by this reaction; F. Jackson, 1 in 16,000. The **carbonates of the alkaline earths and magnesium** do not precipitate cupric salts in the cold, but they do so when heated to 60°. Aqua **ammonia** added slowly to a cupric salt soln. precipitates a green pulverulent basic salt soluble in excess of ammonia, forming an azure-blue soln. T. G. Wormley detected one part of copper in 12,500 of liquid by this reaction; A. B. Prescott and E. C. Sullivan, 1 in 20,000; A. Wagner, 1 in 25,000; and F. Jackson, 1 in 8000. If alcohol be added to the conc. blue soln., a bluish-violet ammino-sulphate is precipitated. Ammonia produces no precipitate with solns. of cuprous salts, and the ammoniacal soln. is colourless, but turns blue on exposure to air. Similar results are obtained with **ammonium carbonate.**

When a neutral or slightly acid soln. of a cupric salt is treated with **hydrogen sulphide,** black colloidal cupric sulphide, CuS, is formed, which runs through the filter paper. If an excess of acid be present, the precipitate is coagulated. The sensitiveness of the reaction is such that T. G. Wormley was able to detect one part of the metal in 12,500 of liquid; A. B. Prescott and E. C. Sullivan detected 1 in 100,000; F. Jackson, 1 in 16,000; and A. Wagner, 1 in 2,500,000. The precipitate becomes blue on exposure to air owing to its being oxidized to sulphate. Copper sulphide is soluble in hot dil. acid, insoluble in boiling sulphuric acid, soluble in a soln. of potassium cyanide, appreciably soluble in ammonium sulphide, but, unlike mercuric sulphide, it is insoluble in potassium or sodium sulphide. Hydrogen sulphide gives no precipitate with cupric salts if an excess of potassium cyanide be present—the complex salt, K_3CuCy_4, is formed. With cuprous salts, hydrogen sulphide gives a black precipitate of cuprous sulphide, Cu_2S, and this is soluble in warm nitric acid, forming blue cupric nitrate and free sulphur; and also in a soln. of potassium cyanide. An aq. soln. of an **alkali sulphide** gives similar results.

Cupric salts with **potassium cyanide** give at first a yellow precipitate of cupric cyanide, $CuCy_2$, which immediately changes to white cuprous cyanide, Cu_2Cy_2, and this dissolves in more potassium cyanide, forming the complex salt, K_3CuCy_4. F. Jackson detected one part of the salt in 2000 parts of liquid by this reaction. With cuprous salts, white cuprous cyanide is formed, and this is soluble in an excess of the reagent. Cupric salts with **potassium thiocyanate** give black cupric thiocyanate, $Cu(CyS)_2$, which is slowly changed into white cuprous thiocyanate, CuCyS, or quickly on adding sulphurous acid. Cuprous salts give the white cuprous thiocyanate directly. This latter salt is insoluble in water, dil. hydrochloric, and sulphuric acid. When a neutral or acid soln. of a cupric salt is treated with **potassium ferrocyanide,** an amorphous dark reddish-brown precipitate of cupric ferrocyanide, Cu_2FeCy_6, is formed, which is insoluble in dil. acids, and soluble in ammonia. T. G. Wormley detected one part of copper in 31,250 parts of liquid by this reaction; A. B. Prescott and E. C. Sullivan, 1 in 100,000; and F. Jackson, 1 in 16,000. A. Wagner says that the ferrocyanide test is nearly as delicate as the hydrogen sulphide test, and, according to A. J. Cooper, it is ten times more sensitive than the ammonia test. In acid soln. one part of copper in 1,000,000 parts of soln. can be detected by the ferrocyanide test; in neutral soln.. 1 in 1,500,000; and in neutral soln. containing ammonium nitrate or chloride, 1 in 2,500,000. The red precipitate does not occur in alkali soln. since the precipitate is decomposed by potassium hydroxide, forming blue cupric hydroxide and potassium ferrocyanide; the blue hydroxide when heated forms the black oxide. With cuprous salts, potassium ferrocyanide gives a white precipitate which becomes brownish-red on exposure to air. With cupric salts under similar conditions, **potassium ferricyanide** gives a brownish-yellow precipitate; and a brownish-red precipitate with cuprous salts. **Potassium iodide** gives a white precipitate of cuprous iodide, CuI, with both cuprous and cupric salts. T. G. Wormley detected one part of copper in 12,500 of liquid by this reaction; and F. Jackson, 1 in 8000. **Potassium chromate** gives a yellowish-brown precipitate with a soln. of cupric sulphate. T. G. Wormley found the reaction sensitive to 1 in 125 000 and F. Jackson, 1 in 16,000. **Potassium xanthate** gives a yellow coloration with very dil. soln. of a cupric salt, and A. Wagner detected one part of copper in 900,000 parts of water by its means. A soln. of **nitroso-β-naphthol** in 50 per cent. acetic acid was found by M. Ilinsky and G. von Knorre to precipitate copper quantitatively from a soln. of a copper salt acidulated with hydrochloric acid, and this in presence of lead, mercury, cadmium, manganese, and zinc salts. P. Cazeneuve found that an alcoholic soln. (1 : 100) of *s*-**diphenylcarbazide** in neutral or feebly acid soln. of cupric salts gives an intense violet coloration which can be recognized with one part of the metal in 100,000 parts of soln. Soln. of silver and gold give rose colorations with the precipitation of the metal; ferric salts give a peach-flower coloration; mercuric salts give a blue; and chromates a violet. K. W. Charitschkoff found that a soln. of **naphthenic acid** in benzene is a delicate test for copper giving a green coloration with neutral or feebly acid soln. Cobalt salts give an eosin-red, and nickel salts a pale green, coloration.

Some uses of copper.—Copper is used for making various utensils—boilers, cooking utensils, steam pipes, etc. Owing to its high thermal conductivity it is used for locomotive fire-boxes and similar purposes. It is used still more extensively in the form of alloys—bronzes, brasses, etc. Enormous quantities are used in the electrical industries as fittings, battery plates, etc. Owing to its high electrical conductivity it is used for telephone and other conducting wires. Copper nails, rivets, and sheets were once extensively used for sheathing wooden ships. Owing to its being little acted upon by many chemical dye-stuffs, and its being so soft as to be easily engraved, it is used for rollers for calico and other kinds of printing. The oxide and various salts are used for colouring glass and pottery glazes green, blue, or red. The hydroxide, carbonate, silicate, etc., are made into blue or green paints. The salts are used medicinally; for combating plant diseases and pests; and as an antiseptic. Copper is used in a finely-divided condition as a catalyzer in oxidizing and reducing reactions.[36] It was once largely used for coinage, but it is now generally replaced by alloys—*e.g.* bronze in Great Britain, nickel-silver in Germany and the United States.

§ 7. The Atomic Weight of Copper

According to H. E. Roscoe and A. Harden,[1] in a note-book, dated March, 1804, J. Dalton wrote 44 for the at. wt. of copper when oxygen is 5·5 ; this number becomes 56 when oxygen is 7, and this is the number—or 28, $\frac{1}{2}$ of 56—employed by J. Dalton in his *A New System of Chemical Philosophy* (Manchester, **2.** 352, 1810)—if oxygen be 16, Dalton's number becomes 2×64. In 1814, from the analytical data of J. L. Proust and R. Chénevix, W. H. Wollaston calculated the value Cu=40 if oxygen is 10, or 64, if oxygen be 16.

(1) *The determination of the ratio* CuO : Cu.—Between 1811 and 1820, J. J. Berzelius made numerous analyses of cupric oxide, and determined the weight of metal set

free when purified cupric oxide is reduced in hydrogen; he calculated the ratio $CuO : Cu = 79{\cdot}3 : 63{\cdot}3$, which gave the at. wt. of copper 63·298 when that of oxygen is 16. These experiments have been discussed by J. Sebelien, and H. G. Söderbaum. The standard for oxygen used by J. J. Berzelius was 100. As late as 1820, J. Dalton's theory had not been refined by Avogadro's hypothesis, and there were some differences of opinion as to whether the at. wt. of copper should be 2×64, 64, or $\frac{1}{2} \times 64$—J. J. Berzelius employed the first value, J. J. G. Meinecke the second, and L. Gmelin the third. The value approximating to 64 fits in with the rule, and the law of isomorphism. An application of Avogadro's hypothesis to the volatile chlorides is not so decisive because the smallest quantity of copper present in a molecule of the vapour of cuprous chloride (*q.v.*) is twice as great as corresponds with the accepted at. wt. This is attributed to the doubling of the molecule. With some solvents, J. H. van't Hoff's methods furnish results in harmony with the accepted value as representing the at. wt. of a single atom. Thus, G. Tammann and G. Meyer have shown that the element dissolved in mercury is probably monatomic on the assumption that the at. wt. approximates 64; F. Haber, however, regards this as doubtful.

In 1844, O. L. Erdmann and R. F. Marchand repeated J. J. Berzelius' determination, and corrected the results for weighing in air; they obtained 63·462. J. B. A. Dumas reduced copper oxide, and transformed the product into cuprous sulphide. He said that his numbers varied from 63 to 64, but gave no details, and he put 63·5 for the at. wt. of copper. In 1863, N. A. E. Millon and A. Commaille reduced cupric oxide by hydrogen, and checked the results by weighing the synthesized water. They obtained 63·125. In 1873, W. Hampe tried reducing a silver salt by means of copper, but did not get satisfactory results, and fell back on the original Berzelian method, reducing the weighings to the vacuum standard. He thus obtained 63·344. In 1891, T. W. Richards showed that all previous results were vitiated by the occlusion of gases by the reduced copper, for these are not expelled by heat. By making the necessary correction, he obtained 63·602 for the at. wt. of copper. In 1906, E. Murmann reduced cupric oxide, and reoxidized the metal. He selected values varying between 63·512 and 63·560 to represent his results.

(2) *The analysis of cupric sulphate or cupric bromide.*—H. Baubigny calcined anhydrous cupric sulphate and calculated the at. wt. 63·466 from the ratio $CuSO_4 : CuO$, or $CuO : SO_3$. T. W. Richards also obtained 63·555 from the ratio $CuO : CuSO_4$, obtained by the synthesis of cupric sulphate from cupric oxide; 63·472 from the ratio $Cu : CuSO_4$, obtained by the synthesis of the same salt from copper; and 63·601 from the ratio $CuSO_4 : Cu$, obtained by decomposing a soln. of anhydrous cupric sulphate electrolytically—W. Hampe had previously used the same process and obtained 63·32. T. W. Richards also analyzed the pentahydrated sulphate and obtained 63·550. He electrolyzed a soln. of cupric sulphate; determined the free acid by titration with a standard soln. of sodium carbonate; and obtained from the ratio $Cu : Na_2CO_3$, 63·533. He also measured the amount of sodium sulphate produced, and obtained from the ratio $Cu : Na_2SO_4$, 63·558; and in another series the sulphuric acid was determined as barium sulphate, $Cu : BaSO_4 = 63{\cdot}679$. The data enable the at. wt. of copper to be computed from other ratios, $CuSO_4 : Na_2CO_3$, 63·441; $CuSO_4 : Na_2SO_4$, 63·481; $CuSO_4 : BaSO_4$, 63·802; $CuSO_4.5H_2O : Na_2CO_3$, 63·533; $CuSO_4.5H_2O : Na_2SO_4$, 63·558; and $CuSO_4.5H_2O : BaSO_4$, 64·082. T. W. Richards also analyzed cupric bromide—determining the copper by electroylsis, and the acid as silver bromide; this gave the ratios, $CuBr_2 : Cu : 2AgBr$, from which he computed at. wts. varying, in five different series, from 63·548 to 63·589.

(3) *The determination of the electrochemical equivalent of copper, that is, the ratio* $Cu : 2Ag$.—Lord Rayleigh and H. Sidgwick measured the ratio in 1885, and obtained for the at. wt. of copper 63·38 (silver, 107·93); T. Gray likewise in 1886–9 obtained 63·31 to 63·50; W. N. Shaw in 1886, 63·49; T. W. Richards in 1887 and 1888,

63·599 and 63·600 respectively; A. Vanni in 1891, 63·41; T. W. Richards, E. Collins, and G. W. Heimrod in 1899, 63·60; T. W. Richards and G. W. Heimrod in 1902, 63·601; and G. Gallo in 1905, 63·555.

Taking all these values into consideration, and applying corrections for the various known sources of error in the earlier work, F. W. Clarke arrived at 63·5550 as the best representative value for the at. wt. of copper; and added: "This value is possibly, but not certainly, a little too low. The rejection of the values derived from cupric oxide raises the general mean to 63·564, which may be nearer the truth." B. Brauner also arrives at what he calls the *antiker Wert* 63·60, with silver 107·93, as the basis of calculation; and the *moderner Wert* 63·56, with silver 107·883, as the basis. The International Table of Atomic Weights for 1920 gives 63·57, or, in round figures, 63·6. The **atomic number** of copper is 29.

Lord Kelvin [2] estimated from the theory of contact electricity that 10^{-8} cms. is the minimum admissible diameter for the molecules of copper or zinc; or that it would be impossible to make thinner plates without splitting atoms; or that when these metals combine to form an alloy, they do not approach closer than this. G. Jäger also calculated a value from the electrical conductivity of the sulphate.

According to M. Traube,[3] copper is bivalent both in cupric compounds and in cuprous compounds. The extraordinary compounds found in the brasses and bronzes have led N. A. Puschin and others to believe that the ordinary valency rules are quite inapplicable. B. Brauner and B. Kuzma suggested that the atom has a maximum tervalency in the so-called potassium tellurocuprate, $2K_2O.Cu_2O_3.3TeO_3.nH_2O$, although there is very little evidence to justify the deduction. E. Müller also believes that copper may be uni-, bi-, ter-, and quadri-valent in its behaviour towards oxygen; he assumes the individuality of the oxides, Cu_2O, CuO, Cu_2O_3, and CuO_2. A. Rosenheim and W. Stadler, and J. V. Kohlschütter assign to copper the co-ordination number 3.

In his statement of the periodic law, D. I. Mendeléeff pointed out that when an element like copper forms two series of compounds, in one of which it has the same valency as its neighbour in the horizontal row, its compounds in this state of oxidation will be similar to those of its neighbour, and the resemblance of copper to zinc is cited in illustration. D. I. Mendeléeff considered the possibility of allocating copper to Group VIII, because this element does seem out of place when grouped along with the univalent elements of the alkali family. In developing Mendeléeff's law, it was the fashion to seek for similarities rather than dissimilarities, for analogies rather than discrepancies. If the periodic rule be confined to the elements, there are many striking relations and analogies. When it is remembered that the cuprous and cupric compounds represent two states of matter which are very different, and which have no other relation than that the corresponding compounds can be converted one into the other by oxidation or reduction, the form of matter representing cuprous copper is distinct from that representing cupric copper, although each can be converted into metallic copper. The one form is univalent, the other is bivalent, and, according to G. Bodländer and O. Storbeck,[4] and E. Abel, cuprous copper is a much nobler element than cupric copper, perhaps even nobler than silver. In allocating the metal copper to Group I of the periodic table, the properties of the cuprous compounds are arbitrarily selected as typical of the element. Had it been necessary to fit the element into Group II, the bivalent properties would have been emphasized. This has actually been done with thallium whose univalent qualities are even more pronounced than those of copper, and yet it is as arbitrarily grouped with the tervalent elements in the periodic table. M. Reinganum showed that the spectral series justified the inclusion of silver and copper in one family; and R. Lorenz believes his rule of twin elements agrees with the recognized position of copper in the periodic table.

W. Ramsay and A. T. Cameron [5] believed that they had transmuted copper into lithium by exposing sat. soln. of cupric sulphate or nitrate to the emanation from radium. E. Gleditsch could find no simple relation between the amounts of lithium and copper in a number of radioactive minerals such as would be anticipated if W. Ramsay's transmutation were real. For example:

	Per cent. Cu.	Per cent. Li.	Radioactivity.
Joachimsthal pitchblende	1·2	0·00017	1·5
Colorado pitchblende	0·15	0·00034	1·75
Carnotite	0·15	0·030	0·52
Chalcolite	6·54	0·00011	2·0
Autunite	0	0·00083	1·48
Thorite	trace	0·0033	0·59

M. S. Curie and E. Gleditsch, however, showed that the inference is faulty since the lithium was derived from extraneous sources; by using apparatus—quartz and glass vessels—quite free from lithium, none was found.

§ 8. Alleged Allotropic Forms of Copper

The temp. at which there is an abrupt change in any physical property may be employed to determine the *transition temperature* of a substance. There is therefore a comparatively wide range of available methods, and the right choice is determined by the particular conditions most suitable for the specific problem in hand.

The more common methods employed in the determination of transition points are; (1) Solubility; (2) Vapour press.; (3) Heating or cooling curves; (4) Change of colour; (5) Change of volume. In this method, a dilatometer *D*, Fig. 21, contains the metal under investigation. The dilatometer *D* is placed in a bath fitted with stirrer *SS*, thermometer *T*, and thermostat *P* for maintaining any required uniform temp. The level *l* of the liquid in the dilatometer is read from time to time by means of a cathetometer. If expansion or contraction occurs, the substance under investigation is above or below its transition temp. If no change in volume occurs the substance is at its transition temp. (6) Change in the electromotive force of a cell. The cell shown in the diagram, Fig. 22, contains white tin in one limb, grey tin in the other, and is nearly filled with a soln. of ammonium stannic chloride. The cell is placed in a bath which can be adjusted at any desired temp. A delicate galvanometer is placed in the circuit. When the temp. is *above* 18°, the current flows from the grey tin through the soln. to the white tin so that the former is dissolved, and white tin is deposited; *below* 18°, the direction of the current and the behaviour of the metals, are reversed. Hence it is inferred that 18° is a transition temp.

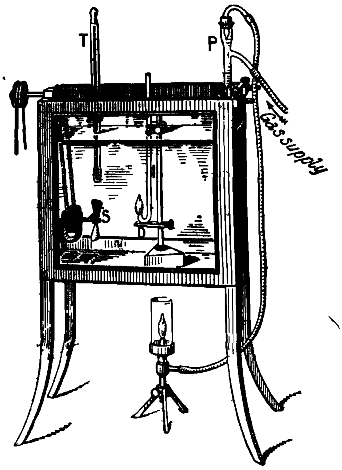

FIG. 21.—The Determination of Transition Temperatures.

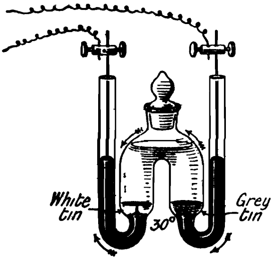

FIG. 22.—Electrical Method for Finding the Transition Point.

A number of allotropic modifications of copper have been reported, but in no case is the evidence clear and decisive. In spite of the many reports which have been made of the existence of allotropes of copper, it is assumed that the form which is stable at ordinary temp. is the same as that which occurs at lower and higher temp. The thermal analysis, electrical resistance measurements, and the microscopic examination do not disclose unequivocal evidence of a chemical transformation of copper into different allotropic forms.

P. Schutzenberger's allotrope.—In 1878, P. Schützenberger [1] electrolyzed a neutral or feebly alkaline 10 per cent. soln. of copper acetate between a copper anode and a small platinum cathode, and, by keeping the temp. low, obtained a metallic deposit which (i) was extremely brittle; (ii) was easily oxidized, so that plates washed with boiling water became deep indigo-blue when exposed to air; the deposit also oxidized quickly in water (with air in soln.), and in conc. soln. of basic copper acetate; (iii) developed nitrous oxide, N_2O, with 10 per cent. nitric acid; (iv) had a sp. gr. of 8·0 to 8·2—lower than copper; (v) was less red and more of a bronze colour than copper; and (vi) had a higher electrical resistance than copper. The deposit passed into ordinary copper when rapidly warmed to 100°, or by prolonged contact with dil. sulphuric acid. Ordinary copper was also obtained if the temp. of the soln., during electrolysis, was raised, or if the electrolyte was too acid. It was accordingly inferred that P. Schützenberger had prepared an allotropic form of copper. If the alleged allotrope be powdered under water and washed, some acetate and oxide are obtained; the deposit obtained by P. Schützenberger's process contains less than 5 per cent. of oxide.

G. Wiedemann (1856) had previously shown that in the electrolysis of neutral soln. of cupric acetate, a peculiar bronze-like deposit is produced at the cathode, and that "the copper deposited at the negative pole takes with it a quantity of copper oxide from the soln. and the deposit is then very brittle and dark brown. The amount of copper oxide held by this deposit is dependent on the conc. of the soln." G. Wiedemann prepared specimens with 12 to 35 per cent. of oxide by increasing the conc. of the soln. It was therefore suggested that the alleged allotrope is nothing more than a soln. or an intimate mixture of copper oxide and copper. This, however, cannot be right because, as P. Schützenberger showed, the sp. gr. of the allotropic form is too low, and the peculiar properties disappear spontaneously when the alleged allotrope is heated to 100° or 150°. J. B. Mackintosh showed that the alleged allotrope contained appreciable amounts of carbon and hydrogen, as well as of oxide, and he explained the rapid oxidation, etc., by assuming that the deposit is very porous. D. I. Mendeléeff attributed the peculiar properties of P. Schützenberger's allotrope to the presence of occluded hydrogen or to the formation of a hydride. Again, according to C. Benedicks, although the copper prepared by P. Schützenberger's process contains some cuprous oxide, the amount is small, and this the less the greater the current density and the less the conc. of the soln. By using a current density of about 0·025 amp. (10 volts) per sq. cm. between 18° and 29°, a rapidly rotating cathode, and an electrolyte containing 0·7*N*-copper acetate and 0·3*N*-acetic acid, a deposit can be obtained practically free from cuprous oxide. Hence, C. Benedicks argued that it is more likely that P. Schützenberger's allotrope is a solid soln. of acetic acid in copper because the product invariably contains carbon and hydrogen very nearly in the proportions corresponding with anhydrous acetic acid, and, when warmed, sometimes without warming, it smells of acetic acid. T. R. Briggs rejects P. Schützenberger's allotrope hypothesis and C. Benedicks' solid soln. hypothesis. By analogy with other known colloidal forms of the elements, and by its behaviour and mode of preparation, the alleged allotrope is a colloidal hydrogel of the normal metal. Its formation during the electrolysis of acetate soln. is explained by assuming that in such soln. a gelatinous protective colloid, probably copper hydroxide, is formed by hydrolysis; and this has been confirmed by emulsion experiments with benzene.

E. Cohen's allotropes.—E. Cohen and W. D. Heldermann [2] found that the density of cast copper, 8·890, did not change when kept for 24 hours in a soln. of copper sulphate (half sat. at 100°), but if kept for 24 hours at 25°, the sp. gr. rose to 8·900; and, by measuring the rate at which the volume of the copper changes when heated in a dilatometer at temp. between 25° and 90°, the minimum rate of expansion occurred about 70°. Hence it is argued: (i) there are two modifications of copper—the form stable below 71·7° is called **α-copper**, and the one stable above that temp. **β-copper**; (ii) the transition temp. from the one form to the other is in the vicinity of 70°; (iii) the so-called pure copper at ordinary temp. is always a mixture of two modifications—stable and unstable; (iv) the unstable variety is in a metastable condition at ordinary temp.; and (v) the physical constants of copper hitherto determined refer to indefinite mixtures of the two modifications. A. Smits and P. Spuyman could find no signs of a transition temp. at 70° in their study of the e.m.f. of a copper-silver couple immersed in a soln. of cupric sulphate.

G. K. Burgess and I. N. Kellberg could find no signs of the supposed modifications of copper in the continuity of the curves relating to the electrical resistance of the metal at temp. between 0° and 100°; nor could P. W. Bridgman find any evidence of the supposed allotropism in the effects of press. on the electrical resistance of the metal. A. Smits and J. Spuyman could find no sign of a transition point at about 70°; nor did P. W. Bridgman's measurements of the e.m.f. of thermocouples suggest any allotropism of the copper. E. Janecke, however, subjected the metal to a high press., and measured the press. at different temp. (heating and cooling), the resulting *PT*-curves showed a slight bend in the vicinity of 99°. This was taken to agree with the existence of two allotropic modifications of copper. The fact that the transition temp. by E. Cohen and others is somewhat divergent may mean that some other phenomenon, not allotropism, is under observation—*e.g.* (i) press. may distort the crystal grains and make them decrease the intercrystalline spaces and so change the density; and (ii) small changes in density may be produced by the gradual water-logging of a specimen heated in a soln. of the metal sulphate, for water can be forced through many metals when subjected to high press. The small backward and forward changes of density on a falling and rising temp. may be explained by the changes in the amounts of soln. retained in the interstitial spaces at different temp., owing to the expansion and contraction of the soln. It is also possible that E. Cohen's results are due to the presence of cuprous oxide or to the use of chips or wire in a state of internal strain or of unstable fine crystalline structure. In reply, E. Cohen said that (i) the transformations often take place so slowly that, to accelerate them to such an extent as to enable them to be detected, it is necessary to work with fine powders in contact with a soln of an electrolyte with which the metal is in equilibrium; (ii) W. Rosenhain's objection that the electrochemical eq. by different observers negatives the hypothesis that the metal *en masse* is a mixture of unstable forms is explained by the fact that the eq. is a question of mass, and independent of the polymorphic form taken by the metal after losing its charge.

§ 9. The Copper Suboxides

In the first century of our era, Dioscorides knew that when copper is heated it becomes covered with a red film which can be removed from the surface of the metal, and he added that the powder is black if the metal be heated too strongly. Pliny, and Geber also made analogous statements. The chemists of the phlogiston period knew that the metal can be oxidized (dephlogisticated) in different stages, but J. L. Proust [1] first showed that in addition to the black copper oxide which is formed during the calcination of ordinary salts of copper, a definite lower oxide can be prepared by reducing a soln. of one of the copper salts with stannous chloride, and treating the resulting cuprous chloride with potash lye. The new oxide so precipitated was found to furnish metallic copper and a salt of the higher oxide when treated with sulphuric or dil. nitric acid.

Copper thus forms two well-defined oxides, the lower oxidized form is now called *cuprous oxide*, Cu_2O, and the other *cupric oxide*, CuO. Each oxide is the base of a characteristic series of salts. The copper base in each series behaves as if two different elements are involved—one a univalent element related to silver, and the other a bivalent element related to nickel. There are also hydrated forms of cuprous and cupric oxides which are colloidal gels, or true hydroxides. In addition, *copper sesquioxide*, Cu_2O_3, and *copper dioxide or peroxide*, $CuO_2.H_2O$, have been reported. The so-called *cuprosocupric oxide*, $2Cu_2O.CuO$, might be more correctly symbolized $Cu_2O.nCuO$, since it is probably a solid soln of one oxide in the other. Two suboxides, *copper tritoxide*, Cu_3O, and *copper quadrantoxide, or tetritoxide*, Cu_4O, have been also reported, but proofs of their individuality as homogeneous chemical species are wanting.

H. Rose [2] prepared what he regarded as **copper quandrantoxide**, Cu_4O, or **copper tetritaoxide**, by adding freshly prepared and moist cuprous chloride to a dil. soln. of stannous chloride in potassium hydroxide—if the soln. be too dil. or if too much stannous chloride be employed metallic copper is precipitated. The same product was obtained by using a soln. of cuprous sulphate instead of cuprous chloride. H. Rose's directions are:

300 c.c. of a soln. of copper sulphate (containing the eq. of 10 grms. of copper) are added, with constant agitation, to a litre of a well-cooled soln. of 50 grms. of potassium oxide and

mixed with sufficient stannous chloride to oxidize 30 grms. of iodine. The operation is conducted in a flask just large enough to hold the soln. After the mixture has stood for 24 hrs. the olive-green precipitate is washed in an atm. of an inert gas—hydrogen or nitrogen —first with dil. potassium hydroxide; then with aqua ammonia which flocculates the precipitate; and finally with water.

J. H. Gladstone and A. Tribe also say that if a copper-silver couple be placed in a soln. of cupric nitrate, a film of this oxide may be deposited on the silver plate. A. Recoura obtained Rose's oxide by the decomposition of cuprous oxide, *q.v.* H. Rose thus describes the properties of copper quadrantoxide: The olive-green powder is stable if kept under water out of contact with air, and it gradually becomes denser and less readily oxidized; but it cannot be dried without change. When the oxide is heated in a limited supply of air, it acquires a yellow film of cuprous oxide. Dil. sulphuric acid converts it into copper and cupric sulphate in the proportions $Cu : CuSO_4 = 3 : 1$ (nearly); the equation is presumably $Cu_4O + H_2SO_4 = H_2O + CuSO_4 + 3Cu$ —since cuprous oxide is soluble in dil. sulphuric acid, L. Moser says that the quadrantoxide is either decomposed by the dil. acid or else it is a mixture of cuprous oxide and copper. Hydrochloric acid first darkens the quadrantoxide—possibly forming *copper subchloride*—and then furnishes a mixture of copper and cuprous chloride; and hydrocyanic acid forms a black substance—possibly *copper subcyanide*—soluble in dil. nitric acid. Hydrogen sulphide transforms copper quadrantoxide into a black homogeneous substance—possibly *copper subsulphide*—which gradually gives off hydrogen and forms a higher sulphide. The quadrantoxide is insoluble in aqua ammonia or in an ammoniacal soln. of ammonium carbonate. J. H. Gladstone and A. Tribe add that silver nitrate is reduced to filiform silver by copper suboxide. Analyses of the product correspond with 95 per cent. Cu_4O, and 5 per cent. of stannous oxide. The chemical individuality of the quadrantoxide has not therefore been established, and when further investigated, it may prove to be a hydrogel of variable composition. L. Wöhler and O. Balz observed no signs of the quadrantoxide in their study of the dissociation $2CuO \rightarrow Cu_2O \rightarrow 2Cu$.

Cuprous oxide, Cu_2O.—It is probable that the copper mineral likened by Theophrastus to the "carbuncle," refers to a native form of this oxide, and called by G. Agricola[3] (1546) "red copper." References to the same mineral occur in the writings of J. B. L. Romé de l'Isle (1783), A. J. Cronstedt (1758), B. G. Sage (1772), J. C. Wallerius (1778), and R. J. Haüy (1801). The latter called it *cuivre oxydé rouge*, and pointed out that, unlike the carbonate, it dissolves in hydrochloric acid without effervescing; he expressed the opinion that the earth is nothing more than *cuivre peu chargé d'oxygène.* This was proved by R. Chénevix, who showed by analysis that the Cornish mineral *red copper ore* is a crystalline form of cuprous oxide—copper 88·5, oxygen 11·5 per cent.—and M. H. Klaproth confirmed this by analyzing a sample from Siberia. In consequence of this colour cuprous oxide has received many different designations—*livery copper ore; ruberite;* and *Ziegelerz*—that is, *tile ore*—a term which was contracted to *ziguéline*. In 1845, W. Haidinger suggested the term *cuprite* which is now generally accepted. A form of the same mineral occurring in slender fibres resembling fine hair, is called *chalcotrichite*—χαλκός, copper; τριχός, hair—and also *flowers of copper*, or *flores cupri.* According to F. Sandberger, and E. Weinschenk, this mineral is the colouring agent of the hyacinth. W. Autenrieth found 0·07 per cent. of iodine in some samples of red copper oxide. Octohedral crystals of cuprite have been reported in copper slags and furnace products by E. Mitscherlich, J. L. Jarman and J. F. McCaleb, J. F. L. Hausmann, A. Arzruni, etc. Crystals of the mineral along with cassiterite have been found by B. G. Sage, J. Davy, C. Grewingk, A. Lacroix, etc., in the oxidized crust on old bronze figures. The synthesis of the mineral artificially has been discussed by L. Bourgeois, C. W. C. Fuchs, F. Fouqué and A. Michel-Levy, etc.

The preparation of cuprous oxide by oxidizing metallic copper.—R. F. Marchand[4] heated thick copper wire in a muffle for half an hour to a white heat, and then for several hours to a dull red heat. He said the cuprous oxide is deposited on the remaining button of metal in black masses of crystals which give a purple-red powder. A. Vogel and C. Reischauer found that cupric oxide is converted into cuprous oxide when heated to a high temp. H. Debray and A. Joannis say that even if a large excess of copper be heated to redness in a stream of air, cuprous oxide is formed. There is nothing here to show how much cupric oxide is formed at the same time, since it is all a question of temp. and press. how much of each is formed. According to R. H. Bradford, at ordinary press., cupric oxide is transformed into cuprous oxide at 1050°. L. Wöhler and A. Foss found that the reaction is of the balanced type: $4CuO \rightleftharpoons 2Cu_2O + O_2$, and the dissociation press. at different temp. is quite analogous in principle with the dissociation of barium dioxide: $2BaO_2 \rightleftharpoons 2BaO + O_2$. The partial press. p of the oxygen, at different temp., expressed in mm. of mercury, is:

	960°	1000°	1010°	1020°	1030°	1040°	1050°	1060°	1070°
p .	50	118	142	174	212	258	314	380	458
p' .	31	65	—	—	108	—	—	164	—

There is a complication, however, for they assumed that cuprous and cupric oxides are soluble in one another forming a single phase, and the dissociation press. of this soln. likewise depends on the temp. and the conc. of the cuprous oxide dissolved in the cupric oxide. For a mixture of equimolecular parts of the two oxides, the dissociation press. p' at different temp. are indicated in the above table, and the values of p and p' are likewise plotted in Fig. 23. The two-component system—solid soln. of the two oxides, and gas—remained until all the oxygen required by the reaction was removed and cuprous oxide alone remained. H. W. Foote and E. K. Smith showed that the values estimated for the dissociation press. by W. Stahl are much too small. F. H. Smyth and H. S. Roberts showed that it is unlikely that a solid soln. of the two oxides is formed at a temp. at which both oxides remain solid, and that previous results are vitiated by inadequate temp. control; and in their study of the dissociation press. they found no evidence of the formation of solid soln. between copper, and cuprous and cupric oxides. The reaction has also been studied by R. N. Pease and H. S. Taylor.

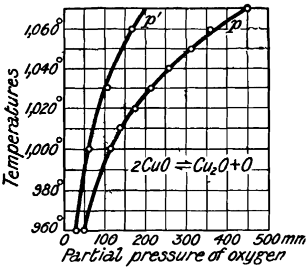

FIG. 23.—Dissociation Pressures, $2CuO \rightleftharpoons Cu_2O + O$.

G. H. Bailey and W. B. Hopkins heated cuprous oxide to a high temp.—over 1500°—in a gas injector furnace, and obtained a yellowish-red mass of sp. gr. 3·81. Analysis corresponded with Cu_3O, **copper tritoxide.** The finely-powdered product was not acted upon by conc. or dil. mineral acids, but it was slowly attacked by hydrofluoric acid. It could be obtained in a soluble form by fusion with potassium hydroxide, in which it dissolved. Brown flakes separated when the cold cake of potassium hydroxide was digested with water. These flakes dissolved readily in acid. E Jordis and W. Rosenhaupt believe the product to be a solid soln. of copper in cuprous oxide or of cupric oxide and copper quadrantoxide. In any case, although the attempt was made to maintain an oxidizing atm., it is very improbable if the attempt was successful in view of the known difficulties of obtaining oxidizing atm. in high temp. gas furnaces.

R. Chénevix prepared cuprous oxide by heating a mixture of finely-divided metallic copper with 1·25 times its weight of cupric oxide to a low red heat in a closed vessel; and J. J. Berzelius heated alternate layers of copper oxide and copper plate. The red oxide can then be readily separated from the unoxidized metal. F. Emich, and P. Sabatier and J. B. Senderens obtained cuprous oxide of a fine cochineal red colour by heating reduced copper above 250° and below a dull red heat in a stream of nitric or nitrous oxide. The oxidation is said to go no further than the desired Cu_2O. A. C. Becquerel obtained crystals of cuprous oxide by dipping a strip of copper in wetted mercurous chloride or a mixture of mercurous and silver chlorides.

The preparation of cuprous oxide by reducing cupric oxide or salts.—The higher temp. reduction of cupric oxide by heat and by red-hot metallic *copper* has been already discussed. A. C. Becquerel[5] obtained crystals of cuprous oxide by forming a soln. of cupric nitrate on an excess of cupric oxide and allowing the mixture to stand in contact with a copper plate for some time. L. Bourgeois also obtained orange-red octahedra by adding cupric oxide to molten calcium chloride—oxygen is given off and cuprous oxide formed. L. Bourgeois found that if an excess of copper oxide be melted with *tin* or *stannic oxide* in a porcelain crucible, and slowly cooled, dark reddish-yellow crystals of cuprite and colourless needles of stannic oxide are formed. Many other reducing agents may be used. A. Knop added a mixture of *ferrous sulphate* and sodium carbonate to a soln. of copper sulphate, and after the mixture had stood some time, he obtained crystals of cuprite. F. Wibel added ammonia to the same mixture. J. de Girard and A. de Saporta used *hydrazine sulphate* in alkaline soln.—E. Rimini says the reduction here goes to metallic copper; W. H. Foster used *phenylhydrazine;* E. Péchard, D. Vörlander and F. Meyer, and L. Moser used *hydroxylamine hydrochloride* in alkaline soln.—W. H. Foster says some cuprous oxide remains in soln. P. Jannasch used an alkaline soln. with *tartaric acid and hydrogen peroxide.* D. Tommasi treated a mixed soln. of potassium chlorate and cupric sulphate with *zinc.*

A. Étard heated a mixture of cuprosocupric sulphite in a current of *carbon dioxide* and obtained a mixture of both cupric and cuprous oxide; S. B. Newbury heated a basic cupric sulphite with water; T. Curtius and R. Jay heated hydrazine cupric sulphate. P. Cazeneuve heated a soln. of cupric acetate to 200°; J. Riban heated cupric oxide with a soln. of *acetic acid;* E. Priwoznik heated metallic copper with acetic acid and ammonium chloride; A. Vogel heated a soln. of cupric acetate with *sulphur dioxide;* J. M. Eder heated cupric acetate or oxalate with *potassium ferro-oxalate;* E. Ehrmann boiled Schweinfurt's green with alkali-lye; K. G. Thurulakh heated a dil. soln. of cupric glycerate; M. Prud'homme heated a blue soln. of cupric hydroxide in alkali-lye with chromic acid; A. Guérout heated malachite with *ether* in a sealed tube at 280°. A convenient way of making cuprous oxide is to reduce a conc. soln. of cupric sulphate and sodium chloride with *sulphur dioxide,* and expel the excess of the latter by heat. The addition of sodium carbonate to the hot soln. precipitates bright red cuprous oxide, which can be readily washed by decantation.

Many organic agents reduce copper oxide, cupric hydroxide. For example, with sugar, E. Mitscherlich reduced cupric sulphate, and R. Böttger, cupric hydroxide suspended in water. E. Mitscherlich's process offers a convenient method of preparing cuprous oxide:

> Sodium hydroxide is added to a soln. containing equal parts of cupric sulphate and grape sugar until the precipitated cupric hydroxide at first formed is redissolved. When this soln. is warmed, the cuprous oxide is precipitated as a powder, which is free from hydroxide, and is not changed by exposure to air.

L. Grünhut used *benzoic acid;* H. W. F. Wackenroder used *gallic acid;* J. J. Berzelius, *indigo white;* A. Vogel, *turpentine;* A. M. Butleroff, *mannite* soln. at 60°–70°—G. C. Wittstein denied this reaction; L. Hunton and W. H. Foster, and R. Böttger also used *mannite* in alkaline soln.; N. A. E. Millon and A. Commaille, and E. Mitscherlich employed several different kinds of *sugar;* R. Böttger used sugar and *potassium sodium tartrate;* J. Habermann and M. Honig used *levulose, dextrose, invert sugar, cane sugar,* and *lactose,* and found the reduction proceeds faster in the presence of barium hydroxide. J. Löwe used *glycerol* and *grape sugar;* P. Degener, E. Feder, and H. Frischer used *potassium sodium tartrate* in alkaline soln.; T. A. Glendinning used *maltose.* E. Feder and E. Schaer found that the alkali can be replaced by oxides of the alkaline earths, magnesia, borax, sodium carbonate, by many alkaloids, and by organic nitrogen bases. W. Müller and J. Hagen used *grape sugar* in neutral soln.; R. Böttger, *dextrine* in alkaline soln. F. W. Traphagen and W. M. Cobleigh say that cuprous oxide reduced by sugar is not pure; and F. Zerban and W. P. Naquin say it is more or less hydrated. According to V. V. Sarma, the yellow substance formed by the reduction of an alkaline cupric salt contains besides cuprous oxide an appreciable amount of cuprous hydroxide, which persists after heating the substance to 110°. Red crystalline cuprous oxide is precipitated by boiling Fehling's soln. with *dextrose*.

M. Ruoss prepared a colloidal soln. of cuprous oxide by boiling 1 c.c. of Fehling's soln. with 0·5 c.c. of a 1 per cent. soln. of dextrose, and 1·5 c.c. of urine, and 7 c.c. of water. The filtrate contains bright red colloidal cuprous oxide. The character of the precipitated cuprous oxide depends upon the relative proportion of tartrate used; with an excess of tartrate, red crystalline cuprous oxide is formed, and with but little tartrate, the cuprous oxide is yellow and amorphous—probably a hydroxide. L. Moser says the yellow precipitate is probably a hydroxide, and, in the absence of air, the colour passes quickly through orange to brick-red, probably with the loss of water; it can then be dried without further change—it then contains 2 to 3 per cent. of water. At a low red heat the red crystalline form appears; consequently, the yellow oxide is the primary metastable form, and the red crystalline oxide the stable form. A yellow precipitate of cuprous oxide is obtained by treating a soln. of cuprous chloride with sodium hydroxide, and drying the washed precipitate in an atm. of hydrogen free from oxygen. Some consider the yellow precipitate is cuprous hydroxide—Cu(OH); and the red precipitate, cuprous oxide—Cu_2O. According to M. Gröger, the difference in colour is due to the difference in the size of the granules. As in the case of red and yellow mercuric oxide, the larger the granules the redder the tint.

The so-called Egyptian ointment, the *unguentum Ægypliacum* of the older pharmacopœia, was for a long time considered a valuable medicine; it was prepared by boiling a mixture of verdigris, honey, and a few drops of vinegar. A. Baumé attributed the striking change of colour which occurs to the phlogiston of the acetic acid uniting with the verdigris, forming metallic copper. H. Vogel (1815) showed that the reddish-brown precipitate is not metallic copper but cuprous oxide, and is also produced if the honey be replaced by many other varieties of sugar. J. A. Buchner confirmed the results of H. Vogel, but believed the precipitate was a compound of copper with one of the cleavage products of sugar. C. Trommer (1841) showed that an alkaline soln. of a copper salt becomes a valuable means of differentiating between different sugars. L. C. A. Barreswil, stimulated by a prize offered by the *Société d'encouragement pour l'industrie nationale*, prepared a soln. which could be employed volumetrically for the quantitative determination of sugar. H. Schwartz extended the method to starch which was to be hydrolyzed to glucose by a prior treatment with dil. sulphuric acid. H. von Fehling worked out many details for the success of the method, and the liquid came to be called after him. F. Soxhlet demonstrated the exact conditions necessary in order that the test might give satisfactory results, and to avoid the use of an unstable standard liquid, introduced the two-standard soln. to be mixed when required. The so-called **Fehling's solution** is an alkaline soln. of copper sulphate mixed with *Rochelle salt* or *Seignette's salt*—two names for potassium sodium tartrate, $C_4H_4O_6KNa.4H_2O$, applied in honour of its discovery by P. Seignette of Rochelle in 1672—to keep the cupric oxide in soln. When required it is made by mixing equal volumes of a soln. of 34·64 grms. of cupric sulphate in 500 c.c. of water, with 76·5 grms. of sodium hydroxide and 175 grms. of Rochelle salt, also made up to 500 c.c. The mixture is a very sensitive test for dextrose —0·00001 grm. of dextrose produces a red precipitate of cuprous oxide and 0·000001 grm. a red coloration.

A sample of H. von Fehling's soln. which had stood 10 years was reported by F. Cornu to have spontaneously deposited cuprite crystals on the walls of the flask; L. G. Patterson says exposure for a month to sunlight brings about the same result; I. Bolin and G. Linder, A. Benrath and J. Oberbach, studied the precipitation of cuprous oxide from Fehling's soln. by exposure to light filtered through glass, and to ultra-violet light. L. Rosenthaler also studied the decomposition of Fehling's soln. F. Gaud reduced Fehling's soln. with *alcohol* in a sealed tube; A. Renard used *benzoyl glycol;* C. Böttinger, *ammonium imidopyroracemate;* H. Hlasiwetz, *phloroglucin ;* H. Hlasiwetz and L. Barth, *resorcin ;* etc. N. A. E. Millon stated that when Fehling's soln. is treated with chlorine or a hypochlorite, the precipitate first obtained is pale yellow cuprous oxide, and later orange-yellow oxide. He showed that the tartaric acid is oxidized by the chlorine. With calcium hypochlorite, said he, a yellow double salt of calcium carbonate and cuprous formate is produced. J. Aldridge and M. P. Appleby could find no evidence of the formation of carbon dioxide, and say the yellow product is finely divided cuprous oxide.

C. Ullgren heated cupric sulphate with copper filings in a closed vessel; F. Förster left a neutral soln. of copper sulphate standing in contact with metallic copper in a stoppered vessel; and F. Förster and F. Blankenberg assume that some copper dissolves, forming cuprous sulphate, which is then hydrolyzed to cuprous oxide—E. Abel has also studied the reaction. E. Weinschenk heated an ammoniacal soln. of cupric sulphate for 6 hrs. in a sealed tube at 150°. F. J. Malaguti heated a mixture of dry cupric sulphate, sodium carbonate, and copper filings, and leached the product with water. L. Ouvrard melted cupric phosphate with cupric oxide ; and C. Reichard heated the basic arsenate with alkali-lye.

L. Moser found the best way of making the yellow oxide is to reduce an alkaline soln. of a cupric salt with hydroxylamine ; and he made it electrolytically by using a soln. of alkali sulphate as electrolyte, and an anode of copper. According to J. Errera, a soln. of copper nitrate may be partially reduced by electrolysis in the presence of metallic copper or by simply heating the soln. with the metal. In a $0{\cdot}2N$-copper nitrate soln. at 97°, in the presence of copper, the conc. of the cuprous ions is 5×10^{-4} g. per litre, while the ratio $\mathrm{Cu}''/(\mathrm{Cu}')=5\times10^{5}$; and, by hydrolysis, cuprous oxide is formed. It is probably by some similar reaction that this compound is formed in carbonate and silicate soln., for experiment has shown that it is produced on heating an aq. suspension of the carbonate in a sealed air-free tube in the presence of copper gauze. This is suggested as a possible explanation of the occurrence of cuprite with malachite and native copper in ore deposits.

The preparation of cuprous oxide from cuprous salts.—Cuprous oxide can be obtained from cuprous salts. For example, M. Gröger[6] slowly dropped a soln. of 10 grms. cuprous chloride, 50 grms. of sodium chloride, and 250 c.c. of water, freed from dissolved air, into a soln. of 10 grms. of potassium sodium tartrate, 10 grms. of sodium hydroxide, and 150 c.c. of water. The flask was then filled with water and agitated on a shaking machine. The product was allowed to settle, washed by decantation with a soln. of potassium sodium tartrate, then with air-free cold water, filtered, and dried on a plate. W. Hampe, and F. Wöhler and J. von Liebig melted a mixture of dry cuprous chloride and dry sodium carbonate in a covered crucible, and washed out the red pulverulent cuprous oxide from the cold mass. J. L. Proust had previously employed a similar process using potassium carbonate. E. J. Russell reduced a conc. soln. of cupric sulphate and sodium chloride with sulphur dioxide, and after removing the excess of gas by boiling, precipitated the cuprous oxide from the hot soln. by means of sodium carbonate. A. Guntz and H. Bassett were unable to remove all the cuprous chloride from the precipitate by 150 washings in an atm. of hydrogen.

The preparation of cuprous oxide by electrolysis.—G. Bird[7] made crystals of cuprous oxide by the slow electrolysis of a soln. of cupric sulphate. D. Tommasi found crystals of cuprite to be formed on the copper anode during the electrolysis of dil. sulphuric acid with high voltage currents. P. Schoop, and T. A. Edison found that reduced copper in a finely-divided state is oxidized when made the anode during the electrolysis of dil. potassium hydroxide. R. Luther electrolyzed H. von Fehling's soln., and found cuprous oxide was copiously produced on the anode. A. Chassy obtained crystals of cuprous oxide during the electrolysis of a neutral soln. of cupric sulphate at 100°—current density 1 amp. per sq. dm., platinum electrodes ; analogous results were obtained by E. Wohlwill, F. Oettel, and Q. Majorana. The electrolysis of a soln. of sodium chloride between copper electrodes below 60°

furnishes yellow cuprous hydroxide; above 95°, red cuprous oxide; and at intermediate temp. a mixture of the two compounds. A. C. Becquerel conducted the electrolysis under high press. L. Wernicke electrolyzed a soln. containing 30 grms. of sodium hydroxide, 60 grms. of potassium sodium tartrate, 25 grms. of hydrated cupric sulphate, and 500 c.c. of water between a one sq. dm. platinum cathode, and two anodes of copper about a sq. mm. surface and 2 cms. apart. The current for electrolysis was obtained from a Bunsen's cell. The surface of the platinum becomes yellow, brown, purple, blue, pale green, and finally red. A piece of freshly coppered tinfoil was charged with hydrogen by using it as cathode in the electrolysis of soda-lye of sp. gr. 1·035, and it was then placed in an alkaline soln. of cupric sulphate. The foil then acquires the gradation of colours just indicated, and if the treatment be repeated a thick film of cuprous oxide is formed.

The properties of cuprous oxide.—Native cuprite occurs in well-formed carmine or cochineal-red lustrous octahedral and cubic **crystals** belonging to the cubic system. There is also the hair-like chalcotrichite. It also occurs massive, and earthy (tile ore). According to W. L. Bragg,[8] F. Rinne, W. P. Davey, and A. Grühn, the **X-radiogram** of cuprite is typical of a face-centred cubic lattice with the heavy copper atoms arranged in a face-centred lattice, with the shortest distance between the atoms of 1·84 A. The oxygen atoms are so light that they make comparatively little difference to the intensitics of the spectra, and they lie on a cube-centred lattice which intersects the face-centred lattice of the copper atoms. This structure has a holohedral symmetry—the mineral is usually plagihedral. The artificial crystals are also carmine-red, and the colour is the brighter the finer and purer the sample; these crystals are commonly octahedral and less frequently dodecahedral and hexahedral. The artificial oxide or hydrated oxide may be yellow, brownish-yellow, or orange-yellow, and amorphous. The **etching figures** in sulphuric, hydrochloric, and nitric acid, and in potash-lye have been studied by H. Traube, H. A. Miers, and F. Wallerant. The **specific gravity** by J. F. Persoz varies from 5·375 to 5·340; F. Gaud's sample reduced from Fehling's soln. had a sp. gr. 5·881; L. Wernicke's electrolytically prepared sample, 5·975. For the natural crystals, J. B. A. Dumas and M. A. le Royer gave 5·749; C. J. B. Karsten gives 6·093; W. Herapath, 5·992; and W. Haidinger, 5·975. The **hardness** of cuprite is stated to be 3·5 to 4·0, and a little harder than the similarly coloured proustite, Ag_3AsS_3, which has a hardness of 3·5.

H. Fizeau's value for the **coefficient of cubical expansion** of cuprite is 0·00000279 at 40°. The linear coeff. a is 0·00000093, and da/dT=0·0000000210. The expansion per degree decreases rapidly with a falling temp., and attains a minimum at 4·1°, thus:

	50°	40°	30°	20°	10°	4·1°	0°
a .	$+0·0_5 1059$	$+0·0_6 823$	$+0·0_6 597$	$+0·0_6 367$	$+0·0_6 136$	0	$-0·0_7 95$

below 4° a contraction occurs with a rise of temp. Like water, cuprite thus has a temp. of maximum density at 4°; the diamond has one at —38·8°. Cuprite melts at a red heat. R. Cusack gives 1162° for the **melting point**; H. S. Roberts and F. H. Smyth gave 1235° at 0·6 mm. mercury; E. Heyn gives 1084°, and R. E. Slade and F. D. Farrow give 1210°. The three workers last-named have also investigated the m.p. of mixtures of cuprous oxide and copper, and their results are illustrated by the curves, Fig. 24. There is a eutectic at 1065° with 3·5 per cent. cuprous oxide. At a temp. exceeding 1195° mixtures having a composition between 20 and 95 per cent. cuprous oxide separate into two layers—one a soln. of cuprous oxide in copper, the other a soln. of copper in cuprous oxide. The solubility curves for these solns. gradually converge as the temp. rises to 1400°, showing that the increase of temp. increases only slightly the solubility of each component in the other. The system within this range of composition is analogous to that of phenol and water—characteristic of partially miscible liquids which approach a critical soln. temp. where miscibility is complete. The cuprous oxide separates from soln. in the molten metal on cooling. The amount of cuprous oxide in a sample of copper can be estimated on a polished surface under the microscope, by measuring the relative areas of the portions occupied by the eutectic and by the copper. Hence, E. Jordis and W. Rosenhaupt could say that oxygen alloys with copper as if it were a metal. H. S. Roberts and F. H. Smyth made observations ranging from copper alone up to copper with 81 per cent. of cuprous oxide. A maximum at 1235° represents the m.p. of cuprous oxide, and there is a eutectic at 1080·2° with about 69 per cent. of cupric oxide. According to F. Beijerinck, when cuprite is heated it becomes dark and opaque, owing, it is assumed, to its decomposition into cupric oxide and copper; on cooling, the mineral again becomes transparent and crystalline. If the mineral be heated near to its m.p., it remains opaque on cooling J. L. Proust said that at a high temp. cuprous oxide is converted into a brown mixture of cupric oxide and metallic copper. H. W. Foote and E. K. Smith say that cuprous oxide is stable only between 1025° and 1070°—below these limits it rapidly passes into cupric oxide—P. T. Walden says that even at 750° the change is rapid. Cuprous oxide dissociates when heated to a high temp. $2Cu_2O \rightleftharpoons 4Cu+O_2$. W. Biltz, and L. Wöhler and O. Balz have discussed the dissociation of cuprous oxide. A. J. Allmand measured the e.m.f. of the cell $Cu|Cu_2O.NaOH|Pt.H_2$, and calculated the dissociation press. of the system, $Cu_2O_{solid}-Cu_{solid}-Cu_{vapour}$, at 17°, and found 3×10^{-53} atm. He also calculated this press. p by means of W. Nernst's formula, $\log p=-Q/4\cdot57T+1\cdot75\log T+\mathbf{C}$, where $\mathbf{C}=2\cdot8$, and $Q=81{,}600$, whence at 17°, $p=3\times10^{-55}$ atm. W. Stahl also calculated that at 1662°, $p=0\cdot21$ atm., and R. E. Slade and F. D. Farrow, at 1250°, $p=0\cdot45\times10^{-3}$ atm. Cuprous oxide is therefore volatile at about 1300°. E. Heyn found that the equilibrium temp. between the partial press. of oxygen of the air and that of the dissociating oxide is 1935° K. W. Biltz gave 1800° as the dissociation temp. E. Heyn computed the dissociation press. to be :

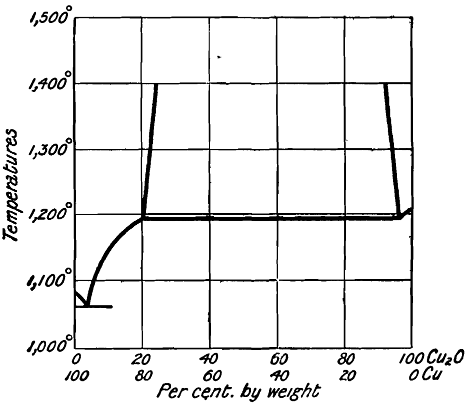

FIG. 24.—Fusion Curve of Mixtures of Copper and Cuprous Oxide.

p .	$0\cdot0_{28}65$	$0\cdot0_{3}16$	$0\cdot0_{3}28$	0·038	0·138	0·446	0·292	8·312	40·19

H. S. Roberts and F. H. Smyth found the dissociation press. between 1119° and 1184·6° to be between 0·028 and 0·041 mm. The **heat of fusion** of cuprous oxide is given as 12·5 Cals. per mol, or 87 cals. per gram. They also show that solid soln. between cupric oxide, cuprous oxide, and copper are non-existent, or negligibly small. F. E. Neumann's value for the **specific heat** is 0·1073, and the mol. ht. is 15·3; H. Kopp's values are respectively 0·111 and 15·9. A. Magnus gave 0·1146 from 17° to 100° and 0·1242 from 17° to 541°. J. Thomsen gives for the **heat of formation,** $(2Cu, O)=Cu_2O+40\cdot81$ Cals.; (Cu, CuO), 3·66 Cals.; and $(Cu_2O, O)=2CuO+33\cdot6$ Cals. M. Berthelot gave for $(2Cu,O)$, 43·8 Cals., and added that the heat of formation from cuprous sulphide, Cu_2S, is 23·5 Cals.; from the selenide, Cu_2Se, 35·0 Cals.; and from the telluride, Cu_2Te, 35·4 Cals. The heat of dissociation is $2Cu_2O=4Cu+O_2+81\cdot600$ Cals. at 17°; and between 1205° and 1260° was estimated at $-90\cdot060$ Cals.—by R. E. Slade and F. D. Farrow; and at $-55\cdot890$ Cals. between 1260° and 1324°. J. Thomsen gave 40·81 Cals. for the heat of formation $(Cu_2O.nH_2O)$. M. Berthelot and J. Thomsen give respectively for the **heats of neutralization** of the solid oxide with dil. hydrochloric acid, 17·2 and 14·66 Cals., with dil. hydriodic acid, 32·8 and 33·72 Cals., and, according to J. Thomsen, with hydrobromic acid, 20·76 Cals.

G. K. Burgess gives for the relative **emissivity** of cuprous oxide at 1100°, 0·68 for $\lambda=0{\cdot}500\mu$, and 0·60 for $\lambda=0{\cdot}650\mu$. The **index of refraction** by L. Wernicke is 2·534 for the *B*-line; 2·558 for the *C*-line; 2·705 for the *D*-line; 2·816 for the *E*-line; carbon disulphide is 1·6120, and he found the **magnetic rotatory power,** *i.e.* rotation of the plane of polarization in a magnetic field, to be forty-five times as large as that of water. A. de Gramont obtained the **spectrum** of copper when the mineral is sparked. W. Hallwachs found the **photoelectric effect** for cuprous oxide is nearly the same as for copper.

S. Meyer found the cuprous oxide to be paramagnetic; the **magnetic susceptibility** is $+0{\cdot}73\times10^{-6}$ mass units at 17°. Cuprite has rather a low **electrical conductivity.** K. Bädeker gives the specific resistance of cuprite as 40 when that of copper is 0·0000017. F. Beijerinck says that the **electrical resistance** of cuprite to a continuous current is 5000 Siemens' units at 120°, and this falls to 4000 at 125°, 3000 at 140°, 1800 at 180°, 1500 at 205°, and 700 at 250°, when electrolysis occurs. With an alternating current, the resistance falls to 2200 units at 50° much more rapidly, but no electrolysis occurs. The resistance of a column of cuprous oxide 1 cm. diam. and 10 cms. long at 137° was found by A. Sommerville to be 10^7 ohms. K. Bädeker gives 480 microvolts per 1° for the thermoelectric force towards platinum between 0° and 100°. G. C. Schmidt found that electrodes of cuprite in sodium hydroxide gradually become more positive but are not affected by light. T. W. Case found that exposure to light made no difference to the conductivity of chalcotrichite, but increased that of cuprite as predicted by A H. Pfund. T. W. Case also made a photosensitive cell Cu | Cu_2O, copper formate+formic acid, Cu_2O | Cu, which gave an e.m.f. up to 0·085 volt and a current of 0·003 amp. with plates 20×3·2 cms., when one electrode was illuminated. K. Bädeker found the **thermoelectric force** of cuprous oxide against platinum to be 480 microvolts per degree between 0° and 100°.

Cuprous oxide is not soluble in **water.** It forms a colourless soln. in aqua **ammonia.**

An ammoniacal soln. of cuprous oxide probably containing a complex **cuprous ammino-oxide** is formed by shaking together in a stoppered flask copper filings with aq. ammonia; or copper filings with a compound of cupric oxide and ammonia; or cuprous oxide or hydrated cuprous oxide with aq. ammonia. The reactions were studied by T. Bergmann, and by J. L. Proust.[9] R. Wagner made the ammoniacal soln. by mixing equal mol. parts of cupric sulphate and sodium thiosulphate, precipitating with sodium hydroxide, and dissolving the washed precipitate in aqua ammonia. D. Vorländer and F. Meyer reduced the cupric salt with hydroxylamine or ferrous sulphate and dissolved the product in aqua ammonia; and H. Frischer used soln. of ferrous salt. The colourless liquid gradually turns blue from the surface downwards, on exposure to air. The oxidation has been studied by P. Schützenberger and C. Risler, and by J. Meyer. The soln. of cuprous ammino-oxide is a powerful reducing agent. The same product has also been obtained by the electrolytic reduction of Schweitzer's liquid. G. Bodländer studied the electrical properties of the soln.; and S. Kern proposed to take advantage for gas analysis of the property this soln. possesses of absorbing oxygen

Although precipitated by alkali-lye, this oxide is soluble in excess. Cuprous oxide is soluble in molten **copper,** but insoluble in the cold metal—*vide* Fig. 24. C. H. Mathewson and C. H. Stokesburg found that cuprous oxide dissolves in molten **silver** and that the system Ag-Cu_2O closely resembles that of Cu-Cu_2O. There is a eutectic at 1·3 per cent. Cu_2O and 945°. The slope of the f.p. curve is 1·5 times as great as that calculated for the presence of Cu_2O alone, thus showing that a balanced reaction, $Cu_2O+2Ag\rightleftharpoons2Cu+Ag_2O$, is involved; but in the solid state the copper is all present as cuprous oxide. M. Gröger found it is dissolved by a soln. of **potassium sodium tartrate** in the presence of air. J. L. Proust found that **nitric acid** attacks cuprous oxide with the development of much heat, and evolution of nitrous fumes. P. Schützenberger showed that when finely powdered cuprous oxide is treated with cold 10 per cent. nitric acid it behaves like a mixture of copper

and cupric oxide; cupric nitrate is formed in soln. without **any evolution of gas**, and finely-divided copper remains in a condition not attacked by dil. nitric acid at ordinary temp. J. L. Proust found that **sulphuric acid** or **phosphoric acid**, or cold very dil. nitric acid decomposes cuprous oxide into metallic copper, which separates as a red powder, and cupric oxide which dissolves. The reaction has also been studied by R. Ehrenfeld. W. Jäger noticed **hydrofluoric acid** behaved similarly, and J. L. Gay Lussac and E. Pelouze found many **organic acids**—*e.g.* lactic acid—behaved like sulphuric acid. A soln. of **sulphurous acid** dissolves cuprous oxide forming the cuprous salt. J. L. Proust says that **hydrochloric acid** forms cuprous chloride; and N. Schoorl[10] found that **hydriodic acid** forms cuprous iodide, and if sulphuric acid and air be present some iodine is separated.

Cuprous oxide is reduced to the metal when heated in a stream of **hydrogen**. The reaction has been studied by A. Osann, and by S. Hauser; the latter found the reduction temp. ranges from 232° to 248°. H. Debray and A. Joannis found that hot but not molten cuprous chloride absorbs **oxygen** from the air more easily than copper; T. Andrews gives 36·608 Cals. for the heat of combustion to cupric oxide. E. Nihoul, L. Grünhut, and A. Prager have experimented on the oxidation of cuprous oxide by heat with or without a preliminary moistening with nitric acid. H. Rose found that when heated with sulphur, in hydrogen, cuprous sulphide is formed; and A. Orlowsky found that, unlike cupric and many other metal oxides, cuprous oxide is blackened by boiling the acid soln. with milk of **sulphur**, or if it be allowed to stand in the cold in contact with a piece of roll sulphur. J. B. Senderens found that when sulphur and cuprous oxide are boiled with water, cupric sulphate is first formed and then cupric sulphide—the reaction at 100° is completed in a few hours, at 90° in some days. J. Thomsen gives 38·53 Cals. for the heat of the reaction Cu_2O+H_2Saq. A. Vogel, and L. P. de St. Gilles have also studied the reaction of sulphur dioxide on hydrated cuprous oxide. For the action of alkali polysulphides see these salts. J. Landauer found that cuprous oxide is blackened when boiled with a soln. of **sodium thiosulphate**, and F. Field and C. and J. Bhaduri found that cold sodium thiosulphate forms a colourless soln. with hydrated cuprous oxide, and cuprous sulphide is later precipitated.

According to A. J. Balard, **bromine** water oxidizes cuprous oxide to cupric oxide and bromide; and it is also oxidized by **chlorine** and by bromine. G. Gore said that cuprous oxide is attacked by **liquid ammonia**. A. Guntz and H. Bassett say two hours' treatment of precipitated and washed cuprous oxide with **ammonia** converts it into copper nitride, Cu_3N_2. S. Hauser found that above 280°, cuprous oxide is reduced by the gas. P. Sabatier and J. B. Senderens found that **nitrogen peroxide** at 300° rapidly converts cuprous into cupric oxide; **nitrous oxide** acts at 350°, and **nitric oxide** does not oxidize at a red heat. With **phosphorus**, copper phosphide is formed. Cuprous oxide is reduced by **carbon**. C. R. Wright and A. P. Luff found no action occurred with hydrogen at 150°, but the reduction was marked at 160°. F. Glaser gives 155° for the temp. at which reduction begins. W. Manchot and J. A. N. Friend say the hydrated oxide does not absorb carbon monoxide. According to H. Erdmann and P. Köthner, F. A. Gooch and F. Baldwin with **acetylene** at 225° or 250°, a polymerized product is formed. S. Hauser found that cuprous oxide is reduced by **carbon monoxide** at temp. exceeding 195°; while C. F. Schlagdenhauffen and M. Pagel say the reaction commences above 100°, and is complete at 300°. R. Brauns says red copper oxide can be reduced by **carbon dioxide** to copper, but P. N. Raikow found freshly precipitated cuprous hydroxide is not reduced. The oxide is reduced by the vapour of **alcohol**. G. Rauter found the **silicon tetrachloride** forms silica and cuprous chloride when heated 14 hrs. at 270°–280° with cuprous chloride. When melted with **silica** and **ferrous sulphide**, FeS, it forms cuprous sulphide, Cu_2S, and ferrous silicate, Fe_2SiO_4.

Molten **alkali metals** reduce cuprous oxide with incandescence. **Magnesium** and **aluminium** were found to act similarly when strongly heated with cuprous oxide in a closed glass tube. C. H. Mathewson and C. H. Stokesburg found that cuprous oxide readily dissolves in molten **silver**. There is a eutectic at 914°, with 1·3 per cent. of the oxide; and with 12 per cent. of the oxide, the f.p. rises to 1085°. Solid soln. are not formed. The observed lowering of the f.p. is greater than the value calculated from the latent heat, possibly owing to the reaction: $Cu_2O+2Ag\rightleftharpoons 2Cu+Ag_2O$. Small amounts of the oxide are not decomposed by melting the soln. in hydrogen. J. A. Hedvall and N. von Zweigbergh noted that cuprous oxide reacts violently with **barium dioxide**, forming cupric oxide, which then decomposes the dioxide catalytically. M. Gröger found that soln. of the **chlorides of the alkalies and alkaline earths**—in an atm. of carbon dioxide but not in hydrogen—form double salts; and, according to H. Ost, the reaction proceeds more quickly at 100°. M. Gröger says that when a sat. soln. of sodium chloride is digested with cuprous oxide in an atm. of hydrogen, only a small trace of cuprous chloride is formed. The sulphates do not act in this way. W. Bersch states that cuprous oxide is soluble in a soln. of **potassium iodide** giving a soln. with an alkaline reaction. When digested with a soln. of cuprous chloride, free from hydrochloric acid, M. Gröger found that a basic chloride is precipitated. E. Wohlwill says a boiling soln. of **copper sulphate** neutralized with ammonium carbonate does not affect cuprous oxide; metallic copper under similar conditions is dissolved, so that this soln. can be used for separating copper from cuprous oxide. A soln. of **silver nitrate** was stated by C. J. B. Karsten to have no action on cuprous oxide; but C. F. Rammelsberg, H. Rose, W. Hampe, J. Dewey, and P. Sabatier find that a mixture of silver and a basic cupric nitrate is precipitated; the reaction with a cold dil. soln. begins slowly and progresses with a rapidly increasing velocity; the reaction begins immediately in conc. soln., or at 40° in dil. soln., and proceeds the more rapidly the more finely divided the cuprous oxide. R. H. Bradford found that with silver nitrate at 670° the metal is formed. According to R. Gedault, an ammoniacal soln. of **silver chloride** forms cupric oxide and chloride. J. H. Gladstone and A. Tribe have studied the action of silver nitrate on hydrated cuprous oxide. T. S. Hunt found soln. of **magnesium or zinc chloride** form magnesium or zinc hydroxide and magnesium or zinc cuprous chloride, and that **ferric chloride** partially reduces cuprous oxide to copper: $4Cu_2O+3FeCl_3=6CuCl+2Cu+Fe_2O_3$. W. Stahl and H. Koch found with **ferric oxide** at 750°-800°, a mixture of ferrosoferric oxide and cupric oxide is formed. According to P. T. Walden, the product of the reaction does not include magnetic oxide of iron, but rather $Cu(FeO_2)_2$, cupric ferrite, which at 750° decomposes into cupric oxide, etc. D. Miklosich, R. K. Meade, H. O. Jones and F. W. Carpenter, F. Thomas, and M. de K. Thompson have studied the quantitative oxidation of cuprous to cupric oxide by soln. of ferric salts. C. F. Schönbein found that some potassium ferrocyanide is produced when **potassium ferricyanide** is treated with finely divided cuprous oxide. The oxidizing action of **potassium permanganate** has been studied by R. M. Caven and A. Hill. D. Vorländer and F. Meyer have studied the reduction of aromatic **diazonium salts** in ammoniacal or hydroxylamine soln. Platinum was found by E. Ehrmann, and B. B. Ross to be quantitatively precipitated from soln. of **alkali chloroplatinates**.

In the reaction between cupric and cuprous oxide in the decomposition of cupric oxide, by heat: $4CuO=2Cu_2O+O_2$, the solid product obtained by heating cuprous oxide to different temp. will contain a mixture or a solid soln. of nCuO with mCu$_2$O, and if the heating be conducted under definite conditions, a product with a constant composition will be obtained—but not necessarily a chemical individual—a **cuprosic oxide.** This remark applies to P. A. Favre and L. Maumené's Cu_5O_3, *i.e.* $2Cu_2O.CuO$, obtained by heating cupric oxide to the m.p. of copper,[11] A. Joannis could find no sign of this compound, or of Cu_5O_4, on the dissociation press. curve of cupric oxide. L. Wöhler and A. Foss showed that the cupric oxide forms a solid soln. with the cuprous oxide formed by its dissociation: $4CuO=2Cu_2O+O_2$; the conc. of the soln. increases slowly as the dissociation progresses, and this lowers the dissociation press.

Similar remarks might be applied to the products precipitated from soln. containing partially oxidized cuprous salts, or partially reduced cuprous salts. For instance, E. Francke obtained a product which he regarded as $CuOH.3Cu(OH)_2.5H_2O$ by adding hydroxylamine to cupric hydroxide; with a still greater quantity of reducing agent, cuprous hydroxide was obtained. Similarly, the salt $2Na_2S_2O_3.Cu_2S_2O_3.CuS_2O_3.4NH_3$ obtained by adding ammonia to a mixed soln. of sodium thiosulphate and a cupric salt, can be regarded as being derived from a partially reduced cupric salt; and when a soln. is precipitated with caustic-lye furnishes a mixture of oxides, which M Siewert regarded as Cu_5O_3, *i.e.* $2Cu_2O.CuO.nH_2O$. M. Siewert also obtained a pale blue precipitate of what he regarded as $Cu_2O.2CuO.5H_2O$, by allowing an ammoniacal soln. of sodium cuprous chloride to stand for 12 hrs.

Cuprous oxide in the form of ground scales is used in preparing some ceramic colours; in making some galvanic baths; and in making some anti-rust paints. A. Lionet[12] recommended it for purifying hydrogen. He says metallic copper removes all the impurities except hydrogen phosphide and silicide, and the hydrocarbons; while cuprous oxide removes all but hydrogen silicide and the hydrocarbons; and that cupric oxide removes all the hydrocarbons.

Hydrated cuprous oxide, cuprous hydroxide.—The so-called *hydrocuprite* is hydrated $Cu_2O(H_2O)_n$, and it is amorphous or colloidal. According to W. T. Schaller the supposed *vanadium ochre* from Lake Superior is really hydrocuprite. A. Brochet[13] obtained hydrated cuprous oxide by the action of a normal soln. of chloric acid on copper. Many of the methods of preparation indicated above furnish hydrated amorphous orange-yellow cuprous oxide. For example, working with dil. soln. R. Böttger reduced freshly-precipitated cupric hydroxide with milk sugar; T. Sandmeyer reduced a soln. of cupric sulphate with grape sugar in alkaline soln; E. Müller reduced cupric hydroxide suspended in alkali-lye with copper; F. D. Chattaway reduced an ammoniacal soln. of cupric hydroxide with phenylhydrazine—ferrous sulphate can be here used as reducing agent. A. Vogel reduced a soln. of cupric acetate with sulphurous acid. A neutral soln. of cupric sulphate can be reduced by ferrous sulphate and potassium fluoride. J. L. Proust treated a hydrochloric acid soln. of cuprous chloride with alkali-lye—E. Frémy used alkali carbonate; and T. S. Hunt used boiling milk of lime. The reduction is best conducted in an atm. of hydrogen to prevent oxidation. N. A. E. Millon and A. Commaille found that yellow-hydrated cuprous oxide never contains less than 4 per cent. of cupric oxide. F. Fischer, E. Müller, R. Lorenz, and J. H. Gladstone and A. Tribe, also prepared hydrated cuprous oxide by electrolytic processes—*e.g.* R. Lorenz electrolyzed a soln. of potassium chloride constantly stirred with a rotating copper anode.

C. Paal and co-workers prepared **colloidal cuprous oxide** as an intermediate product in the preparation of colloidal soln. of copper by the reducing action of alkali lysalbinate; and by heating finely-powdered and dry colloidal cupric oxide to 150°–170° in a stream of hydrogen. C. A. L. de Bruyn prepared the hydrosol with gelatine as a protective colloid. M. Gröger also prepared colloidal cuprous oxide by reducing a soln. of sodium cuprous chloride with potassium sodium tartrate in the cold. P. Pascal made colloidal cuprous oxide by gradually adding a soln. of cupric sulphate to a soln. of alkali ferropyrophosphate. The precipitate first formed redissolves, forming a colloidal soln. A. Gutbier prepared a colloidal soln. by reducing ammoniacal cupric sulphate soln. with hydrazine; and A. Lottermoser, by reducing with stannous chloride.

According to H. G. F. Schröder, the sp. gr. of the hydrate prepared by reducing cupric oxide with lactic acid is 3·368. E. Mitscherlich found that when heated to 100°, J. L. Proust's product holds most of its water, but it retains only 3 per cent. at 360°, and becomes orange-yellow; at red-heat, the red oxide is formed. When hydrated cuprous hydroxide is exposed to air it gradually forms cupric hydroxide.

Cuprous oxide or hydroxide may be regarded as the basic oxide of **cuprous salts** where copper is univalent, Cu′. Cuprous oxide is decomposed by many acids—sulphuric, phosphoric, dil. nitric, acetic, oxalic, and many other organic acids—furnishing metallic copper, and a soln of cupric oxide, and since the same oxide is oxidized by many other acids, comparatively few cuprous salts have been prepared. E. Frémy[14] said that hydrated cuprous oxide prepared by J. L. Proust's process, dissolves in even the weakest of acids, forming cuprous salts, and that if the cuprous oxide is dehydrated, it loses its basic property and is decomposed by the same acids. Cuprous salts have been obtained by reducing cupric salts with copper and other reducing agents—*e.g.* P. Rohland used a methyl alcohol soln. of ferrous sulphate; E. Ebler used hydroxylamine or hydrazine salts, etc.

The cuprous salts are generally colourless, but some are yellow, others red. They are usually insoluble in water, but soluble in ammonia, pyridine, and hydrochloric acid. They are readily oxidized to cupric salts by exposure to air while moist, and by treatment with oxidizing agents. R. M. Caven and A. Hill studied the oxidation of cuprous salts with nitric or hypochlorous acid, and with potassium permanganate. P. Sabatier proposed to detect nitrites from the violet coloration produced when a little cuprous oxide, or a small quantity of a cuprous salt, is added to a soln. containing a little nitrite dissolved in sulphuric acid. The colour disappears slowly on standing, rapidly on heating, or on dilution with water. Cuprous oxide is reduced to the metal by many reducing agents—*vide* cupric oxide. Soln. of potassium or sodium hydroxides, carbonates or bicarbonates precipitate yellow cuprous hydroxide insoluble in excess. Aqua ammonia or ammonium carbonate gives colourless soln. if air be excluded—if otherwise the soln. is blue—alkalies precipitate cuprous hydroxide from these soln., but barium carbonate was found by H. Rose to give no precipitate. Soln. of sodium phosphate give a yellow precipitate. A. Orlowsky found milk of sulphur precipitates the copper as cuprous sulphide, ammonium hydrosulphide acts similarly on neutral soln.; the precipitate is insoluble in excess. Potassium cyanide precipitates cuprous cyanide which is soluble in excess, forming a soln. from which hydrogen sulphide, ammonium sulphide, or the alkali hydroxides give no precipitation. Potassium ferrocyanide gives a rose-coloured precipitate; and potassium ferricyanide a reddish-brown precipitate. According to F. Herrmann, ferric sulphide oxidizes acid soln. of the cuprous salts, but, according to H. R. Ellis and W. H. Collier, only by a prolonged boiling. Ammonium oxalate gives a bluish-white precipitate. A. Fonseca found with silver sulphide and cuprous chloride: $Ag_2S+2CuCl=CuCl_2+CuS+2Ag$. Acetylene precipitates acetylides from ammoniacal soln. of cuprous chloride; and ammoniacal or acid soln. of cuprous chloride are good solvents for carbon monoxide.

§ 10. Cupric Oxide

Black oxide of copper, **cupric oxide**, CuO, must have been known for a very long time, since it is formed when copper is heated in air. *Black copper, cuivre oxidé noir*, or *Kupferschwärze* is mentioned by the mineralogists near the end of the eighteenth century—C. A. S. Hoffmann,[1] L. A. Emmerling, J. F. L. Hausmann, etc.—and the beginning of the nineteenth century as occurring in nature, and it was classed with the red oxide of copper and iron oxide among the mineral oxides. J. G. Wallerius called it *ochra cupri nigra;* and J. C. Delamétherie, *oxide noir de cuivre*. F. S. Beudant called it *melaconise*—from μέλας, black; and κόνις, dust—and this term was altered by J. D. Dana to *melaconite;* E. F. Glocker called it *chalkomelan*—χαλκός, copper; μέλας, black—and, as others had done previously, he emphasized the fact that it usually contained both manganese and iron oxides as impurities. G. Semmola named the black oxide found among the Vesuvian minerals, *tenorite*, in honour of the Italian botanist. Crystalline tenorite is rare—samples have been reported from Cornwall, Vesuvius, Keweenaw Point (Michigan). Amorphous or colloidal melaconite, $CuO(H_2O)_n$, is fairly common in the oxidized zone of a copper mine. It is considered to be either an adsorption compound or a solid soln. of cupric oxide and water, with silica, and often manganese dioxide as impurities. The so-called melanochalcite of G. A. Koenig [2] is a cupric silicocarbonate, and is considered by E. H. Kraus and W. F. Hunt to be a mechanical mixture of melaconite, tenorite, and chrysocolla.

The preparation of cupric oxide from metallic copper.—Cupric oxide can be prepared by heating finely-divided copper or cuprous oxide in air or oxygen. If the latter be not finely divided R. Hefelmann [3] found the reaction is not completed; and analogous remarks apply to copper, for E. C. C. Stanford found but a 40 per cent. conversion after 12 hrs. heating in a muffle; while P. Schützenberger found that the so-called allotropic copper powder oxidizes very rapidly in air to cupric oxide. According to W. Müller, pure oxygen acts more slowly than air, because it forms a protective film of a non-volatile oxide on the surface of the metal; while E. Jordis and W. Rosenhaupt found that the oxidation of copper by oxygen commences at about 80°—with tin at 100°, and with zinc at 150°. The fact that above 145° air attacks copper more energetically than does oxygen, and the more energetic action of moist than of dry oxygen is ascribed to the participation of oxidation products of nitrogen and water in the reaction. Progressive oxidation depends on the behaviour of the surface layer. An oxidizable surface may be the result of (*a*) the soln. of the oxygen in the metal as such or as an alloy of copper and oxygen; (*b*) the diffusion of the oxygen through the layer of oxide which may dissolve the oxygen or be merely porous to it; (*c*) the alternate formation of lower and higher oxides; or (*d*) the layer of oxide scaling off from the metal. The dissociation press. of cupric oxide and the formation of cuprous and cuprosocupric oxides have been discussed in connection with the preparation of cuprous oxide. According to J. C. Richardson, copper filings, dipping in alkali-lye, are oxidized to cupric oxide by exposure to air. V. Kohlschütter and T. Goldschmidt found black microscopic plates were deposited on the edges of a copper cathode in oxygen.

A. C. Becquerel converted ordinary cupric oxide into crystals by heating it to 500°–550° with four to six times its weight of potassium hydroxide; washing the cold mass with water; and separating the flocculent from the crystalline cupric oxide by levigation with water.

The preparation of cupric oxide from cupric salts.—Cupric oxide is formed by heating the hydroxide to 100°, or by boiling it in water. Cupric oxide is formed by the calcination of cupric nitrate, $Cu(NO_3)_2$. By soaking asbestos in a soln. of cupric nitrate, and afterwards igniting the mass; or by soaking asbestos in a soln. of copper sulphate and afterwards treating the mass with dil. potash-lye, washing, and igniting, U. Kreusler[4] obtained *copper oxide-asbestos*, used as a catalytic agent in gas analysis. O. L. Erdmann and R. F. Marchand, and W. Hampe have discussed the preparation of a highly-purified cupric nitrate for this purpose. T. W. Richards also discussed the preparation of cupric oxide of a high degree of purity, and studied the contamination of the product with occluded gases.

O. L. Erdmann and R. F. Marchand noticed that cupric oxide readily condenses air on its surface, and, according to P. Holland, the absorbed air is given off when the oxide is heated to redness. G. S. Johnson found cupric oxide absorbs carbon dioxide, and gives it up again on melting; E. Frankland and H. E. Armstrong that cupric oxide absorbs both nitrogen and carbon dioxide; T. Hilditch that red-hot cupric oxide occludes oxygen, but, according to P. Schützenberger, no peroxide is formed; J. L. W. Thudichum and C. T. Kingzett that in order to obtain cupric oxide wholly free from carbon dioxide, the oxide must be ignited in vacuo. A. Joannis noted that water is retained very tenaciously by cupric oxide, even at 110° in vacuo, and it required 8 hrs. at 440° in vacuo to remove all the water from 5 grms. of the oxide; E. W. Morley that when cupric oxide is heated in vacuo it slowly gives off a gas; and T. W. Richards that cupric oxide prepared from the nitrate contained 0·004 per cent. of occluded gas—mainly nitrogen; and he also showed that cupric oxide can absorb four or five times its own volume of nitrogen. Hence, the use of cupric oxide prepared from the nitrate is not recommended for the determination of nitrogen in organic products. The wire form of cupric oxide prepared by oxidizing the metal is not open to this objection. T. W. Richards also showed that there is no appreciable amount of oxidized nitrogen or of water in copper oxide that has been calcined at a red heat. According to A. Lionet, cold cupric oxide absorbed the hydrogen compounds of arsenic, sulphur, phosphorus, silicon, antimony, selenium, and chlorine, but not hydrogen or the hydrocarbons.

H. D. A. Ficinus described the preparation of cupric oxide by calcining the basic copper nitrate made by exposing a mixture of copper filings with twice its weight of copper nitrate to the air until all is converted into a basic nitrate. G. Rousseau and G. Tite also prepared the oxide by heating basic copper nitrate with water for 20 hrs. in a sealed tube. A. Vogel and C. Reischauer divided a neutral soln. of cupric nitrate into two parts, treated one half with ammonia until the precipitate just redissolved, mixed the two parts together and boiled the soln. The precipitated black oxide was well washed with water. E. Erlenmeyer removed chlorine from cupric oxide by heating the oxide in a stream of water vapour. T. Klobb obtained crystalline cupric oxide by calcining cupric sulphate or basic sulphate red hot; H. Schulze heated cuprous chloride in oxygen and obtained crystals of cupric oxide. J. A. Morrell heated cupric sulphide with ammonium nitrate; E. C. C. Stanford calcined a mixture of equimolecular parts of cupric sulphate and sodium carbonate; T. W. Richards obtained cupric oxide free from occluded gas by calcining cupric carbonate; K. Seubert and G. Rauter calcined cupric ammino-oxalate; and A. Lieben and A. Rossi heated a dil. soln. of cupric valerianate. F. Zambonini obtained artificial tenorite by heating cupric chloride in water vapour.

M. Prud'homme found that cupric oxide is deposited when an alkaline soln. of cupric chromate has stood some time. The dark red crystals of cupric oxide prepared by J. W. Mallet by leaving a copper plate to stand in a soln. of the nitrate were probably basic cupric nitrate.

The preparation of cupric oxide by electrolysis.—The black precipitate obtained on the copper anode during the electrolysis of dil. sulphuric acid, or of acidified cupric sulphate, is not cupric oxide as supposed by H. Buff[5] and G. Planté, but, according to H. Meidinger, it is derived from the impurities in the metal, and, according to E. Wohlwill, it contains some disintegrated copper. E. Müller prepared cupric oxide by the electrolysis of $5N$-sodium hydroxide for a long time with a copper cathode either at 12° with stirring, or at 60° without stirring. E. Müller and F. Spitzer also electrolyzed a soln. of cupric hydroxide in 12–$14N$-NaOH with not too high a current density. W. D. Bancroft and G. H. Burrows electrolyzed a 5 per cent. soln. of potassium chlorate between copper electrodes at 93°—the anode was small. Possibly cupric chlorate is first formed which is converted by alkali hydroxide and the copper anode into oxide. A part of the oxide is reduced by the hydrogen of the cathode. The subject has been investigated by M. Wildermann, C. Luckow, W. Borchers, A. Brochet, R. Kroupa, etc.

The properties of cupric oxide.—Cupric oxide usually appears as a brownish-black powder which is jet black when hot, or else in brownish-black brittle scales or granules. The measurements of N. S. Maskelyne[6] show that the **crystals** of Cornish melaconite are pseudomonoclinic and belong to the triclinic system; they have the axial ratios $a:b:c=1{\cdot}4902:1:1{\cdot}3604$ with $\alpha=90°$; $\beta=99° 32'$; $\gamma=90°$. E. Kalkowsky showed that these measurements agree with G. Jenzsch's for Vesuvian tenorite. The **X-radiogram** has been studied by J. A. Hedvall; and he concluded that all the different forms of the oxide—artificial and natural—have the same X-radiogram. The native oxide usually occurs in black or greyish-black earth. G. A. König reported a tetragonal modification of cupric oxide at Bisbee (Arizona), and it was called *paramelaconite*—the analysis agreed with CuO, 87·66 per cent.: Cu_2O, 11·70, and Fe_2O_3, 0·64 per cent. The reported[7] values for the **specific gravity** of cupric oxide range from 6·130 of P. F. G. Boullay and J. F. Persoz to 6·451 of G. Jenzsch. W. Herapath gives 6·401 at 16·5°, and an analogous number was also obtained by J. F. Persoz. L. Playfair and J. P. Joule obtained 5·90 for the dried oxide, and 6·414 for the ignited oxide, C. F. Rammelsberg's value for melaconite is 5·952, and J. D. Whitney's, 6·25. G. A. König gives 5·833 for paramelaconite. The **hardness** of melaconite is between 3 and 4; G. A. König gives for paramelaconite a hardness of 5. According to F. Streintz, powdered cupric oxide is not united to a rod by a press. of 13,000 atm.

L. Wöhler and A. Foss[8] found the **melting point** to be 1064°. F. H. Smyth and H. S. Roberts found that cupric oxide alone does not melt without dissociation below 1233°, and that the eutectic temp. with cuprous oxide is 1082°–1080·2° and 390 mm.; they also found that from 900° up to the temp. at which no liquid phase appears—the eutectic temp. 1082°—the dissociation press., p, of cupric oxide, expressed in mm. of mercury, is $\log_{10} p=-13216T^{-1}+12{\cdot}35$. The dissociation press. of cupric oxide have been also measured by L. Wöhler and A. Foss, H. W. Foote and E. K. Smith, and J. Hagenacker—*vide* cuprous oxide. When molten cupric oxide has cooled, it has a crystalline fracture. According to A. Gouy, a flame which reduces cupric oxide can retain that compound in the state of vapour. The flame of coal gas is coloured green when it has passed over cupric oxide at a dull red heat. The oxide also volatilizes in pottery ovens over 1000°; L. Elsner also noticed that the oxide volatilizes in porcelain ovens, say, at 1400°. The oxide is partially decomposed when the vap. press. of the oxide attains one-fifth of that of the atm.; this occurs at a red heat; the reaction is $4CuO=2Cu_2O+O_2$, and the porous mass reoxidizes when cooled in air. H. Moissan found that the decomposition: $2CuO=2Cu+O_2$, occurs at 2500° in the electric arc. The equilibrium conditions in the dissociation: $4CuO \rightleftharpoons 2Cu_2O+O_2$ have been discussed in connection with cuprous oxide; similar remarks apply to W. Stahl's calculations of the **dissociation pressures** for both reactions between 500° and 2500°. H. le Chatelier says the quotient of the latent heat of dissociation by the absolute dissociation temp. is not constant. L. Wöhler and A. Foss believed that cupric oxide forms solid soln. with the cuprous oxide produced in its dissociation, but F. H. Smyth and H. S. Roberts showed that this is probably not the case. L. Wöhler and O. Balz have discussed the dissociation of cupric oxide. F. E. Neumann gave 0·137 for the **specific heat** of the oxide; H. V. Regnault, 0·1420; and H. Kopp, 0·128; the respective atomic heats are then 10·9, 11·3, and 10·2. A. Magnus found 0·1342 for the sp. ht. from 17° to 100°, and 0·1537 between 17° and 537°. J. Thomsen's value[9] for the **heat of formation** is (Cu, O) 37·16 Cals.; M. Berthelot's, 42·0 Cals.; and P. A. Favre and J. T. Silbermann's, 43·77 Cals.; A. Joannis gives 32·12 Cals. for the heat of formation from the sulphate; 32·36 Cals. from the nitrate; and M. Berthelot gives from the sulphide, 30·1 Cals.; and from the selenide, 22·4 Cals. P. L. Dulong gives for (Cu_2O, O), 35 Cals.; J. Thomsen, 33·51 Cals.; and T. Andrews, 36·2 Cals. F. H. Smyth and H. S. Roberts calculate 60,568 cals. for the change $4CuO \rightarrow 2Cu_2O + O_2$; and for the decrease in free energy $2{\cdot}303RT\log_{10}(p/760)$, or $-60719+43{\cdot}604T$. M. Berthelot and J. Thomsen respectively give for the **heat of neutralization** of $\frac{1}{2}$Cu with sulphuric acid (one eq. in 4 litre), 9·2 and 9·4 Cals.; hydrochloric acid, 7·5 and 7·635 Cals.; nitric acid, 7·5 and 7·625 Cals.; and acetic acid, 6·2 and 6·59 Cals. W. Ostwald has discussed the affinity of cupric oxide towards nitric and hydrochloric acids. J. Thomsen also found with chloric acid, ($CuO, 2HClO_3aq.$) 15·91 Cals.; hydrobromic acid, ($CuO, 2HBraq.$) 15·27 Cals.; and ethyl hydrosulphuric acid, ($CuO, 2(C_2H_5)HSO_4aq.$) 15·2 Cals. P. Sabatier gave ($CuO, 2HClaq.$) 16·4 Cals.; ($CuO, 2HBraq.$) 16·1 Cals.; ($CuO, 2HNO_3aq.$) 16·2 Cals.; and ($CuO, H_2SO_4aq.$) 19·2 Cals.

W. W. Jaques,[10] J. Stefan, and A. Schleiermacker have studied the **radiation of heat** by cupric oxide. With respect to the work of the former, H. Kayser says *es ist nicht ein einziges der gefundenen Resultate richtig.* F. Paschen gives for the total radiation of cupric oxide at different temp.:

288°	373°	473°	573°	673°	773°	973°	1173°	1373° K.
0·378	1·23	3·62	8·71	18·1	34·1	97·5	22·8	467

not far from the corresponding values for carbon. O. Vogel found that the **spectrum** in the oxycoal-gas flame gives the characteristic green lines of copper. W. N. Hartley found that in the oxyhydrogen blowpipe flame, cupric oxide gives a fine band spectrum with two lines of the metal. L. de Boisbaudran studied the **fluorescence** of cupriferous lime, and V. Klatt and P. Lenard, cupriferous sulphides of the alkaline earths. E. L. Nicols and D. T. Wilber observed no signs of flame phosphorescence with cupric oxide. A. Kundt found the mean **index of refraction** for forms of cupric oxide for the red ray to be 2·63, for the white, 2·84, and for the blue, 3·18. The **photoelectric effect** was found by W. Hallwachs to be nearly the same as for copper.

According to S. Meyer,[11] cupric oxide is paramagnetic; the **magnetic susceptibility** is about $+3{\cdot}1\times10^{-6}$ mass units at 17°; and, according to G. Chéneveau, $+3{\cdot}6\times10^{-6}$. C. B. Thwing gives 18·10 for the **dielectric constant.** F. S. Smith said that additions of small proportions of cupric oxide to ferric oxide make the latter magnetic. E. Thomson noted the orientation of finely divided particles of cupric oxide in an intense magnetic field. The subject was discussed by O. J. Lodge, R. W. Gray, and J. B. Speakman.

F. Streintz said powdered cupric oxide is a non-conductor of electricity, but it conducts much better when it has been fused. According to K. Bädeker, the specific resistance is 400 when that of copper is 0·0000017. F. Horton measured the **resistance** and **conductivity** of fused rods of cupric oxide $1{\cdot}006\times1{\cdot}994\times0{\cdot}2179$ c.c., and found:

	12°	66°	157°	385°	618°	733°	944°	1038°
Resistance	645100	74560	5930	96·2	5·87	1·455	0·196	0·021
Conductivity	$3{\cdot}38\times10^{-7}$	$2{\cdot}92\times10^{-6}$	$3{\cdot}67\times10^{-5}$	$2{\cdot}26\times10^{-3}$	0·03711	0·1497	1·111	10·37

No sign of electrolysis was here observed at ordinary temp., but at 700°, electrolysis can be detected. K. Bädeker gave 400 absolute units for the metallic conductivity of cupric oxide (the value for copper is 0·0000017). According to A. A. Sommerville, a column of oxide, 1 cm. diam. and 10 cms. long, has a resistance of 10^7 ohms at 395° if it has been twice heated, and at 290° if once heated. The resistance at the m.p. is 35 ohms. The resistance of cupric oxide after melting is greater at all temp. T. W. Case found that exposure to light had no measurable effect on the conductivity of tenorite. According to P. Fritzsch, the addition of the oxides of magnesium, zinc, cadmium, aluminium, or bismuth raises the conductivity of cupric oxide, while it is lowered by lead oxide. According to J. Perrin, cupric oxide is electrically neutral in aq. soln., positive in acid and negative in alkaline liquids; and, according to G. C. Schmidt, the electrodes of cupric oxide in sodium hydroxide gradually become more positive. According to E. A. Byrnes, the e.m.f. of cupric oxide against copper in molten sodium hydroxide at 360° is 0·20–0·25 volt. E. van der Ven has also studied the e.m.f. of cells with cupric oxide. G. C. Schmidt and M. Wildermann studied the effect of illumination on the potential of electrodes in sodium hydroxide. A. Coehn and Y. Osaka found 1·48 volts are necessary for the development of oxygen at an anode of cupric oxide against a standard hydrogen cathode.

Cupric oxide is hygroscopic, so much so that W. Müller-Erzbach suggested the absorbed water is chemically united with the oxide; the **hygroscopicity** is less when the oxide has been calcined to a high temp., and this the more the higher the temp. of calcination; C. F. Cross[12] says that the oxide prepared by heating copper in oxygen is not hygroscopic even in an atm. sat. with water vapour, while the oxide prepared by precipitation or by calcining the nitrate is hygroscopic. Cupric oxide is insoluble in water. The oxide prepared at a low temp. quickly dissolves in dil. acids, but the oxide which has been calcined at a high temp. dissolves very slowly even in hot conc. acids. A. Joannis says the oxide dissolves quickly in a mixture of ammonium iodide and hydrochloric acid. Cupric oxide is readily reduced by gently heating it in a current of **hydrogen.** During the reduction, the mass sometimes becomes incandescent. J. J. Berzelius noticed that the action seems to begin at a definite temp., which is lower the lower the temp. at which the oxide has previously been calcined. Thus, W. Müller-Erzbach found that the oxide prepared by drying the hydroxide at 300° is reduced at 135°; if the oxide has been pre-heated to a higher temp., reduction occurs at 140°; the oxide prepared by the direct oxidation of the metal is reduced at 193°, and that prepared from the nitrate is reduced at 205°. C. R. A. Wright and A. P. Luff found that precipitated cupric oxide washed and dried at 130° showed no signs of reduction at 83°, but at 87°–90° reduction could be detected; with a sample prepared by ignition, no action could be detected up to 170°, but at 175° reduction was appreciable. F. Glaser gives 150° for the temp. at which reduction begins with oxide prepared from the nitrate; and 199° for powdered cupric oxide prepared by direct oxidation. The reaction has also been studied by A. Osann, and by S. Hauser. According to R. N. Pease and H. S. Taylor, the reduction of copper oxide by hydrogen is autocatalytic, metallic copper being the catalyst. The reaction takes place at the copper-copper oxide interface. The presence of water vapour retards the formation of the copper nuclei but does not interfere with the subsequent action at the interface; oxygen has the reverse action. For the **adsorption of gases**—hydrogen, etc.—*vide supra.* The reduction also occurs about the cathode from which electrolytic hydrogen is being evolved; A. Löb also found that the reduction occurs in potassium cyanide soln. of cupric salts with an alternating current.

According to H. Moissan,[13] **fluorine** does not react in the cold with cupric oxide, but when red hot, a black substance is produced which is assumed to be *cupric oxyfluoride.* For the solubility of the oxide in **hydrofluoric acid,** *vide* cupric fluoride. M. G. Levi and M. Voghera obtained cupric chloride and chlorine when cupric oxide is heated to 300° in a stream of air and **hydrogen chloride,** the cupric chloride then forms an oxychloride. L. Santi says ammonium chloride calcined with cupric oxide forms cuprous chloride coloured brown by a little cupric chloride. According to W. D. Bancroft, hypochlorites are decomposed by cupric oxide, and F. Oettel has shown that the yield of **hypochlorites** in the electrolysis of soln. of calcium chloride is diminished by this agent. W. O. de Coninck and L. Arzalier stated that when a mixture of cupric oxide and **ammonium chloride** is pounded in a mortar, or strongly compressed, some cupric chloride is formed and ammonia evolved; while with **ammonium bromide,** an unstable ammoniacal copper oxybromide is formed which is soluble in dil. ammonia, and gradually loses ammonia, forming a green hydrated copper oxybromide mixed with a little bromide. According to G. Denigès, oxygen is formed when **bromine** drops into sodium hydroxide in the presence of cupric oxide. Liquid **hydrogen iodide** was found by R. S. Norris and F. G. Cottrel to produce cupric iodide, CuI_2. B. Szilard has shown that iodine is liberated when cupric oxide is added to a soln. of cupric nitrate and **potassium iodide.** Cupric oxide also stimulates the decomposition of potassium chlorate—*q.v.*; according to C. R. A. Wright and A. P. Luff, some chlorine is formed at the same time.

According to M. Jordan,[14] if cupric oxide be heated with an excess of sulphur, cupric sulphide and a trace of the sulphate are formed; with the cupric oxide in excess, the products are cuprous oxide and cupric sulphate—in the former case much sulphur dioxide is produced, and in the latter case very little. If the temp. be near the decomposition point of the sulphate, the reaction is symbolized: $7CuO+S=CuSO_4+3Cu_2O$. When heated with sulphur in a stream of hydrogen, H. Rose and K. Klüss found all the cupric oxide is converted into cuprous sulphide. When cupric oxide is triturated with **sulphur** and water, and heated in a closed vessel to 100°, J. B. Senderens noted that blue crystals of cupric sulphate are formed. G. Keppeler obtained a quantitative reduction of cupric oxide by **sulphur dioxide** at 450°: $3CuO+SO_2=CuSO_4+Cu_2O$. H. Brieglieb showed that the cupric oxide may be employed as a contact catalyst for accelerating the union of sulphur dioxide and oxygen in the formation of sulphur trioxide for sulphuric acid, and several patents have been taken in this connection. It might also be added that M. Traube, W. A. Bone and R. V. Wheeler, J. Krutwig and A. Dernoncourt, C. D. Brindley, and F. Eschbaum have drawn attention to the use of cupric oxide in stimulating the oxidizing action of oxygen. **Ammonium monosulphide**, according to K. Heumann, forms cuprous sulphide with some cupric sulphide and yellow ammonium sulphide; the **alkali or ammonium polysulphides** were found by E. Priwoznik to form salts of the type $M_2Cu_2S_7$; H. Debus says thiosulphates are formed. H. B. Baker found that dry **sulphur trioxide** has no action on dry cupric oxide. W. Spring found that **sodium hydrosulphate**, $NaHSO_4$, reacts energetically when ground with copper oxide in an agate mortar.

When **ammonia** is passed over heated copper oxide, nitrogen gas is obtained—*q.v.*—and this is one of the recognized methods of preparing that gas in the laboratory. S. Hauser [15] found the reduction commences between 265°–308°. H. N. Warren said that if the cupric oxide be warm, a green powdered copper nitride is formed which detonates at a more elevated temp. F. de Lassone, and J. L. Proust noted the solubility of cupric oxide in aqua ammonia, a series of cupric ammino-oxides has been reported—*q.v.* According to E. Murmann, the dissolution takes place very slowly if the oxide has been calcined, and if ammonium salts are present, the solvent action is much greater. According to L. Maumené, cupric oxide is soluble in aqua ammonia only if ammonium salts be present. According to J. L. Proust, the oxide dissolves in a hot soln. of **ammonium chloride**, and an equal portion forms a basic chloride and the addition of much water or alcohol precipitates a blue hydrated compound from the soln. L. Juman found the oxide also dissolves in hot soln. of **ammonium sulphate** or **ammonium sulphite**; and C. Schnabel found 15 per cent. of oxide dissolves in a soln. of **ammonium carbonate** in 24 hrs., and cupric oxide or a basic carbonate is precipitated by boiling the soln.; while zinc precipitates the copper from the soln. D. Lance has studied the solubility of cupric oxide in various **amines**; V. Dessaignes in **benzamide**; R. Piria in **acid amides**; E. Fischer in **polypeptides**; and K. Kraut in **piperidine acetate**. According to A. Cahours, it is not soluble in **piperidine**. J. L. Proust said that **oils** dissolve cupric oxide forming a green soln. Soln. of the **ammonium salts** when boiled with precipitated cupric oxide give green soln. and form a basic cupric salt. P. Sabatier and J. B. Senderens say that **nitric oxide** below 500° has no action. C. A. L. de Bruyn found **hydrazine** to react vigorously with cupric oxide; and, according to A. Thum, the same is also the case with **hydroxylamine**—the cupric oxide is reduced in both cases. F. Haber found the reaction to proceed more quickly in the presence of alkali-lye. E. Francke found the speed of the reduction is reduced by lowering the temp. With **phosphorus** and water, W. J. J. Le Venier obtained red copper; copper phosphide and phosphate are formed. A. Michaelis found that when cupric oxide is heated to 160° in a sealed tube with **phosphorus trichloride**, cupric phosphate and chloride, cuprous chloride, and phosphorus oxychloride are formed; and A. Gautier reported that some of the lower oxides of phosphorus are quickly oxidized by cuprous oxide.

Copper oxide is reduced to the metallic state by gentle ignition with **carbon**. According to C. R. A. Wright and A. P. Luff,[16] freshly precipitated and dried cupric oxide is reduced by sugar charcoal at 390°, cupric oxide from the nitrate at 430°, and that made by roasting copper, at 440°. J. Garnier, and A. C. Becquerel followed the course of the reduction by noting the changes in the resistance of an electric current passing through the mixture. F. O. Doeltz and C. A. Graumann say that cupric oxide is reduced by carbon at 700°. I. L. Bell said that the reduction by **carbon monoxide** is incomplete at the temp. of melting zinc. W. Spring adds that if the temp. of reduction be below the m.p. of copper, the metal will be obtained in a finely powdered condition. C. R. A. Wright, A. P. Luff, and E. H. Rennie reported that as in the case of hydrogen the higher the pre-heating of the cupric oxide, the higher the temp. required for the reduction with carbon monoxide to begin. Thus, the reduction begins at 60° with precipitated cupric oxide, washed, and dried at 130°, and the action is well marked at 68°; with ignited cupric nitrate the action begins at 125° and is well marked at 133°; and with roasted copper, the action begins at 146° and is well marked at 150°. S. Hauser found the reduction begins about 265°. E. D. Campbell found that with a given sample of cupric oxide, the reduction with hydrogen began at 175°–180°; with carbon monoxide, at 100°–105°; with **acetylene**, at 315°–325°; with **propylene**, at 270°–280°; and with **butylene**, at 320°–340°. E. Jäger found **methane** begins its action at a red heat. F. C. Phillips says that the **hydrocarbons** can be completely oxidized by hot cupric oxide; and L. Pfaundler adds that if **coal gas** be used for the reduction, as indicated by A. Osann, the reduced copper will be contaminated with carbon and adsorbed hydrogen. J. N. Pring noted the reduction of cupric oxide by **aluminium carbide**, and B. Neumann and O. Fröhlich by **calcium carbide**. A. Gautier says that the vapour of **carbon disulphide** does not form cupric oxysulphide, CuOS. F. A. Gooch and de F. Baldwin says that acetylene acts on cupric oxide like it does on cuprous oxide. K. Andrlik and H. Hranicka, and W. Bruhns noted the reduction of cupric oxide with **methyl alcohol**; A. Geurout with **ether**; F. Bullnheimer with **glycerol**; L. Hunton, with **sugar**; A. Kling, **acetal**; O. Loew, **petroleum ether**; T. Weyl, **formic acid**; P. Woog, **toluene**; L. Maumené, **naphthalene**; etc.

G. Lunge, and W. C. Zeise have studied the removal of sulphur from rock oils and petroleum by distillation with cupric oxide. According to H. N. Warren, when cupric oxide is heated with **silicon** it forms a silicide or metallic copper; and O. Ruff and K. Albert says that **silicochloroform**, $SiHCl_3$, exerts a reducing action. According to C. H. Burgess and A. Holt,[17] cupric oxide is not soluble in fused **boric oxide**, B_2O_3, but it is soluble if one of the alkali bases be present—lithium. sodium, potassium, cæsium, or rubidium. E. Dufau says that alumina and magnesia are coloured reddish-brown by cupric oxide. The **alkali silicates** are coloured blue by cupric oxide, and pottery glazes are usually coloured green by cupric oxide. According to H. Schwarz, an old blue Venetian glass contained 1·32 per cent. of cupric oxide. The green colour imparted to glass by copper oxide was known to the ancients and to the later alchemists; advantage was taken of this property to make artificial emeralds. Thus, the pseudo-Basil Valentine says "the emerald contains sulphur veneris." There is a delicate relation between the various constituents of a pottery glaze which enables the copper turquoise blue to be obtained. Old Persian-blue tiles have the turquoise-blue glaze. With less than one per cent. of cupric oxide and a reducing atm. copper colours glazes red. This colour is shown on the Chinese *sang de bœuf* and *rouge flambé* glazes. The colour is probably produced by colloidal copper. An oxidizing atm., says G. Rauter, favours the development of green and blue copper colours.

Cupric oxide is reduced to metallic copper when heated with **potassium** or **sodium** at temp. below their m.p. The reaction proceeds with vivid incandescence. C. Winkler[18] found the reduction of heated cupric oxide by admixed **magnesium** is accompanied by incandescence and a detonation. H. Moissan found **boron** exerts a vigorous reducing action. E. Beckmann found **calcium** is a vigorous reducing agent; F. M. Perkin and L. Pratt say **calcium hydride** also acts energetically. **Copper** reduces cupric to cuprous oxide.

O. Loew,[19] A. Chodneff, and W. F. O. de Coninck have studied the action of alkali hydroxides. A. Völker showed that cupric oxide is slightly soluble in a soln. of **potassium or sodium hydroxide.** A 70 per cent. soln. of sodium hydroxide takes up copper in the proportion Cu : NaOH, and the blue liquid does not deposit copper oxide when diluted with 3 or 4 vols. of water. The oxide also dissolves in fused alkali hydroxides to which it imparts a blue colour, and the product is soluble in a little cold water. According to J. A. Hedvall and W. von Zweigbergk, cupric oxide decomposes **barium dioxide** catalytically with an optimum temp. of 600°. Soln. of **salts of the alkalies, alkaline earths, and magnesium** were found by H. Ost not to attack pure cupric oxide. According to J. A. Hedvall and coworkers, they found that potassium chloride could not be used as a flux in the fusion of cupric oxide with aluminium oxide on account of a reaction taking place between the potassium chloride and copper aluminate. When cupric oxide is added in small quantities to a mixture of potassium and sodium chlorides at 1000° and the heating continued for one and a half hours, cuprous oxide is formed and oxygen evolved. At the same time, a basic cupric chloride is formed. C. R. C. Tichborne says a 10 per cent. soln. of **sodium hydrocarbonate** mixed with phenolphthalein, and just decolorized with nitric acid is not altered by trituration with cupric oxide. J. von Liebig found cupric oxide to be reduced and alkali cyanate to be formed by fusion with **potassium cyanide**; and J. Lemberg found that black oxide of copper is soluble in a boiling soln. of potassium cyanide. J. L. Proust, and A. Vogel noted that when cupric oxide is boiled with **stannous chloride,** cuprous chloride passes into soln., and stannic oxide is precipitated. M. de K. Thompson found that a soln. of **ferrous sulphate** forms ferric oxide and cupric sulphate, **ferric sulphate** furnishes the same end-products, but if the cupric oxide is in excess, a basic sulphate is formed. According to T. S. Hunt, **ferrous chloride** furnishes cuprous and cupric chlorides and ferric oxide. A. Levol noted that **hydrated ferrous oxide** and cupric oxide form cuprous and ferric oxides. Gin et Soc. Anon. found cupric oxide precipitates ferric oxide from a soln. of basic ferric sulphate at 90°. C. J. B. Karsten found that when cupric oxide is fused with **ferrous sulphide,** cupric sulphide is formed. M. Vallety says that a soln. of **silver nitrate** forms basic copper nitrate. According to G. Bonnet, a soln. of **arsenious acid** in potassium or sodium hydroxide gives the alkali arsenate and cuprous oxide; the reaction does not occur with the alkali carbonates or with calcium hydroxide; with aqua ammonia, half the cupric oxide is reduced to cuprous oxide and half dissolves in the ammonia, forming a blue soln. M. Prud'homme found alkaline soln. of the **alkali chromates** dissolve cupric oxide, and when boiled, deposit cuprous oxide, leaving the alkali chromate in soln. According to a patent by the Chemische Fabriken Billwärder, cupric oxide acts as a catalytic agent in oxidizing chrome iron ore or chromate during its fusion in alkali hydroxides.

According to M. von Nencki,[20] commercial cupric oxide may contain lime; according to P. Drawe, cuprous oxide, and, according to H. Violette, selenium as well as the usual impurities associated with copper. The property possessed by cupric oxide of imparting the necessary oxygen for the combustion of hydrocarbons, and many other organic compounds, has led to its being used extensively in organic and gas analysis. It is also used for colouring glasses, glazes, and enamels green, red, or blue, as previously indicated. A contact process for sulphuric acid is based on the stimulating action of cupric oxide—alone or in conjunction with chrome iron ore or ferric oxide—on the union of sulphur dioxide and oxygen. It has been used by E. Fischer as depolarizer for the cathode in the electrolysis of alkali, chlorides. There are several patents for its use in this connection. F. de Lalande and G. Chaperon, P. Schoop, C. Grimm, etc., have discussed the use of copper oxide as positive electrode in primary and secondary cells. A. Lionet says the precipitated oxide dried at 100° removes arsine from hydrogen, and also, according to H. Reckleben and G. Lockemann, hydrogen sulphide. E. Viel patented its use for removing silicon from aluminium.

Cupric oxide forms with acids a series of stable **cupric salts,** for cupric oxide is generally readily soluble in the acids. Cupric oxide is a stronger base than cuprous oxide. The anhydrous cupric salts are usually white, a few, *e.g.* cupric chloride, are brown. The salts of the volatile acids lose their acids when calcined. The salts are usually readily soluble in water, and their soln. redden litmus owing to hydrolysis. L. Moser found that the cupric salts are not oxidized by ozone; but they are readily reduced by hydrogen, hydrogen sulphide, and the metals. For example, J. B. Senderens, S. Kern, and D. Vitali found that soln. could be reduced with the precipitation of copper by many metals, but the amount of metal dissolved is rarely eq. to the amount of copper precipitated.

§ 11. The Hydrated and Colloidal Cupric Oxides

A. Lottermoser[1] prepared a cupric oxide sol by oxidation of a colloidal soln. of copper in air. T. Svedberg obtained a **colloidal solution of cupric oxide** by sparking the solid under isobutyl alcohol. H. Ley and F. Werner obtained a colloidal soln. of cupric oxide by allowing a dil. aq. soln. of copper succinimide to stand for some days; the colour changes slowly from dark-green to yellowish-brown and finally dark brown. C. Paal and W. Leuze prepared the colloids by their process with sodium protalbinate or lysalbinate. V. Kohlschütter and J. L. Tüscher prepared cupric oxide dispersed in a gaseous medium by making the metal one electrode of an electric arc and oxidizing the vapour.

C. F. Cross[2] found that cupric oxide prepared by the ignition of the nitrate when exposed to an atm. sat. with moisture takes up from 2 to 4 per cent. approximating $8CuO.H_2O$, whereas the oxide prepared by igniting the metal in oxygen takes up no water and is permanently anhydrous. The hydrate prepared by precipitation from the sulphate and drying at 100°, had a composition corresponding with $4CuO.H_2O$. This product was thought to rehydrate *per saltum*, forming in 24 hrs. $CuO.H_2O$; in 48 hrs. $2CuO.3H_2O$; and then approximated slowly to the limit $CuO.2H_2O$. E. Rubénovitch also reported this latter hydrate by precipitating cupric sulphate with potassium hydroxide and washing the product until the water is removed. E. Frémy, and W. Spring and M. Lucion obtained similar results. B. Kosmann regards this product as having the constitution $HCu(OH)_3$. A. Mailhe prepared a similar product to the $4CuO.H_2O$, that is, $Cu(OH)_2.3CuO$, or $Cu_4O_3(OH)_2$ and called *tetracupric trioxydihydroxide*, obtained by C. F. Cross; and P. Sabatier claimed to have obtained $7CuO.H_2O$ by dehydrating $2CuO.H_2O$, in the cold or at 100°.

According to M. Schaffner, the dark brown product obtained when freshly precipitated cupric hydroxide is heated under its own mother liquid, or heated with water, or exposed to direct sunlight, has the composition: $6CuO.H_2O$. E. Müller and F. Spitzer obtained the same product by electrical endosmose. F. Mawrow also claimed to have made this same product by suspending cupric hydroxide in 16·7 times its weight of potash-lye of sp.gr. 1·4 and passing chlorine into the liquid, at 50°–60°, or at a boiling temp., until the colour no longer changes. The product is dried over sulphuric acid. M. Schaffner says that the dark brown pulverulent mass does not lose its water at 130°; and H. Rose, that from 1 to 2·3 per cent. remains when it is heated to 200° or 300°. According to E. Harms, the product $6CuO.H_2O$ is really $3CuO.H_2O$, and, according to E. Francke, it is partially reduced to CuOH by hydroxylamine. There is little more than the analysis to show that these products are individuals, and it is extremely probable that most or all of them are mixtures of cupric oxide with absorbed water. Similar remarks apply to the product obtained by A. Joannis by boiling ammoniacal cupric soln., and to the black products obtained by E. Müller and F. Spitzer on the platinum or iron anodes during the electrolysis of soln. of copper salts in alkali-lye, or of Fehling's soln.

Cupric hydroxide, $Cu(OH)_2$, or $CuO.H_2O$.—A blue colloidal hydrated form of cupric oxide is formed by adding a slight excess of dil. potassium hydroxide to a cold soln. of a cupric salt. It is repeatedly and rapidly washed with large quantities of cold water—a litre of water per gram of hydrate. The mass is collected on a cloth filter after each washing. The operation should not occupy more than an hour. According to P. Grouvelle,[3] the precipitate still retains some alkali after the washing. In order to avoid the formation of basic salts, A. Oglialoro said that it is best to pour the copper soln. into the excess of alkali. The hydrate is liable to turn black, even during washing, owing to the formation of cupric oxide. Hence, A. Villiers recommended using iced water, and keeping the temp. below 0°. G. Fassbender said that the change to the black oxide is retarded if some glycerol be present. According to L. S. Finch, cupric oxide jellies, made by adding a suitable quantity of ammonia to a sat. soln. of copper acetate, are not permanent, for sooner or later cupric hydroxide separates out. The stability is increased if a little manganese sulphate, potassium sulphate, or sulphuric acid be present in the cupric acetate soln. before precipitation.

According to J. M. van Bemmelen, the pure hydrogel is a thick, bright blue jelly, which, after pressing between porous earthenware for two hours, still contains a large quantity (20 mols.) of "water of absorption." It retains its colour under water at the ordinary temp. for several days, whether in the dark or in sunlight, but in hot water, unlike the crystalline variety, undergoes gradual modification, the colour changing to green. When exposed at the ordinary temp. to an artificially dried atm., it loses water until its vap. press. is equal to that of the aq. vapour in the atm., and when the press. is zero, the composition approaches the limit $CuO.H_2O$. This last molecule of water is only partially eliminated at 100° ; the second, although not so tenaciously attached, is more firmly combined than the others, the number of which varies, as before stated, with the press. With the elimination of water, the compound becomes more stable, and like the crystalline hydrate in character, whilst the ease with which the water is eliminated diminishes as time elapses. The dried substance absorbs a certain amount (4 mols.) of the water again, when exposed to a moist atm., the exact amount depending, as before, on the press. of the aq. vapour in the atm. Fig. 25 shows the isothermal hydration and dehydration curves (15°) for the water conc. of the solid in mols. of H_2O per mol. of CuO, and the vap. press. of the gas phase in mm. of mercury. According to V. Kohlschütter and J. L. Tüscher, the dehydration of copper hydroxide is due to an internal neutralization, and is to be represented by the equations $Cu(OH)_2 = Cu^{\cdot\cdot}+2OH'$; $CuH_2O_2 \rightleftharpoons CuO_2^{\cdot\cdot}+2H'$; $2H^{\cdot}+2OH' \rightleftharpoons 2H_2O$; and $CuO_2^{\cdot\cdot}+Cu''=2CuO$. It is, however, not simple $Cu(OH)_2$ mols. that are involved in the reaction, but molecular complexes of colloidal dimensions, so that the degree of dispersity, and hence the reactivity of the complexes, varies with the conditions of formation. N. G. Chatterji and N. R. Dhar regard soln. of the so-called cupric hydroxide as a true peptized colloid, and not of chemical combination.

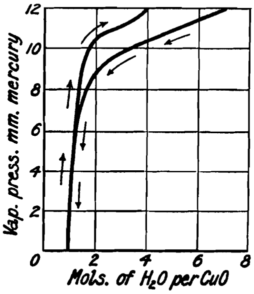

FIG. 25.—Hydration and Dehydration Curves of the Hydrogel of Cupric Oxide.

Cupric hydroxide was prepared by J. Habermann and R. Ehrenfeld by the action of potassium hydroxide on basic cupric sulphate ; J. M. van Bemmelen used basing cupric nitrate ; W. Bonsdorff used ammonium cupric sulphate or nitrate ; J. J. Berzelius, A. Bouzat, J. Löwe, E. M. Péligot, and J. M. van Bemmelen treated a feebly ammoniacal soln. of cupric oxide or carbonate with dil. potassium hydroxide. A. C. Becquerel obtained a growth of crystals of the hydroxide on a sheet of collodion or paper separating a soln. of cupric nitrate from a soln. of potassium hydroxide, potassium aluminate, or potassium silicate. The crystalline hydroxide, $Cu(OH)_2$, is prepared by the slow action of dil. alkalies on various copper salts in the cold. The product is not affected by alkalies or by heat, and may be boiled with water without undergoing any change. The assumption of this stable form is in some way connected with the action of the alkali, as the same phenomenon is observed with beryllia and alumina. A. Krefting obtained thread-like masses of cupric hydroxide by dipping copper in a soln. of potassium ferricyanide and sodium chloride to which one or two drops of sodium hydroxide have been added. The formation develops more quickly if copper be in contact with platinum.

J. L. Proust obtained cupric hydroxide by shaking cupric carbonate with calcium hydroxide and water. J. M. Bell and W. C. Taber obtained cupric hydroxide by adding calcium hydroxide to a soln. of cupric sulphate. A. C. Becquerel found limestone in a soln. of cupric nitrate is gradually covered with green basic nitrate, and when dipped into dil. potassium carbonate forms blue needles of cupric hydroxide. E. Julius used calcium carbonate. G. de Bechi prepared the same compound by adding zinc or magnesium oxide or hydroxide to soln. of cupric salts ; C. Millberg used manganous hydroxide. E. M. Péligot obtained cupric hydroxide by the action of a large proportion of water or cupric ammino-nitrite on an ammoniacal soln. of cupric nitrate. J. M. van Bemmelen diluted with an excess of water, the soln. obtained by exposing copper and ammonia to air.

F. Bullnheimer and E. Seitz added ammonia to a boiling soln. of cupric sulphate until a blue precipitate was formed, and then added a soln. of alkali hydroxide. T. Graham dialyzed the liquid obtained by adding potassium hydroxide to a soln. of cupric chloride and sugar, and obtained a green colloidal soln. of cupric oxide. R. Ludwig mixed gum arabic and added an excess of alkali hydroxide, when a deep blue colloidal soln. of cupric hydroxide was formed. B. Szilard peptized cupric hydroxide by adding it to a boiling 2 per cent. soln. of thorium or uranyl nitrate. The resulting colloidal soln. was blue or green. E. Grimaux dialyzed Schweigger's liquid and also decomposed it by five or six volumes of water, or by small quantities of magnesium, calcium, or aluminium sulphate, acetic acid, or by heating it to 40° or 50°. In the latter case, the precipitate slowly dissolves on cooling. A soln. of native cupric oxide or carbonate in an aq. soln. of an amine; or better, a mixture of amine and aqua ammonia, when heated, forms cupric hydroxide. If the oxides of zinc, cadmium, cobalt, nickel, etc., are also in soln., the hydroxides are precipitated consecutively as the temp. rises—for example, zinc hydroxide separates at 95°, cupric hydroxide at 100°, and silver hydroxide at a still higher temp. A. Gutbier obtained a yellow unstable hydrosol of cupric hydroxide by treating a very dil. neutral soln. of cupric sulphate with hydrazine hydrate. K. Elbs, and R. Lorenz prepared cupric hydroxide by electrolyzing a soln. of potassium nitrate or sodium sulphate with a rotating copper anode.

The properties of cupric hydroxide.—Cupric hydroxide prepared as just described appears as a blue hydrogel or in blue crystals—macro- or micro-scopic. It also forms colloidal sols. The hydrogel dries to greenish-blue friable lumps, with a conchoidal fracture. According to H. G. F. Schröder,[4] the sp. gr. of a sample derived from the action of aqua ammonia on cupric sulphate is 3·368. The dry mass and the crystals are fairly stable at ordinary temp., but, as noted by C. L. Berthollet, the hydrogel standing under water is more or less dehydrated, forming first a green, then a brown, and finally a black more or less hydrated oxide; E. Harms says that the hydrogel can be heated over 100° without change under liquids which exercise no chemical action on the product; and M. Schaffner says that the product dried over quicklime can be heated to over 100° without change. According to H. E. Schenck, copper oxide, precipitated together with alumina by a slight excess of sodium hydroxide from a soln. of copper and aluminium sulphates, is light blue in colour after drying at 110°. On heating successively in a Bunsen flame and a blowpipe flame, the colour changes to light greyish-blue if the mixture does not contain more than 5 per cent. of copper oxide. With 10 per cent. of copper oxide the mixture shows signs of blackening in the blowpipe flame. H. E. Schenck believes that alumina stabilizes the blue oxide, and that the change from blue to black is due to an agglomeration of the particles. N. G. Chatterji and N. R. Dhar also found that blue cupric hydroxide is stabilized by the presence of a trace of undecomposed cupric salt.

The dehydration under water is dependent (i) on the temp.—*e.g.* W. Spring and M. Lucion found freshly precipitated hydrogel which had a composition corresponding with $CuO.2H_2O$, formed the black product when kept at 15° for nine months; at 30°, in 96 hrs.; at 38°, in 38 hrs.; and over 54°, a lower hydrate is usually formed. As shown by J. L. Proust, the dehydration is also dependent (ii) on the nature of the salts in the soln.—thus, D. Tommasi found the dehydration to occur in a 5 per cent. soln. of sodium carbonate at 50°; 10 per cent. soln. of potassium chloride at 71°; 10 per cent. soln. sodium hydroxide at 74°; water at 77°; 10 per cent. soln. of sodium acetate at 79°; 10 per cent. soln. of sodium sulphate at 79°; one per cent. soln. of sodium hydroxide at 83°; 0·5 per cent. soln. of sodium hydroxide at 85°; 10 per cent. soln. of potassium bromide or of potassium chlorate at 85°; and 10 per cent. soln. of potassium iodide at 86°. In the presence of calcium chloride, manganese sulphate, and sugar, cupric hydrogel remains unchanged at 100°—only a trace of manganese sulphate is needed to hinder the formation of the black oxide. W. Spring and M. Lucion say that the chlorides of the univalent metals affect the action in the same way, and nearly half as slowly as chlorides of the bivalent metals. C. Ochsenius also found the sulphates of sodium, magnesium, and manganese to act similarly. According to J. M. van Bemmelen, the blue hydrogel is stable towards alkalies and alkali salts, but it precipitates bromides and iodides almost completely as basic cuprous salts. The fresher the preparation, the more vigorous the action. According to B. Kosmann, the ready dehydration of the hydrogel is connected with the low value of the heat of hydration. W. Spring and M. Lucion believe there is some relation between the dehydrating action of the alkalies and their osmotic press. J. L. Proust says that alcohol does not decompose the fresh or dried hydrate.

According to J. L. Proust, A. Chlodneff, E. Frémy, and W. Spring and M. Lucion, the hydrate is soluble in alkali-lye—at 15°, the latter say that a mol. of the hydrate is soluble in a soln. with 37 mols. of potassium hydroxide, or 32·5 of sodium hydroxide, and H. W. Fischer adds that the solubility of cupric hydroxide in soda-lye is less the more dil. the lye and that the solubility is affected but very slightly by sodium carbonate. According to E. Müller, an aq. soln. of sodium hydroxide, sp. gr. 1·345–1·370, or of potassium hydroxide, of sp. gr. 1·453–1·498, will just dissolve 0·78 grm. of cupric hydroxide per 100 c.c. The bright blue soln. does not give a precipitate when boiled directly, or when diluted. If a more dil. soln. of alkali be used to dissolve the cupric hydroxide, a soln. is obtained which is not stable when further diluted and boiled. The violet soln. obtained when cupric hydroxide is dissolved in $12N$-NaOH, gives a brown precipitate on standing, and it dissolves when more alkali is added, forming a brown soln. E. Müller does not think the explanation is due to colloids. but is rather due to the formation of a complex: $Cu(OH)_2+2OH'=CuO_2''+2H_2O$. The constant $K=[C_{OH^\cdot}]^2/[C_{CuO_2''}]$, and is approximately constant for 6·09 to $15·50N$-NaOH. E. Müller noted that after the soln. has stood a long time, it deposits the black oxide. N. G. Chatterji and N. R. Dhar stated that cupric hydroxide is peptized by sodium hydroxide, and there is no evidence of chemical combination. According to E. Müller, when cupric oxide or hydroxide is shaken with conc. soln. of sodium hydroxide, the amount dissolved depends on the conc. of the alkali. The maximum solubility is reached at about $15·8N$-sodium hydroxide and is about 0·4 mol of copper per litre in the case of the hydroxide and 0·05 mol in the case of the black oxide. On increasing the conc. of the alkali, the solubility suddenly falls in both cases to the same figure, and in $18N$-soln. there is practically no copper in soln. In soln. of lower conc. than $15N$, the stable solid phase is black cupric oxide, whilst with soln. of higher conc. it is **sodium cuprite,** which appears as a blue precipitate similar in appearance to cupric hydroxide, which, however, on warming the soln. in which it is produced and again allowing to cool, crystallizes. The crystals cannot be washed free from excess of alkali as they decompose into the black oxide in contact with an excess of water.

C. Arnold found that freshly precipitated cupric hydroxide is soluble in a sat. soln. of *potassium carbonate or hydrocarbonate.* The hydrate was also found by H. W. Fischer to be soluble in soln. of *sodium carbonate or hydrocarbonate.* The solubility of cupric hydroxide in alkali-lye is augmented by the presence of many organic substances—*e.g.* G. Städeler and W. Krause found *tartaric acid* very effective; B. Coray, *malic and citric acids;* J. Wolff and W. Weith, *salicylic acid;* E. Salkowsky, *milk* and *grape sugar;* F. Hofmeister, *glycerol, sarcosine, leucine, tyrosine,* and *glutaminic acid;* J. Löwe, *glycerol;* Kalle & Co., *albumenoids;* J. Rosenthal, *starch;* A. Vogel and C. Reischauer, *casein* and *soap.* A. C. Becquerel, E. P. Péligot, J. Peschier, J. L. Lassaigne, and E. Hunton studied the effect of *sugar* on the solubility in soln. of the hydroxides of the alkalies and alkaline earths. J. L. Lassaigne obtained a blue compound from a soln. containing sugar, cupric hydroxide, and potassium hydroxide. J. Rosenthal studied the effect of a *magnetic field* on the soln. containing cupric hydroxide and starch. E. Demoussy studied the compounds formed with starch and other carbohydrates. B. Moreau found cupric hydroxide soluble in a solution of *ammonium persulphate.* W. Bonsdorff has studied the solubility of cupric hydroxide in aqua ammonia, and in soln. of the ammonium salts. He found:

Ammonia . . .	2·540	1·965	1·280	0·973	0·870	0·540	0·391N
Grms. Cu per litre .	6·26	6·28	4·13	3·36	3·08	2·35	2·04

and A. Seyewetz and P. Trawitz found that when the soln. is boiled, nitrogen is evolved and cupric sulphate and ammonium hydrosulphate are formed. J. Tüttscheff obtained a basic salt by boiling cupric hydroxide with soln. of ammonium salts; H. von Helmolt obtained a double salt. M. Prud'homme studied the increased solubility of cupric hydroxide in alkali-lye, and in aqua ammonia in the presence of chromic salts. P. Jannasch and W. Cohen found cupric hydroxide to be soluble in hydroxylamine, and, according to A. Thum, and E. Francke, the hydroxylamine is slowly and incompletely oxidized in the cold, and the action is less energetic in the presence of potassium hydroxide. G. von Knorre and K. Arndt say some nitrous and nitric oxides are developed: F. Field, in cold soln. of sodium thiosulphate—on warming the soln. some of the solute is precipitated; H. Grossmann found cupric hydroxide is soluble in alkali cyanide, and C. F. von Reichenbach, in creasote.

Cupric hydroxide is readily soluble in acids. Carbon dioxide was found by P. N. Raikow[5] not to act on cupric hydroxide, but some of the colloidal forms were found by E. M. Péligot to absorb carbon dioxide from the air. G. Carrara and G. B. Vespignani say that cupric hydroxide is more feebly basic than magnesium hydroxide, but stronger than the hydroxides of zinc, cadmium, iron, or aluminium. According to A. Recoura, and P. Sabatier, it forms basic double salts with the metal sulphates. L. Mailhe says the hydroxide dissolves in soln. of most of the metal salts, forming basic salts which are usually amorphous; most of these so-called basic salts are possibly solid soln. D. Tommasi found a little sodium hydroxide is formed when cupric hydroxide is treated with a soln. of sodium carbonate or sodium chloride. W. Spring and M. Lucion found that when cupric hydroxide is agitated with a soln. of potassium bromide at 25°, some potassium hydroxide, $K_2O_2H_2O$, is formed, and that this then decomposes with the evolution of oxygen. J. M. van Bemmelen found the hydrogel does not decompose a 10 per cent. soln. of potassium bromide at 30° to 45°; and a 10 per cent. soln. of potassium iodide is slightly decomposed at 30°, and more so at 45°. A. Levol found that ferrous hydroxide forms ferric and cuprous hydroxides, and E. Braun that a neutral soln. of ferrous sulphate forms a basic ferric sulphate and cuprous hydroxide as a yellowish-brown precipitate; when an excess of a hot soln. of ferrous sulphate is used, a black precipitate is obtained. Cupric hydroxide is reduced by many organic substances as indicated under the preparation of cupric oxide and hydroxide. R. Herth found that cupric hydroxide desulphurizes thiourea in ammoniacal soln., and D. M. Kennedy used it for desulphurizing crude petroleum. Hydrogen peroxide was found by T. Bayley to give a yellowish-red product—probably a peroxide, *q.v.* A. Guyard says potassium ferrocyanide precipitates cuprous ferrocyanide even from soln. in ammonium tartrate. L. de Boisbaudran says that cupric hydroxide gives a precipitate with dil. soln. of gallium salts.

§ 12. Higher Copper Oxides

Anhydrous copper dioxide, CuO_2, is not known, but L. J. Thénard[1] prepared what is regarded as **monohydrated copper dioxide,** $CuO_2.H_2O$, by shaking cupric hydroxide with an excess of a very dil. alkaline soln. of hydrogen peroxide at 0°, washing the product with cold water, and drying it in vacuo by press. between filter paper. G. Krüss worked with conc. hydrogen peroxide at 6°; and W. Schmid believed that a trace of a ferrous salt is necessary for the oxidation, but G. Krüss showed that the ferrous hydroxide or salt accelerates the oxidation, which proceeds in its absence if the cupric hydroxide be finely divided. T. B. Osborne noted that when a small proportion of hydrogen peroxide is used, the blue hydrogel becomes green, and, with increasing proportions of hydrogen peroxide, the green colour changes to yellowish-green, yellow, and brown. The proportions CuO : O in the differently coloured products are :

	Grass-green.	Yellowish-green.	Yellow (green tinge).	Yellow.	Yellowish-brown.	Brown (yellow tinge).	Brown.
CuO : O	12·2 to 12·7 : 1	7·5 : 1	5·14 : 1	3·1 : 1	1·66 : 1	1·48 : 1	1·2 : 1

The products indicated on the left of this table are presumably mixtures of reddish-brown $CuO_2.H_2O$ with blue hydroxide $Cu(OH)_2$. L. Moser prepared the hydrated dioxide by the action of hydrogen peroxide in neutral soln., and washing the product many times by decantation with ice-cold water until the washings were free from hydrogen peroxide by the titanium sulphate test; the product was then washed with alcohol, then with ether, and dried in vacuo. The last traces of ether were retained very tenaciously. C. Weltzien prepared the same compound by adding hydrogen peroxide to a soln. of cupric tetrammino-sulphate; L. J. Thénard, cupric nitrate; and A. Gawalowsky, basic cupric sulphate. D. Vitali obtained a brownish-black precipitate by adding bromine to a soln. of a cupric salt. A. Piccini adds that a true peroxide cannot be obtained by the action of chlorine or bromine on alkaline soln. of cupric salts, and L. Moser found that oxygen is developed during the reaction and the washed product had CuO : O=73 to 79 : 1; and with cupric hydroxide suspended in water, gave a product with CuO : O=64 to 95 : 1. Hence he added that probably a higher oxide is formed as a primary product which rapidly decomposes.

W. Schmid obtained a similar product by shaking cupric sulphate with recently precipitated manganese hydrated dioxide, or lead dioxide, but L. Moser says manganese or lead peroxide forms no copper dioxide under these conditions; nor could L. Moser make the dioxide by the action of chlorine or bromine in alkaline soln., although there is evidence of the formation of an unstable dioxide; ozone was found to have no action on cupric salts; and persulphates in alkaline soln. did not oxidize cupric hydroxide (*vide infra*). B. C. Brodie obtained a higher peroxide by adding sodium peroxide to an excess of a cupric salt soln., but L. Moser found the cupric dioxide could not be isolated because of its rapid catalytic decomposition in alkaline soln. G. Krüss considers that B. C. Brodie's product was a mixture of cupric hydroxide and dioxide, and he obtained the hydrated dioxide by the action of octohydrated sodium peroxide on $\frac{1}{2}N$-$CuSO_4$ soln, cooled by ice-water. L. Moser obtained copper dioxide by the action of ozone on cupric hydroxide in the presence of soda-lye—the product decomposed immediately into oxygen and cupric oxide. E. Bamberger suggested the brownish-black precipitate obtained by adding alkali to a soln. of cupric sulphate, in the presence of Caro's reagent, is a hydrate of cupric dioxide.

Analyses by L. J. Thénard, G. Krüss, C. Weltzien and L. Swiontkowsky indicate that the brown or brownish-black microcrystalline mass has in the limiting case a composition corresponding with $CuO_2.H_2O$; G. Krüss represents the formula graphically: HO.Cu.O.OH. The green or greenish-brown products are probably mixtures of cupric hydroxide with hydrated cupric dioxide. The product obtained by the action of hydrogen peroxide on cupric hydroxide always shows a deficiency of peroxidic oxygen which is due either to the instability of the cupric peroxide or to the inclusion of cupric hydroxide. Either no precipitation occurs when soln. of cupric salts, alkaline soln., or ammoniacal soln. are treated, or else the precipitate is rapidly decomposed. J. Aldridge and M. P. Applebey found that when a soln. of sodium cupric carbonate, in a sat. soln. of sodium carbonate or hydrocarbonate, is treated with hydrogen peroxide, a yellowish-brown peroxide is immediately formed and most of the copper is removed from the soln. The product contains more oxygen than corresponds with copper sesquioxide, but never reaches that required for copper dioxide. This is due to the decomposition of the dioxide in the presence of the alkaline soln.

The product has no taste, and is without action on litmus; when dry, it is fairly stable, but less stable when moist—L. J. Thénard's sample was completely decomposed after keeping 12 hrs. at ordinary temperatures; boiling water decomposed it immediately. The decomposition is accelerated by the presence of conc. alkali-lye. The dioxide was found by L. J. Thénard to be decomposed below 100° into oxygen and cupric oxide; G. Krüss found that the samples he prepared did not change colour at 170° in 10 hrs., but at 180° decomposed to cupric oxide; L. Moser found that specimens with a trace of ether may decompose explosively when heated. The compound is insoluble in water; readily soluble in dil. acids, forming cupric salts and hydrogen peroxide, and the evolution of a little oxygen. With conc. hydrochloric acid oxygen and chlorine are given off; and with dil. hydrochloric acid, in the presence of copper, gold, or mercury, C. Weltzien obtained very little oxygen, but there was formed respectively cupric, auric, or mercurous chloride. L. Moser found that with finely-divided platinum oxygen is evolved; a soln. of potassium permanganate is decolorized; and it acts catalytically on a neutral or alkaline soln. of hydrogen peroxide. L. Moser concluded that the chemical behaviour of cupric dioxide resembles that of a true peroxide, although it may be readily a compound of cupric hydroxide and hydrogen peroxide.

Copper sesquioxide, or cupric anhydride, Cu_2O_3.—This compound is not known in the free state. M. Krüger noticed that when chlorine is passed into alkali-lye in which cupric hydroxide is suspended, gas is evolved, and the soln. reddens owing to the formation of a higher oxide of copper. Such an oxide, however, has not been isolated from these products. E. Müller and F. Spitzer,[2] L. Moser, and F. Mawrow, working at low temp., succeeded in separating cupric hydroxide from the red soln. A trace of active oxygen was present, and this L. Moser regarded as a sign that the primarily formed dioxide has been almost completely decomposed. J. Aldridge and M. P. Applebey said that the pink colour is produced by the formation of permanganates by traces of manganese present as impurity in the soln. By treating cupric hydroxide with potassium hypochlorite, E. Frémy noted the formation of a brown soln. which, on dilution, gave off oxygen and deposited cupric oxide. E. Müller also obtained the same product by the action of alkali hypochlorites or hypobromites on cupric hydroxide; during the reaction the colour changes from sky-blue to a greyish-blue, a brownish-blue, and a bluish-black; if the soln. is very strongly alkaline, the colour becomes carmine red, violet, and finally brownish-black. W. Crum, and also M. Krüger, treated cupric nitrate with bleaching powder. The oxygen evolved by the product corresponded with that required by the equation: $2Cu_2O_3=4CuO+O_2$. The carmine-red precipitate which gradually becomes rose-coloured is assumed by W. Crum to be **calcium cuprate,** $CaCu_2O_4$, the calcium salt of **cupric acid,** $H_2Cu_2O_4$, which has the constitutional formula, HO.Cu.O.Cu.O.OH. The evidence available is not sufficient to establish the formula with any degree of certainty. M. Krüger prepared **barium cuprate,** $BaCu_2O_4$, in a similar manner; and T. B. Osborne made some observations on the cuprates of the alkaline earths. J. Aldridge and M. P. Applebey said that the compounds with the alkaline earths are chemical individuals, and not, like M. Krüger's alkali compounds, mixtures with impurities.

The rose-red coloured liquid obtained by E. Frémy during the dissolution of brass (low in zinc) in nitric acid is supposed to contain a higher oxide of copper. G. Krüss dissolved cupric oxide in molten potassium hydroxide; when the mass is dissolved in water at 18°, a blue liquid is obtained which deposits a mixture of what is thought to be cupric oxide and a yellow higher oxide. The liquid is stable on boiling, but is decolorized by shaking it with the oxides of copper or lead, but not zinc or mercury oxide; soln. of salts of the alkaline earths, magnesium, aluminium, chromium, iron, cobalt, or nickel. G. Krüss obtained a similar product as a yellow precipitate by working at 0°. The same product was obtained by using alkali chlorides in place of the alkali hydroxide. G. N. Antonoff and B. V. Malysheff found that when copper or copper oxide is dissolved in melted potassium hydroxide above 360°, the resulting cake, when dissolved in water and neutralized, decolorizes permanganate solution. The soln., however, gives no reaction for peroxides, and continues to decolorize permanganate when a current of hydrogen is passed through it. This decolorizing action is due to the presence of cuprous oxide, Cu_2O, formed by the dissociation of cupric oxide above 360°.

When potassium or hydrogen peroxide is added to the soln. of copper oxide in potash, a red colour is first produced which vanishes quickly; then a yellow precipitate separates, which also redissolves, quickly reproducing the original blue soln., which now contains no trace of either peroxide or cuprous oxide. The yellow precipitate is **copper dioxide,** $CuO_2.H_2O$, or $CuO.H_2O_2$, its production being a first stage in the decomposition of the peroxide by copper oxide. This reaction is vigorous only in alkaline soln. Commercial potash contains some peroxide, and whilst, when acting on iron, the latter is converted into ferrous oxide, at the expense probably of the water present in the potash, the action on copper and also on silver is due to the presence of these peroxides.

Contrary to the statement of L. Moser (*vide supra*), G. Scagliarini and G. Torelli found that the action of potassium persulphate on cupric hydroxide in presence of barium hydroxide at temp. obtained by cooling with ice and salt results in various changes in the colour of the soln. and in the deposition of a tenuous amaranth-red precipitate, which may be purified by repeated washing with ice-water by decantation. The compound thus obtained yields oxygen when treated with sulphuric acid, and the amount of oxygen is in agreement with the formula Cu_2O_3; it oxidizes hydrochloric acid with liberation of chlorine, oxidizes ammonia in the cold with production of nitrogen, nitrous acid, and traces of nitric acid, decolorizes permanganate, and decomposes potassium iodide with liberation of iodine in quantity greater than that corresponding with the proportion of copper present. Since it does not yield hydrogen peroxide when treated with dil. acid, the compound lacks the grouping characteristic of peroxides, and is thus different from the orange-yellow copper peroxide obtained by means of hydrogen peroxide.

B. Brauner and B. Kuzma obtained an intense red coloration by the oxidation of a soln. containing copper and tellurium with potassium persulphate—if an excess is used the colour is destroyed. The coloration is attributed to the formation of a derivative of *tellurocupric acid.* By processes of hydrolysis, unstable dark red precipitates of *potassium tellurocuprates,* $2K_2O.Cu_2O_3.3TeO_3.nH_2O$, and $2K_2O.CuO.Cu_2O_3.3TeO_3.nH_2O$. The last-named product has also been obtained by the electrolytic oxidation of telluric acid in an alkaline soln., with a copper anode. *Silver telluroargentate* has also been obtained, $Ag_2O.5Ag_2O_3.9TeO_3$

L. Moser thinks that cupric sesquioxide is possibly an intermediate product in the slow decomposition of copper dioxide; and J. Meyer obtained indications of the formation of a higher oxide by shaking ammoniacal cupric sulphate with water and air. The product obtained by A. V. Brochet by heating a conc. soln. of cupric chlorate with copper turnings is thought to be the sesquioxide. According to E. Müller and F. Spitzer, an orange-yellow to red coloured film is obtained by electrolyzing with a copper anode and a platinum cathode in a porous cell, a soln. 12 to $14N$-NaOH, cooled by a freezing mixture, and with a current density less than 0·1 amp. per sq. cm. The product is stable at a low temp. under the soda-lye, but it gives off oxygen and becomes white when warmed; it oxidizes hydrochloric acid, forming chlorine; converts nitrites to nitrates; and oxidizes alcohol to aldehyde. A. C. Becquerel, and F. Schmiedt have also studied the formation of the higher copper oxides during the electrolysis of alkali-lye.

§ 13. Cupric Ammino-oxides

L. Maumené[1] says that it is very doubtful if a definite compound of ammonia and cupric oxide has been prepared, although R. Kane claimed that when aqua ammonia, not in excess, is added to a soln. of cupric chloride, a blue precipitate resembling hydrated cupric oxide is obtained. This precipitate is said to be easy to wash, and not to lose ammonia on drying; it undergoes no change at 149°, but at a somewhat higher temp., it decomposes with a slight hissing noise, yielding nitrogen, ammonia, water, and a red mixture of copper and cuprous oxide. No chlorine appeared in the analysis which agreed with the formula: $3CuO.4NH_3.6H_2O$, that is, **hexahydrated tricupric tetrammino-oxide.** From their study of the soln. obtained by digesting freshly precipitated cupric hydroxide in aq. ammonia, H. M. Dawson and J. McCrae believe that a dissociating compound, *cupric diammino-oxide*, $CuO.2NH_3$, or **cupric diammino-hydroxide,** $Cu(OH)_2.2NH_3$, is formed, which ionizes, forming $Cu(NH_3)_2^{\cdot\cdot}$ and OH'-ions, *i.e.* $Cu(OH)_2+2NH_3 \rightleftharpoons Cu(NH_3)_2^{\cdot\cdot}+(OH)_2''$. The work of W. Bonsdorff on the electrical conductivity of soln. of cupric hydroxide in aq. ammonia points in the same direction when only a small excess of ammonia is present; but with a large excess of ammonia, the complex is probably $Cu(OH)_2.4NH_3$, **cupric tetrammino-hydroxide.** F. J. Malaguti and M. Sarzeau claim to have obtained large azure-blue deliquescent needles of tetrahydrated cupric tetrammino-oxide, $CuO.4NH_3.4H_2O$, by cooling the mother liquid obtained in the preparation of cupric ammino-chromate. The crystals are said to be decomposed by water, and by exposure to air; and when heated, to give off water and ammonia, and leave a residue of copper.

From his study of the heat of neutralization, W. Bonsdorff estimates cupric ammino-oxide to be a stronger base than either of its components, and to be weaker than silver or cadmium oxides, but stronger than zinc oxide. A. Bouzat found that it displaces ammonia from its salts, it precipitates calcium oxide, and enters into competition with potassium hydroxide for the acids. For the heat of formation in soln. containing two mols. of ammonia per litre, CuO (precipitated)$+28NH_3$ (in soln.)$=CuO, 28NH_3$ (in 14 litres of soln.)$+4{\cdot}3$ Cals.; and the heat of neutralization of $CuO.28NH_3$ in 14 litres of soln. with two mols. of acid in 4 litres, is 35·5 Cals. for sulphuric acid; 32·1 Cals. for hydrochloric acid; 31·8 Cals. for nitric acid; and 30·0 Cals. for acetic acid. Variations in the conc. of the ammonia or of the soln. have very little influence on the heat of neutralization.

An azure-blue soln. of cupric ammino-oxide is formed by exposing the soln. of cuprous ammino-oxide to air, the colourless soln. then becomes blue as recorded by T. O. Bergman[2] in the eighteenth century. The same soln. was made by E. M. Péligot, E. Schweizer, and others by exposing copper filings to the action of aq. ammonia and air. J. J. M. A. Vermeesch has described a continuous process. An ammoniacal soln. of cupric oxide is often called *Schweizer's reagent*, or **Schweizer's liquid**; a soln. of copper hydroxide in alkali-lye has many similar properties which were studied by W. Traube. According to C. F. Schönbein, some ammonium nitrite, and, according to F. J. Malaguti and M. Sarzeau, some ammonium nitrate is always formed at the same time; while M. Berthelot noted that oxygen is absorbed by the soln. Several patents have been obtained for the process—*e.g.* Société Anonyme de Bruxelles, E. Bronnert, M. Fremery, and J. Urban, C. L. and A. Schäffer, etc. The same soln. is obtained by treating cupric oxide or hydroxide with aq. ammonia. J. J. Berzelius says that if all acids, even carbonic acid, be excluded, the aq. ammonia dissolves scarcely a trace of the anhydrous oxide, but if a drop of a soln. of an ammonium salt be present, cupric oxide is copiously dissolved. E. Schweizer found the soln. is promoted by adding some ammonium chloride to the aq. ammonia, and H. Kopp found that platinic chloride acts in the same way. The liquid no doubt contains one or more cupric ammino-oxides. W. Bonsdorff's investigation on the electrical conductivity agrees with the assumption that the liquid contains a complex with ammonia and copper in the molecular proportion 4 : 1, and A. Hantzsch and P. W. Robertson's investigation with the spectral photometer likewise indicates that the non-isolated base has the composition $[Cu(NH_3)_4](OH)_2$. M. Prud'homme obtained the blue liquid by treating copper with ammonium nitrate in the presence of aq. ammonia; and H. M. Dawson and J. McCrae by using cupric oxide or nitrite with aq. ammonia and air, and they add that ordinary cupric oxide appears to be dissolved more easily than the oxide obtained by precipitation. W. Bonsdorff found that cupric hydroxide which has been dried dissolves less readily than the fresh and moist hydroxide. A. Froment patented the use of aq. ammonia sat. with nitrogen, which it is claimed dissolves cupric oxide more quickly than when free nitrogen is absent. A. Lecœur, and E. Grimaux recommend removing the nitrites and other crystallizable compounds from the soln. by dialysis. W. Bonsdorff recommends removing the excess of ammonia by keeping the soln. in vacuo over conc. sulphuric acid—hydrogen and air freed from carbon dioxide act too slowly, nor is there any advantage in shaking out with chloroform.

E. Grimaux says the soln. is colloidal, and A. Lecœur adds that if only colloids are present, as is the case when the product has been dialyzed, the liquid does not change at ordinary temp. According to A. Bouzat, the blue liquid gradually changes on exposure to air into cupric nitrite and carbonate. H. M. Dawson and J. McCrae say that a $0{\cdot}08N$-soln. containing the molecular proportion $CuO : NH_3 = 1 : 7$, gradually deposits cupric hydroxide. When E. Schweizer's liquid is diluted with a large proportion of *water*, cupric hydroxide is deposited; a soln. of *potassium hydroxide* likewise precipitates the same compound, and more is needed for the precipitation the greater the excess of ammonia in Schweizer's liquid. According to A. Bouzat, the potassium and ammonium hydroxides attain a state of equilibrium in competing for the complex acidic radicle; on boiling the liquid with potassium hydroxide, black cupric oxide is precipitated. Almost all the copper was found by A. Vogel to be precipitated as reddish-brown cuprous oxide by treating Schweizer's liquid with *sulphur dioxide*. According to N. W. Fischer, *phosphorus* decolorizes the blue soln., forming metallic copper, along with a compound of ammonia and cuprous oxide, and, according to A. Oppenheim, a little copper phosphide. *Zinc* and *cobalt* precipitate the copper; *iron* precipitates the copper imperfectly; *arsenic*, *tin*, and *cadmium* precipitate very little copper; and *lead* precipitates mere traces of copper. G. Wetzlar says iron exerts no action on the pure soln., but there is a slow precipitation of copper if ammonium or sodium chloride, or potassium nitrate or sulphate, be present. A large excess of ammonia prevents the precipitation. According to M. Prud'homme, *indigo* soln. are bleached by Schweizer's liquid. G. Rosset found it to be deoxidized when used as depolarizer in a galvanic cell, and to be reoxidized by exposure to air. When electrolyzed it also gives metallic copper. C. R. A. Wright and C. Thompson found that if a copper plate be dipped in the ammoniacal soln., and connected electrically with a platinum plate, a current of from 0·5 to 0·6 volt is obtained; the voltage is higher if spongy platinum be used, and also higher the greater the conc. of the ammonia. W. Traube and A. Biltz found that ammonium nitrite is formed during electrolysis. C. E. Guignet found that *sugar* soln. do not precipitate the copper and that starch and inuline abstract cupric oxide from the soln.

E. Schweizer showed that unlike *eau céleste*—a soln. of cupric sulphate in an excess of ammonia—the liquid dissolves cellulose at ordinary temp. without the development of heat. The action has been studied by E. M. Péligot, C. Cramer, O. L. Erdmann, M. Payen, A. Haller, W. Minajeff, E. Frémy, J. Schlossberger, W. Massot, H. Baubigny, E. Grandmougin, etc.; and it has been the subject of numerous patents—by J. P. Bemberg, H. Pauly, E. Krusche, etc. The addition of acids, sugar, or gum re-precipitate the cellulose. E. Winterstein found that E. Schweizer's liquid dissolves animal cellulose—*e.g.* tunicine; G. Büttner and J. Neuman, C. G. Schwalbe, that it dissolves hydrocellulose—but E. Bronnert said not so; W. von Bongé that it dissolves nitrocellulose; C. Cramer, inuline and gum arabic; O. Popp, inuloid; and A. Helbronner and E. A. Vallée, osseine. J. Schlossberger said that it does not dissolve gun-cotton; E. Frémy, nor paracellulose, vasculose, fibrine, and cutine; F. A. Flückiger and O. Obermeier, nor Irish moss; W. Meigen and A. Spreng, nor yeast-cellulose. E. Thiele obtained soln. of cupric oxide in alkylamines—*e.g.* methylamine—which dissolved cellulose.

§ 14. Copper Fluorides

According to H. Moissan,[1] fluorine gas acts on copper at a dark red heat forming white clouds of cupric fluoride, but anhydrous hydrofluoric acid, according to C. Poulenc, has scarcely any action on the metal. There are two definite fluorides —cuprous fluoride, CuF, and cupric fluoride, CuF_2.

Cuprous fluoride, CuF.—J. J. Berzelius (1824)[2] prepared a compound which he regarded as cuprous fluoride by the action of an excess of aq. hydrofluoric acid on cuprous hydroxide; the very sparingly soluble salt was rapidly washed with alcohol, pressed, and dried. C. Poulenc (1892), and F. Mauro (1892) were unable to make cuprous fluoride by this process, for they obtained metallic copper and a soln. of cupric fluoride which does not reduce potassium permanganate; they therefore consider that J. J. Berzelius' product was nothing but cupric fluoride and the metal: $2CuOH+2HF=2H_2O+Cu+CuF_2$. F. Mauro could not obtain this salt by passing a stream of hydrogen fluoride and carbon dioxide over heated cuprous oxide; nor did A. G. Betts make it by the action of copper on cupric fluoride. C. Poulenc, however, prepared cuprous fluoride by the action of hydrogen fluoride on cuprous chloride heated to dull redness; the action is complete only when the temp. is between 1100° and 1200°, and near the volatilization temp. of cuprous fluoride. The same compound is obtained by heating anhydrous cupric fluoride to 600° in a stream of hydrogen fluoride, and then raising the temp. between 1100° and 1200° towards the end of the operation.

Cuprous fluoride forms a ruby-red crystalline mass which, according to T. Carnelley, melts at 908°; and, according to C. Poulenc, sublimes between 1100° and 1200° to a dusty red powder. Cuprous fluoride is stable in dry air, but in ordinary air, it is converted into cupric fluoride, and the mass acquires a blue colour; the conversion is much more rapid in contact with water, in which menstruum, says C. Poulenc, cuprous fluoride is insoluble. Cuprous fluoride is insoluble in alcohol at 90°; it is insoluble in hydrofluoric acid; but soluble in conc. hydrochloric acid, and, according to C. Poulenc, unlike cuprous chloride under similar conditions, it is not precipitated when the soln. in boiling conc. hydrochloric acid is diluted. J. J. Berzelius says it is precipitated, but he was possibly dealing with a mixture containing some cuprous chloride, not fluoride. Cuprous fluoride is only slightly attacked by sulphuric acid, even when heated; but nitric acid acts energetically with the evolution of nitrogen oxides. Heated in air, cuprous fluoride is converted into the oxide, and it is easily reduced by hydrogen at a red heat. At 400°, it forms cupric oxide, and hydrogen fluoride with water vapour; cupric sulphide with hydrogen sulphide; and cuprous chloride with hydrogen chloride. When fused with alkali carbonates it is converted into alkali fluoride and cupric oxide.

Cupric fluoride, CuF_2.—H. Moissan[3] made this salt by the action of fluorine on metallic copper; A. G. Betts, by the action of finely-divided copper on ferric fluoride; C. Poulenc, by the action of hydrogen fluoride on cupric oxide at 400°, and by the action of hydrogen fluoride on dihydrated cupric fluoride, CuF_22H_2O, below 500°. An amorphous powder is obtained by fusing dihydrated cupric fluoride with ammonium fluoride at 260° in a stream of carbon dioxide to remove the excess of ammonium fluoride. This powder readily becomes crystalline when heated in a stream of hydrogen fluoride to 500°. A. Pochettino found the order of activity for the **photoelectric effect** with the cupric halides is CuI_2, 39; $CuBr_2$, 32; $CuCl_2$, 20; CuF_2, 3. The order of increasing stability is the order of decreasing photoelectric effect.

Cupric fluoride forms small white crystals which on exposure to moist air become blue owing to the absorption of water; the crystals likewise become blue when placed in ether or alcohol containing traces of water. The salt is soluble in water, and in hydrofluoric, hydrochloric, or nitric acid; with hot sulphuric acid it forms cupric sulphate. When heated above 500°, cuprous fluoride is formed; the dissociation: $2CuF_2 \rightleftharpoons 2CuF+F_2$, is not complete below 1100°. Cupric fluoride is completely converted into cupric oxide when heated in air to 300°; and it is readily reduced by hydrogen; water vapour converts the hot fluoride into hydrogen fluoride and cupric oxide; sulphuric acid, into cupric sulphate; and hydrogen chloride, into cupric chloride. J. Schröder found cupric fluoride to be soluble in pyridine; A. Naumann, soluble in ethyl acetate; and G. Gore, insoluble in liquid ammonia. N. G. Chatterji and N. R. Dhar found that cupric fluoride is not peptized by sodium hydroxide soln. in the presence of glycerol or sugar.

Dihydrated cupric fluoride, $CuF_2.2H_2O$.—Blue crystals of this salt were made by C. W. Scheele,[4] by J. L. Gay Lussac and L. J. Thénard, and by J. J. Berzelius by evaporating the blue soln. obtained by treating cupric oxide or carbonate with an excess of hydrofluoric acid. According to J. J. Berzelius:

> If the copper carbonate be treated with hydrofluoric acid, it will dissolve with effervescence, but a salt is soon precipitated as a heavy powder; if the addition of carbonate be continued, the effervescence continues, and the salt already formed decomposes, especially if the mixture be warmed, and a pulverulent basic salt is produced. If the addition of carbonate be discontinued before the basic salt is formed, and the soln. evaporated, a crystalline crust is formed. . . . In this process, the excess of acid contained by the dissolved salt is given off. If the crystalline salt be covered with a small proportion of water, and allowed to stand at room temp. for a long time, a sat. soln. is obtained which deposits crystals of the same salt on evaporation; but if the mixture is heated to the b.p. with a large proportion of water, the salt is decomposed, part dissolves in the liberated acid, and part remains undissolved as a basic salt.

L. Balbiano obtained J. J. Berzelius' dihydrated fluoride by treating the blue soln. with 95 per cent. alcohol; washing the precipitated crystals with hot alcohol; and drying them over conc. sulphuric acid in vacuo. J. J. Berzelius' analyses of the crystals correspond with $CuF_2.2H_2O$.

E. Böhm evaporated a conc. soln. of cupric oxide or carbonate in hydrofluoric acid, in vacuo over sulphuric acid, and obtained pale-blue monoclinic pleochröic crystals of **hydrated cupric pentahydroheptafluoride,** $CuF_2.5HF.5H_2O$, or, more probably $CuF_2.5HF.6H_2O$. F. H. Edmister and H. C. Cooper preferred to make the fluoride with cupric hydroxide because it reacts faster than the carbonate. The soln. precipitates a basic salt on standing exposed to air, but the product redissolves in more acid. If the soln. be evaporated slowly, small irregular blue crystals are deposited, but if evaporated quickly, a clear crystalline crust appears; both products have the same composition—$CuF_2.2H_2O$. These crystals are sparingly soluble in water, and a white crust forms on the surface, but if dissolved in an excess of warm water, and evaporated, well-defined prismatic monoclinic crystals of hexahydrated cupric pentahydroheptafluoride, $CuF_2.5HF.6H_2O$, are formed. The refractive indices are $\alpha=1{\cdot}395$; $\beta=1{\cdot}440$; $\gamma=1{\cdot}444$; and the crystals are not isomorphous with those of the analogous salts of cobalt, nickel, and manganese. These crystals are very soluble in water and dil. acids; they effloresce rapidly and lose hydrogen fluoride when exposed to air; when heated, they lose water and hydrogen fluoride, and, as E. Böhm showed, are converted into oxides—it is assumed that hydrogen fluoride is lost first, and that the water of crystallization hydrolyzes the cupric fluoride.

According to E. Peterson, the heat of neutralization, $Cu(OH)_2+2HF=20{\cdot}17$ Cals.; and in dil. soln., the heat of formation, $Cu+F_2+aq=CuF_2aq.=89{\cdot}6$ Cals. M. Berthelot found the heat of the displacement of chlorine by fluorine in soln. of cupric chloride to be 27·1 Cals. The blue crystals of dihydrated cupric fluoride pass into the oxyfluoride after standing some days. The crystals are very soluble in water. A. Jäger noticed the solubility is diminished by the addition of alkali fluorides. This is taken to prove the non-existence of complex fluorides. The aq. soln. is hydrolyzed, and a basic salt or an oxyfluoride is precipitated.

The basic salt, prepared as described above by J. J. Berzelius, corresponded with **hydrated cupric oxyfluoride,** $Cu_2OF_2.H_2O$, or **cupric hydroxyfluoride,** $Cu(OH)F$. L. Balbiano attempted to make cupric fluoride by the double decomposition of cupric sulphate and potassium fluoride, but obtained instead a soln. of potassium cupric sulphate, $K_2Cu(SO_4)_2$, and a greenish-white precipitate of the oxyfluoride: $2KF+2CuSO_4+H_2O=CuK_2(SO_4)_2+HF+Cu(OH)F$. L. Balbiano also made the same compound by heating cupric fluosilicate, $CuSiF_6.6H_2O$, above 100°. When this oxyfluoride is heated in air, it passes into cupric oxide. H. Moissan obtained a black mass of what was regarded as the anhydrous oxyfluoride, Cu_2OF_2 or $CuO.CuF_2$, by the action of fluorine on copper oxide or sulphate at a red heat.

L. Balbiano's attempts to make an ammino-fluoride were not successful, for although he found that ammonia is absorbed in accord with: $CuF_2.2H_2O+2NH_3=CuF_2(NH_3)_2+2H_2O$, the oxyfluoride was always obtained. Similarly, if ammonia be conducted over hydrated cupric oxyfluoride, $Cu_2OF_2.H_2O$, or hexahydrated cupric fluosilicate, $CuSiF_6.6H_2O$, much ammonia is absorbed, and **hydrated cupric tetrammino-oxyfluoride,** $Cu_2OF_2.4NH_3.H_2O$, is formed. This compound may also be formulated as *cupric diammino-hydroxyfluoride,* $Cu(OH)F.2NH_3$, so long as the mol. wt. is unknown. The aq. soln. may give a precipitate of hydrated cupric oxyfluoride when treated with alcohol; or when the alcoholic soln. is heated to about 50°; or when the aq. soln. is evaporated to dryness.

H. von Helmholt[5] has prepared double fluorides of copper with ammonium, potassium, and rubidium. The salt, $CuF_2.2NH_4F.2H_2O$, *i.e.* **dihydrated ammonium cupritetrafluoride,** $(NH_4)_2CuF_4.2H_2O$, was obtained as a blue crystalline powder by the slow evaporation of a conc. soln. of ammonium fluoride almost sat. with freshly precipitated cupric hydroxide; or eq. quantities of the two carbonates in a large excess of hydrofluoric acid. The double salt is almost insoluble in water, and decomposes in contact with water into an insoluble white powder and soluble ammonium fluoride. It does not appreciably attack glass, but, according to J. Haas, it dissolves ferrosilicon, developing a gas—possibly H_2SiF_6—with the separation of copper; it has but a slight action on 80 per cent. ferromanganese. The **ammonium cupritrifluoride,** $CuF_2NH_4F.2\tfrac{1}{2}H_2O$, was made as a sparingly soluble bluish-white powder by mixing eq. quantities of copper and ammonium carbonates in hydrofluoric acid; or copper carbonate in an acid soln. of ammonium fluoride; or by treating an acid soln. of cupric fluoride with ammonium carbonate or aq. ammonia. **Potassium trifluorocuprate,** $CuF_2.KF$ or $KCuF_3$, and **rubidium trifluorocuprate,** $CuF_2.RbF$ or $RbCuF_3$, were similarly prepared.

§ 15. Copper Chlorides—Cuprous Chloride

In his paper, *Sur les muriates de cuivre verd et blanc* (1804), J. L. Proust[1] recognized two distinct forms of copper chloride, and these are the two typical chlorides of copper which, in to-day's nomenclature, are called cuprous chloride, $CuCl$; and cupric chloride, $CuCl_2$. Attempts have been made to establish the existence of two others—copper subchloride, Cu_2Cl, and cuprosocupric chloride, $CuCl.xCuCl_2$—but neither of these has been isolated in a pure state, and the evidence in both cases is somewhat dubious in the absence of a decisive test for a chemically homogeneous individual.

E. Wohlwill[2] claimed to have obtained indications of a *copper subchloride* of unknown composition by the electrolysis of hydrochloric acid with copper anodes. When a soln. of cuprous chloride in a conc. soln. of sodium chloride is treated with an excess of aqua ammonia, and the filtrate is allowed to stand for some days, a pale blue precipitate free from ammonia is deposited, which when pressed and dried over sulphuric acid, is claimed by M. Siewert to have the composition $2Cu_2Cl.CuCl_2.10H_2O$. J. H. Gladstone and A. Tribe also claim to have obtained indications of the formation of a subchloride by the action of a copper-silver or copper-platinum couple on a soln. of copper sulphate containing a chloride.

Cuprous chloride was first made by Robert Boyle,[3] in the middle of the seventeenth century, by heating *Venetian sublimate*—mercuric chloride—with copper plates in a retort. He noticed the formation of mercury, and that the plates were covered with a white crust which on further heating melted to a brittle mass, which, said he, " I can compare to nothing more fitly than a lump of good benjamin," and, again, to a " metalline gum." This product was later called Boyle's *resina cupri*, and *cuprum gummatosum*. In modern symbols, Boyle's reaction is symbolized: $HgCl_2+2Cu=2CuCl+Hg$. J. L. Proust prepared cuprous chloride by the action of stannous chloride on cupric chloride, and he called it *white muriate of copper*, and J. Davy called it *cuprane* in contrast with *cupranea* applied to cupric chloride in accord with a nomenclature suggested by H. Davy.

Cuprous chloride occurs in Chile as the mineral *nantokite*, or *nantoquite*, which is white or water-clear, and has a sp. gr. 3·93, and hardness 2·0–2·5. A. Lacroix[4] also found it in the fumaroles of Vesuvius in 1906.

The preparation of cuprous chloride.—1. *By the chlorination of copper or copper oxide.*—Copper foil or finely-divided copper, obtained by reducing the heated carbonate in a stream of hydrogen, burns in chlorine gas at ordinary temp., forming a mixture of cupric and cuprous chlorides—the former can be removed by washing the mass with water acidified with a little sulphurous acid. According to H. Gautier and G. Charpy,[5] liquid chlorine confined in a sealed tube along with a copper plate very slowly attacks metallic copper at 15°. Hydrogen chloride when dry does not act on copper at ordinary temp., but, according to M. Ribalkin,[6] the reaction proceeds slowly at 92°, and fairly rapidly at 230°. There is a condition of equilibrium: $2Cu+2HCl\rightleftharpoons2CuCl+H_2$, at 230°, 93 per cent. of the hydrogen chloride is decomposed; at 440°, 66 per cent. With hydrogen and cuprous chloride at 230°, about 5 per cent. of hydrogen chloride, is formed, and at 440°, about 35 per cent. According to M. Berthelot, the reaction proceeds more quickly if oxygen be present.

J. L. Proust[7] noticed that when a copper plate is immersed in hydrochloric acid, exposed to the air, it is soon covered with small white tetrahedral crystals of cuprous chloride. A. C. and A. E. Becquerel recommended sinking some charcoal with the copper in the acid. If hydrochloric acid be in contact with copper while exposed to air, the liquid becomes greenish-blue, and copper is gradually dissolved as cuprous chloride, and, according to W. Odling, hydrogen is formed. If an oxidizing agent—*e.g.* nitric acid, or potassium chlorate—be present, copper is rapidly dissolved by conc. hydrochloric acid at 70°–80°. The brown liquid first formed is soon decolorized. On cooling the soln., crystals of cuprous chloride are deposited, and when water is added to the soln. more cuprous chloride is precipitated. The precipitate can be washed by air-free water, or better, with water acidified with sulphurous acid. This process is recommended by S. Lupton.[8] Copper can also be chlorinated to cuprous chloride by treatment with a dil. soln. of ferric chloride or of potassium chromate in hydrochloric acid as recommended by H. V. Regnault. J. L. Proust, and R. Chenevix made cuprous chloride by dissolving cuprous oxide in hydrochloric acid under conditions where access of air was prevented. H. Schwarz used a solution of sodium chloride in place of hydrochloric acid. K. Heumann added a mixture of cupric oxide with half its weight of zinc-dust, in small quantities at a time, to hydrochloric acid. If a mixture of cupric oxide and ammonium chloride be pounded together in a mortar, or if strongly compressed, W. O. de Coninck and L. Arzalier found much cupric chloride is formed and ammonia evolved. W. Stahl converted cupric oxide or carbonate into a mixture of cupric and cuprous chlorides by treatment with a solution of ferrous chloride. C. E. Baker and A. W. Burwell prepared cuprous chloride by passing the vapour of sulphur chloride, SCl_2, over heated cupric sulphide.

2. *By the reduction of cupric chloride.*—As J. L. Proust [9] showed in 1799, when cupric chloride is heated to redness in the absence of air, it loses half of its combined chlorine, and forms cuprous chloride. J. L. Proust removed the unconverted cupric chloride by washing with water. A dil. soln. of sulphurous acid is better; thus, F. Wöhler (1864) and M. Rosenfeld (1879) recommend the following procedure:

A mixed soln. of 20 grms. of cupric sulphate and 4¼ grms. of potassium, sodium, or ammonium chloride in 300 c.c. of water is sat. with sulphur dioxide when cuprous chloride is slowly deposited as a white precipitate—an excess of sulphur dioxide retards the precipitation so that when the clear soln. is boiled to expel the excess of sulphur dioxide, a further quantity of cuprous chloride is deposited. The salt is purified by first washing it with sulphurous acid, then with glacial acetic acid, and finally drying it pressed between folds of filter paper, or porous tiles, in a warm place.

Cuprous chloride cannot be washed with water without decomposition, for as soon as the excess of acid is removed, a reaction: $8CuCl+O_2=2Cu_2O+4CuCl_2$, begins in the presence of air, and this is rendered evident by the orange-red coloration. Indeed, the cuprous chloride can be completely decomposed by this treatment. J. L. Proust exposed a mixture of ether and a soln. of cupric chloride to sunlight; a colourless liquid was obtained which by cooling or by treatment with water furnished cuprous chloride. Various reducing agents have been employed for reducing soln. of cupric to cuprous chloride—for example, J. Nicklès used a soln. of phosphorus in carbon disulphide; P. Kulisch, phosphine; L. P. de St. Gilles, W. Wardlaw and F. W. Pinkard, F. Wöhler, and M. Rosenfeld, sulphurous acid or a sulphite; A. Cavazzi, sodium hypophosphite; J. L. Proust, stannous chloride; K. Heumann, zinc; J. L. Proust, copper turnings or filings; E. Vigouroux, and J. B. Senderens, aluminium; S. B. Newbury, powdered silver; A. Purgotti, hydrazine sulphate; W. Lossen, A. Angel, and E. Péchard, hydroxylamine chloride; J. V. Kohlschütter, acetone; V. Thomas, and E. Péchard, nitric oxide, or nitrogen tetroxide; F. C. Phillips, methyl hydrosulphide; and E. Postel, sugar. Numerous other organic substances have been used. The more usual process of preparing cuprous chloride is to reduce the cupric chloride with copper as originally done by J. L. Proust. The following is based on M. Gröger's process [10]:

Dissolve 42 grms. of crystalline cupric chloride in 200 c.c. of hydrochloric acid (sp. gr. 1·175) mixed with 100 c.c. of water, add say 25 grms. of copper turnings, and warm the mixture on a water-bath until the dark colour has disappeared. Pour the clear liquid into a vessel containing two litres of cold water acidified with a little sulphurous acid. The white cuprous chloride which is precipitated is collected by means of a suction filter and washed with dil. sulphuric acid (1 : 20), and then successively with absolute alcohol and with ether. Dry the product in a hot-water oven. Yield, 22–23 grms.

Instead of using a soln. of cupric chloride, an eq. mixture of say one mol. of cupric sulphate with two mols. of sodium chloride, can be employed as recommended by G. Denigès, F. Wöhler, etc. Potassium or ammonium chlorides can also be used in place of the sodium salt.

Cuprocupric chloride is said [11] to be present in the brown-coloured soln. formed when cupric chloride in acetone is allowed to stand; when a hydrochloric acid soln. of cuprous chloride is oxidized; when an aq. soln. of cupric chloride is reduced on or at the cathode; when an aq. soln. of cupric chloride is electrolyzed. There is every sign that the alleged cuprocupric chloride is a mixture of the two chlorides.

3. *By the electrolysis of solutions of copper chloride.*—According to R. Böttger,[12] during the electrolysis of a soln. of cuprous chloride in hydrochloric acid with copper anodes, small white crystals of cuprous chloride are deposited on the anode. By electrolyzing a soln. of cupric chloride, with a copper anode and platinum cathode, cuprous chloride is deposited on the latter, and copper is dissolved from the former; if both electrodes are of platinum, cuprous chloride is deposited on the cathode, and chlorine is given off at the anode.

The properties of cuprous chloride.—Hot soln. of cuprous chloride in hydrochloric acid on cooling furnish small hexakis-tetrahedral **crystals** belonging to the cubic system.[13] R. W. G. Wyckoff and E. Posnjak found that the **X-radiograms** correspond with the double face-centred cubic lattice of the zinc sulphide class with the sides of the cube 5·49 A., and the nearest distance of the atoms 2·32 A. L. Bourgeois made the crystals by passing sulphur dioxide into a soln. of cupric chloride; A. C. Becquerel, by the action of metallic copper on a soln. of sodium chloride; and R. Böttger, by the electrolysis of soln. of copper chloride. The **specific gravities** which have been published [14] range from L. Playfair and and J. P. Joule's mean 3·53 to H. Schiff's 3·70 for the artificial crystals, and 2·6777 for the fused salt; R. W. G. Wyckoff and E. Posnjak gave 4·136 at 30°/4°. P. Walden, and F. A. Henglein studied the mol. vol. of the cuprous halides.

J. L. Proust noticed that cuprous chloride melts below a red heat, without decomposition, and T. Carnelley's [15] value for the **melting point** is 434° ± 4°; K. Mönkemeyer's value is 419°; G. Poma and G. Gabbi's value, 415°; C. Sandonnini's value, 422°; and L. Graetz's value, 440°. C. Sandonnini finds that the thermal analysis of mixtures of cuprous and lithium chlorides—melting respectively at 602° and 422°—shows the existence of two species of mixed crystals, with a gap of miscibility extending from 25 to 55 mols. per cent. of CuCl. The fusion curve has a minimum rich in cuprous chloride, corresponding with 80 mols. per cent. of cuprous chloride. C. Sandonnini, P. de Cesaris, and G. Poma and G. Gabbi find that cuprous chloride forms a eutectic with sodium chloride at 314° with nearly 75 mols. per cent. of cuprous bromide. With potassium chloride there are two arrests in the fusion curve with cuprous chloride—*viz.* 136° to 142° and 226° to 236°. The former represents the eutectic temp. with just over 65 mols. per cent. of cuprous chloride; and a compound CuCl.2KCl is formed which dissociates at 226°–236°. With rubidium chloride, there are three arrests in the fusion curve: (i) a eutectic at 150°; (ii) one corresponding with the dissociation of the compound 2RbCl.3CuCl at 190°; and (iii) one corresponding with the breaking down of the compound 2RbCl.CuCl at 250°. T. Carnelley and W. C. Williams' value for the **boiling point** is 954°–1054°. It has long been known that in melting copper containing chlorine the fumes evolved may interfere with the charging, or drive workmen from the building. The flue-dust from furnaces melting copper with but traces of chlorine, may yield up to 15 per cent. cuprous chloride. S. Skowronsky and K. W. McComas have shown that any copper-leaching process which gives chlorides either from ore or solvent will electrolytically deposit cuprous chloride on the cathode, and that this is subsequently volatilized and lost to the bath.

The **vapour density,** according to V. and C. Meyer.[16] is 6·96 at 1560°; and 6·60 to 6·44 at 1692°. These numbers correspond with a **molecular weight** in agreement with the formula Cu_2Cl_2, which requires a vapour density 6·825. There is, therefore, no dissociation $Cu_2Cl_2 \rightleftharpoons 2CuCl$. E. Beckmann's determinations of the b.p. of dil. soln.[17] of cuprous chloride in quinoline agree with the formula CuCl; and in conc. soln., Cu_2Cl_2; and in soln. of pyridine, and of methyl and ethyl sulphides, A. Werner found a similar variation. N. Castoro obtained values in soln. of urea in agreement with Cu_2Cl_2. L. Rügheimer and E. Rudolfi's value for the f.p. of soln. of cuprous chloride in molten bismuth chloride agrees with CuCl; E. Beckmann and F. Junker's values, with molten mercuric chloride, vary from CuCl to Cu_2Cl_2; and E. Abel's values for the f.p. of hydrogen chloride, with Cu_2Cl_2.

The **specific heat** of solid cuprous chloride,[18] which has been fused, is, according to H. V. Regnault, 0·1383, and the **atomic heat**, 13·7. The **heat of formation**, Cu+Cl=35·6 Cals. (M. Berthelot); 32·875 Cals. (J. Thomsen); Cu+Claq.=26·5 Cals. (M. Berthelot). For its formation from chlorine and cuprous oxide, M. Berthelot gives 26·0 Cals.; and J. Thomsen gives for its heat of formation from hydrogen chloride and cuprous oxide, 24·65 Cals., and from hydrochloric acid, HClaq., 7·33 Cals. M. Ribalkin's value for Cu+HCl is 10 Cals. R. Luther and D. R. Wilson's value for the **work of oxidation** in forming CuCl from copper, —0·5640 volt; M. de K. Thompson gives for the **free energy of formation** —27·8 Cals. with gaseous chlorine, or with liquid chlorine, —28·1 Cals.; G. Bodländer and O. Storbeck give —30·0 Cals.; and M. de K. Thompson's value for the **total energy of formation** is —33·8 and —31·6 Cals. respectively for gaseous and liquid chlorine. M. Berthelot's values (1879) for the **heat of solution** of cuprous chloride in hydrochloric acid vary from —820 cals. for the acid $HCl+5H_2O$ to —9500 cals. for the acid $HCl+66·4H_2O$. This is taken to indicate the formation of a cuprous hydrochloride which progressively dissociates with the absorption of heat by the action of water.

According to B. Gossner,[19] the crystals obtained from conc. soln. are singly refracting, but, according to K. Mönkemeyer, after they have been fused they are doubly refracting. M. Faraday [20] first electrolyzed molten cuprous chloride and thereby obtained metallic copper; cupric chloride is formed at the anode, and copper is dissolved—the loss, according to H. L. Buff, is greater than corresponds with theory. W. Negbauer gives for the e.m.f. of the cell Pt | CuCl | Zn, 0·725 volt. The **electrical resistance** of a c.c. at 50° over the m.p. is 6 ohms. L. Graetz's values for the **electrical conductivity** (mercury unity) are: $37·25\times10^{-6}$ at 490°; $21·20\times10^{-6}$ at 460°; $19·60\times10^{-6}$ at 450°; $19·60\times10^{-6}$ at 420°; $19·5\times10^{-6}$ at 400°; $14·20\times10^{-6}$ at 300°; $0·71\times10^{-6}$ at 200°; and $0·09\times10^{-6}$ at 140°.

Cuprous chloride is reduced to the metal: $2CuCl+H_2 \rightleftharpoons 2HCl+2Cu$, when heated in a stream of hydrogen. According to M. Ribalkin,[21] if the gas is dry, the reaction begins at about 230° when about 5 per cent. of hydrogen chloride is formed in 18 hrs.; at 270°, 10 per cent. of hydrogen chloride is formed in 9 hrs.; and at 440°, 35 per cent. of hydrogen chloride is formed. Cuprous chloride is also reduced by water gas. According to M. Trautz, sulphuryl chloride, SO_2Cl_2, has no perceptible action after an hour's heating at 99·3°, 742 mm. press.; C. Poulenc found that hydrogen fluoride forms cuprous fluoride; H. Rose, that phosphine forms copper phosphide, Cu_3P; and W. A. Jones, that dry carbon monoxide has no action on dry cuprous choride.

Dry cuprous chloride remains unchanged in dry air, and it is not affected by light [22]; but if moisture be present, it slowly turns green and yellowish-brown, the colours due to the formation of a green basic salt, possibly atacamite, $CuCl_2.3CuO.3H_2O$. F. Thomas studied the influence of light on the oxidation of cuprous chloride. J. L. Proust stated that the salt is insoluble in water, but with the more sensitive methods available to modern chemistry, G. Bodländer [23] showed that the solubility of cuprous chloride in water in an atm. of hydrogen or carbon dioxide between 19·3° and 21·7° is 0·000629 mol per litre. In contact with water, the cuprous chloride is partially hydrolyzed: $2CuCl+H_2O \rightleftharpoons Cu_2O+2HCl$; and partially decomposed: $2CuCl \rightarrow CuCl_2+Cu$. A sat. soln. contained 0·002222 mol of cupric and 0·000629 of cuprous chloride per litre, together with 0·000363 mol of HCl. H. Lescœur, and J. K. Haywood found that when cuprous chloride is washed with successive portions of water of approximately the same volume each washing, the amount of acid in the wash water, after the first few washings, remains practically constant until all the chloride is converted into oxide. If the extraction be carried out in darkness in an atm. of hydrogen or carbon dioxide, the residue is almost pure cuprous oxide ; but in light, the residue is red owing to the formation of a little copper. The system contains three components—cuprous oxide, water, and acid—and four phases—cuprous chloride, cuprous oxide, solution, and vapour. By the phase rule, therefore, at any given temp. there can be only one conc. for which the system is in equilibrium ; and as long as there is an excess of hydrochloric acid, there will be no cuprous oxide, and the system will be bivariant, and capable of existing at different conc. for a given temp.

According to M. Gröger, when water acts on cuprous chloride in the presence of a little air, an orange-red residue of cuprous oxide, mixed with about 5 per cent. of basic cupric chloride, is formed. The amount of cupric compound in the residue is always small, presumably because most passes into soln. ; by the action of water and air, sufficient for complete oxidation, the end-product has a composition approximating to that of atacamite, $3CuO.CuCl_2.3H_2O$. The primary action is the hydrolysis of cuprous chloride, and the liberated hydrochloric acid in the presence of oxygen acts upon more cuprous chloride forming the cupric compound which reacts with the cuprous oxide formed during the primary hydrolysis producing cuprous chloride and basic cupric chloride. Cuprous chloride remains white in the presence of a soln. of **cupric chloride,** when protected from air, and this even in sunlight. Boiling water soon changes cuprous chloride into cuprous oxide and copper, and cupric chloride passes into soln. According to J. W. Mallet, a stream of moist **air** between 100° and 200°, converts cuprous chloride almost instantaneously into the oxychloride atacamite, $CuCl_2.3CuO.3H_2O$.

Dil. **nitric acid,** said M. Rosenfeld, does not attack cuprous chloride in darkness, but in light, the salt rapidly darkens and acquires a copper lustre ; while J. L. Proust said that nitric acid develops much heat with the evolution of nitric oxide, and the soln. becomes violet and then blue. B. Lean and W. H. Whatmough found that freshly precipitated cuprous chloride is redissolved by **sulphurous acid.** According to G. Vortmann and C. Padberg, a boiling acid soln. of cuprous chloride reacts with **sulphur :** $2CuCl+S=CuS+CuCl_2$; W. Wardlaw and F. W. Pinkhard found that the oxidation $4CuCl+SO_2+4HCl=4CuCl_2+2H_2O+S$ does not occur at 95° if the conc. of the acid be less than 38 c.c. of 33 per cent. hydrochloric acid per 250 c.c. of soln. ; with soln. containing over 150 c.c. of acid per 250 c.c. of soln., sulphur is precipitated ; with between 112 and 150 c.c. of acid, sulphur and cuprous sulphide is precipitated ; while in soln. with 38 to 112 c.c. of acid, cuprous sulphide alone is precipitated. Dil. **sulphuric acid** does not act on cuprous chloride ; the conc. acid has no appreciable action in the cold, but the attack is perceptible when the acid is warmed. H. Feigel[24] found a soln. of **sulphur chloride** in benzene colours cuprous chloride brown, and it is partly converted into cupric chloride, and sulphur. Very dil. **hydrochloric acid** in an inert atm. changes the colour of cuprous chloride from white, through green, to a dark copper brown, and the residue contains metallic copper : $2CuCl \rightarrow Cu+CuCl_2$. Conc. hydrochloric acid dissolves cuprous chloride without changing colour, and this the more the greater the proportion of hydrogen chloride. This is shown by the measurements of H. le Chatelier at 17°, and of R. Engel at 0°. Extracting a few numbers from their data, and expressing the results in mols. per litre :

	0°				17°			
HCl. .	1·8975	4·475	6·85	10·4	0·8975	1·57	4·78	5·70
CuCl .	0 0475	0·825	1·55	3·3	0·0475	0·14	0·825	1·15
Sp. gr. .	1·50	1·08	1·261	1 345	—	1·050	1·135	—

The fact that the solubility of cuprous chloride in hydrochloric acid is greater the more conc. the acid, led A. Ditte [25] to infer the presence of a hydrochloride; and, as previously indicated, the fact that the heat absorbed during the soln. of cuprous chloride in hydrochloric acid is greater the more dil. the acid, led M. Berthelot to a similar conclusion. M. le Blanc and A. A. Noyes argued that the soln. contains a complex of cuprous chloride and hydrogen chloride, because the f.p. of hydrochloric is not changed by the addition of cuprous chloride; and from solubility determinations, E. Abel deduced the presence of the complex ion, Cu_2Cl_4, which would make the complex $H_2Cu_2Cl_4$, or $(HCuCl_2)_2$, *i.e.* $Cu_2Cl_2.2HCl$—**chlorocuprous acid**, or **cuprous dihydro-dichloride.** R. Engel was not able to isolate any crystals by cooling to —40° a soln. sat. at 0°, but G. Neumann claims to have obtained grey needle-like crystals of this compound by dissolving cuprous chloride in hydrochloric acid in the presence of powdered copper, in an atm. of carbon dioxide, and then saturating the soln. by means of hydrogen chloride, while cooled by a freezing mixture. The crystals become blue on exposure to air, and the soln. in water is colourless.

The soln. of cuprous chloride in hydrochloric acid is used in gas analysis for the absorption of carbon monoxide.[26] F. W. K. Brandt studied the absorption of carbon monoxide, ethylene, and nitric oxide by soln. of cuprous chloride. One eq. of copper dissolves nearly one eq. of carbon monoxide, and **carbonyl cuprous chloride** is formed. There appears to be a reversible reaction between the cuprous hydrochloride in soln. and the carbon monoxide. By saturating the soln. with carbon monoxide M. le Blanc obtained a compound $2CuCl.CO.2H_2O$; and W. A. Jones, $CuCl.CO.2H_2O$. According to H. Hammerl, the heat of soln. of carbon monoxide in the soln. is 11·37 Cals. The soln. is not applicable for the determination of small proportions of carbon monoxide. A. Frank reported that carbon monoxide is but incompletely removed from water-gas by this solvent. H. Drehschmidt says that if a soln. of carbon monoxide in the cuprous chloride soln. be shaken in nitrogen gas, some carbon monoxide is given up to the nitrogen. The soln. of cuprous chloride in hydrochloric acid becomes brown on exposure to air, and, says M. Traube,[27] the autoxidation of the soln. in the presence of water develops some hydrogen peroxide. The acid soln. of cuprous chloride copiously absorbs phosphine—according to J. Riban, about 132 times its volume. The soln. deposits needle-like crystals of $CuCl.PH_3$, which are stable only in the mother liquid from which they have separated. When exposed to the air, or when heated, or when treated with water, the crystals rapidly dissociate into a black copper phosphide, Cu_3P, and phosphine and hydrogen chloride: $3CuCl.PH_3=Cu_3P+2PH_3+3HCl$. If the passage of gas be continued, the crystals dissolve, and a compound richer in phosphine is in all probability formed, but which has not been isolated. The soln. so obtained can be preserved and used for giving off pure phosphine. According to W. Hempel, 10 c.c. of the soln. absorbs 2 c.c. of carbonyl sulphide, and the soln., says M. Berthelot, gradually forms carbon dioxide and cuprous sulphide. A. R. Frank says acetylene is not appreciably absorbed; and, according to N. Caro, the organic sulphides are absorbed in small quantities. W. Hempel found that the soln. absorbs the heavy hydrocarbons. Fuming nitric acid colours the soln. brown; G. Vortmann and C. Padberg found that when boiled with flowers of sulphur cupric chloride and cuprous sulphide are formed; J. Riban found that mercury is attacked by the brown soln., forming mercurous chloride, but it is not attacked by the colourless soln.

Cuprous chloride is soluble in soln. of the alkali chlorides. T. S. Hunt found that a sat. soln. of *sodium chloride* dissolves more than 16 per cent. of cuprous chloride at 90°, and more than 8 per cent. at 40°. A soln. with 15 parts of sodium chloride in 100 of water dissolves 10 per cent. of cuprous chloride at 90°; 60 per cent. at 40°; and 3·5 per cent. at 14°. A soln. with 5 parts of sodium chloride in 100 of water dissolves 2·6 per cent. of cuprous chloride at 90°, and 1·1 per cent. at 40°. When the soln. are diluted with water, cuprous chloride is deposited as a white crystalline powder. G. Bodländer [28] and O. Storbeck found cuprous chloride dissolves without decomposition in a soln. of *potassium chloride* if the soln. are more conc. than 0·05*N*. Some of the cuprous chloride is converted into the cupric salt. For example, expressing the conc. in grams per litre, 16°–20°, the two forms of copper in soln. of various conc. of potassium chloride are:

KCl . .	0	0·186	0·746	1·492	7·460	14·92	149·2
Cu (ous) .	0·040	0·034	0·048	0·071	0·299	0·603	24·42
Cu (ic) .	0·141	0·090	0·030	0·021	0	0	0

K. Hachmeister[29] determined the f.p. and b.p. curves of binary mixtures of cuprous and ammonium chlorides. With mixtures with *w* per cent. of ammonium chloride:

w . . .	53·31	43·45	38·52	32·64	27·40	21·61	12·91	5·06
B.p. . . .	338°	339°	—	345°	351°	361°	378°	415°
F.p. . . .	—	305°	253°	201°	170°	196°	320°	390°

The eutectic temp. of the f.p. curve is near 140°. P. P. Dehérain prepared prismatic crystals of **ammonium trichlorodicuprite,** $NH_4Cu_2Cl_3$, or $NH_4Cl.2CuCl$, from a soln. of cuprous hemiammino-chloride. They are stable only when kept in contact with the mother liquid. H. L. Wells and E. B. Hurlburt prepared crystals of **ammonium pentachlorocuprite,** $(NH_4)_2Cu_3Cl_5$, or $2NH_4Cl.3CuCl$, from a hot hydrochloric acid soln. of the component salts cooled in the presence of copper wire. H. Ritthausen also prepared crystals of this salt. The colourless crystals can be kept in air for a long time without change, but they gradually turn green. P. P. Dehérain obtained needle-like crystals of **ammonium dichlorocuprite,** NH_4CuCl_2, or $NH_4Cl.CuCl$, but they are stable only under the mother liquor; H. L. Wells and E. B. Hurlburt could not make them. E. Mitscherlich mentioned **ammonium trichlorocuprite,** $2NH_4Cl.CuCl$, and H. L. Wells and E. B. Hurlburt obtained colourless prisms by dissolving cuprous chloride in a large excess of a hot soln. of ammonium chloride in dil. hydrochloric acid, and cooling in the presence of copper wire and an atm. of carbon dioxide. The crystals rapidly turn brown and then green on exposure to air. P. P. Dehérain reported brown crystals of a monohydrate.

A. Chassevant found cuprous chloride is readily soluble in a hot conc. soln. of lithium chloride in an atm. of carbon dioxide, and colourless octahedral crystals, presumably lithium chlorocuprite, are formed, which immediately decompose as the mother liquor is withdrawn, and also on exposure to light, or contact with organic matter—*e.g.* paper. E. Mitscherlich prepared what he regarded as **sodium trichlorocuprite,** $NaCuCl_3$; O. Dieffenbach obtained a sodium salt by heating cupric sodium chloride; and J. B. J. D. Boussingault, and A. C. Becquerel also prepared the sodium salt in colourless tetrahedra. A. Chassevant said the salt readily decomposes, while J. B. J. D. Boussingault found it does not volatilize at 550°. G. Bodländer and O. Storbeck assumed that soln. of cuprous chloride in 0·05 to 0·4N soln. of potassium chloride contain **potassium dichlorocuprite,** $KCuCl_2$, or $KCl.CuCl$, and that more conc. soln. contain **potassium trichlorocuprite,** K_2CuCl_3. E. Mitscherlich, H. le Chatelier, and A. C. Becquerel made the former salt in colourless octahedral crystals isomorphous with potassium chloride. The crystals in conc. soln. remain colourless; in dil. soln. they gradually turn green or violet; P. P. Dehérain[30] said they are decomposed by cupric or zinc chloride. H. L. Wells prepared white prisms of **cæsium trichlorocuprite,** $CsCu_2Cl_3$, or $CsCl.2CuCl$, from a hot dil. soln. of cupric chloride, copper wire, an excess of cæsium chloride and hydrochloric acid. The crystals become yellow when dried. He also obtained **cæsium pentachlorodicuprite,** $3CsCl.2CuCl$, in colourless plates, and prismatic crystals of monohydrated **cæsium tetrachlorocuprite,** $3CsCl.CuCl.H_2O$, or $Cs_3CuCl_4.H_2O$. They dissolve in ammonium thiosulphate soln. and form colourless crystals of $NH_4(CuCl_2).4(NH_4)_2S_2O_3$.

When a conc. soln. of cuprous chloride in alkali halide is treated with a soln. of iodine in xylene, G. A. Barbieri found that cuprous iodide is formed. The mixed soln. of cuprous and alkali chloride transforms silver sulphide into the chloride, converts ruby silver ore into a grey mixture of[31] copper and silver chloride, antimony, and sulphur; and, according to F. Raschig, it converts lead, zinc, cadmium, iron (ous), cobalt (ous), bismuth, and tin (ous and ic) into the respective chlorides—with cuprous, lead, and zinc sulphides the conversion is incomplete; and with mercuric sulphide it forms the double salt, $HgS.2CuCl$; and with silver sulphide, $AgS.2CuCl$. Sulphur is separated from the arsenic sulphides. C. Häussermann states that metallic copper is attacked. G. Bodländer and O. Storbeck have measured the solvent action of soln. of *copper sulphate* on cuprous chloride, and F. Raschig, the solvent action of *cupric chloride.* In the latter case, the soln. becomes brown, and this the more the higher the temp., and the greater the conc. of the soln., and much of the cuprous chloride separates during the cooling of a boiling conc. soln. With cupric sulphate soln. a portion of the cuprous chloride is converted into the cupric salt. Expressing conc. in milligram-molecules per litre :

$CuSO_4$ . . .	0	0·987	1·975	2·962	4·937
Total Cu . .	2·880	3·602	4·553	5·193	7·276
Cu (ic) . . .	2·258	3·145	4·131	4·625	6·546
Cu (ous) . .	0·622	0·457	0·422	0·509	0·730

If calcium hydroxide be added to a hydrochloric acid soln. of cuprous chloride, C. Künzel[32] considers that **cuprous oxychloride,** CuO.CuCl, or Cu_2OCl, is formed. J. L. Proust previously stated that a similar oxychloride remains after the calcination of cupric oxychloride, $3CuO.CuCl_2$. B. Kosmann also supposed that **trihydrated cuprous oxydichloride,** $CuO.2CuCl.3H_2O$, is slowly formed when a soln. of barium or zinc chloride acts upon hydroxide, and also when cupric hydroxide is mixed with cupric chloride, and the excess of cupric chloride removed by dialysis. It is not clear if these products are the result of arrested reactions.

J. L. Proust,[33] in his early work at the end of the eighteenth century, noted the solubility of cuprous chloride in aqua ammonia ; and W. Gaus obtained a soln. containing 0·02*N*-CuCl in a normal soln. of ammonia. According to N. A. E. Millon and A. Commaille, 100 c.c. of aqua ammonia, of sp. gr. 0·924, dissolves 13·98 grms. of cuprous chloride. The colourless soln. rapidly turns blue on exposure to air. The ammoniacal soln., like that in hydrochloric acid, absorbs carbon monoxide.

The ammoniacal soln. of cuprous chloride is also used by W. Hempel, etc., in place of the hydrochloric acid soln. for gas analysis,[34] and some consider with better results. According to G. Denigès, it absorbs phosphine, and, according to M. Berthelot, propylene. A. Favorsky, and A. Béhal obtained a red precipitate with acetylene, propyl acetylene, and hexylene, but not with dimethyl-acetylene, methyl-ethyl-acetylene, or ethyl-propyl-acetylene. E. A. le Sueur found that on electrolysis, half the copper is precipitated as metal and half is converted into the cupric form.

E. C. Franklin and C. A. Kraus[35] also found cuprous chloride to be easily soluble in liquid ammonia. Five different cuprous ammino-chlorides have been reported, but S. J. Lloyd's study of the vap. press. obtained by saturating cuprous chloride with ammonia gas, and measuring the vap. press. at a constant temp. between 0° and 150° as the ammonia was gradually withdrawn, shows that only three such compounds can exist under these conditions—dark brown **cuprous hemiammino-chloride,** $2CuCl.NH_3$, melting about 162°, is made by saturating cuprous chloride with ammonia, and removing the excess until the press. of the gas is 522 mm. at 90°. The vap. press. at 87° is 518 mm. ; at 120°, 680 mm. ; and at 135·5°, 819 mm. P. P. Dehérain claimed to have made a dihydrated salt: $2CuCl.NH_3.2H_2O$, by boiling ammonium chloride soln. with cupric oxide and an excess of copper. According to S. J. Lloyd, light brown **cuprous sesquiammino-chloride,** $2CuCl.3NH_3$, melting about 144°, is made like the hemiammino-chloride, but at a press. of 650 mm. The vap. press. at 67·5° is 324 mm. ; at 85°, 567 mm. ; at 92°, 700 mm. ; and at 100°, 845 mm. ; W. Biltz and W. Stollenwerk found the heat of formation to be 16·73 Cals., and the dissociation press. at 326° is 100 mm. Green **cuprous triammino-chloride,** $CuCl.3NH_3$, melting at about 123°, is formed by leading ammonia gas slowly over cuprous chloride cooled by a freezing mixture. Its vap. press. at 88° is 736 mm. ; at 90°, 780 mm. ; at 110°, 1650 mm. F. Ephraim gives the vap. press. 760 mm. at 46·3° ; and he added that the cuprous trihalides are almost of identical stability. W. Biltz and W. Stollenwerk found the heat of formation of the triammino-chloride to be 9·48 Cals.

In 1853, H. Ritthausen reported the formation of **cuprous ammino-chloride,** $CuCl.NH_3$, and this was confirmed by P. P. Dehérain in 1862. The latter boiled a soln. of cuprous chloride in hydrochloric acid, along with a little ammonia and copper; H. Ritthausen boiled ammonium chloride with finely-divided copper until ammonia began to be evolved. With rapid cooling the soln. deposits small white crystals of this salt, and with slow cooling blue rhombohedral crystals of $2NH_4Cl.CuCl_2.2H_2O$, so that by rightly timing the operation, the crystallizing liquid can be decanted from the white crystals before the blue ones are deposited. The crystals can be washed with alcohol. H. Ritthausen also says that the white crystals can be obtained by pouring the boiling liquid into half its volume of water; filtering off the precipitated cuprous hydroxide, and cooling the soln. F. Förster and F. Blankenberg also says this salt is formed when copper is treated with a strong soln. of cupric chloride in aqua ammonia of sp. gr. 0·88. The crystals are colourless rhombohedra which acquire a violet colour on exposure to air, and at 100° lose ammonia, and are browned by oxidation. Water decomposes the crystals, colouring them yellow; they are also decomposed by acids, but not by alcohol. W. Biltz and W. Stollenberg found the heat of formation of the monamminochloride to be 16·73 Cals., and the dissociation press. at 417·5° to be 100 mm. According to H. Ritthausen, the crystals formed by A. C. and A. E. Becquerel when a mixed soln. of copper sulphate and ammonium chloride is electrolyzed have the same composition; and, according to P. P. Dehérain, crystals of this salt with two molecules of water are formed along with $CuCl_2.2NH_4Cl$, when copper is allowed to stay in contact with a soln. of ammonium chloride. P. P. Dehérain's report that crystals of $CuCl.2NH_3$ are formed by the action of ammonia on cuprous chloride lack confirmation. On account of the extreme readiness with which the ammino-compounds absorb water, their formation in aq. soln. seems to S. J. Lloyd to be improbable.

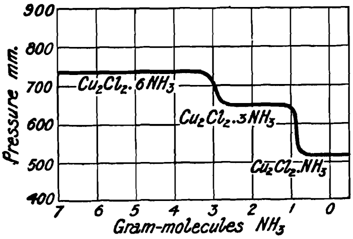

FIG. 26.—Vapour Pressure Curves of the Cuprous Ammino-chlorides.

What H. Ritthausen considers to be **hydrated cuprosic tetrammino-chloride,** $CuCl.CuCl_2.4NH_3.H_2O$, is deposited in blue rhombic prisms when a soln. of cuprous ammino chloride, $CuCl.NH_3$, is exposed to the air; and P. P. Dehérain also made it by boiling ammonium chloride with copper oxide and an excess of copper. The crystals decompose rapidly on exposure to air; but they are more stable if well dried, although even then they gradually lose water and ammonia, and absorb oxygen. They lose water rapidly at 100°, traces of ammonia are also lost, and the colour becomes dark brown. They are decomposed by acids —with hydrochloric acid prisms of $2CuCl.NH_4Cl$ and cubes or octahedra of $2NH_4Cl.CuCl_2.2H_2O$ are deposited. According to C. Winkler,[36] soln. of *sodium thiosulphate*, $Na_2S_2O_3$, dissolve freshly prepared acid-free cuprous chloride. The cold soln. is not altered by dil. nitric, hydrochloric, or sulphuric acid, but when warmed, black cuprous sulphide is precipitated without the evolution of sulphur dioxide; and R. Böttger says the soln. is not readily oxidized; but M. Rosenfeld found a brown precipitate is slowly formed by potassium chromate. Cuprous chloride dissolves in a soln. of *ammonium thiosulphate,* and the soln. gives tetragonal crystals which A. Rosenheim and S. Steinhäuser's analysis makes: $4(NH_4)_2S_2O_3.NH_4Cl.CuCl$. When the colourless liquid is treated with ammonia it becomes blue. According to M. Siewert, cuprous chloride is insoluble in soln. of *sodium dithionate*, $Na_2S_2O_6$.

According to W. Eidmann,[37] it is insoluble in *phosgene, methylal,* and *acetone;* according to E. Alexander, in *ethyl acetate;* and, according to H. Arctowsky, in *carbon disulphide.* It forms a double compound with *acetanilide* investigated by W. J. Comstock[38]; with *benzonitrile* and other aromatic nitriles (A. Werner, C. Rabaut, and A. Naumann); with *ethyl sulphide* (A. Werner); with *thioacetamide* (N. Kurnakoff); with *alkyl phosphates* (A. E. Arbusoff), etc. It dissolves in *pyridine* (J. Schröder)[39]; in *piperidine* (A. Werner and P. Ferchland); and in *quinoline* (E. Beckmann and W. Gabel). W. A. Jones obtained evidence of the formation of a compound $4CuCl.3CO$ when carbon monoxide is passed into a pyridine soln at 0°, but the compound was not isolated. It decomposes on raising the temp., and at 100° the decomposition is nearly complete. *Hydrocyanic acid,* says R. Varet, transforms cuprous chloride into cuprous cyanide.

§ 16. Cupric Chloride

The existence of cupric chloride as a distinct individual apart from cuprous chloride was established by the work of J. L. Proust, about 1799. M. de la Durandière [1] reported the presence of crystals of hydrated cupric chloride in the underground concrete of Paris. A. Scacchi, A. Lacroix, and P. Franco also found the hydrated salt in sublimates in the fumaroles of Vesuvius, and the mineral $CuCl_2.nH_2O$ has been called *eriochalcite.*

The preparation of cupric chloride.—Cupric chloride is formed along with some cuprous chloride during the combustion of copper in chlorine gas, but if heated in an excess of chlorine, the cuprous is soon converted into the cupric salt. The action of hydrochloric acid on metallic copper is too slow for this to be a satisfactory means of preparing this salt; and further, if prepared by wet processes, **dihydrated cupric chloride,** $CuCl_2.2H_2O$, is formed. For example, copper is dissolved in aqua regia and the product repeatedly evaporated with hydrochloric acid to drive off the nitric acid. Precipitated cupric oxide or cupric oxide prepared at a low temp. is readily soluble in dil. hydrochloric acid, but if the oxide has been calcined at a high temp., it dissolves very slowly even in the conc. acid. A soln. of cupric chloride can therefore be formed by dissolving the oxide or carbonate in the acid.

Dissolve cupric oxide by warming it in a flask with four times its weight of 25 per cent. hydrochloric acid. Evaporate the filtered soln. on a water-bath until a film begins to form on the surface. The crystals which separate on cooling are pressed between filter paper or porous tiles. Good crystals can be obtained by recrystallization from boiling alcohol to which a few drops of hydrochloric acid have been added.

T. Rieckler [2] mixed soln. of cupric sulphate and sodium chloride and obtained crystals of dihydrated chloride after the crystals of sodium sulphate and chloride had separated out. The crystals of the dihydrated salt readily separate by concentrating the soln. in hydrochloric acid. According to H. M. Dawson and J. McCrae,[3] the neutral salt can be obtained if a soln. of the oxide in the acid be evaporated to dryness, the residue dissolved in water and again evaporated.

The hydrated salt loses its water when heated over 100°; or, according to P. Sabatier, when heated to 150° in a stream of hydrogen chloride. The anhydrous salt is also formed, according to R. Kane and C. Hensgen, by the action of dry hydrogen chloride on powdered copper sulphate—$CuSO_4$, or $CuSO_4.H_2O$. It is possible that the addition product, $CuSO_4.2HCl$, is first formed, which subsequently decomposes into cupric chloride, etc. H. C. Jones and W. R. Veazey say that the last traces of adsorbed hydrogen chloride can be removed from the salt by allowing it to stand in vacuo over sulphuric acid and potassium hydroxide. According to P. Sabatier, also, the crystals lose their combined water if they are allowed to stand for three months at the room temp. over conc. sulphuric acid, in vacuo ; the dehydration is much quicker over phosphorus pentoxide ; and, according to K. Krafft, the salt loses its water in a day over barium oxide.

D. Vitali [4] also obtained cupric chloride by pouring conc. sulphuric acid into a soln. containing an excess of cupric sulphate along with an alkali chloride ; by adding hydrochloric acid to a soln. of cupric sulphate in conc. sulphuric acid ; or by mixing a little cupric chloride with an excess of conc. sulphuric acid. This shows that although conc. sulphuric acid liberates the halogen acids from their alkaline salts when salts of the heavy metals are absent, this does not always occur when such salts are present. G. Viard has shown that if an aq. soln. of cupric chloride (1 : 10) be treated with twice its volume of sulphuric acid, yellow anhydrous cupric chloride separated from the hot soln. if the acid be added so slowly that the temp. does not rise high enough to decompose the chloride ; but if the liquid contains less than 68·4 per cent. of sulphuric acid, green dihydrated cupric chloride separates out.

According to F. W. O. de Coninck and L. Arzalier,[5] anhydrous cupric oxide is formed by heating a mixture of ammonium chloride and cupric oxide under press. ; and, according to C. E. Baker and A. W. Burwell, by heating cupric sulphide with sulphur chloride, S_2Cl_2 ; and by heating to 60° or 70° a soln. of carbonyl chloride in toluene in which the copper compound of benzoylacetone is suspended. Crystals of anhydrous cupric chloride are formed when a strip of silver dipping in silver chloride is covered with a conc. soln. of cupric nitrate.

Properties of cupric chloride.—Anhydrous cupric chloride occurs as a yellow or yellowish-brown micro-crystalline powder. The dihydrated salt forms sky-blue or greenish-blue [6] rhombic bipyramidal **crystals** whose axial ratios, according to J. C. G. de Marignac,[7] are $a : b : c = 0{\cdot}9179 : 1 : 0{\cdot}4627$. They show slight pleochroism. O. Lehmann obtained microscopic needles from strongly acid soln. F. Rüdorff did not find the crystals to be isomorphous with ammonium chloride with which it forms characteristic double salts ; nor did J. W. Retgers find it isomorphous with dihydrated barium chloride. The **specific gravity** of the anhydrous cupric chloride is 3·054, according to L. Playfair and J. P. Joule,[8] and for the dihydrated salt 3·535 (16°), according to C. H. D. Bödeker, 2·47 (18°), and, according to P. A. Favre and C. A. Valson, 2·390 (22·9°).

The anhydrous salt has the **melting point** 498° ± 4°, according to T. Carnelley,[9] and it forms cuprous chloride when heated to just over redness. G. Rousseau found that the dihydrated salt melts at about 110° in its water of crystallization, and, according to E. Bödtker, it loses all its water at 110° without forming a basic salt. H. Lescœur found the **dissociation pressure** of the dihydrated salt at 80° to be 62 mm. ; at 90°, 107 mm. ; and at 100°, 185 mm. ; and F. Ephraim found the dissociation pressure of anhydrous cupric chloride to be :

	450°	465°	478°	494·5°	501·5°	510°	515°	520°
Press. .	28	53	85	225	296	410	535	650 mm.

and he says that the reported m.p. 498° is right only when the chlorine is given off during the heating of the substance. According to T. Carnelley and W. C. Williams, the **boiling point** of cupric chloride is between 954° and 1032°. The **molecular weight** of cupric chloride determined by A. Werner [10] from its effect on the b.p. of pyridine and methyl sulphide, by H. Ley in alcohol, and by L. Rügheimer in bismuth trichloride, is normal—in the latter case there is a very small amount of cuprous chloride formed. The salt is strongly polymerized in acetone. N. Castoro's determination of the effect of cupric chloride on the f.p. of urethane gives a mol. wt. corresponding with Cu_2Cl_4.

The reported values for **heat of formation** of cupric chloride from its elements vary from J. Thomsen's 51·63 Cals. to M. Berthelot's 66·2 Cals.[11] M. Berthelot's value for its formation from cupric oxide is 11·7 Cals. ; from cupric oxide in soln., 22·8 Cals.; from cupric bromide, 11·3 Cals.; from cupric bromide in soln., 14·2 Cals.; from cuprous chloride, 16 Cals.; and from cuprous chloride in soln., 27 Cals. J. Thomsen's value for the heat of formation of cupric chloride in soln. (Cu, Cl_2, aq.) is 62·71 Cals.; for (CuO, $2HCl$, aq.), 15·27 Cals. For the **heat of solution** of the anhydrous chloride, J. Thomsen gives 11·08 Cals. for 600 mols of water, a value which agrees with P. Sabatier's values 11·2 (13°), 10·8 (11°); and 3·455 Cals. are developed when a mol of the solid absorbs a mol of water. According to L. T. Reicher and C. M. van Deventer the heat developed in the solution of a mol of $CuCl_2.2H_2O$ in *m* mols of water rises from -800 cals. for $m=83$ to $+4210$ cals. for $m=398$; and the heat developed by the soln. of *n* mols of $CuCl.2H_2O$ in 198 mols of water falls from $+3710$ cals. when $n=1$ to -19800 cals. when $n=24·75$; the heat of dissolution attains a maximum when $n=8$, so that 8 mols of the dihydrated salt dissolves in 198 mols without any thermal effect. The heat of soln. of a mol of the dihydrated salt in 400 mols of water is 4·21 Cals., and the heat of soln. when the dil. soln. contains a mol of $CuCl_2$ to 200 mols of water, 3·71 Cals. The heat of soln. in the sat. soln. is negative, -300 cals.; and the integral heat of soln., -800 cals.; the **heat of hydration,** $CuCl_2+2H_2O_{liq.}=CuCl_2.2H_2O+6·87$ Cals.

Anhydrous cupric chloride is hygroscopic and readily dissolves in water; the solubility of the dihydrated salt in water[12] expressed as the number of grams of the salt in 100 grms. of soln. is:

	−20°	0°	20°	40°	60°	80°	100°
Solubility .	37·0	41·4	43·5	45·6	47·7	49·8	51·9

A. Étard's equation for the solubility *S* at θ° represents a straight line: $S=41·4+0·105\theta$. This equation was found by L. T. Reicher and C. M. van Deventer to give rather low results below 91°. The fact that the solubilities between $-20°$ and $+91°$ can be represented by a straight line shows that the dihydrated salt is stable between these limits, provided slight deviations in the results have not been smoothed out as experimental errors. F. Rüdorff represents the solubility when ice exists as a solid phase in equilibrium with the soln., as 20·7 and 33·9 grms. of $CuCl_2$ in 100 grms. of water at $-10°$ and $-18·1°$ respectively. E. Chuard, and H. Lescœur reported that *trihydrated cupric chloride,* $CuCl_2.3H_2O$, crystallizes from aq. soln. below 0°; and A. Ditte, and H. Lescœur also reported *hydrated cupric chloride,* $CuCl_2.H_2O$, to be formed when the dihydrated salt is heated to 100°, and when hydrogen chloride is passed into a soln. of 29 grms. of salt in 100 c.c. of water at 12°; if the soln. be cooled by a freezing mixture, the trihydrated salt is formed. The salt is said to furnish ochre-yellow needles with a greenish tinge. Neither P. Sabatier nor R. Engel could confirm the individuality of the monohydrated salt, nor could R. Engel confirm the individuality of the trihydrated salt. P. Sabatier and A. Werner also believe that tetrahydrated cupric chloride, $CuCl_2.4H_2O$, exists, but H. Ley questions the validity of the evidence.

The **specific gravities** of aq. soln. containing *w* per cent. of cupric chloride at 17·5° (water at 17·5° unity), and the volumes which 100 c.c. of water assumes when *w* grms. of $CuCl_2$ are dissolved therein, are, according to B. Franz[13]:

w . .	5	10	15	20	25	30	35	40
Sp. gr. .	1·0455	1·0920	1·1565	1·2223	1·2918	1·3618	1·4447	1·3284
Vol. . .	100·68	101·25	101·72	102·27	103·21	104·83	106·49	109·04

E. Irueste has also measured the sp. gr. of soln. of cupric chloride, and he found that the conc. per gram of soln. at 15° when *D* and D_0 respectively denote the sp. gr. of soln. and of water, is $1·05390(D-D_0)-0·42804(D-D_0)^2$. J. Traube's **molecular solution volumes** *v*, for soln. of different sp. gr. (water at 0° unity), are:

	8·073 per cent. $CuCl_2$			39·417 per cent. $CuCl_2$		
θ° . . .	0°	30·5°	65°	0°	30·5°	65°
Sp. gr. . .	1·0796	1·0766	1·0734	1·4797	1·4642	1·4541
v . . .	11·7	9·5	9·3	23·9	25·4	23·9

The **viscosities** of N-, $\frac{1}{2}N$-, $\frac{1}{4}N$-, and $\frac{1}{8}N$-soln. of cupric chloride[14] at 25° are respectively 1·2050, 1·0977, 1·0470, and 1·0179. H. Sentis has measured the **surface tension** of aq. soln. J. Schuhmeister's value for the **diffusion coefficient** at 10° is 0·426 for 0·1N- to 2N-soln. J. C. G. de Marignac's values[15] for the **specific and molecular heat** of aq. soln. between 19° and 51°, containing an eq. of the salt in m eq. of water, are :

m	10	25	50	100	200
Sp. ht. . . .	0·6241	0·7790	0·8642	0·9200	0·9563
Mol. ht. . . .	196·1	455	894	1778	3571

W. von Beetz's value for the **thermal conductivities** between 8° and 14° is 407 and 425 respectively for soln. of sp. gr. 1·125 and 1·255 (water 413) ; and between 28° and 36°, 666 and 566 for soln. of sp. gr. 1·125 and 1·258 respectively (water 662).

H. Lescœur's values for the **vapour pressures**[16] of sat. soln. at 10° is 4·8 mm. ; at 40°, 41·5 mm. ; at 80°, 310 mm. ; and T. Ewan and W. R. Ormandy's value for 1·69 grms. of $CuCl_2$ in 100 grms. of water is 18·410 mm. (water 18·521 mm.) ; 12·99 grms. $CuCl_2$, 17·472 mm. (water 18·405 mm.) ; and 43·98 grms. $CuCl_2$, 14·946 mm. (water 18·462)—between 20·9° and 21·02°. W. Pieper measured the vap. press. of soln. of cupric chloride. A. Benrath's value for the raising of the **boiling point**,[17] by the soln. of 3·7 grms. of the dihydrated salt in 100 grms. of water, is 0·190° ; for 3·7 grms. of $CdCl_2.2H_2O$, 0·100° ; and for a mixture of the two, 0·298°, whereas the calculated value, by the law for the raising of the b.p., is 0·290 ; similarly for 7·1 grms. of HCl, the rise is 1·860°, and for a mixture of the two 2·090°, whereas the calculated value is 2·050°. With 5 grms. of mercuric chloride, the rise is 0·108°, and for the mixture, 0·208°, whereas the calculated value is 0·298°, which is greater than the observed value ; with the other mixtures, the reverse obtains. D. Isaachsen found for soln. with between 2·298 and 5·652 grms. of $CuCl_2$ per 100 grms. of water, the mean value 55·4 for the mol. wt. ; this gives the value $i=2·43$ for J. H. van't Hoff's ionization constant ; W. Biltz and J. Meyer[18] found the mol. lowering of the **freezing point** to fall from 48·9 for with 0·035 mol per litre soln. to 48·1 for soln. with 0·1337 mol per litre and then to rise with increasing conc. to 53·2 for soln. with 0·7149 mol per litre. H. C. Jones and co-workers also found a decrease to a minimum value which is attributed to the hydration of the constituent in soln. S. Arrhenius calculates for the mol. lowering of the f.p. of soln. with 0·0377 mol of $CuCl_2.2H_2O$ per litre, 5·12° ; and for soln. with 0·393 mol per litre, 4·86° ; the corresponding values for J. H. van't Hoff's i are 2·71 and 2·57, representing the degrees of ionization 85 and 78 per cent.

According to G. Chéneveau,[19] the **refractive index** of soln. of cupric chloride minus that of water is 0·0002466 ; and, according to H. C. Jones and F. H. Getman, the refractive index of soln. with 0·065 mol of $CuCl_2$ per litre is 1·32735 ; for 1·3010 mols, 1·36163 ; and for 2·6030 mols, 1·3949.

For the **photoelectric effect,** see cupric fluoride.

The **electrical conductivity** of soln. of dihydrated cupric chloride shows that this salt is as easily ionized as hydrochloric acid. From the work of T. Ewan,[20] it appears that the ionization occurs in two stages, there is first $CuCl_2 \rightleftharpoons CuCl^{\cdot} + Cl'$ in conc. soln. followed by $CuCl_2 \rightleftharpoons Cu^{\cdot\cdot} + 2Cl'$. The specific conductivity curve shows a maximum when the conc. is near 18 per cent. $CuCl_2$. V. Kohlschütter measured the specific conductivities of soln. of different conc. expressed in grms. of cupric chloride per litre of water ; the results are graphed in Fig. 27.

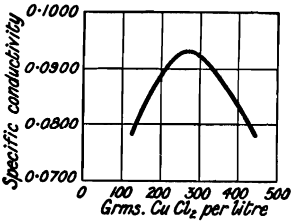

FIG. 27.—Specific Conductivity and Concentration Curve of $CuCl_2$.

According to H. C. Jones and A. P. West, the mol. conductivities μ and percentage degrees of ionization α for soln. containing a mol of the salt in v litres of water are, at 0° :

v	2	8	16	32	128	512	1024
μ	68·95	87·57	94·82	101·3	111·5	118·4	123·0
α	56·1	71·1	77·1	82·4	90·7	96·3	100·0

and at 25° :

μ	119·8	158·3	173·5	187·5	210·1	224·0	232·2
α	51·6	68·2	74·7	80·7	90·5	96·5	100·0

The percentage ionization is therefore smaller the higher the temp. According to S. Arrhenius, the percentage ionization by the f.p. method is greater than by the conductivity method.

According to D. Isaachsen, the curve showing the variation of the electrical conductivity of soln. of copper chloride with temp. has a point of inflexion at about 40°. R. J. Holland represents the conductivity λ at $\theta°$ by $\lambda=\lambda_{20}\{1+0·01841(\theta-20)-0·0000405(\theta-20)^2\}$. V. Kohlschütter attributes the fall in the specific conductivity with rising temp. to the presence of a hydrated cation, $[CuCl(H_2O)_3]^{\cdot}$, which is in equilibrium with water: $[CuCl(H_2O)_3]^{\cdot}+H_2O \rightleftharpoons [Cu(H_2O)_4]^{\cdot\cdot}+Cl'$, and the equilibrium is displaced in favour of the components on the right side when the temp. rises. G. Dickhaus also studied this subject.

According to W. Bein,[21] the **transport number** of $Cu^{\cdot\cdot}$ ions in a 0·05 eq. soln. of cupric chloride, at 23°, is 0·405 ; and, according to G. Carrara, in methyl alcohol soln. for $v=5·3$, 0·358 ; and for $v=16·4$, 0·382. According to V. Kohlschütter, the transport numbers of the Cu-ion in soln. of cupric chloride are :

Mols $CuCl_2$ per litre	5·29	4·35	3·72	3·30
Transport number	−0·835	−0·632	−0·411	+1·795

The negative numbers mean that the copper element is accumulating about the anode, and the fact that the positive number is greater than unity means that the copper ion is associated as a complex with some chlorine, say $(CuCl)'$, or even more complex anions—*vide* cupric bromide. V. Kohlschütter translated the facts by the aid of the assumption that the ions are hydrated ; and he represented the changes in terms of A. Werner's theory :

$$[Cu(H_2O)]^{\cdot\cdot} \rightarrow \left[Cu^{Cl}_{(H_2O)_3}\right]^{\cdot} \rightarrow \left[Cu^{Cl_2}_{(H_2O)_2}\right] \rightarrow \left[Cu^{Cl_3}_{H_2O}\right]' \rightarrow [CuCl_4]''$$

A soln. of cupric chloride in pyridine has the same blue colour as the aq. soln., although the latter is almost a non-conductor. Hence, it is inferred that both in soln. and in the solid state the un-ionized or neutral molecules, $[CuCl_2Py_2]$ and $[Cu(H_2O)_2Cl_2]$, are blue. The difference between aq. and pyridine soln. is that the former can furnish complex ions, $[Cu(H_2O)_3Cl]^{\cdot}$, $[Cu(H_2O)_4]^{\cdot\cdot}$, etc. The green or greenish-yellow soln. in ethyl alcohol and acetone have a small electrical conductivity, and in alcohol, the molecule approximates to $CuCl_2$, in acetone it is more complex. Excluding the possible association of solute and solvent, F. G. Donnan suggests that the soln. contains un-ionized molecules and the ions $Cu^{\cdot\cdot}$ and $CuCl_4''$, while the acetone soln. contains a more complex molecule, say $Cu[CuCl_4]$, which suffers less ionization. The "double molecule" in urethane soln. is regarded as a complex $Cu[CuCl_4]$.

The **magnetic susceptibility** of the powdered salt by J. Königsberger[22] is $9·1\times10^{-6}$ mass units at 22° ; S. Meyer gave 11×10^{-6} at 17°, and G. Chéneveau 10×10^{-6} ; and for the aq. soln., J. Königsberger gave 13×10^{-6} at 22°, and O. Liebknecht and A. P. Wills, 12×10^{-6} at 18°. A. Heydweiller found the **dielectric constant** of the powdered and compact dihydrate to be 3·51 and 7·51 when $\lambda=478$ cm.

The colour of cupric chloride solutions.—In 1843, E. Solly[23] noted that the soln. of cupric chloride, $CuCl_2$, in a small proportion of water is dark brown, and J. H. Gladstone showed that the colour gradually changes to very dark green as the proportion of water is increased, and this passes through various shades of green to light green, bluish-green, greenish-blue, and with very dil. soln. the colour is pale sky-blue. One part of dihydrated cupric chloride, $CuCl_22H_2O$, with one of water is dark green; with two of water bluish-green; and with five parts of water pure blue. W. N. Hartley found that in diluting a soln. of a mol of $CuCl_2.2H_2O$ with 50 mols of water, 2·565 Cals. of heat are developed. According to L. C. de Coppet, a soln. with 60 parts of $CuCl_2.2H_2O$ and 100 parts of water at 21·5° is green; at 0°, it is bluish-green; and at —23°, blue; a soln. with 40 parts of the same salt to 100 of water at 21·5°, green; at 0°, greenish-blue; and at —14·5°, at which temp. the soln. freezes, the colour is blue; a soln. with 18 parts of the same salt to 100 parts of water is green at 50°; greenish-blue at 24°; and blue at +10·5°, and at —6·4° when the soln. freezes. According to R. C. Tichborne, if a blue soln., slightly acidified to avoid the formation of a basic salt, be sealed up in a tube and heated, it becomes green, then yellow, and finally dark brown. These colour changes are reversed on cooling.

According to J. H. Gladstone, conc. soln. of cupric chloride become yellow when treated with hydrochloric acid, and they turn blue again when treated with water; while the addition of sodium, ammonium, calcium, and other chlorides have no effect on the colour. A. Ditte made similar observations. H. C. Jones and H. P. Bassett found that the addition of salts with a strong tendency to form hydrates—*e.g.* anhydrous calcium chloride or bromide, aluminium chloride, etc.—turn blue soln. green; A. Benrath found that a warm dil. green soln. of cupric chloride becomes blue when treated with mercuric chloride—most other chlorides either have no perceptible action, or turn green soln. yellow.

The absorption spectrum of soln. of copper in all the solvents tried, excepting acetone, show two regions of absorption, one in the ultra-violet, and one in the red. Acetone soln. also give an absorption band about $\lambda=4700$. It is convenient to assume that the absorption of light is due to the presence of vibrating electrons associated with ions, molecules, or complexes, and the character of the absorption will generally depend on the nature of the system with which the vibrating electron is associated—which, for convenience, may be called the absorber. E. Wiedemann attributed the changes which occur when chromatic salts soln. are diluted to the progressive hydration of the solute: (brown) $CuCl_2+nH_2O\rightleftharpoons CuCl_2.nH_2O$ (blue). E. Chuard (1888) said the blue soln. formed below 0° is due to the presence of trihydrated cupric chloride, $CuCl_2.3H_2O$, in the soln., above that temp. to the dihydrated salt, $CuCl_2.2H_2O$. F. Rüdorff (1862) also attributed the variation in the tint to the formation of hydrates. W. Ostwald assumed that the absorbers in the soln. were ions and un-ionized molecules which were supposed to have different colours: $CuCl_2$ (brown)$\rightleftharpoons Cu^{\cdot\cdot}$ (blue)$+2Cl'$ (colourless). W. Ostwald sought to establish his theory by showing that the absorption spectra of thirteen permanganates were identical at great dilutions when presumably the salts were completely ionized; W. Ostwald did not examine conc. soln., but when they were examined, they too were also identical, so that the spectroscopic evidence cannot be cited in favour of the ionic hypothesis. Y. Shibata and K. Matsuno studied the absorption spectra of soln. of cupric ammino-salts. F. G. Donnan and H. Basset attributed the colour changes on dilution to the formation and dissociation of complex ions: $CuCl_4''$ (brown)$\rightleftharpoons CuCl_2$ (blue)$+2Cl'$. G. N. Lewis tried to show that neither W. Ostwald's nor F. G. Donnan and H. Basset's hypothesis fits in with the law of mass action which requires that the equilibrium between the brown and blue constituents depends only on the conc. of the Cl′-ions; while if the equilibrium depends on some such relation as $CuCl_2$ (brown)$+H_2O=Cu(H_2O)_n^{\cdot\cdot}$ (blue)$+2Cl'$, the equilibrium will depend upon the conc. of both the Cl′-ions and the water. The last-named equation may also be taken to cover the case where the colour change is due to the passage from one hydrate to another with more or less water. The colour changes with cupric chloride, though similar are not so marked as is the case with cupric bromide, so that the results obtained for the one salt apply to the other. In order to decide between these two types of hypotheses, G. N. Lewis made the following experiment:

> The same quantity of cupric bromide was added to 10 c.c. of a thrice-normal soln. of each of the following bromides, KBr, NH_4Br, NaBr, LiBr. In these soln. the conc. of bromide-ion are nearly alike, being somewhat greater in the case of KBr, somewhat less in the case of LiBr. If this were the only factor determining the colour, we should expect the soln. in KBr to be the most brown, that in LiBr the least. The facts are just opposite. The NH_4Br and NaBr soln. have nearly the same colour, that of KBr is less brown, while the LiBr soln. is very much browner. In all these soln. the blue is so faint, as compared with the brown, that the relative brownness of the soln. can be found by means of a colorimeter. Columns of LiBr, NaBr, and KBr soln., respectively 14, 18·5, and 20 mm. thick, appeared equally brown. These experiments were repeated several times, a different quantity of cupric bromide being used in each instance. The results were the same. A small change in the conc. of cupric bromide in any soln. changes only the density of the colour, but not its character. It is obvious that something influences the colour besides the conc. of the bromide-ion. . . . Similar experiments were made with cupric chloride and soln. of the five chlorides, KCl, NH_4Cl, NaCl, LiCl, and HCl. Here the colours are not so pronounced as in the previous case. All the soln. are green. No difference could be detected in the first three, but the LiCl soln. was decidedly greener and the HCl soln. still more so. When the chlorides of the alkaline earths were used, the influence upon the colour was found to be much greater, the order being $SrCl_2$, $CaCl_2$, $MgCl_2$, $BeCl_2$.

Consequently, G. N. Lewis inferred that in addition to the Cl′-ion, water enters into the reactions which produce the colour changes, and the salt is hydrated in soln. S. U. Pickering studied the effect of acids on the colour of various copper salts.

G. N. Lewis, and W. Biltz have shown that a rise of temp. should cause a dissociation of the hydrated ion into one less hydrated or even a non-hydrated ion, and H. C. Jones and A. P. West deduced from their measurements of the temp. coeff. of a great number of salts with varying degrees of hydration: (i) The temp. coeffs. of an aq. soln. are greater the greater the hydrating power of the electrolyte; (ii) the large increase in conductivity with rise of temp. with salts forming hydrated ions, is in part due to the complexity of the hydrates, so that the equilibria $Cu(H_2O)_n{}^{\cdot\cdot}\rightleftharpoons Cu(H_2O)_{n-m}{}^{\cdot\cdot}+mH_2O\rightleftharpoons Cu^{\cdot\cdot}+nH_2O$ will be driven to the right, and abnormally low transport numbers must then tend to approach the normal value with rise of temp. provided the abnormality arises from a hydration effect. On the other hand, according to the complex ion theory, the formation of complexes is an endothermal process. and is therefore favoured by a rise of temp., so that a rise of temp. should result in a decrease in the transport number due to the equilibrium: $2Br'+nCuBr_2\rightleftharpoons[(CuBr_2)_nBr_2]''$. S. B. Watkins and H. G. Denham have also shown that the decrease in the transport number with rise of temp. favours the complex ion theory and contradicts the hydration theory. W. Bein has also shown that the effect of temp. is but slight on many salts which are believed to be much hydrated—*e.g.* $CaCl_2$ and LiCl.

The mechanism of the cathode process with a soln. of a copper salt may be represented by (i) $Cu^{\cdot\cdot}\rightarrow Cu^{\cdot}+\odot$; (ii) $Cu^{\cdot}\rightarrow Cu+\odot$; or (iii) $Cu^{\cdot\cdot}\rightarrow Cu+2\odot$, or if the copper ions are hydrated, by (i*a*) $Cu(H_2O)_n{}^{\cdot\cdot}\rightarrow Cu(H_2O)_m{}^{\cdot}+(n-m)H_2O+\odot$; (ii*a*) $Cu(H_2O)_n{}^{\cdot}\rightarrow Cu+mH_2O+\odot$; or (iii*a*) $Cu(H_2O)_n{}^{\cdot\cdot}\rightarrow Cu+nH_2O+2\odot$. If equation (iii) or (iii*a*) represents the cathode process, the ratio of Cu : Ag by weight will be 0·295, and with any of the other four equations 0·590. The results obtained by S. B. Watkins and H. G. Denham for cupric chloride and bromide in aq. or alcoholic soln., as well as confirmatory results by F. Förster and O. Seidal, F. Förster and G. Coffetti, M. von Bose, M. E. Heiberg, E. Abel, G. Bodländer and O. Storbeck show that with dil. soln. the discharge is mainly from cupric to cuprous ions, so that the deposits are heterogeneous mixtures of copper and cuprous halides, so that the electrode processes are mainly (i) or (i*a*), or (iii) or (iii*a*), where the cuprous ion is precipitated as cuprous halide. The result depends on temp., conc. of soln., current density, and conc. of acid, but it is not influenced by the hydration of the ions. With conc. soln. the Cu : Ag ratio does not agree with Faraday's laws because the ratio may fall down to zero where no copper or cuprous salt is deposited on the cathode. The hydration theory does not fit into these facts, but the theory of auto-complexes gives a satisfactory explanation, for, the un-ionized salts of weak electro-affinity form complex anions, and since cuprous salts have a weaker electro-affinity than cupric salts, they will be more prone to form complex anions; and hence, where no copper or copper salt is precipitated on the cathode during electrolysis, the discharge at the cathode is wholly : $Cu^{\cdot\cdot} \rightarrow Cu^{\cdot} + \odot$, or $Cu(H_2O)_n^{\cdot\cdot} \rightarrow Cu(H_2O)_m^{\cdot} + (n-m)H_2O + \odot$, and the cuprous salt formed is not precipitated in conc. soln. as it is in dil. soln., but rather forms a soluble cupricupro-salt; and the transport number is negative.

A compromise between the hydration theory and F. G. Donnan and H. Basset's theory of complex ions, explains the colour changes as a result of displacing the equilibrium condition: $CuCl_2.nH_2O$ (brown) $+ mCl' \rightleftharpoons (n-p)H_2O + [CuCl_2.Cl_m.pH_2O]'$. V. Kohlschütter bases his equilibrium equation on the assumption that the hydrates formed in soln. correspond with the ammonia complexes whose existence has been demonstrated, and in accord with A. Werner's co-ordination theory, assigning to copper the co-ordination number 4.

H. C. Jones attributes the absorption band in the ultra-violet to the hydrated un-ionized molecules, (i) because this band narrows rapidly with dilution even when the mol. conc. is kept constant; and (ii) because the band also widens rapidly with a rise of temp., showing that the absorbing power of the complex increases rapidly with a decrease in the complexity of the complex. The absorption band in the red is attributed to the solvated metallic ion.

If a ray of light of intensity I passes through a layer of homogeneous medium of thickness dx, the intensity is reduced dI so that $dI = -kIdx$, where k is a constant whose magnitude depends on the nature of the substance and the wave-length of the incident light. Integrating this relation for the condition that when $x=0$, $I=I_0$, then neglecting any loss due to reflection, it follows that $I=I_0e^{-kl}$, a relation known as *J. H. Lambert's law.* For soln. and gases, the absorption on the conc., C, as well as on the thickness, l, of the layer, J. H. Lambert's law was extended by A. Beer to include the assumption that each molecule—absorber—absorbs the same fractional portion of the incident light when the conc. C is proportional to the number of the molecules in the soln. Hence follows the so-called *Beer's law* for monochromatic light: $I=I_0e^{-kCl}$, meaning that the absorption of light of a given wave-length is proportional to the number of absorbers in the path of the light. When Beer's formula is referred to the base a, instead of the base e, it becomes $I = I_0a^{-aCl}$, where a denotes a constant sometimes called the *molecular extinction coefficient.* If the absorption is proportionally greater in the more conc. solutions, A. Beer's law fails, and the coeff. a decreases inversely as the concentration. It is found that for dil. soln. the deviations from A. Beer's law are small. The rule, of course, will not be applicable if mol. aggregates or complexes are formed.

With the chromatic soln. whose colour changes with conc. the relative conc. of the absorbers are continually changing, and hence A. Beer's law is not applicable, for it assumes that the conc. of the different absorbers do not change with dilution. The law breaks down, for example, with the ultra-violet band of cupric chloride, which narrows with dilution even when the number of molecules in the track of the beam of light is kept constant, so that the product of the conc. C and thickness l is constant. For conc. soln. of cupric chloride, bromide, sulphate, and nitrate, E. Müller showed that the values of a are nearly the same; while, according to T. Ewan, the absorption spectra of these soln. change on dilution, tending to become identical in dil. soln., so that a change in the conc. of the soln. has not the same effect as a corresponding change in the thickness of the layer through which light passes, as would be the case if Beer's rule obtained. This is taken to mean that the acid and basic parts of the salt are associated in producing absorption in conc. soln., but in dil. soln. they act independently. He also adds that the results can be explained by the ionization hypothesis, but not by hydrolysis as postulated by H. Knoblauch, or mol. aggregation assumed by H. E. Armstrong and J. Traube. H. C. Jones also assumes that the results are not produced by mol. aggregates which are broken down by a rise of temp., since the absorption is increased and not decreased by a rise of temp.

W. N. Hartley and others have shown that the absorption bands which widen with a rise of temp. also widen with increased conc., so that a rise of temp. produces much the same effect as an increased conc. If the observed change were due to the formation of complexes between the solute molecules and the solvent, this would not be expected, because the change produced by a rise of temp. on such complexes is just the opposite to that produced by an increase in conc. On the other hand, H. C. Jones and J. A. Anderson have shown that the changes produced in the properties of complexes formed by the union of ions and the solvent by a rise of temp. are the same as are produced by an increase in conc. As a soln. becomes more conc. these complexes beome simpler and simpler, since fewer molecules of the solvent are combined with each part of the dissolved substance; and a rise in temp. also breaks down the complexes into simpler ones. The work of E. Müller and R. A. Houstoun has shown that ionization alone, as postulated by W. Ostwald, is not able to explain the deviations from A. Beer's law, hence, R. A. Houstoun assumes that a watery atm. forms round the acid radicle and another round the basic radicle, and only when there is not sufficient water to form a proper watery atm. the spectrum is affected. H. C. Jones therefore argued that Ostwald's theory may be dismissed, not because it is erroneous, but because it is incomplete. It leaves out of account certain changes which occur in soln. which produce other absorbents for light than those which the ion theory considers. H. C. Jones further considers that the coloured ion is usually surrounded by an "atmosphere" of the solvent, in other words, the coloured ions are hydrated.

From his study of the absorption spectra of soln. of cupric chloride and of binary mixtures of cupric chloride with the chloride of hydrogen, potassium, lithium, calcium aluminium, or zinc, F. H. Getman inferred that in extremely dil. soln., the absorption of light is assumed to be due to the presence of copper atoms holding in combination as many molecules of solvent as correspond to the co-ordination number of the metal, which, in this case, is four. In extremely conc. soln., complex anions containing copper have been shown to be present, and to these the hypothetical formula, $CuCl_4$, has been assigned. Other complex ions, in which, one, two, or three of the water molecules of the tetrahydrated copper ion have been replaced by chlorine atoms, are assumed to be present in soln. of intermediate concentrations.

Solutions of cupric chloride in non-aqueous solvents.—Anhydrous cupric chloride is soluble in alcohol. The soln. in *methyl alcohol* is brown when cold, and, according to A. Étard,[24] it deposits a green precipitate when heated to 30°. According to C. A. L. de Bruyn, 100 parts of methyl alcohol dissolve 68 parts of the salt at 15·5°; and, according to A. Étard, the sat. soln. at 22° contains 36·8 per cent.; at 40°, 37·5 per cent.; at 50°, 37·1 per cent.; and at 60°, 37·5 per cent. The mol. vol. of a mol of the salt in 1·979 to 126·656 litres of methyl alcohol ranges from 0·52 to 33·4. The mol. conductivity μ for a mol of $CuCl_2$ in v litres of methyl alcohol is $\mu=8·08$ when $v=1·997$; and $\mu=61·014$ when $v=225·616$. The corresponding degrees of ionization, α, are $\alpha=0·08$ and $\alpha=0·12$ respectively. H. C. Jones and W. R. Veazey have studied the electrical conductivity and the temp. coeff. of the conductivity of this salt in mixtures of methyl alcohol and water. F. W. O. de Coninck also found the dihydrated salt to be very soluble in methyl alcohol, forming a green or yellow soln. The anhydrous and dihydrated salts are both soluble in *ethyl alcohol*. E. Bödtker[25] found much heat to be developed in the former case, and a dark brown soln. is formed; in the latter case the colour of the soln. varies from green to yellow. According to C. A. L. de Bruyn, 100 parts of ethyl alcohol at 15·5° dissolves between 52·9 and 53·9 parts of the anhydrous salt; and, according to A. Étard, the solubility rises from 25 per cent. at —20° to 45 per cent. at 55°. According to E. Bödtker, if a drop of water is added to the alcoholic soln., crystals of $CuCl_2.2H_2O$ are immediately precipitated, and if the alcoholic soln. be conc. in vacuo, crystals of *cupric dialcoholchloride*, $CuCl_2.2C_2H_5OH$, are formed. H. C. Jones and C. F. Lindsay observed a maximum viscosity and a minimum conductivity in mixtures of alcohol and water, and W. M. Blanchard attributes this to the presence of a maximum in the amount of the associated cupric chloride molecules. The refractive indices of alcoholic soln. have been determined by C. Chéneveau; the thermal conductivity by W. von Beetz; the raising of the b.p. by H. Ley; the eq. conductivity by H. Ley; the mol. conductivity by V. Kohlschütter and M. Kutscheroff; and the electrical conductivity and the temp. coeff. of soln. in aq. alcohol by H. C. Jones and W. R. Veazey. According to A. Étard, a sat. soln. of the salt in normal *propyl alcohol* contains 30·9 per cent. of $CuCl_2$ at 19°, and 30·5 per cent. at 60°; *isopropyl alcohol,* 11·0 per cent. at 32°, 28·3 per cent. at 70°, and 28·7 per cent. at 84°; *allyl alcohol,* 23·4 per cent. at —20°, 23·3 per cent. at 32°; and normal *butyl alcohol,* 15·8 per cent. at 23°, 16·1 per cent. at 55°, and 16·7 per cent. at 92°. F. W. O. de Coninck also found the dihydrated salt is very soluble in propyl, isobutyl, or *amyl alcohol.*

A conc. soln. of anhydrous cupric chloride in *acetone* is dark yellowish-green and, according to H. Ley,[26] after standing some weeks it becomes pale yellowish-brown, and its electrical conductivity increases. H. C. Jones and W. R. Veazey found that a compound is formed between cupric chloride and acetone; with long standing the soln. forms cuprous chloride. A sat. soln. at 20° contains 8·86 per cent. of $CuCl_2.2H_2O$, and at 20°, 2·88 per cent. of $CuCl_2$. According to A. Étard, and W. Eidmann, the solubility increases with rise of temp. rather more than is the case with ethyl alcohol. A. Naumann's value for the sp. gr. of a sat. soln. at 18° is 0·8154. H. Ley has measured the electrical conductivity and the b.p. of the soln. A. Naumann, and W. Eidmann report that stannous chloride precipitates cuprous chloride from the acetone soln.; ammonia gas precipitates $CuCl_2.2NH_3$; arsenic, chromium, gold, and platinum do not act on the soln.; silver, magnesium, cadmium, copper, mercury, cobalt, nickel, lead, and bismuth act slowly forming cuprous chloride; iron acts slowly, zinc acts rather more quickly forming copper; aluminium and tin form both copper and cuprous chloride. The soln. of dihydrated cupric chloride in acetone is greenish-yellow.

Anhydrous *ether* dissolves a little anhydrous cupric chloride, 0·043 per cent. according to G. Bodtker,[27] the soln. is greenish-yellow, and it is decolorized on exposure to light with the formation of cuprous chloride which, according to A. F. Gehlen and P. Rohland, is precipitated on the addition of water; it is also decolorized in a blue but not in a red flask, and when ammonia is added to the liquid no blue coloration appears. According to F. W. O. de Coninck, dihydrated cupric chloride is insoluble in ether, but, according to G. Bödtker, 100 grms. of absolute ether dissolves 0·061 grm. of the chloride. The salt also dissolves in acidified ether forming a brown soln. 100 grms. of *ethyl acetate,* says E. Alexander, dissolves 0·4 part of $CuCl_2$, forming a brown soln. of sp. gr. 0·9055 (18°); A. Étard says the solubility is 3 per cent. at —20°, and 1·3 per cent. at 72°; and *ethyl formate,* 10·2 per cent. at —20°, 9·4 per cent. at 24°, and 7·2 per cent. at 50°.

Anhydrous cupric chloride forms double compounds or other products [28] with the *fatty amines, acetamide, piperidine, pyridine, quinoline, aniline, methylaniline, toluidine, naphthylamine, dimethylaniline, thiourea, methyl sulphide,* and with *ethyl sulphide* the soln. forms cuprous chloride when boiled for a long time. According to R. Varet, anhydrous cupric chloride and zinc cyanide in soln. or dry at 160°–170° gives cyanogen, and this has been recommended as a convenient means of preparing this gas.

According to G. Bruni and A. Manuelli,[29] anhydrous cupric chloride is soluble in *urethane;* according to A. Werner, it is soluble in *benzonitrile* and the other aromatic nitriles. According to F. W. O. de Coninck, dihydrated cupric chloride dissolves in *formic acid, pyridine, a-picoline,* and *acetonitrile;* it is insoluble in *benzaldehyde, trimethylamine, aniline, o-toluidine, methylene chloride, ethyl iodide, propyl iodide, ethylene bromide, benzene, toluene, o-xylene, ligroin, nitrobenzene,* and *turpentine;* and is insoluble in cold but soluble in hot *glycol, glycerol, paraldehyde,* and *acetic acid.*

Chemical properties of cupric chloride.—M. C. Lea [30] did not succeed in transforming cupric into cuprous chloride by press.; and R. Abegg, and E. Wiedemann and G. C. Schmidt observed no change when the anhydrous salt is exposed to cathode rays. The anhydrous chloride deliquesces in air and forms the dihydrated salt. P. Fireman and E. G. Portner found anhydrous cupric chloride shows the first sign of dissociation at 344°; when calcined in oxygen, H. Schulze found cupric chloride to be transformed into oxide with the evolution of chlorine; and when heated with a mixture of hydrogen chloride and oxygen, it stimulates the oxidation with the formation of chlorine as in Deacon's process for chlorine—probably forming an oxychloride. C. Poulenc found cupric chloride to be incompletely decomposed by hydrogen fluoride at 300°. The salt is reduced to the metal when heated in a stream of **hydrogen, coal gas,** or when heated with **calcium carbide.** According to F. Wöhler, if cupric chloride be fused in an atm. of **ethylene,** C_2H_4, large bubbles of ethylene chloride, $C_2H_4Cl_2$, are evolved which ignite and burn with a red flame, forming hydrogen chloride and soot; copper and cuprous chloride are formed. E. Filhol and J. B. Senderens found that no sensible decomposition occurs when **sulphur** is heated with soln. of cupric chloride, nitrate, or sulphate; but W. Wardlaw and F. W. Pinkard showed that in the presence of conc., not dil., hydrochloric acid, about five per cent. of the cupric chloride is reduced: $6CuCl_2+S+4H_2O=6CuCl+6HCl+H_2SO_4$; and A. Manuelli found that when a soln. of cupric chloride acidified with hydrochloric acid is heated with sulphur in a sealed tube at 150°–180°, part of the cupric chloride is reduced to the cuprous salt. P. Fireman found cupric chloride is reduced to cuprous chloride when heated with **ammonium chloride** in a tube at 400°—hydrogen chloride, nitrogen, and ammonium chloride vapours are evolved. H. Rose showed that cupric chloride is not decomposed in the cold by **sulphur trioxide** vapour; and when melted with **phosphorus,** phosphorus pentachloride and cupric phosphide are formed; heated with **phosphine,** cupric phosphide and hydrogen chloride are produced. When heated with **arsenic sulphide,** cupric sulphide and arsenic trichloride are readily formed, but, according to C. F. Rammelsberg, not so readily with antimony sulphide. H. Feigel found that cupric chloride is converted by **sulphur chloride** into cupric sulphide. **Nitrosyl chloride** does not affect cupric chloride. T. S. Hunt said that when heated with **ferrous oxide,** cuprous chloride or copper is produced, and ferrous chloride and ferric oxide. K. Heumann obtained a brilliant orange-yellow powder, CuCl.HgS, by heating a mixture of cupric chloride and **mercuric sulphide:** $3HgS+2CuCl_2=2(CuCl.HgS)+HgCl_2+S$. According to G. Quincke, molten cupric chloride dissolves metallic **copper.** According to N. Dhar, when cupric chloride is boiled with **organic acids**—tartaric, citric, lactic, and malic acid—no reduction to the cuprous salts occurs, but if an oxidizing agent like potassium permanganate be present, reduction occurs. No precipitation of the cuprous salts occurs, but a complex remains in soln. Cupric oxalate is immediately precipitated from soln. of cupric chloride by **oxalic acid.**

Cupric oxychlorides.—When cupric chloride is exposed to the air, what appears to be an oxychloride is formed. A great number have been reported, but probably most of them are mixtures, and there is no guide in distinguishing chemical individuals from mixtures until they have been investigated in the light of the phase rule. For convenience, representing the mol. ratio $CuO:CuCl_2:H_2O$ by numbers, the following eighteen basic cupric chlorides have been reported:

1.1.1 (G. Rousseau,[31] and C. Reichard); 2.1.0 (R. Kane, and J. H. Gladstone); 2.1.3 (A. Scacchi, and C. F. Rammelsberg)—represented by the mineral *ateline*; 3.1.0 (M. Berthelot, and J. L. Proust); 3.1.1½ (A. Colson, and H. Baubigny); 3.1.2 (W. L. Miller and F. B. Kenrick); 3.1.3; 3.1.3½; 3.1.4; 3.1.4½ (F. Field, C. A. Burghardt and J. Tüttscheff)—represented by *atacamite* from Tocopilla (Bolivia); 3.1.5 (K. Kraut); 3.1.6 (P. Berthier, F. Field, and A. H. Church)—represented by the minerals *botallacite* (Cornwall), and *atacamite* from Tocopilla (Bolivia); 3½.1.4½ (F. Reindel); 4.1.6. (R. Kane); 4.1.8 (A. H. Church)—represented by the mineral *tallingite* (Cornwall); 6.1.9 (C. A. Neumann); 6.1.12 (A. H. Church)—found as a natural product in Cornwall; and 8.1.12 (G. A. König, and L. Darapsky)—represented by the mineral *footeite*. J. A. Hedvall and G. Booberg obtained 3.1.4 by the action of copper oxide on a mixture of alkali chlorides at 1000°, and heating for a long time with a soln. of alkali chloride.

The basic salt, $3CuO.CuCl_2.3H_2O$, or $3Cu(OH)_2.CuCl_2$, is regarded by A. Werner[32] as a *hexolcupric chloride*, $[Cu(HO.Cu.OH)_3]Cl_2$; E. Ludwig supposes the copper in the molecule to be quadrivalent; while J. Dupont and H. Jansen, finding that two-thirds of the water is lost at 200°, supposed the last molecule to be differently constituted: Cl—Cu—O—Cu—Cl.H_2O; while A. Mailhe regards it as a tetracupric chloride. The mineral called *atacamite* has a composition which varies between 3.1.3 and 3.1.6; and which is usually taken to be 3.1.4; and to distinguish this from 3.1.3-salt, G. F. H. Smith proposed to call the latter *paratacamite.*

J. Dupont and H. Jansen prepared the 3.1.3-salt by heating a neutral dil. soln. of cupric chloride, or a mixture of cupric oxide and a soln. of cupric chloride, in a sealed tube at 225°; P. Sabatier treated cupric oxide, CuO, hydroxide, $Cu(OH)_2$, or the brown $4CuO.H_2O$, with a hot or cold soln. of cupric chloride; A. Mailhe treated a soln. of cupric chloride with cold nickel hydroxide or carbonate, or with heated nickel oxide; A. Mailhe also obtained a blue precipitate by adding freshly precipitated mercuric oxide to a soln. of cupric chloride—the dry yellow or red oxide acts very slowly—according to H. Rose, only the oxide is precipitated. L. Sabbatani boiled a soln. of ammonium cuprichloride with water.

The bluish-green amorphous precipitate remains many hours in contact with water in a sealed tube unchanged. It begins to decompose at 200°, and at 250° forms a dark brown hygroscopic mixture of cupric chloride and oxide; and at a higher temp. water and hydrogen chloride are given off.

The 3.1.3-mineral paratacamite forms trigonal crystals; hardness, 3; sp. gr., 3·74; refractive index, 1·864. The 4.1.4-mineral atamacite forms emerald-, grass-, or dark green crystals which are rhombic bipyramids with axial ratios $a:b:c=0·6613:1:0·7515$; hardness, 3·0–3·5; sp. gr., 3·763–4·314.

M. Berthelot[33] synthesized the 4.1.4-mineral by exposing copper foil, moistened with hydrochloric acid or a soln. of ammonium chloride, to the action of air. The resulting green powder was washed. Sodium chloride and sulphuric acid can be used in place of hydrochloric acid. Copper foil can also be laid on a mush of copper sulphide, sodium chloride, and water. K. Kraut warmed a mixture of copper oxide and hydrochloric acid; C. Friedel heated a mixture of cuprous oxide with ferric chloride soln. for 48 hrs. in a sealed tube. Green crystals of artificial atacamite appeared. J. L. Proust made it by exposing moist cuprous chloride to the air, and removing the cupric chloride simultaneously formed by washing; M. Gröger passed air through a soln. of cuprous chloride in cupric chloride free from hydrochloric acid; E. Brun sat. a hot soln. of potassium, sodium, or ammonium chloride with cuprous chloride, and on cooling a crystalline powder separated out. G. Rousseau heated a mixture of cupric chloride soln. and magnesite in a sealed tube for three days at 180°–200°; J. L. Proust digested a soln. of cupric chloride with cupric hydroxide, or of cupric chloride mixed with a little alkali hydroxide; L. Bourgeois treated a soln. of cupric chloride with urea in a sealed tube at 130°. V. von Lang decomposed the double compound $CuCl_2.2C_5H_5N$ with boiling water; W. Crum boiled a soln. of cupric nitrate or sulphate with a little calcium or sodium hypochlorite; H. Debray heated a conc. soln. of sodium chloride with basic copper nitrate or copper tetrammino-sulphate for some days at 200°. The product of these reactions is a green powder, crystalline or amorphous. The heat of formation, according to M. Berthelot, $3CuO+CuCl_2+4H_2O=23$ Cals. According to G. Rousseau and G. Tite,[34] the product scarcely loses any weight if dried for several days between 150° and 200°, between 210° and 220° it loses all its water and blackens; at 240° it begins to decompose. According to T. C. Cloud, when heated in a current of oxygen, cupric oxide remains, cuprous chloride sublimes. It is not soluble in water; it is decomposed by sulphuric acid. The so-called 3.1.3½-salt is probably the 3.1.4-salt. W. T. Casselmann, and F. Field obtained what was considered to be this product by treating a boiling soln. of cupric chloride with acetates of the alkali or alkaline earths, magnesium, zinc, cadmium, manganese, nickel, or cobalt; or by treating copper acetate under similar conditions with the chlorides in question. Formates, propionates, or valerates may be used instead of the acetate. F. Reindel, and J. Habermann have also studied this product.

§ 17. Complex Salts of Cupric Chloride

The solubility of cupric chloride in hydrochloric acid first decreases as the proportion of the acid increases and reaches a minimum when about 20 per cent. of HCl is present. The following is a selection from R. Engel's results[1] with the conc. expressed in milligram eq.—$\frac{1}{2}CuCl_2$—per 100 c.c. at 0°:

HCl . .	0	4·5	10·5	37·5	70·25	102·5	128·0
$CuCl_2$ . .	91·75	86·8	79·35	50·0	22·8	23·5	26·7
Sp. gr. .	1·490	1·475	1·435	1·319	1·231	1·288	1·323

The increase in solubility is attributed to the formation of complexes. R. Engel obtained dark red needles of the compound **trihydrated cupric hydro-trichloride,** $CuCl_2.HCl.3H_2O$, by passing hydrogen chloride over dihydrated cupric chloride, or by saturating a soln. of about 20 per cent. cupric chloride at 20°–25° with hydrogen chloride, and cooling the product to 0°. The compound can be regarded as a **trichlorocupric acid,** $HCuCl_3.3H_2O$, corresponding with the sodium, ammonium, and rubidium salts. This product rapidly loses hydrogen chloride in dry air and becomes green; and the green crystals become red again in a stream of hydrogen chloride. According to A. Naumann and E. Alexander, when the yellowish-brown soln. of cupric chloride in ethyl acetate is treated with dry hydrogen chloride, a brown mass is obtained which becomes green on exposure to air. W. Eidmann found a similar product is formed when a soln. of cupric chloride in acetone is similarly treated. It is readily soluble in water, and its composition corresponds with cupric dihydro-tetrachloride, $CuCl_2.2HCl$, or tetrachlorocupric acid, H_2CuCl_4; P. Sabatier obtained hyacinth-red needles of the **penta hydrated cupric dihydro-tetrachloride,** $CuCl_2.2HCl.5H_2O$, by leading hydrogen chloride into a soln. of cupric chloride sat. with hydrogen chloride, and cooling the brown product to —10°. It loses hydrogen chloride on exposure to air, forming dihydrated cupric chloride. G. Naumann obtained red needles of **cupric trihydro-pentachloride,** $CuCl_2.3HCl$, or **pentachloro-cupric acid,** H_3CuCl_5, by passing chlorine and hydrogen chloride into a soln. of 18 grms. of $CuCl_2.2H_2O$ in 45 c.c. of water, and after standing for an hour separating the crystals by means of a suction filter.

A. Chassevant [2] found that transparent garnet-red crystals of the double chloride of lithium and copper were formed when conc. soln. of eq. amounts of cupric and lithium chlorides are mixed together and the magma evaporated in vacuo over phosphoric acid or on a water-bath. The green crystals of cupric chloride first formed dissolve forming a red soln., and this deposits crystals of the double salt which A. Chassevant regarded as $CuCl_2.LiCl.2\frac{1}{4}H_2O$, but which W. Meyerhoffer showed to be **dihydrated lithium trichlorocuprate,** $CuCl_2.LiCl.2H_2O$. W. Meyerhoffer found the saturation curve of the double salt and lithium chloride to be $0·67CuCl_2+30·8LiCl$ per 100 mols of water at 14·6°, and $4·00CuCl_2+50·9LiCl$ at 98·6°; while the saturation curve of the double salt and dihydrated cupric chloride at 18·3° is $4·04CuCl_2+21·0LiCl$ at 18·3° and $14·22CuCl_2+19·4LiCl$ at 98·5°. In this temp. interval the double salt is decomposed by the water, and it is present in aq. soln. only when an excess of lithium chloride is present. F. A. H. Schreinemakers and A. C. Noorduyn studied the ternary system, $LiCl—CuCl_2—H_2O$, at 30°, and found dihydrated lithium cuprichloride to be the only double salt formed.

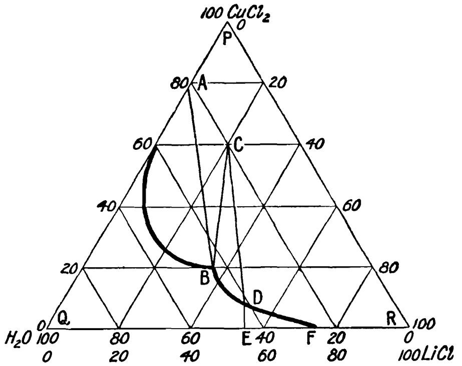

FIG. 28.—Equilibrium Diagram for the Ternary System, $CuCl_2—LiCl—H_2O$, at 30°.

Fig. 28 represents an equilateral triangle, *PQR*, with each side divided into 10 equal parts and with lines parallel to each of the three sides. If the apices be taken to represent pure components; points on the sides of the triangle will represent corresponding binary mixtures; and points in the interior of the triangle ternary mixtures. The vertical distance of any line from the side opposite the apex represents the percentage amount of that constituent in the ternary mixture. The area *ABC* represents sat. soln. which for equilibrium deposit dihydrated cupric chloride, and *CB* represents the composition of a sat. soln. of this salt at 30° when in equilibrium with the solid phase; *A* represents the solid salt. Similarly, the region *BDC* represents sat. soln. which for equilibrium deposit the double salt $CuCl_2.LiCl.2H_2O$, and *BD* represents a sat. soln. of the solid in equilibrium with the solid phase. Likewise also the area *DEF* and the line *DF* with respect to the solid phase

$LiCl.H_2O$. The above data for the mutual solubilities of the two chlorides are plotted in Fig. 29. Points in the area *ABDQ* represent unsaturated soln.; points on the line *AB* represent sat. soln. of sodium chloride, in the presence of cupric chloride—*A* represents the solubility of sodium chloride in water at 30°, and *D*, that of cupric chloride—points on *DB* represent sat. soln. of cupric chloride in the presence of sodium chloride; the point *B* represents a soln. sat. with respect to both sodium chloride and cupric chloride. Soln. represented by points in the sector *BDP* represent soln. which for equilibrium break up into a sat. soln. and $CuCl_2.2H_2O$ as a solid phase; points in the sector *ABR* represent soln. which for equilibrium break up into sat. soln. and NaCl as a solid phase; and points in the sector *RBP* represent soln. which for equilibrium break up into a sat. soln. with both NaCl and $CuCl_2H_2O$ as two solid phases. The triangular diagram, Fig. 30, for the ternary system, $CuCl_2$—NH_4Cl—H_2O, is a step more complicated.

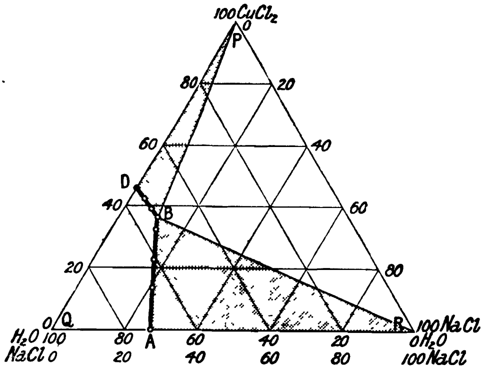

FIG. 29.—Equilibrium Diagrams for the Ternary System, $CuCl_2$—$NaCl$—H_2O, at 30°.

When crystals of the double salt are exposed to the air, they become opaque and decompose, forming crystals of dihydrated cupric chloride and deliquescent lithium chloride. The salt is also decomposed by water, but can be recovered by crystallization from a soln. of lithium chloride. The crystals melt in their water of crystallization when rapidly heated to 130°, forming a black liquid which, like lithium chloride, when heated to a higher temp., decomposes with the evolution of chlorine; if slowly heated between 100° and 120°, they become anhydrous and at the same time lose some hydrochloric acid; the crystals are best dehydrated by heating to 120° in a stream of dry air mixed with hydrogen chloride. L. Cambi has prepared dark red $LiCuCl_3.HCOOH$ and yellowish-red $LiCuCl_3.CH_3CN$ by crystallization respectively from formic acid and acetonitrile.

T. S. Hunt[3] has made a few determinations of the solubilities of cupric chloride in soln. of sodium chloride of different conc. between 11° and 90°. No double salt has been made. M. Siewert also failed to crystallize a *sodium chlorocuprocuprate*, which he claims to have obtained as an oily liquid by boiling a soln. containing cupric, cuprous, and sodium chlorides in the mol. proportions 1 : 2 : 2, and adding a mixture of alcohol and ether. F. A. H. Schreinemakers and F. W. C. de Baat have investigated the ternary system, $CuCl_2$—$NaCl$—H_2O, and found no evidence of the formation of a double compound. The following numbers are selected from their data, representing the percentage solubility of cupric chloride in soln. of sodium chloride at 30°:

NaCl . .	0	4·28	6·41	10·25	12·25	15·40	20·61	26·47
$CuCl_2$ . .	43·95	41·06	39·40	36·86	32·40	23·72	11·03	0

O. Hautz[4] reported that blue crystals of the double chloride, **dihydrated ammonium trichlorocuprate,** $CuCl_2.NH_4Cl.2H_2O$, are obtained by mixing eq. quantities of cupric and ammonium chloride in aq. soln.—one prepared by neutralizing copper carbonate with hydrochloric acid, and the other by neutralizing ammonia with the same acid. The crystals are soluble in twice their weight of water. P. P. Dehérain made the same salt by dissolving cupric ammino-chloride in hydrochloric acid. According to P. A. Meerburg, O. Hautz's salt is not stable in aq. soln. in the vicinity of 11°, and he doubts if it is a chemical individual. The ternary system, $CuCl_2$—NH_4Cl—H_2O, at 11°, shows no evidence of Hautz's compound.

The results are indicated in Fig. 30. The curve *ABCD* is plotted from the following observations, where 100 grms. of a sat. soln. at 30° contain:

$CuCl_2$ . .	0	1·9	3·6	10·5	19·9	29·4	41·4	43·2	43·9
NH_4Cl . .	29·5	28·6	25·9	16·5	9·4	4·9	2·1	2·0	0

The curve *AB* represents the composition of soln. in equilibrium with ammonium chloride whose solubility in water at 30° is represented by the point *A*; the line *DC* represents similarly the composition of soln. in equilibrium with dihydrated cupric chloride; and the curve *BC* represents the solubility of dihydrated ammonium cupri-tetra chloride. The quadruple points *B* and *C* represent the composition of soln. in equilibrium with two solid phases, $CuCl_2.2NH_4Cl.2H_2O$ respectively with NH_4Cl and with $CuCl_2.2H_2O$. The composition of unsaturated soln. at 30° is included. Within the region *ABCDQ* the soln. is unsaturated; and the composition of soln. which separates at 30° into one or two solid phases is included in the region *ABCDPR*. All points in the sector *ABR* represent soln. which form a soln. and solid ammonium chloride; *BCX*, soln. and solid $CuCl_2.2NH_4Cl.2H_2O$; *CDT*, soln. and solid $CuCl_2.2H_2O$; *BXR*, soln. and two solid phases NH_4Cl and $CuCl_2.2NH_4Cl.2H_2O$; *CTX*, soln. and the two solid phases $CuCl_2.2H_2O$ and $CuCl_2.2NH_4Cl.2H_2O$; and *TPR*, systems which separate into three solid phases NH_4Cl, $CuCl_2$, and $CuCl_2.2H_2O$. The point *a* represents the salt 1.2.2; *b*, the salt 1.2.1; and *c*, the salt 1.2.4, none of which finds a place in this diagram as a chemical individual at 30°, and a further quest between —11° and 80° likewise proved nugatory.

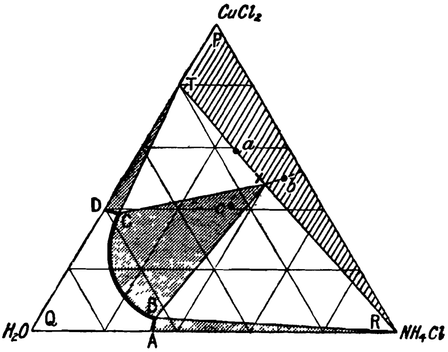

FIG. 30.—Equilibrium Curves for Ternary Systems, $CuCl_2$—NH_4Cl—H_2O, at 30°.

The 1.2.2-double chloride, *i e.* **dihydrated ammonium chlorocuprate,** $CuCl_2.2NH_4Cl.2H_2O$, was prepared by A. Vogel by mixing soln. of cupric sulphate and ammonium chloride; the first crop of crystals was a double sulphate of the two bases, then followed crystals of the 1.2.2-double chloride. The same salt was more conveniently prepared, by T. Graham, and E. Mitscherlich,[5] by mixing conc. soln. of dihydrated cupric chloride and ammonium chloride in mol. proportions. P. A. Cap and O. Henry made it by evaporating a soln. formed by adding ammonia to a soln. of cupric chloride until the precipitate first formed redissolved. A. Bouzat made the salt in an analogous manner; R. H. Brett crystallized the soln. obtained by dissolving cupric oxide, hydroxide, or carbonate in a soln. of ammonium chloride; and P. P. Dehérain, by dissolving cupric diammino-chloride in hydrochloric acid.

According to G. Wyrouboff, the pale blue crystals form ditetragonal bipyramids which have the axial ratios: $a : c = 1 : 0{\cdot}7417$. According to O. Lehmann, this salt forms mixed crystals with ammonium chloride, the double salt, $3NH_4Cl.FeCl_3$ (bluish-green), and cobalt chloride (rose-red). G. Tschermak gives the sp. gr. 2·066; A. Johnsen, 2·01; G. Wyrouboff, 1·963. V. von Lang found the ratio of the thermal conductivities parallel and vertical to the chief axis to be in the ratio 1 : 0·93; he also found the crystals to be paramagnetic. A. de Sénarmont showed that the crystals have a negative double refraction with refractive indices for the *D*-line $\omega = 1{\cdot}744$, $\epsilon = 1{\cdot}724$. According to A. Bouzat, the heat of formation, $CuCl_2.2NH_{3solid} + HCl_{gas} = 38{\cdot}9$ Cals, and in soln., 31·75 Cals. The solubility, according to P. A. Meerburg, rises steadily from 20·46 per cent. of $CuCl_2.2NH_4Cl$ at —10° to 43·36 per cent. at 80°; or,

	−10·5°	−10·8°	−11°	−10°	0°	20	50°	80°
$CuCl_2.2NH_4Cl$.	3·87	20·12	20·3	20·46	22·02	25·95	33·24	43·36
Solid phase .	ice		←Both→	$CuCl_2.2NH_4Cl.2H_2O$				

H. L. Maxwell found by diffusion experiments evidence of the partial separation of the complex in aq. soln. into its component salts. H. C. Jones and H. P. Bassett have measured the electrical conductivity and the lowering of the f.p.; the latter has also been determined by P. A. Meerburg, and by F. Rüdorff. Soln. with a mol of the salt per litre are approximately 43·6 per cent. ionized, and soln. with 0·05 mol per litre 83·2 per cent. According to W. Meyerhoffer, the sat. soln. freezes at —13°, at —18° in the presence of ammonium chloride, and at —30° in the presence of dihydrated cupric chloride. Aqua ammonia precipitates a basic chloride from the aq. soln., and, according to R. Engel, hydrogen chloride gas precipitates the salt from its aq. soln. The crystals lose their water completely when heated between 110° and 120°—without decomposition, said C. Temme; with the loss of ammonium chloride, said T. Graham. According to W. Meyerhoffer, the transition temp., $CuCl_2.2NH_4Cl.2H_2O \rightleftharpoons CuCl_2.NH_4Cl+NH_4Cl+2H_2O$, is 146°. According to P. A. Cap and O. Henry, the crystals decompose when strongly heated with the loss of ammonium chloride, and the formation of some acid vapour and cuprous chloride. The aq. soln. of ammonium cupric tetrachloride dissolves iron but not carbon, and consequently a conc. soln. with about 5 per cent. of hydrochloric acid can be used for the determination of carbon in steel. The soln. decomposes when heated with ferrous sulphide. According to E. C. Franklin and C. A. Kraus, the salt is soluble in liquid ammonia; and, according to P. A. Cap and O. Henry, it dissolves in alcohol without decomposition.

P. A. Meerburg could find no evidence of the 1.2.1 monohydrated salt, $CuCl_2.2NH_4Cl.H_2O$, reported by P. A. Cap and O. Henry; nor of the 1.2.3 trihydrated salt reported by L. Bourgeois; nor of the tetrahydrated salt reported by F. Rüdorff, K. Heumann, and P. A. Cap and O. Henry. Nor is there any satisfactory evidence of P. P. Dehérain's $CuCl_2.4NH_4Cl$, or of his $CuCl_2.6NH_4Cl$. H. Ritthausen obtained cubic crystals of **ammonium diammino-tetrachlorocuprate**, $CuCl_2.2NH_4Cl.2NH_3$, in the mother liquid remaining after the precipitation of ammonium cupric tetrachloride.

F. A. H. Schreinemakers and A. C. Noorduyn[6] have investigated the ternary system, $CuCl_2$—LiCl—H_2O, at 30°. W. Meyerhoffer has investigated the conditions of equilibrium for part of the ternary system, $CuCl_2$—KCl—H_2O, and established the existence of the two double salts, $CuCl_2.2KCl.2H_2O$ and $CuCl_2.KCl$, which can be conveniently represented as the 1.2.2-salt and the 1.1-salt respectively. The system has three components, $CuCl_2$, KCl, and H_2O. From the phase rule, therefore, bivariant systems will have three phases—one solid, a liquid, and a vapour; univariant systems will have four phases—two solids, a liquid, and a vapour; and invariant systems, five phases—three solids, a liquid, and a vapour. W. Meyerhoffer's experiments, ranging between 39° and 92°, may be represented on a triangular diagram as indicated by W. D. Bancroft, but they cover only a small portion of the field. The triangular diagrams, Figs. 30 and 31, represent isothermal systems. If the apices of a triangle also represent the m.p. of the components, and the temp. of points on the sides of the triangle are known, a series of isothermal curves can be drawn for the interior of the triangle, and thus not only composition, but a rough idea of the corresponding temp. can be obtained. In Fig. 31, *M* is the cryohydric point —11·4° for ice and potassium chloride; *N*, approximately —23°, is the corresponding point for ice and dihydrated cupric chloride. Following W. D. Bancroft's treatment: along *MS*, ice and potassium chloride are solid phases; along *NT*, ice and dihydrated cupric chloride. The two curves do not meet, since probably the 1.2.2-salt appears at both *S* and *T*. Each of these points, therefore, represents an invariant system with three solid phases, liquid, and vapour; but this portion of the diagram has not been closely investigated. Along a curve connecting *S* and

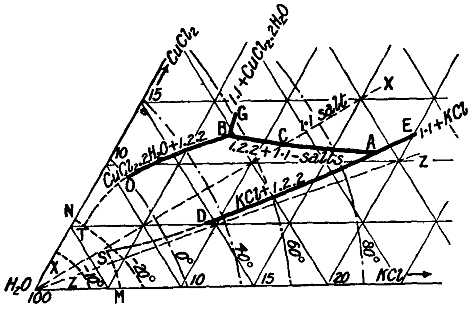

Fig. 31.—Equilibrium Curves of Portion of the Ternary System, $CuCl_2$—KCl—H_2O, between —25° and 100°.

T the solid phases will be ice and the 1.2.2-salt, and, as shown below, the temp. will rise in passing from *T* to *S*. Along *SDA*, the solid phases are the 1.2.2-salt and potassium chloride, and at *A*, 92·4°, the red 1.1-salt is formed. The point *A* represents an invariant system with three solid phases—KCl, and the 1.2.2 and 1.1-salts—and along *AE* the univariant system with two solid phases—1.1-salt and KCl. Starting from *T* along *TOB*, the solid phases are the 1.2.2-salt and $CuCl_2.2H_2O$. The point *B*, 56·2°, is a quintuple point representing an invariant system with three solid phases—$CuCl_2.2H_2O$, the 1.2.2-salt and 1.1-salt—liquid, and vapour. Beyond *B*, along *BG*, the univariant system has two solid phases—1.1-salt and $CuCl_2.2H_2O$. Along *BA*, the two solid phases are the 1.2.2-salt and the 1.1-salt. Potassium chloride exists as solid phase in the bivariant region bounded by *MSDAE*; dihydrated cupric chloride in the region bounded by *NTOBG*; the 1.2.2-salt, in the region *SDABOT*; and the 1.1-salt, in the region *GBAE*. The dotted line *ZZ* represents soln. containing twice as much KCl as $CuCl_2$, yet it does not pass into the region of stability for the 1.2.2-salt, and therefore this salt is decomposed by water with the precipitation of potassium chloride, and the green colour of the 1.2.2-salt corresponds with a slight decomposition and the presence of traces of mother liquid containing cupric chloride. The aq. soln. is stable in the presence of potassium chloride. The dotted line *XX* represents soln. with the ratio $CuCl_2$; KCl=unity; the field for the 1.1-salt is cut by this line at *C*, 72°, and from this temp. upwards it is possible to obtain a soln. with the salts in the same ratio as they are in the solid phase. Between 56·2° and 72°, the 1.1-salt is decomposed by water, forming the 1.2.2-salt—the range of instability is nearly 16°. The line *ZZ*, extending from the $100H_2O$ apex representing the m.p. of ice, connects this point with the m.p. of potassium cupric tetrachloride, and hence the temp. should rise in passing from *T* to *S*. The salt component present at *S* is necessarily that which is precipitated by the action of water on the 1.2.2-salt, or, as F. A. H. Schreinemakers expresses it:

> The cryohydric temp. of a soln. in equilibrium with a double salt and the component which does not precipitate, is lower than the cryohydric temp. of a soln. in equilibrium with double salt and the component which precipitates.

If the double salt be not decomposed by water, the points *T* and *S* in Fig. 31 would lie on opposite sides of the line *ZZ*, and there would be a maximum temp. at the point where *ZZ* cuts the curve, joining *T* and *S*. According to the so-called theorem of A. C. van Rijn van Alkemade, and in agreement with F. A. H. Schreinemakers and W. Meyerhoffer:

> If the two points in the triangle which correspond to the compositions of two solid phases be connected by a line, the temp. at which these same two phases can be in equilibrium with soln. and vapour, rises as the boundary curve approaches this line, becoming a maximum at the intersection, though the boundary curve often ceases to be stable before this point is reached. When the two solid phases are two of the components, the line connecting the m.p. is one of the sides of the triangle—

and therefore, if this theorem be correct, the temp. must rise in passing along a boundary curve to the side of a triangle. For example, dihydrated ammonium cupric tetrachloride, $CuCl_2.2NH_4Cl.2H_2O$, is in equilibrium with ice and ammonium chloride at —15°, with ice and dihydrated cupric chloride at —42°, while the curve connecting these points passed through a maximum at —12·7°.

M. Gröger[7] made **potassium trichlorocuprate,** $KCuCl_3$ or $KCl.CuCl_2$, by the action of a soln. of cupric chloride in hydrochloric acid (sp. gr. 1·19) on powdered potassium chloride—say by shaking for 3 hrs. a mixture of 10 grms. of dihydrated cupric chloride; 4 grms. of potassium chloride; and 50 c.c. of hydrochloric acid. Filter the mixture out of contact with air; press the crystals on filter paper; and dry in vacuo over sulphuric acid. W. Meyerhoffer purified the 1.2.2-salt by dissolving it in fairly warm conc. acetic acid; garnet-red needles of the 1.2.2-salt separate out on cooling the brown soln. The needle-like crystals are filtered while still warm, and dried in the air-bath at 100°. W. Meyerhoffer showed that this compound is formed by melting the two solids together—but there is a considerable loss of chlorine; or by evaporating a mixed soln. of the two salts with continued stirring so as to avoid the separation of potassium chloride. The sp. gr. of the crystals is 2·86; and, according to A. Chassevant, they can be heated to redness without decomposition. They dissolve in cold water, forming a blue soln.; they decompose in moist air, $2KCuCl_3+4H_2O=CuCl_2.2KCl.2H_2O+CuCl_2.2H_2O$, but the mixture reforms $KCl.CuCl_2$ after standing some hours in a desiccator. W. Meyerhoffer investigated the solubility of this salt in the presence of cupric and potassium chlorides. J. G. C. Vriens found the heat of soln. of a mol of the salt $KCuCl_3$ in 200 mols of water to be 3·55 Cals., and also showed that the vap. press. of $1.2.2+CuCl_2.2H_2O+$soln.+vapour, and of $1.2.2+1.1+CuCl_2.2H_2O+$vapour; 1.2.2+1·1+soln.+vapour; and $1.2.2+1.1+CuCl_2.2H_2O+$vapour; and of $1.1+CuCl_2.2H_2O+$soln.+vapour, all coincide at 56°.

F. Godeffroy [8] mixed a conc. soln. of potassium chloride and of cupric chloride in conc. hydrochloric acid, and obtained no precipitate. C. Hensgen claimed to have prepared anhydrous potassium cupric tetrachloride, K_2CuCl_4 or $CuCl_2.2KCl$, by passing hydrogen chloride into a sat. soln. of $K_2SO_4.CuSO_4.6H_2O$, when green crystals of the **dihydrated potassium tetrachlorocuprate,** $K_2CuCl_4.2H_2O$, separate out; if the crystals themselves be treated with the gas, the colour changes from blue to green, and bright red spots appear, which disappear if the crystals be melted. The red crystals were probably the 1.1-salt, the green crystals the 1.2.2-salt. E. Mitscherlich, C. F. Rammelsberg, and V. A. Jacquelain prepared the 1.2.2-salt by cooling a warm conc. soln. of the two component salts. According to W. Meyerhoffer, the soln. can be evaporated just under the b.p. without decomposition. According to G. Wyrouboff,[9] C. F. Rammelsberg, and A. Fock, the greenish-blue crystals form ditetragonal bipyramids with the axial ratio $a:c=1:0·7525$. They form mixed crystals with the corresponding ammonium salt, and, according to A. Fock, there is a lacuna in the series between 27·77 and 54·87 per cent. of $CuCl_2.2KCl.2H_2O$. The sp. gr. is 2·392, according to H. G. F. Schröder; H. Kopp gave 2·359; and H. Schiff, 2·4. According to W. Meyerhoffer, when heated, the salt decomposes into $KCl.CuCl_2$ and KCl In sat. soln. the garnet-red 1.1-salt is formed at 93°; at lower temp., in the presence of cupric chloride, the 1.2.2-salt appears at 56°. The transformation $CuCl_2.2KCl.2H_2O\rightleftharpoons CuCl_2.KCl+KCl+2H_2O$ occurs at 92·4° and the transformation $2KCuCl_3+4H_2O\rightleftharpoons CuCl_2.2KCl.2H_2O+CuCl_2.2H_2O$ is at 56·2°. These two transformations illustrate the rule stated by W. D. Bancroft: when one of the solid phases can change at a quintuple point into the other two with the addition or subtraction of water, the inversion point is a minimum temp. for that phase if water be added to complete the reaction, and a maximum temp. if the water be subtracted —for 92·4° is a maximum and 56·2° a minimum temp. According to P. A. Favre and C. A. Valson,[10] the heat of soln. of $K_2CuCl_4.2H_2O$ is —6·982 Cals., while for the individual salts $CuCl_2.2H_2O+2KCl$ it is —4·502 Cals.; J. G. C. Vriens, the heat of soln. of a mol of the 1.2.2-salt in 200 mols of water is —6·958 Cals. F. M. Raoult, and H. C. Jones and H. P. Bassett have determined the lowering of the f.p., and the two latter also the sp. gr. and electrical conductivities of soln. of this salt. J. G. C. Vriens' values for the vap. press. of the systems 1.2.2+KCl+soln. and vapour; 1.2.2+1.1+soln. and vapour; and 1.2.2+1.1+KCl+vapour; 1.1+KCl +soln.+vapour, all coincide at 92·6°.

An aq. soln. of cupric chloride with an excess of cæsium chloride is bright yellow, resembling the yellow colour of the soln. of cupric chloride in hydrochloric acid. F. Godeffroy [11] prepared brilliant yellow rhombic prisms of **cæsium tetrachlorocuprate,** $CuCl_2.2CsCl$ or Cs_2CuCl_4, by mixing in soln. 50 grms. of cæsium chloride with 5 to 25 grms. of cupric chloride. The salt can be crystallized if redissolved to form very conc. soln.; with dil. soln. hydrated salts are deposited. H. L. Wells and L. C. Dupre found an unstable bluish-green **dihydrated cæsium tetrachlorocuprate,** $Cs_2CuCl_4.2H_2O$, to be formed by the spontaneous evaporation at low temp. of soln. containing nearly eq. proportions of the two salts. They also made dark brown triclinic crystals of **dihydrated cæsium heptachlorodicuprate,** $Cs_3Cu_2Cl_7.2H_2O$ or $3CsCl.2CuCl_2.2H_2O$, by allowing soln. with the required proportions of the two salts to evaporate at ordinary temp. If the soln. be too conc. and warm, one or both of the anhydrous chlorides, Cs_2CuCl_4 or $CsCuCl_3$, will be deposited. The crystals are nearly stable at ordinary temp.; the crystals lose their water at 100°. Similarly, H. L. Wells and L. C. Dupre made garnet-red slender hexagonal prisms which were black by reflected light, and which had the composition of **cæsium trichlorocuprate,** $CuCl_2.CsCl$ or $CsCuCl_3$. The crystals were formed under a wide variation of conditions up to the point where the mixed soln. is sat. with cupric chloride. E. H. Duclaux studied the cæsium salt.

When a soln. of cupric chloride is treated with aqua ammonia, a greenish-blue hydroxide is precipitated, and this is soluble in excess of the ammonia, forming an intense blue soln. The soln. contains a compound with at least $CuCl_2 : NH_3 = 1 : 4$, and a higher ammino-compound may be formed if the conc. of the ammonia be great and the temp. low. The reaction between the ammonia and copper salt is attended by the development of much heat. A. Bouzat[12] found that by treating a mol of cupric chloride with four mols of ammonia, 18·05 Cals. of heat are developed; with 5 mols, 19·5 Cals.; with 6, 20·20 Cals.; with 7, 20·65 Cals.; with 8, 21·0 Cals.; with 10, 21·50 Cals.; and with 12, 21·9 Cals. N. W. Fischer treated a soln. of cupric chloride in an excess of aqua ammonia with cadmium, and found the copper to be completely precipitated as metal and basic salt; iron partially precipitates the copper; lead, a little copper; and tin, antimony, or bismuth, no copper.

M. Faraday noted that "chloride of copper fused is powerfully acted upon by ammonia. It immediately bursts open upon being placed in the gas and, absorbing great quantities, falls into a blue powder." H. Rose's estimate of the amount —73·7 per cent.—absorbed was shown by A. Bouzat to be too high, and his result was probably complicated by the presence of moisture, because not more than 43·5 per cent. of dry ammonia gas is absorbed after the anhydrous chloride has stood 22 hrs. in the gas. This corresponds with **cupric hexammino-chloride,** $CuCl_2.6NH_3$. According to G. Gore, dihydrated cupric chloride is insoluble in liquid ammonia; but A. Bouzat found the anhydrous chloride is converted into a similar blue powder when in contact with liquid ammonia at —30°. If the temp. of the liquid be at —70°, and subsequently raised to —40°, A. Bouzat thinks there are indications of an ammino-compound still richer in ammonia than the hexammino-salt. E. Alexander and A. Naumann also obtained cupric hexammino-chloride as a green precipitate by the action of dry ammonia on a soln. of cupric chloride in ethyl acetate. The product was washed with ethyl acetate. According to A. Bouzat, the heat of formation is 94·5 Cals. M. Faraday said that when the product is heated, it melts and gives off its ammonia while cupric chloride remains; E. Alexander said that some chlorine is lost as ammonium chloride and H. Rose that cuprous chloride remains. According to R. Kane and A. Bouzat, it loses $2NH_3$ at 90°, and another $2NH_3$ is lost between 135° and 149°—L. Sabbatani gives 100°–125°. According to F. Ephraim, at room temp. a mol of cupric chloride takes up 5·75 mols of ammonia, and the resulting compound on heating slowly loses ammonia up to 103°, when it contains 5·08 mols; a further elevation of the temp. up to 107°, produces a sudden fall in the ammonia content to 3·36 mols, corresponding with the deep ultramarine-blue, **tricupric decammino-chloride,** $3CuCl_2.10NH_3$; the ammonia content then remains constant up to 124°, when gas is again evolved, and at 127°, the residue contains 2·09 mols of ammonia, and does not evolve ammonia until 270°, when it melts, and on cooling solidifies to a hard cake. D. W. Horn found that the hexammino-compound is stable up to 20°, and dissociates at 46·7° under a press. of 20 mm. The salt is insoluble in liquid ammonia, but is soluble in water, forming an ammoniacal soln. of cupric chloride—some blue hydroxide may be precipitated if the proportion of water is great.

Anhydrous **cupric pentammino-chloride,** $CuCl_2.5NH_3$, is not known, but F. Ephraim says that cupric pentammino-chloride forms solid soln. below 105°, which attain the composition $CuCl_2+5NH_3$ at about —15°. A. Bouzat claims to have prepared the sesquihydrated pentammino-salt, $CuCl_2.5NH_3.1\frac{1}{2}H_2O$, by cooling an ammoniacal soln. of cupric chloride to —15°, or by the action of ammonia on the same soln. at 0°. The heat of formation, according to A. Bouzat, is 84·1 Cals. at 14°; 81·7° cals. at 13°. The dark blue crystals form the diammino-salt when heated, and are soluble in water and in aq. ammonia. The aq. soln. precipitates cupric hydroxide when diluted. The crystals remain unchanged in an atm. of dry ammonia, but if allowed to stand under a bell-jar over potassium hydroxide and a mixture of lime and ammonium chloride the hemihydrated salt, $CuCl_2.5NH_3.\frac{1}{2}H_2O$, is formed.

A. Bouzat prepared anhydrous **cupric tetrammino-chloride,** $CuCl_2.4NH_3$, obtained by heating the hexamino-salt to 90° in a closed vessel with an exit tube dipping under mercury; and L. Sabbatani by allowing the dihydrated salt to stand over a mixture of lime and ammonium chloride. The blue salt is unstable, it is soluble in a little water, and when diluted, cupric hydroxide is precipitated, but not if ammonium chloride be present. It dissociates at about 140°, forming the diammino-salt; its heat of formation is 72·07 Cals. According to F. Ephraim, **tricupric decammino-chloride,** $3CuCl_2.10NH_3$, is formed at 105° and is stable up to 124° when it furnishes the diammino-salt. By passing ammonia through a hot sat. soln. of cupric chloride, until the precipitate first formed has redissolved, and the soln. allowed to cool, R. Kane and A. Johnsen obtained blue monoclinic crystals of **hydrated cupric tetrammino-chloride,** $CuCl_2.4NH_3.H_2O$. V. Kohlschütter precipitated the same compound by adding alcohol to an ammoniacal soln. of cupric chloride. It forms deep blue pleochroïc crystals belonging to the monoclinic system. The salt loses ammonia on drying, and if heated below 149° it loses all the combined water and half the ammonia. The violet soln. obtained by the addition of potassium chloride and ammonia, becomes blue when warmed. The addition of a *N*-KCl soln. precipitates the diammino-salt. **Dihydrated cupric tetrammino-chloride,** $CuCl_2.4NH_3.2H_2O$, was made by A. Bouzat by evaporating an ammoniacal soln. of cupric chloride in an atm. of ammonia at ordinary temp.—say under a bell-jar over a mixture of lime and ammonium chloride. The same salt was made by cooling a hot conc. soln. of cupric chloride in ammonia. The deep blue crystals lose ammonia and water between 100° and 125°, forming the diammino-compound. The salt dissolves in a little water, and when the soln. is diluted, cupric hydroxide is precipitated. The heat of formation is 79·0 Cals. at 11°, 75·9 Cals. at 13°.

R. Kane made **cupric diammino-chloride,** $CuCl_2.2NH_3$, by heating the higher ammino-compounds to 149°; A. Bouzat to 135°; and L. Sabbatani to 100°–125°. F. Ephraim describes it as being pure green when hot, and light greenish-blue when cold. T. Graham made it by saturating warm cupric chloride with ammonia; V. Kohlschütter, by adding ammonia to a sat. soln. of cupric chloride; and W. Eidmann by leading ammonia into a soln. of cupric chloride in acetone. The green salt does not change in air; it yields cuprous chloride and nitrogen, ammonia, and ammonium chloride when heated. With water it gives a bluish-green precipitate of a basic chloride, $4CuO.CuCl_2.6H_2O$. According to F. Ephraim, the diammino-chloride decomposes below 270°. V. Kohlschütter found it to be soluble in an excess of aqua ammonia, forming complex cations $Cu(NH_3)_4''$. The heat of formation is 45·55 to 45·6 Cals., and that of the $\frac{1}{4}$-hydrated salt, 46·2–46·6 Cals. Small bluish-green microscopic crystals, which A. Bouzat claims to be $CuCl_2.2NH_3.\frac{1}{4}H_2O$, are formed by precipitation from an ammoniacal soln. of cupric chloride at 50° by the addition of alcohol. If the temp. is too low, some cupric tetrammino-chloride is precipitated; and if too high, some cupric hydroxide is precipitated.

K. A. Hofmann and E. C. Marburg treated cupric chloride with an alcoholic soln. of hydrazine hydroxide and obtained pale blue crystals approximating in composition **cupric dihydrazine chloride,** $Cu(N_2H_4)_2Cl_2$; they soon decomposed when kept in a desiccator.

§ 18. Cuprous Bromide

Copper reacts with bromine vapour at a dark red heat vigorously and with incandescence, forming a mixture of cupric and cuprous bromides; if the bromine be in excess, cupric bromide is formed. According to A. Colson,[1] the reaction occurs at ordinary temp. with finely divided copper which has been reduced at a temp. below 280°. According to H. Gautier and G. Charpy, copper wire is slowly attacked in darkness by dry bromine—thus, at 15° a copper wire lost 0·371 per cent. in weight in 8 days and 1·740 per cent. in four months; at 100°, it lost 6·62 per cent. in 8 days; and a piece of wire 5 cms. in length and 2 mm. in thickness dissolved in bromine water in contact with an excess of bromine in 7 to 8 days. M. B. Renault found a layer of cuprous bromide is formed by boiling a plate of copper with a soln. of bromine in potassium, ferric, or cupric bromide; and G. Bodländer and O. Storbeck obtained a film of colourless tetrahedral crystals of cuprous bromide under these conditions. T. Sandmeyer also boiled one part of copper turnings with a soln. of one part of crystalline copper sulphate, and four parts of potassium bromide, acidulated with one or two parts of acetic acid. The cuprous bromide is precipitated as a white powder which is then washed and dried. G. Denigès employed a similar process for the chloride.

C. F. Rammelsberg [2] noted that when cupric bromide is heated to redness, it is reduced to cuprous bromide, and E. A. Atkinson found that by heating copper to redness in a stream of hydrogen bromide cuprous bromide is formed—if elements which form volatile bromides are present they are expelled—arsenic and antimony each in 1½ hrs., and bismuth in about 2½ hrs. With hydrogen chloride, under similar conditions, a much longer period—6 to 8 hrs.—is required for the separation of these elements. Hence the method is recommended for certain analytical separations.

B. Lean and W. H. Whatmough [3] extended F. Wöhler's process to the preparation of cuprous bromide by the action of sulphur dioxide on a mixed aq. soln. of copper sulphate and alkali bromide:

> About 20 grms. of copper sulphate and 8 grms. of sodium bromide were dissolved in 300 c.c. of water, and treated with a stream of sulphur dioxide. Small white crystals of cuprous bromide were formed. These were filtered rapidly from the mother liquid, washed with sulphurous acid, spread on a porous tile, and exposed over potassium hydroxide in vacuo. The resulting crystals were coloured pale greenish-yellow. The mother liquid furnished more crystals when warmed to expel the sulphur dioxide. G. Bodländer and O. Storbeck used a similar process working with a warm soln. The water used for washing the cuprous bromide was previously boiled in a stream of carbon dioxide to expel dissolved air which decomposes cuprous bromide.

Cupric bromide, according to V. Thomas, is reduced to the cuprous salt by nitrogen dioxide, NO, or tetroxide, NO_2; and, according to A. K. Christomanos, phosphorous bromide, PBr_3, reacts turbulently with cupric nitrate—solid or in soln—forming cuprous bromide, and at the same time, nitrogen peroxide and bromine vapour are evolved. A. Naumann also found that a soln. of calcium bromide in acetone precipitates a little cuprous bromide from a soln. of cupric chloride in the same solvent—presumably the acetone reduces a little of the solute to the cuprous form.

The properties of cuprous bromide.—Cuprous bromide, CuBr, like the corresponding iodide and chloride, crystallizes in hexakis-tetrahedra. According to B. Gossner,[4] the tetrahedral **crystals** are readily obtained by crystallization from hot hydrobromic acid; and by G. Bodländer and O. Storbeck, by leaving a copper plate standing in a soln. of potassium bromide. The crystals are possibly isomorphous with those of the chloride. K. Mönkemeyer obtained a continuous series of mixed crystals between cuprous bromide and cuprous iodide, between cuprous chloride and cuprous bromide, and between cuprous chloride and cuprous iodide; with the latter, there is a gap in the mixed crystal series so that the liquidus curve forms two separate branches meeting at a eutectic. R. W. G. Wyckoff and E. Posnjak found that the **X-radiograms** correspond with the double face-centred cubic lattice of the zinc sulphide class, with sides 5·82 A., and the nearest distance of the atoms 2·49 A. According to C. H. D. Bödeker, the **specific gravity** of cuprous bromide is 4·72 (12°). P. Walden studied the mol. vol.

C. Löwig[5] reported in 1829 that cuprous bromide melts at a red heat, and T. Carnelley and W. C. Williams found the **melting point** to be 504° ± 7°, while K. Mönkemeyer, and P. de Cesaris gave 480°. According to K. Mönkemeyer, there is a transformation at about 384°, which corresponds with the fact that between this temp. and the m.p. the solid is doubly refracting, and singly refracting below this temp., α-CuBr (doubly refracting)$\rightleftharpoons\beta$-CuBr (singly refracting). P. de Cesaris places the transition temp. at 384°. According to K. Mönkemeyer, α-cuprous bromide, melting at 480°, forms a continuous series of mixed crystals with cuprous chloride, melting at 419°, and the liquidus curve has a minimum about 408°, corresponding with about 60·71 per cent. of cuprous chloride. The progressive addition of cuprous chloride steadily lowers the transition temp. of cuprous bromide from 384° to 373° when 22·82 per cent. of cuprous bromide has been added. P. de Cesaris found that when mixed with cuprous bromide, the m.p. of potassium bromide falls from 760° down to a minimum at 182° when about 66 mol. per cent. of cuprous bromide has been added. At 234°, a new solid phase, 2KBr.CuBr, appears. This is illustrated by P. de Cesaris' curve, Fig. 32. T. Carnelley and W. C. Williams' value for the **boiling point** of cuprous bromide is 861° to 954°. A. Werner's values[6] for the **molecular weights** of cuprous bromide determined from its effect on the b.p. of pyridine, methyl sulphide, and ethyl sulphide are respectively 148·44, 139, and 220–226; when the calculated value for CuCl is 143. G. Bodländer and O. Storbeck's calculations from the equilibrium between cuprous and cupric ions and of the undissociated salt; and from the e.m.f. of conc. cells, agree with the formula Cu_2Br_2.

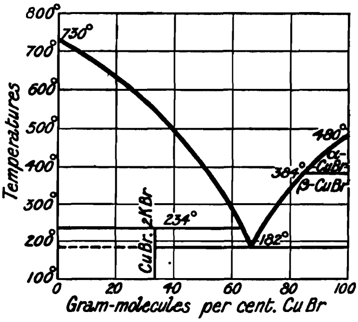

FIG. 32.—Fusion Curves of the Binary mixtures, KBr—CuBr.

The **heat of formation** of cuprous bromide from its elements is $Cu+Br_{liq.}=CuBr+24·985$ Cals. (J. Thomsen),[7] 30 Cals. (M. Berthelot), the heat of formation $Cu_2O_{solid}+2HBr=60·64$ Cals. (M. Berthelot), or in soln., 20·76 Cals. (J. Thomsen). Assuming the heat of formation is 25 Cals., G. Bodländer and O. Storbeck give the **free energy** of formation —22·3 Cals. R. Luther and D. R. Wilson's value for the **work of oxidation** in the formation of cuprous bromide from copper corresponds with an e.m.f. of —0·5640 volt. M. de K. Thompson's value for the free energy of formation from liquid bromine is —23·7 Cals. at 18°; and the **total energy,** —25 Cals. The heat evolved in replacing chlorine by bromine is 2·9 Cals.

According to M. B. Renault, and P. Rohland, cuprous bromide forms a white crystalline powder which, when exposed to sunlight, becomes a dark blue; the change is much slower in diffused daylight. F. Thomas also studied the action of light on the oxidation of this salt. Cuprous bromide does not decompose when heated in a closed tube, but in a crucible, the vapour which is given off colours the flame green. J. B. Berthemot[8] supposed this salt to be insoluble in water, but between 18° and 20°, G. Bodländer observed a solubility of 0·0002501 mol of cuprous bromide per litre. As in the case of cuprous chloride, cuprous bromide is hydrolyzed in aq. soln., $2CuBr+H_2O=2HBr+Cu_2O$, and it is partly converted into cupric chloride and metallic copper, $2CuCl=CuCl_2+Cu$. The hydrolysis is not so marked with cuprous bromide as with the chloride. According to B. Lean and H. W. Whatmough, in the presence of air, cuprous bromide, like the chloride, is decomposed by water, but the action does not take place so readily. Cuprous bromide is soluble in hydrochloric or hydrobromic acid, and the soln. in the last-named acid, *sans doute*, contains in soln. colourless **cuprous hydro-bromide.** Water precipitates cuprous bromide from the soln. According to C. Löwig, the soln. of cuprous bromide in hydrobromic acid when treated with ferrous sulphate gives a precipitate of metallic copper while ferrous bromide and ferric sulphate are formed: $2CuBr+3FeSO_4=2Cu+FeBr_2+Fe_2(SO_4)_3$; mercuric bromide is reduced to mercurous bromide; and gold is precipitated from soln. of gold chloride or bromide. Cuprous bromide is soluble in sodium chloride, and sodium thiosulphate, and the solubility, says M. B. Renault, is much less when the cuprous bromide has been previously exposed to light. The solubility, add G. Bodländer, and O. Storbeck, is increased if potassium bromide be present. Thus, with soln. containing in mols per litre:

KBr . . .	0·025	0·040	0·060	0·080	0·100	0·500
Cu (total) . .	0·000119	0·000200	0·000310	0·000423	0·0005836	0·008719
Cu (ous) . .	0·000107	0·000187	0·000285	0·000411	0·0005836	0·008719

This is evidence of the formation of complexes analogous to those with cuprous chloride. According to G. A. Barbieri, when cuprous bromide dissolved in a conc. soln. of an alkali halide is treated with a soln. of iodine in xylene in an atm. of carbon dioxide, cuprous iodide is formed. When cuprous hydroxide is treated with a soln. of potassium bromide a green product is obtained which W. Spring and M. Lucion regard as a **cuprous oxybromide,** $Cu_2O.2CuBr.H_2O$. Cuprous bromide, says C. Löwig, dissolves in *nitric acid* with the evolution of nitric oxide; it also dissolves in *sulphurous acid*, but, according to B. Lean and W. H. Whatmough, less readily than cuprous chloride. J. B. Berthemot found that it is not decomposed by boiling conc. *sulphuric acid*, or by boiling *acetic acid; hydrocyanic acid*, says R. Varet, converts it into copper cyanide. A. Werner found cuprous bromide to be soluble in *methyl* and *ethyl sulphides;* and J. Schröder, and A. Naumann, soluble in *pyridine.* W. Eidmann says cuprous bromide is not soluble in *acetone.* T. Sandmeyer noticed that with *aromatic amido-compounds* the bromine of cuprous bromide displaces the NH_2-group.

Cuprous bromide dissolves in aqua *ammonia*, and, according to J. B. Berthemot,[9] the soln. gives crystals of a double compound. T. W. Richards and B. S. Merigold prepared **cuprous ammino-bromide,** $CuBr.NH_3$, by dissolving 10 grms. of cuprous bromide in the least possible quantity of ammonia, and adding 25 c.c. of acetic acid. The crystalline product was washed with alcohol and ether, and dried over sulphuric acid under diminished press. All the operations were conducted in an atm. of hydrogen. The crystals are long flat colourless prisms which are quite stable when dry, but quickly oxidize when exposed to air in contact with water. The salt is readily soluble in ammonia and in nitric acid, but not in the other mineral acids, or in acetic acid. According to S. J. Lloyd, if cuprous bromide be sat. with ammonia gas, at 0°, and a curve be drawn showing the relation between the vap. press. and temp. as the ammonia gas is gradually withdrawn from the system, curves corresponding with the formation of $CuBr.1\frac{1}{2}NH_3$ and $CuBr.3NH_3$ are obtained—*cf.* Fig. 26, at 100° and 90°. The first compound, **cuprous sesquiammino-bromide,** $2CuBr.3NH_3$, is made by saturating cuprous bromide at 0° with ammonia gas, and gradually withdrawing the gas from the system until the press. reaches 352 mm. at 100°. The salt has a brown colour, and melts at 135°. The vap. press. at 83° is 200 mm.; at 100°, 352 mm.; at 110°, 456 mm.; and at 120°, 620 mm. By withdrawing ammonia gas from cuprous bromide sat. with ammonia gas until the press. reaches 86·7 mm. at 100°, S. J. Lloyd prepared **cuprous triammino-bromide,** $CuBr.3NH_3$, as a green compound melting at 115°. According to T. W. Richards and B. S. Merigold, the same compound is obtained by conducting dry ammonia gas over finely-powdered cuprous bromide, cooled in ice. The black powder is decomposed by water, it is soluble in aq. ammonia and in nitric acid; it is very unstable and readily gives off ammonia; its vap. press. at 69° is 214 mm.; at 78·5°, 347 mm.; at 90·5°, 601 mm.; and at 100°, 865 mm. F. Ephraim obtained a vap. press. of 760 mm. at 49·3°. According to W. Biltz and W. Stollenwerk:

	$CuBr.3NH_3$	$CuBr.1\frac{1}{2}NH_3$	$CuBr.NH_3$
Heat of formation in Cals.	9·50	13·15	14·64
Temp. when diss. press. is 100 mm. . .	283·0°	339·0°	369·0°

H. L. Wells and E. B. Hurlburt[10] prepared **ammonium cuprotribromide,** $CuBr.2NH_4Br$, or $(NH_4)_2CuBr_3$, by mixing hot soln. of an excess of ammonium bromide, with cuprous bromide and hydrobromic acid in presence of copper wire, and cooling the mixture for crystallization. This product does not oxidize so readily as the corresponding chloride, but the long colourless prisms do become green after a prolonged exposure to air. By using rather more cuprous bromide, colourless rhombohedra of **hydrated ammonium cuprodibromide,** $NH_4CuBr_2.H_2O$ or $NH_4Br.CuBr.H_2O$, are formed more stable than the preceding salt. E. Fleurent has prepared **ammonium triammino-cuprotribromide,** $NH_4Br.2CuBr.3NH_3$. Cuprous and potassium bromides also form **potassium cuprotribromide,** $CuBr.2KBr$, melting at 234°. Cuprous bromide melts at 480°, and potassium bromide at 730°. These salts can also be regarded as **bromocuprites.**

§ 19. Cupric Bromide

T. W. Richards[1] prepared anhydrous cupric bromide, $CuBr_2$, by treating the action of an excess of bromine in the presence of water upon copper.

Copper is treated with a slight excess of purified bromine in the presence of water. When the reaction is complete, the excess of bromine is expelled by gentle evaporation to dryness in a glass dish, and the nearly normal cupric bromide dissolved in a small amount of water, and the soln. filtered through asbestos contained in a Gooch's crucible. The filtrate is barely acidified with hydrobromic acid, and conc. to the consistency of syrup, and the containing vessel left in vacuo for 36 hrs. On agitation and cooling with ice, the resulting odourless, black, supersaturated soln. immediately crystallized to a mass of brownish-green needles which were collected on a Gooch's crucible, and washed three times with a very little water.

According to N. S. Kurnakoff and A. A. Sementschenko, if the evaporation occurs below 29°–30·5°, **tetrahydrated cupric bromide,** $CuBr_2.4H_2O$, is formed. The transition from the hydrate to the anhydrous salt, therefore, occurs at a lower temp. with the bromide than with the chloride. If the brown soln. of cupric bromide be evaporated spontaneously at the ordinary temp. of a winter's day the pale blue dil. soln. becomes emerald green, and as the conc. proceeds, the colour becomes darker and darker until at last it acquires a brownish-red colour recalling that of iodine; crystals of the tetrahydrated salt are deposited. The seeding of the soln. may be required if under-cooling occurs.

P. Jannasch and E. Rose made the anhydrous salt by passing bromine vapour in a stream of carbon dioxide over heated cupric sulphide. C. Löwig evaporated a soln. of cupric oxide or carbonate in hydrobromic acid, and melted the mass at a low temp. J. B. Berthemot used a mixture of hydrobromic and nitric acid; C. F. Rammelsberg, P. Sabatier, and T. W. Richards evaporated the soln. in vacuo over sulphuric acid. H. and W. Biltz used the following process:

A soln. of 16 grms. of copper oxide in hydrobromic acid (33 grms. of HBr) is filtered; and evaporated to a small volume whereby the colour becomes very dark. The basin and contents are placed in a desiccator which, for preference, is evacuated. A solid mass of crystals is formed in a few days. The mass is thoroughly broken up each day to facilitate the desiccation.

The addition of conc. sulphuric acid to a soln. of cupric bromide precipitates that salt as in the corresponding case of cupric chloride; and, according to G. Viard, the bromide is attacked rather more than the chloride, although, even if the soln. be warm, the proportion decomposed is small. According to W. O. de Coninck and L. Arzalier, when a mixture of cupric oxide and ammonium bromide is pounded in a mortar, or strongly compressed, an unstable ammoniacal cupric oxybromide is formed which is soluble in ammonia, and gradually loses ammonia, and forms a green hydrated oxybromide, and a little cupric bromide. A. C. Christomanos obtained a dark bluish-green soln. of cupric bromide as a by-product in the preparation of copper phosphide by shaking a soln. of phosphorus in ether or benzene with an excess of a 10 per cent. soln. of cupric nitrate and bromine; he then converted cuprous bromide into the cupric salt by warming it with bromine on a water-bath. According to C. Löwig, if the emerald green soln. of cupric bromide in water be evaporated rectangular crystals of **dihydrated cupric bromide,** $CuBr_2.2H_2O$, are formed; and, according to J. B. Berthemot, greenish-yellow needles of the same salt.

The properties of cupric bromide.—According to P. Sabatier,[2] the prismatic **crystals** of anhydrous cupric bromide belong to the monoclinic system; they are almost black with a colour resembling that of iodine; and the crystals of the tetrahydrated salt form long green needle-like crystals also belonging to the monoclinic system. According to T. Carnelley, the **melting point** of cupric bromide lies between

491° and 511°—say 498°. P. Jannasch and E. Rose found the salt is rather more volatile than lead bromide. Some bromine is lost when it is heated to its m.p., and, according to J. B. Berthemot, and C. F. Rammelsberg, it loses half its bromine when heated below redness, forming cuprous bromide; and C. Löwig applied similar remarks to the hydrated salt. If the cupric bromide is calcined in air, P. Sabatier showed that a little oxybromide is formed at the same time.

M. Berthelot[3] found the **heat of formation** of cupric bromide from its elements to be 60 Cals.; and J. Thomsen gives $Cu+Br_{2\,liq.}=CuBr_2+32{\cdot}58$ Cals., and the heat of formation in dil. soln. is $Cu+Br_2+aq.=CuBr_2aq.+40{\cdot}83$ Cals.; this makes the **heat of solution** of a mol of the bromide in 400 mols of water at the room temp., 8·25 Cals. P. Sabatier gives for the **heat of solution** of a mol of $CuBr_2$ in dil. soln. at 12°, 7·9 Cals., and for the heat of soln. of a mol of the tetrahydrated salt, $CuBr_2.4H_2O$, at 7·5°, —1·5 Cals. For the **heat of hydration,** $CuBr_{2\,solid}+4H_2O_{liq.}=CuBr_2.4H_2O_{solid}+9{\cdot}7$ Cals.; or, if all the constituents are in soln., 3·7 Cals. M. Berthelot also gives for the heat evolved in the displacement of the bromine by chlorine, $2\times3{\cdot}4$ Cals. For the **photoelectric effect,** see cupric fluoride. The **magnetic susceptibility** has been measured by J. Königsberger, O. Liebknecht and A. P. Wills, and S. Meyer, and they obtained 7·0 to $7{\cdot}5\times10^{-6}$ mass units for the powdered salt, and $2{\cdot}5\times10^{-6}$ mass units for the aq. soln. at 17°.

The anhydrous and hydrated salts are deliquescent, and, according to P. Sabatier, the tetrahydrated salt effloresces in dry air, and loses all its water; its behaviour in moist air depends on the degree of humidity. The solubility, calculated by G. Bodländer, is 1·3 eq. per litre. The changes of colour which occur with soln. of cupric bromide of various conc. are analogous with those which obtain with cupric chloride, and they are explained in a similar manner. Presumably, on account of the small electro-affinity of the Br′-ions there is a greater tendency to form complexes with cupric chloride than with the bromide. According to P. Sabatier, even when protected from light, the soln. of cupric bromide, after a little time, contain free bromine, the quantity of which increases rapidly with an increase in the quantity of cupric bromide, but is not proportional to it, the proportions of free bromine per litre after several months being 0·880 grm., 5·120 grms., and 6·08 grms., for 0·0255 grm., 0·175 grm., and 1·2 grms. of copper. The hydrobromic acid is probably oxidized in presence of the cupric bromide in the same manner as hydrochloric acid in presence of certain chlorides. P. Sabatier further found that very conc. soln. of cupric bromide are comparatively opaque, and their absorption spectrum can be obtained only in layers less than 1 mm. thick. The absorption spectrum of such a soln. resembles that of a soln. in alcohol. The absorption is greatest in the green, and the transmission is a maximum in the red. As the soln. is diluted, the absorption in the green decreases, and that in the red increases, until, with very dil. soln., the absorption is a maximum in the red, and very slight in the green.

The general properties of soln. of cupric bromide resemble those of the corresponding chloride (*q.v.*). The colour and the transport number, *v*, with soln. of different conc., *C*, at 25°, are, according to H. G. Denham[4]:

C . .	0·106	0·414	1·690	2·218	3·187	4·055	5·288
v . .	0·445	0·440	0·069	0·052	—0·086	—0·159	—0·392
Colour . .	Bl-green	Green	Br-green	Br-green	Brown	Deep br.	Deep br.

The negative values for the migration numbers are interpreted to mean that complex anions are formed—say $(CuBr_4)''$, $(Cu_2Br_6)''$, etc.—which carry out all the copper from the cathode compartment. If the equilibrium $Cu^{\cdot\cdot}+CuBr_2+2Br'\rightleftharpoons Cu^{\cdot\cdot}+(CuBr_4)''$ lies almost wholly to the right, the transport number would be zero; and if appreciable $(Cu_2Br_6)''$-ions were present, $Cu^{\cdot\cdot}+2CuBr_2+2Br'=Cu^{\cdot\cdot}+(Cu_2Br_6)''$, the values would be less than zero.

P. Sabatier[5] says that *alcohol* dissolves the anhydrous bromide, forming highly opaque yellowish-red soln. According to W. Eidmann, cupric bromide, $CuBr_2$, is soluble in *acetone*, forming a dark green soln. which slowly deposits cuprous bromide as a pale green precipitate ; and mercuric chloride precipitates cupric bromide from the dil. soln. J. Schröder, and A. Naumann find it to be soluble in *pyridine ;* and D. W. Horn, soluble in liquid ammonia.

C. Löwig [6] reported that during the evaporation of a soln. of cupric bromide, some bromine is lost, and when water is added some cuprous bromide is precipitated. A. Löwig also noted that a little ammonia gives a pale green precipitate with aq. soln. of cupric bromide which is regarded as an oxybromide ; and T. W. Richards that cuprous bromide, under water, deposits a little oxybromide after standing six months in darkness. The composition of the **cupric oxybromide** is generally represented as $3CuO.CuBr_2.3H_2O$, *i.e.* $3Cu(OH)_2.CuBr_2$. E. Brun claims to have made it by allowing a hot sat. soln. of cuprous bromide in potassium bromide to stand in the air ; and by adding hydrogen peroxide to the soln., an immediate precipitate is obtained. An aq. soln. of cupric bromide deposits a little oxybromide ; and J. Dupont and H. Jansen prepared the oxybromide by heating a neutral dil. soln. of cupric bromide in a sealed tube to 200° or 225°. The oxybromide was made by T. W. Richards by the prolonged digestion of cupric oxide with a conc. soln. of cupric bromide ; and P. Sabatier obtained a similar result with cupric hydroxide—with cupric oxide, said he, crystals are slowly formed, with the hydroxide the product is amorphous. A. Mailhe also obtained the oxybromide by the action of nickel oxide, hydroxide, or carbonate on a soln. of cupric bromide. E. Brun also made the oxybromide by adding a conc. soln. of potassium bromide to a soln. of copper ammino-sulphate at 100°.

The crystals of the oxybromide are dark green hexagonal or rhombohedral plates. According to T. W. Richards, the crystals do not lose their combined water when dried over conc. sulphuric acid ; and, according to E. Brun, they lose very little water at 180° to 190° ; at 210° to 215°, almost all is lost ; and at 240° to 250°, they are completely transformed into cupric bromide and oxide ; while, according to J. Dupont and H. Jansen, they lose about two-thirds their water at 200°, and all the water at 250°—hence they regarded the oxybromide as being analogous with atacamite, and as being constituted $Br—Cu—O—Cu—OH+H_2O$. The oxybromide is insoluble in water, but by a prolonged boiling in water, T. W. Richards converted it into cupric bromide and a dark insoluble product. According to E. Brun, the oxybromide is soluble in ammonia and in dil. mineral acids ; and, according to T. W. Richards, it is soluble in dil. acetic acid, but not in dil. potassium bromide, although it is slightly soluble in a conc. soln. of cuprous bromide.

According to P. Sabatier, when a minute quantity of cupric bromide is added to conc. hydrobromic acid, an intense purple coloration is produced, in consequence, probably, of the formation of a hydrobromide of the bromide. This reaction is more sensitive than either the ferrocyanide or sulphide reaction, and will detect 0·0015 milligram of copper in a drop of a soln. of the bromide, but the hydrobromic acid must be conc. A mixture of potassium bromide with a sat. soln. of phosphoric acid can be used instead of hydrobromic acid. By leading hydrogen bromide into a conc. soln. of cupric bromide, the black crystals of cupric bromide first deposited are redissolved, and when the soln. cools crystals of the **dihydrated cupric hydrobromide,** either $CuBr_2.HBr.2H_2O$ or $3CuBr_2.2HBr.6H_2O$ are formed—the available analyses may represent either, but the first formula is the more probable. The crystals are separated from the mother liquid, and dried on porous tiles. The crystals easily decompose with the evolution of hydrogen bromide, but they are fairly stable in an excess of conc. hydrobromic acid which is thereby coloured purple, and the purple soln. slowly becomes yellow on standing. If a soln. of cupric bromide in 40 per cent. hydrobromic acid be left in contact with the product of the action of hydrogen bromide on heated molybdenum trioxide, R. F. Weinland and W. Knöll found that black hygroscopic needle-like crystals of **decahydrated cupric hydrobromide,** $CuBr_2.HBr.10H_2O$, are formed. If the molybdenum salt be omitted, crystals of cupric bromide are alone obtained. When dry cupric bromide is exposed to ammonia gas, it swells up, forming a voluminous blue powder to which

C. F. Rammelsberg[7] ascribed the formula $CuBr_2.5NH_3$, but T. W. Richards showed that C. F. Rammelsberg must have analyzed a product which had lost some ammonia by exposure to air, and D. W. Horn also suggests that C. F. Rammelsberg must have used a cupric bromide which was not thoroughly dried, because to get **cupric hexammino-bromide,** $CuBr_2.6NH_3$, the cupric bromide should be finely powdered and thoroughly dried over phosphorus pentoxide. At atm. press., this compound is stable over temp. ranging from its sat. soln. in liquid ammonia up to 20°; and under a press. of 20 mm. it dissociates at 54·9°. F. Ephraim found that blue **cupric pentammino-bromide,** $CuBr_2.5NH_3$, is unstable above 116°, yielding solid soln. below this temp., which may have the composition $CuBr_2.6NH_3$ at about 0°. He obtained the following relation between temp. θ and composition $CuBr_2+nNH_3$:

θ .	−10°	0°	15°	32°	51°	65°	81°	92°	103°	115°	124°
n .	6·04	6·04	5·89	5·82	5·65	5·48	5·28	5·19	5·15	5·08	3·32

He also says that greyish-black **tricupric decammino-bromide** is formed decomposing at 155°, at 170° decomposition being complete, and the product containing $2·01NH_3$; this melts at 260° and gives off gas. The higher ammino-salts lose part of their ammonia on exposure to the air, forming an olive-green powder of **cupric diammino-bromide,** $CuBr_2.2NH_3$. The colour is almost black at 200°. The same product is obtained by heating the hexammino-salt to 165°. This salt dissolves in a conc. soln. of ammonium bromide, but it is decomposed by water whereby a trace of copper passed into soln. but most is precipitated as hydroxide or hydroxybromide. The diammino-salt absorbs ammonia reforming the hexammino-bromide, and it can be heated to 200° without decomposition. F. Ephraim says it decomposes at about 260°. At higher temp. all the ammonia is lost—a small part as ammonium bromide, and a residue of cupric bromide with a little cupric oxide is obtained. The salt forms a blue-coloured liquid when treated with a little water, and the soln. deposits cupric hydroxide on dilution. It dissolves in an aq. soln. of ammonium bromide without decomposition, and may seemingly be recrystallized from this liquid. Similar crystals are formed when ammonia is cautiously added to a mixture of cupric and ammonium bromides.

C. F. Rammelsberg, in 1842, reported the preparation of *cupric triammino-bromide*, $CuBr_2.3NH_3$, by treating an ammoniacal sat. soln. of cupric bromide with alcohol; the dark green crystalline product behaves like the hexammino-salt when heated, and when treated with water. T. W. Richards and H. G. Shaw made repeated attempts to prepare this salt, but always obtained deep indigo, almost black crystals, of a **tricupric decammino-bromide,** $3CuBr_2.10NH_3$; consequently, it is supposed that C. F. Rammelsberg's salt does not exist. The crystals are best obtained by cautiously adding conc. hydrobromic acid to a mixture of cupric bromide and alcohol with just enough ammonia to keep all the copper in soln. When enough hydrobromic acid has been added to neutralize all the ammonia, the crystals which are almost insoluble in alcohol begin to form. V. Kohlschütter and P. Pudschies dissolved cupric bromide in conc. ammonia and added rather more than an eq. quantity of potassium bromide. On warming, crystals of the salt are obtained. The crystals rapidly lose ammonia when exposed in the moist state to air, but if dry, they are much more stable. When heated slowly to 160°, they form the olive-green diammino-salt. Water decomposes the decammino-salt; a little copper passes into soln. in the form of the hexammino-salt while cupric hydroxide is precipitated: $Cu_3(NH_3)_{10}Br_6+4H_2O=Cu(NH_3)_6Br_2+4NH_4Br+2Cu(OH)_2$, but the exact nature of the product depends on the proportion of water. When a cold soln. of the decammino-salt is decomposed with potassium bromide, V. Kohlschütter and P. Pudschies found that crystals of a bluish-green **cupric diammino-oxybromide,** $2CuO.CuBr_2.2NH_3.3H_2O$ or $Cu(NH_3)_2Br_2(CuO)_2.(H_2O)_3$, are formed.

L. L. de Koninck[8] gradually added bromine to a well-cooled mixture of 100 grms. of copper turnings and 200 c.c. of water until the copper and cuprous bromide had disappeared, the excess of bromine was expelled by gently warming the dark brown soln.; 309 grms. of ammonium bromide are added, and the filtered claret-coloured soln. is crystallized by evaporation. Dil. soln. are bluish-green, conc. soln. claret-red. Emerald-green crystals of **dihydrated ammonium bromocuprate,** $2NH_4Br.CuBr_2.2H_2O$, are formed; they are probably monoclinic, and isomorphous with the corresponding chloride. The crystals gradually lose water in a desiccator, and form a black powder; at 100° they are partially decomposed. T. W. Richards and A. H. Whitridge made an ammonium cupri-bromide by leading ammonia into a soln. of cupric bromide in alcohol and glacial acetic acid; and ammonio-complexes of ammonium cupri-bromide were also prepared. P. Sabatier prepared lithium cupri-bromide, $LiBr.CuBr_2$, by slowly evaporating, over sulphuric acid, a conc. soln. of lithium bromide mixed with three times its weight of cupric bromide; and N. S. Kurnakoff and A. A. Sementschenko evaporated on a water-bath a mixed soln. of cupric bromide with twice its weight of lithium bromide, and obtained black prismatic crystals of hexahydrated dilithium cupri-bromide, $CuBr_2.2LiBr.6H_2O$, which melt in a closed tube between 75° and 80°. The crystals decompose in air. The purple-red soln. is supposed to contain undecomposed salt. P. Sabatier made **potassium bromocuprate,** $CuBr_2.KBr$, by a process analogous to that employed for the corresponding lithium salt. The crystals are probably monoclinic and lose one-third of their bromine when heated. H. L. Wells and P. T. Walden prepared **dicæsium bromocuprate,** Cs_2CuBr_4 or $2CsBr.CuBr_2$. from mixed soln. of 50 grms. of cæsium bromide in the presence of 5 to nearly 70 grms. of cupric bromide; with a higher proportion of cupric bromide, the rhombic crystals are small, short prisms, and with the lower proportions elongated prisms. The crystals are black with a greenish tinge. Opaque, dark, hexagonal crystals of **cæsium bromocuprate,** $CsCuBr_3$ or $CsBr.CuBr_2$, are formed from soln. containing 50 grms. of cæsium bromide and 70 of cupric bromide with 70 grms. of cupric bromide in 200 c.c. of water; the proportion of cupric bromide can be increased until the soln. is sat. with that salt. Unlike the corresponding $CsCuCl_3$, if the salt $CsCuBr_3$ be recrystallized from water, Cs_2CuBr_4 is obtained. No hydrated salts are obtained, so that it cannot be said that the tendency to combine with water increases with the at. wt. of the halogen, as I. Remsen observed to be the case with the alkaline lead halides.

§ 20. Cuprous Iodide

Small translucent reddish-brown crystals of cuprous iodide, CuI, occur in nature as the mineral *marshite* from Broken Hill (Australia). C. W. Marsh[1] regards the mineral as being tetragonal and hemihedral, and H. A. Miers as being cubic and hemihedral. W. Autenrieth also believes that iodine occurs in some New South Wales cuprites as marshite. When finely-divided copper is heated, it reacts with iodine vapour, and, according to M. B. Renault,[2] if a copper plate be exposed to iodine vapour, or to a soln. of iodine, it becomes covered with crystals of cuprous iodide; and if a strip of copper in mercuric iodide be covered with a layer of magnesium chloride soln., A. C. Becquerel found octahedral crystals of cuprous iodide are deposited electrolytically on the plate. H. Rose noted that copper is readily dissolved by hot conc. hydriodic acid with the evolution of hydrogen and the formation of cuprous iodide; the action, said M. Berthelot, is more vigorous than with hydrochloric acid. Iodine is liberated during the reaction, and the resulting cuprous iodide is pulverulent—if a trace of hydrogen sulphide be present, the separation of iodine is prevented. E. Meusel noted that when the reaction takes place slowly at ordinary temp., the resulting cuprous iodide is crystalline. Dil. hydriodic acid does not act on the metal, while R. S. Norris and F. G. Cottrel found that liquid hydrogen iodide dissolves copper slowly, and cupric oxide rapidly, forming in both cases cuprous iodide—in the latter case, iodine is separated.

E. Meusel noted that when cuprous sulphide is treated with hydriodic acid, yellowish-green tetrahedral crystals are formed. Cuprous iodide is precipitated from a hydrochloric acid or ammonium chloride soln. of cuprous chloride by the addition of potassium iodide; and J. A. Buchner has shown that if too much hydrochloric acid be present, some cuprous iodide remains in soln., and if too little be present, some cuprous chloride is precipitated. According to R. Varet,[3] cuprous cyanide is transformed into the iodide when it is treated with hydriodic acid.

J. B. Berthemot found that when soln. of copper sulphate are treated with potassium iodide, half the iodine is precipitated as cuprous iodide, and half is liberated as free iodine: $2CuSO_4+4KI=I_2+2CuI+2K_2SO_4$. The precipitate can be washed with alcohol. Measurements show that the speed of the reaction is proportional to the conc. of the cupric sulphate, and to the square of the conc. of the potassium iodide. Hence, the reaction may be represented $CuSO_4+2KI =CuI+K_2SO_4+I$, followed by $I+I=I_2$. According to M. Traube, if not more than 4 mols of potassium iodide are present for every 2 mols of cupric sulphate, the precipitate contains a mixture of cupric and cuprous iodides; but J. W. Walker and M. V. Dover do not agree with this, and they show some evidence that more probably the precipitate contains some polyiodide, CuI_4. L. Moser showed that, in dil. soln., the reaction is not complete, and that the presence of sulphuric acid favours the reaction. According to A. H. Low, cupric acetate gives better results than the sulphate.

It is probable that in the reaction between cupric sulphate and potassium iodide, cupric iodide is first formed: $CuSO_4+2KI \parallel K_2SO_4+CuI_2$, and that the latter is immediately decomposed: $2CuI_2 \rightleftharpoons I_2+2CuI$, by a reversible reaction, so that some cupric iodide remains in soln. K. Elbs, therefore, argued that if the cupric salt or cupric ions are removed the reaction must proceed from right to left; this may be achieved by adding to the mixture of cuprous iodide and iodine a salt which forms complexes with the cupric ion. Ammonium oxalate serves this purpose, and if ammonium oxalate is added to the mixture of cuprous iodide and iodine, an intensely blue soln. of cupric ammonium oxalate is formed. Conversely, if the free iodine be removed from the system as fast as it is formed, the formation of cuprous iodide will proceed to an end; for quantitative results P. E. Browning showed that an excess of potassium iodide and the presence of iodine, or hydriodic acid, should be avoided. K. Elbs used sodium thiosulphate for removing the liberated iodine in the reaction to ensure the complete conversion of cupric to cuprous iodide; A. Duflos used sulphurous acid for this purpose; P. N. Raikow, phenylhydrazine; E. Fleischer, stannous chloride; and E. Souberain, ferrous sulphate. The reaction by A. Duflos' process is represented: $2CuSO_4+2KI+SO_2+2H_2O=2CuI+K_2SO_4+2H_2SO_4$, and it is conducted by B. Lean and W. H. Whatmough in the following manner:

Two mols of copper sulphate are dissolved in three litres of water, the soln. is sat. with sulphur dioxide, and two mols. of potassium iodide dissolved in 150 c.c. of water are added. The pale yellow precipitate which is immediately formed is allowed to settle, the supernatant liquid poured off, and the residue washed with sulphurous acid soln. by decantation until the whole of the sulphate has been removed. It is then boiled with water to make it granular, collected on linen, spread on a porous tile, and finally exposed over sulphuric acid in vacuo. Cuprous iodide retains moisture somewhat obstinately; after an exposure for three weeks over sulphuric acid, a sample still contained 0·18 per cent. of moisture, but this was removed after further exposure.

According to M. Guichard, dry hydrogen iodide liberates iodine in the presence of dry cupric chloride at ordinary temp., heat is developed and iodine is sublimed; a white residue of cuprous iodide remains. If cupric chloride, dehydrated at 200° in a current of dry hydrogen chloride, is cooled to —40° in a stream of hydrogen iodide, the gas liquefies on the chloride and iodine is liberated colouring the mass violet-red. The free iodine can be removed by washing with cold dry ether, and grey cuprous iodide remains. Thus, the reactions in the dry state and at low temp. are the same as in aq. soln. at ordinary temp. According to A. Naumann, soln. of cupric chloride in acetone or ethyl acetate furnish precipitates of cuprous iodide when treated with a metal iodide—*e.g.* cadmium iodide. According to D. Vitali, a conc. sulphuric acid liberates iodine from an alkali iodide, and if cupric sulphate be present, the mixture becomes black and cuprous iodide is formed, which remains as a white precipitate on adding water. Chlorides under similar conditions give a yellow coloration, and bromides a deep violet coloration; both colours are discharged on adding water, and hence D. Vitali suggests the reactions as a means of distinguishing the three halides. P. Rohland precipitated cuprous iodide from a soln. of a cupric salt in the presence of a ferric salt, by mercuric iodide. B. Lean and W. H. Whatmough obtained cuprous iodide of 98 per cent. purity by heating copper with iodoform. By the action of a soln. of potassium iodide on cupric hydroxide, W. Spring and M. Lucion obtained a dark green substance whose analyses corresponded with **cuprous oxyiodide,** $CuO.2CuI.H_2O$.

The properties of cuprous iodide.—M. B. Renault[4] found cuprous iodide to be less sensitive to light than either cuprous bromide or chloride. G. Tammann studied the colour of films of cuprous iodide. The **crystals** probably belong to the cubic system. R. W. G. Wyckoff and E. Posnjak found that the **X-radiograms** correspond with the double face-centred cubic lattice of the zinc sulphide class with side 6·10 A., and the nearest distance of the atom centres 2·63 A. According to W. Spring, the **specific gravity** is 5·631–5·653 (15·5°) for the dried or fused salt, and 5·289 for the freshly precipitated and moist salt. G. T. Prior's value for the marshite of Broken Hill is 5·590. H. Schiff's value 4·41 is in all probability wrong. R. W. G. Wyckoff and E. Posnjak gave 5·667 at 30°/4°. P. Walden studied the mol. vol. The sp. vol., according to W. Spring, is 33·61 to 34·73, when the additive rule gives a calculated value 32·72; consequently, the formation of the compound is attended by a slight expansion. According to W. Spring, the salt is not decomposed into its elements by a press. of 8000 atm. P. W. Bridgman found that there are two modifications of cuprous iodide with a **transition** of the ice-type. B. Gossner stated that the ordinary cubic form becomes doubly refracting at a high temp. P. W. Bridgman found the form stable at a low temp. is the less compressible, for it has a coeff. of compressibility of 0·0000004; it also has a smaller expansibility; and a lower sp. ht. P. W. Bridgman found the transition temp. $\theta°$ to be related to the press. as follows:

$\theta°$	100°	120°	140°	160°	180°	200°
Press.	11950	11544	11138	10732	10326	9920
δv	0·00538	0·00525	0·00515	0·00505	0·00495	0·00485
L	0·405	0·419	0·432	0·444	0·455	0·466

when the press. is expressed in kgrms. per sq. cm. Expressing the change in vol., δv, in. c.c. per grm., and the **latent heat,** L, in kilogram-metres per grm., he also found the results indicated above.

Numbers representing the m.p. range from T. Carnelley and L. T. O'Shea's[5] 628°, T. Carnelley's 601° ± 3°, to K. Mönkemeyer's 590°. According to E. J. Houston, when cuprous iodide is heated, the colour changes to dark red, then to reddish-brown, brown, dark brown, and black; on cooling, the original colour is soon restored. According to T. Carnelley and W. C. Williams, cuprous iodide boils between 759° and 772°. By adding cuprous chloride, K. Mönkemeyer found the m.p. falls to a minimum at 290° with 60 mols per cent. of cuprous chloride, and then gradually rises up to the value for pure cuprous chloride. L. Houllevigue gives **refractive index** 2·09; and, according to B. Gossner, the salt is singly refracting at ordinary temp., and doubly refracting at higher temp. For the **photoelectric effect,** see cupric fluoride.

G. F. Rodwell failed to find the transition temp. by the dilatometric method, but K. Mönkemeyer found the transition temp.: β-CuI (singly refracting)$\rightleftharpoons\alpha$-CuI (doubly refracting) lies between 397° and 400° by the thermal method. When mixed with 10 per cent. of cuprous chloride, the transition temp. falls to 372°, with 20 per cent. cuprous chloride to 238°, and with over 30 per cent. to 216°. With additions of cuprous bromide, the m.p. falls to a minimum at 443° when 69 mols per cent. of cuprous bromide has been added. The transition temp. also falls to a minimum at 357°, with about 44 mols per cent. of cuprous bromide.

J. Thomsen's value[6] for the **heat of formation** of cuprous iodide from its elements is 16·26 Cals.; M. Berthelot's value is $Cu+I=21·9$ Cals., the thermal value of the reaction: $Cu_2O+2HI=72·15$ Cals.; and for $Cu_2O+2HI+aq.=33·73$ Cals. G. Bodländer and O. Storbeck's value for the **free energy** of formation is —16·6 Cals.; M. de K. Thompson gives —23·7 Cals. for liquid or solid iodine, and for the **total energy** of formation, —16·6 Cals. iodine solid. A. Klein's value for the exothermal reaction: $CuBr_{solid}+KI_{sol.}=CuI_{solid}+Br_{sol.}$, is 6·495 Cals., calculated from the e.m.f. 0·2041 volt, and for the change of free energy, 4·744 Cals. According to M. Berthelot, the displacement of iodine by chlorine develops 23·4 Cals., and by bromine, 7·3 Cals.

According to K. Bädeker,[7] cuprous iodide has a relatively high electrical conductivity (electrolytic); the **specific resistance** of cuprous iodide is 0·045 when that of 30 per cent. sulphuric acid is 1·35; with a layer $180\mu\mu$ thick, the resistance is 0·010 ohm, and this increases after standing some days in the presence of air or hydrogen to a very high value. K. Bädeker also found that cuprous iodide absorbs about 0·003 per cent. of iodine vapour in three days, and its conductivity then increases very much; the conductivity of cuprous iodide alone also increases when exposed to light. G. O. Greiner studied the conductivity of cuprous iodide with dissolved iodine. G. Trumpler measured the e.m.f. of cells with cuprous iodide.

Air-dried cuprous iodide, said E. Souberain,[8] retains 4 per cent. of moisture;

and after standing 24 hrs. in vacuo, or for several days at 130°, M. Guichard still found 0·2 per cent. to be retained, and this is lost when heated to 300° in vacuo. B. Lean and W. H. Whatmough found that cuprous iodide may be heated until it fuses in a stream of carbon dioxide; but M. Guichard found that it oxidizes below 200° when heated in air: $2CuI+O_2=2CuO+I_2$; the action of air is fairly rapid at 220°–240°, and B. Lean and W. H. Whatmough prepared iodine of a high degree of purity by passing air over purified cuprous iodide at this temp.; they also found that if air be passed over cuprous iodide at ordinary temp. there are indications of the liberation of iodine after 3 hrs. in light, but none after 3 days in darkness; nor could any effect be noticed with oxygen in darkness; nitrogen peroxide or nitric oxide liberates iodine at once, in light or in darkness. H. Rose observed an incomplete decomposition when heated with hydrogen. E. Souberain noted that iodine is liberated when the iodide is heated with oxidizing agents—*e.g.* manganese peroxide.

F. Kohlrausch and F. Rose calculated the **solubility** of cuprous iodide from the electrical conductivity of aq. soln., and found 8·0 mgrms. or 0·04 mgrm. eq. of CuI to be dissolved per litre at 18°; and it is not perceptibly decomposed by water. The salt is soluble in sulphuric acid if freshly precipitated—E. Fleischer, and B. Lean and W. H. Whatmough; in sulphuric acid forming a violet soln.—D. Vitali; but insoluble in $\frac{1}{10}N$-sulphuric acid—L. Moser, and decomposed by conc. sulphuric acid into iodine, sulphur dioxide, and cupric sulphate—E. Souberain; soluble in $\frac{1}{10}N$-hydrochloric acid; decomposed by nitric acid giving iodine, nitric oxide, and cupric nitrate—E. Souberain; the freshly-precipitated iodide, and that which has changed by exposure to light, are soluble in aq. ammonia, dil. nitric, hydrochloric, or sulphuric acid, and in soln. of sodium thiosulphate—E. Meusel. According to E. Brun, the soln. in sodium thiosulphate gives no sign of the formation of double thiosulphates, and ammonium hydrosulphide precipitates copper quantitatively from thiosulphate soln. Cuprous iodide is soluble in potassium cyanide, but not in soln. of sodium chloride, or sulphate, in potassium nitrate, or bromide, or in ammonium chloride—J. B. Berthemot. According to G. Bodländer and O. Storbeck, $\frac{1}{5}N$-soln. of potassium iodide dissolves 0·000157 mol of cuprous iodide per litre. G. O. Greiner found that the absorption of iodine by cuprous iodide is a reversible process, and that the iodine is dissolved, not adsorbed. A soln. of ferrous chloride dissolves cuprous iodide—E. Fleischer; but ferric chloride displaces iodine—G. L. Ulex; cupric chloride forms cuprous chloride and iodine—G. Topf; alkali hydroxides give iodides with the formation of cuprous oxide, while alumina and the carbonates of the alkaline earths or magnesia do not decompose cuprous iodide —J. B. Berthemot. A warm soln. of cupric sulphate liberates no iodine. G. A. Barbieri found that when cuprous iodide is heated with cupric bromide or chloride, it loses all its iodine, *e.g.* $2CuI+2CuCl_2=4CuCl+I_2$; and conversely cuprous chloride or bromide dissolved in a conc. soln. of alkali chloride when treated with a soln. of iodine in *o*-xylene, is converted into cuprous iodide, *e.g.* $4CuCl+I_2=2CuCl_2+2CuI$. The conc. of the salts and the temp. determines which of these reactions predominates. H. Moissan found that fluorine does not attack cold cuprous iodide, but it does do so at a dark red heat; nor does boron attack cuprous iodide. If water with cuprous iodide in suspension be treated with hydrogen sulphide, hydriodic acid is formed—G. Langbein. According to J. B. Berthemot, and G. L. Ulex, when cuprous iodide is boiled with zinc, tin, or iron it is reduced to the metal, and the metal iodide is formed as well as some free iodine. S. M. Jörgensen says the reaction with zinc is complete. E. C. Franklin and C. A. Kraus found cuprous iodide to be soluble in liquid ammonia. According to J. W. Retgers, it is virtually insoluble in methylene iodide; and, according to H. Arctowsky, insoluble in carbon disulphide.

In 1839 C. F. Rammelsberg [9] reported that 100 parts of cuprous iodide absorbed 19·728 parts of ammonia which could be completely expelled by heat. This amount of ammonia corresponds with cuprous diammino-iodide, $CuI.2NH_3$. If cuprous iodide at 0° be sat. with ammonia gas, and a curve be drawn corresponding with the change of press. with the composition, as in Fig. 26, S. J. Lloyd found that there are two terraces corresponding respectively with cuprous sesquiammino-iodide, $2CuI.3NH_3$; and cuprous triammino-iodide, $CuI.3NH_3$, and no others. The last-named compound—**cuprous triammino-iodide,** $CuI.3NH_3$—is formed when dry ammonia is passed slowly over cuprous iodide cooled by a freezing mixture. It is a pale green hygroscopic compound, with vap. press. 150 mm. at 18·25°; 422 mm. at 37·5°; 615 mm. at 46°; and 794 mm. at 52°. F. Ephraim gives a vap. press. of 760 mm. at 50°. According to S. J. Lloyd, the triammino-salt melts at 105° if the press. of the gas be allowed to fall to 490 mm.; at 51·75°, a dark brown hygroscopic compound—**cuprous sesquiammino-iodide,** $2CuI.3NH_3$—is formed which melts at 117°; and which has a vapour press. of 60 mm. at 17·5°; 75 mm. at 20·25°; 272 mm. at 41°; 490 mm. at 51·75°; 742 mm. at 59·5°; 999 mm. at 65°.

A. Levol also prepared what he regarded as **cuprous diammino-iodide,** $CuI.2NH_3$, by shaking a copper plate with ammonia and a sat. soln. of a cupric salt in a flask until the colour disappeared; the resulting fluid was poured into a soln. of potassium iodide, and colourless crystals of this compound separated. These crystals cannot be dried without decomposition in air, ammonia is given off, and the residue is green. The mother liquid becomes blue on exposure to the air, and forms an ammino-cupric iodide. A. Saglier made the same product by boiling copper with equal parts by weight of an ammoniacal soln. of cupric hydroxide and a 10 per cent. alcoholic soln. of iodine, until the soln. was decolorized. On cooling, white needle-like crystals of cuprous diammino-iodide separate from the liquid, O. Silberrad reported the formation of an olive-green crystalline powder of **dihydrated cuprous hemiammino-iodide,** $CuI.\frac{1}{2}NH_3.2H_2O$, by treating cupric ammino-polyiodide, $2CuI.I_4.5NH_3.H_2O$, with a 25 per cent. soln. of potassium iodide. The residual salt is insoluble in water, soluble in aqua ammonia. According to W. Biltz and W. Stollenwerk:

	$CuI.3NH_3$	$CuI.2NH_3$	$CuI.NH_3$	$CuI.\frac{1}{2}NH_3$
Heat of formation in Cals. . .	10·37	11·00	14·70	15·22
Diss. press. is 100 mm. at . .	286·5°	298·0°	371·0°	390·0°

A. Saglier dissolved 100 grms. of ammonium iodide in a litre of water, and mixed the soln. with 10–15 grms. of cupric hydroxide which dissolves in the warm liquid. This liquid was boiled with a large excess of copper until it became colourless; the liquid was conc. and allowed to cool slowly, when it deposited white needle-like crystals of what he regarded as $Cu_2I_2.2NH_4I.H_2O$. H. L. Wells and E. B. Hurlburt could obtain only one **ammonium iodocuprite,** $CuI.NH_4I$, by the use of varying proportions of ammonium and cuprous iodides in soln. of hydriodic acid; and this compound corresponds in every respect with A. Saglier's description of his product, except that it is anhydrous. The crystals can be preserved under the mother liquid, but even here they become brown on standing. In air, the compound loses ammonia and ammonium iodide, and when heated furnishes black cuprous iodide; it is decomposed by water and alcohol. The mother liquid, on standing, deposits crystals of **dihydrated ammonium ammino-iodocuprite,** $CuI.NH_4I.NH_3.2H_2O$. E. Fleurent also prepared **ammonium triammino-iodocuprite,** $NH_4I.2CuI.3NH_3$. A. C. Becquerel reported the formation of white needle-like crystals of potassium cupro-iodide by dipping a copper cathode in a soln. of potassium iodide in a cell, with the anode dipping in a soln. of cupric sulphate. E. Brun prepared a double compound of cuprous iodide with potassium thiosulphate and also with ammonium thiosulphate. A. Rosenheim and S. Steinhauser also obtained the complex $4(NH_4)_2S_2O_3.NH_4I.CuI$.

§ 21. Cupric Iodide and the Copper Polyiodides

Solid cupric iodide has not been prepared, but there is some evidence that cupric iodide exists in dil. aq. soln. If the formation of cuprous iodide depends on the reaction: $2Cu^{\cdot\cdot}+4I\rightleftharpoons 2CuI+I_2$, the assumed backward change implies the existence of cupric iodide. M. Traube[1] showed that when a very dil. soln. of potassium iodide is added to a dil. soln. of cupric sulphate, the separation of iodine and the precipitation of cuprous iodides takes place very slowly. A soln. of $\frac{1}{3}$rd per cent. of potassium iodide added to a 1 per cent. soln. of cupric sulphate produces a precipitate in 10 minutes; with a $\frac{1}{4}$th per cent. soln. the liquid becomes yellow in an hour; and with a $\frac{1}{20}$th per cent. soln. the liquid remains clear and colourless, there are no signs of a blue coloration with starch, and the liquid gives the reactions of a cupric salt. M. Traube digested cuprous iodide with a sat. soln. of iodine in water, and obtained a green soln. containing 0·08 grm. of what he regarded as cupric iodide per 100 c.c. Later, D. J. Carnegie claimed to have made a soln. by working at

80°. In no case could the alleged cupric iodide be isolated in the solid form because, although it is stable in soln. at a boiling temp. it loses half its iodine when evaporated to dryness, and when the attempt is made to concentrate it by removing the water as ice. For the **photoelectric effect,** see cupric fluoride.

J. W. Walker and M. V. Dover found that the precipitate obtained when, say, 200 c.c. of a soln. containing a mol of $CuSO_4$ per litre, and 60 c.c. of water, were shaken for half an hour with 20 c.c. of a soln. of potassium iodide (2 mols per litre) in which 5·08 grms. of iodine had been dissolved, contains a heavy green substance along with cuprous iodide; much of this green substance is soluble in water, forming a deep brown soln. which contained only traces of potassium iodide. The olive-green substance is unstable in that on exposure to air, it changes to white cuprous iodide. The soln. and solid contain copper and iodine in approximately the atomic ratio 1 : 4, which would make it appear as if the olive-green solid at least contains a **copper tetraiodide,** CuI_4. By heating the soln. to 80° with an excess of iodine, values approximating with those required for **copper hexaiodide,** CuI_6, were obtained, but on cooling, the soln. deposited iodine, leaving a remainder in agreement with the ratio $Cu : I_4$. By the action of alcoholic soln. of iodine on cuprous iodide at 30°, S. M. Jörgensen likewise obtained indications of decaiodide, CuI_{10}. By washing the precipitate with alcohol, and evaporating the alcoholic soln., J. W. Walker and M. V. Dover obtained a product roughly corresponding with **copper ennea-iodide,** CuI_9.

When the deep red soln., obtained by treating copper tetraiodide with water, is diluted and shaken with cuprous iodide, the liquid becomes bluish-green, and it contains no iodine capable of reacting with starch, nor does it yield up iodine when shaken with ether or carbon tetrachloride. Soln. of the polyiodides under similar conditions give up iodine and precipitate cuprous iodide. According to M. Traube, the soln. of cupric iodide gives no precipitate with a soln. of silver nitrite, but J. W. Walker and M. V. Dover show that at the conc. in question cupric and potassium chlorides give only an opalescence, and that a soln. of cupric chloride with 0·095 per cent. $CuCl_2$ gives a precipitate at once with silver nitrate, while a 0·063 per cent. soln. gives no precipitate. According to M. Traube, the soln. of cupric iodide is decomposed by ferrous sulphate in the presence of hydrogen peroxide in acid soln., and in this way may be distinguished from other metal iodides. The soln. also gives the reaction of a cupric salt with potassium hydroxide and potassium ferrocyanide. The bluish-green soln. of cupric iodide containing 0·104 per cent. of cupric iodide does give a colour reaction with starch which is discharged by the addition of 0·05 c.c. of $\frac{1}{50}N$-sodium thiosulphate. This means that at 24°, a soln. containing more than 0·1 per cent. of cupric iodide decomposes into polyiodide, and D. J. Carnegie's soln. therefore contained polyiodides. According to J. W. Walker and M. V. Dover, the insolubility of cuprous iodide and the existence of a polyiodide, CuI_n, explain the apparent instability of cupric iodide, since, from the equation: $(n-2)CuI+CuI_n \rightleftharpoons (n-1)CuI_2$, the mass law requires that for equilibrium $C_2 = KC_1$, where C_1 and C_2 respectively denote the conc. of the polyiodide and of cupric iodide. Any variation in the volume of water must therefore displace the equilibrium point, decreasing the volume, for instance, causes C_1 to increase relatively to C_2. Values of n agreeing with $CuI_6+4CuI \rightleftharpoons 5CuI_2$, give values of K of one order of magnitude.

The affinity or driving force [2] of the conversion of cupric salts, or of cupric to cuprous ions: $Cu^{\cdot\cdot} \rightarrow Cu^{\cdot}$ is $0·204+0·058 \log [Cu^{\cdot\cdot}]/[Cu^{\cdot}]$ volt-coulombs per faraday (95,540 coulombs=one farad., F), where the conc. of the ions are represented by the square brackets. The reaction $Cu^{\cdot\cdot} \rightarrow Cu^{\cdot}$ is usually accompanied by a decrease of free energy, and has therefore a tendency to occur spontaneously. If, however, the cupric ions are in the presence of anions with a strong electroaffinity —*e.g.* SO_4-, NO_3-, F-, Cl-, and Br-ions—the net decrease is not sufficient to enable the reaction to occur. For instance, the driving force of the reaction $Cu^{\cdot\cdot} \rightarrow Cu^{\cdot}$ is opposed by that of, say, $I \rightarrow I'$, for which the decrease of free energy, or the driving force of the reaction, is 0·520–0·058[I'] volt-coulombs per faraday. Consequently, for the reaction $Cu^{\cdot\cdot}+I' \rightarrow Cu^{\cdot}+I$, when the soln. is sat. with iodine, the free energy or the affinity of the reaction is $-0{\cdot}316+0{\cdot}058\{\log([Cu^{\cdot\cdot}]/[Cu^{\cdot}])+\log[I']\}$. On account of the negative term —0·316 in this expression, and the small value of [I'], the decrease of free energy can be large only when the ratio $[Cu^{\cdot\cdot}]/[Cu^{\cdot}]$ is large; and since the conc. [$Cu^{\cdot\cdot}$] cannot increase very much, the driving force of the reaction $Cu^{\cdot\cdot} \rightarrow Cu^{\cdot}$ can exceed that of $I \rightarrow I'$ when the conc. [$Cu^{\cdot}$] is very small. The low solubility of cuprous iodide supplies this condition. With sat. soln. of cuprous iodide, the solubility product at 18°, when the system is in equilibrium, and the free energy is zero, is obtained from (1): $-0{\cdot}316+0{\cdot}058\log[Cu^{\cdot\cdot}][I']^2/[Cu^{\cdot}][I']=0$; it follows that $[Cu^{\cdot}][I']=5{\cdot}06\times10^{-12}$; and for cupric iodide $[Cu^{\cdot\cdot}][I']^2=0{\cdot}14\times10^{-5}$. Consequently, with the greatest possible conc. of [I'], the solubility product of cupric iodide cannot be attained in conc. aq. soln.; and therefore (excluding cases of false equilibria), it will be impossible to obtain solid cupric iodide from aq. soln. at 18°; and further, cupric ions in the presence of cuprous ions will form solid cuprous iodide and solid iodine until the product $[Cu^{\cdot\cdot}][I']^2$ has fallen to $0{\cdot}14\times10^{-5}$. Consequently, when cuprous iodide and iodine are shaken together with water at 18°, only very little cupric iodide can be formed in the soln.

The corresponding value for the free energy or driving force of the reaction $Cl' \rightarrow Cl$ is 1·417–0·058 log [Cl'] volt-coulombs per faraday; and for $Br' \rightarrow Br$, 0·993–0·058 log [Br']. For sat. soln. also the solubility products of the copper halides are:

	Chloride.	Bromide.	Iodide.
Cuprous . . .	$1{\cdot}2\times10^{-6}$	$4{\cdot}15\times10^{-8}$	$5{\cdot}06\times10^{-12}$
Cupric . . .	10	$1{\cdot}66\times10^{-6}$	$0{\cdot}14\times10^{-5}$

Here the solubility products of both these cupric salts are comparatively large, cuprous bromide or chloride will be transformed by the halogens into the solid cupric salts. The factors which condition the instability of cupric iodide are therefore: (1) The low solubility of the cuprous iodide; (2) The tendency to form complex cuprous salts; (3) The low electroaffinity of the iodine anions; and (4) the low solubility of the anions.

The heat of formation of cupric iodide computed by J. Thomsen[3] is $Cu+I_2+aq.=10{\cdot}41$ Cals. W. Autenrieth assumes that iodine is present in iodiferous malachites in the form of *cupric oxyiodide*, $CuO.CuI_2.H_2O$. Several cupric ammino-iodides have been reported. V. Kohlschütter and P. Pudschies,[4] and F. Ephraim prepared **tricupric decammino-iodide,** $3CuI_2.10NH_3$, that is, $Cu_3(NH_3)_{10}I_6$, by warming a soln. of cupric tetrammino-iodide on a water-bath for a long time; or by mixing soln. of cupric tetrammino-iodide and potassium iodide. The colour of the soln. changes from violet to green, and then deposits black crystals. T. W. Richards and G. Oenslager prepared the same salt by boiling on a water-bath a soln. of 8 grms. of cupric acetate in 50 c.c. aqua ammonia (sp. gr. 0·90) with 30 c.c. of 57 per cent. acetic acid, 6 grms. of ammonium iodide, and 50 c.c. of alcohol; black crystals are obtained on evaporating the soln. in air. The crystals are three-sided pyramids with a bronze lustre. They lose ammonia and iodine on exposure to air; they are decomposed by water, and the deep blue soln. in hot aq. or alcoholic ammonia furnishes pale blue needles on cooling. When powdered $3CuI_2.10NH_3$ is exposed to ammonia gas, the brown powder becomes green, then blue, and forms **cupric hexammino-iodide,** $CuI_2.6NH_3$; the same compound is formed by dissolving $3CuI_2.10NH_3$ in liquid ammonia. D. W. Horn found the deep blue crystals to be stable at all temp. between the b.p. of a sat. soln. in liquid ammonia, and 20°, under atm. press.; they dissociate at 67·4° under a press. of 20 mm. They are stable if moisture be excluded, but they decompose rapidly in air leaving a dark brown residue. F. Ephraim found 6·3 mols of ammonia are taken up by a mol of cupric iodide at —18°; at room temp. 5·9 mols of ammonia; at 119·5°, 5·0 mols, so that cupric hexammino-iodide yields solid soln. with cupric pentammino-iodide,

$CuI_2.5NH_3$, which have the composition of the latter at 119·5°. As the temp. rises, ammonia is given off continuously, until the residue has the composition $3CuI_2.10NH_3$; this remains stable up to 147°, and at 152° the greenish-grey diammino-salt is formed.

In 1830, J. B. Berthemot prepared blue crystals of **hydrated cupric tetrammino-iodide,** $CuI_2.4NH_3.H_2O$, by treating a sat. soln. of cupric sulphate or acetate with warm aqua ammonia; the crystals can be purified by recrystallization from warm ammonia water. In 1839, C. F. Rammelsberg noted that aqua ammonia does not dissolve an appreciable quantity of cuprous iodide unless air has access to the liquid; a blue soln. is then formed. If the warm liquid be cooled, colourless crystals of cupric diammino-iodide, $CuI_2.2NH_3$, separate, and the mother liquid gives crystals of hydrated cupric tetrammino-iodide on the addition of alcohol. D. W. Horn (1908) prepared the same salt by adding a soln. of potassium iodide to ammoniacal copper sulphate, and saturating the liquid with ammonia at 0°; M. E. Pozzi-Escot (1900) treated an ammoniacal soln. of a cupric salt with ammonium iodide, or sodium iodide; and A. Saglier (1886) by allowing a mixture of an ammoniacal soln. of cupric hydroxide and alcoholic iodine to stand for some hours. The dark blue tetrahedral crystals decompose rapidly in air with the loss of ammonia, forming a dark brown residue. If the violet soln. is warmed on a water-bath the colour changes to steel-blue, and on cooling crystals of **tricupric decammino-iodide,** $3CuI_2.10NH_3$, separate. Cold alcohol or ether has no action, but the soln. becomes brown when boiled. According to F. Ephraim, the decammino-salt passes into **cupric diammino-iodide,** $CuI_2.2NH_3$, at 147°.

Some ammino-compounds of the copper polyiodides have been prepared;[5] thus O. Silberrad obtained small crystalline plates of **hydrated dicupric pentammino-hexaiodide,** $2CuI.I_4.5NH_3.H_2O$ or $2CuI_3.5NH_3.H_2O$, by dropping 100 c.c. of a 20 per cent. soln. of potassium iodide in a soln. with a small excess of cupric tetrammino-sulphate in 1200 c.c. of water. The compound is not explosive, and when heated it gives off iodine. S. M. Jörgensen made **cupric tetrammino-tetraiodide,** $CuI_2.I_2.4NH_3$ or $CuI_4.4NH_3$, by adding warm alcoholic ammonia to the brown soln. of cupric iodide in a soln. of iodine in alcohol at 30°, the crystalline precipitate was washed with alcohol and dried over calcium chloride. A. Saglier made the polyiodide by gradually adding 20 grms. of iodine to 100 c.c. of an ammoniacal soln. of cupric sulphate on the water-bath, and then cooling the liquid; and M. E. Pozzi-Escot, by adding sodium or ammonium iodide to a warm soln. of a cupric salt in more ammonia than is required for the soln. of the precipitate first formed. The dark brown rhombic crystal plates decompose on exposure to air. F. Ephraim and P. Mosimann made **cupric tetrammino-hexaiodide,** $[Cu(NH_3)_4]I_2.2I_2$.

S. M. Jörgensen also prepared cupric tetrammino-hexaiodide, $CuI_2.I_4.4NH_3$ or $CuI_6.4NH_3$, with some combined water—xH_2O—by mixing warm (30°) soln. of cupric tetrammino-nitrate and of iodine in potassium iodide, and filtering through a hot water funnel as rapidly as possible; on standing, brown rectangular plates separate which can be washed with cold water, and preserved under water a long time without decomposition, otherwise they decompose too quickly for analysis. A. Saglier made the same crystals by dissolving iodine in the mother liquid remaining after the separation of crystals of $CuI_4.4NH_3$.

A. Guyard prepared dark violet or garnet red crystals of cupric iodide and nitrogen iodide, $CuI_2.N_2H_4I_2$, by the action of a soln. of iodine in potassium iodide on cupric tetrammino-sulphate; A. Saglier crystals of tetrahydrated *ammonium cupric diammino-iodide,* $2NH_4I.CuI_2.2NH_3.4H_2O$, by boiling mixed soln. of 100 grms. of ammonium iodide in 200 c.c. of water, and 10 to 15 grms. of cupric hydroxide; very dark green needles separate from the filtered soln. on cooling. The crystals are insoluble in alcohol and water, but soluble in ammonia water. The last-named soln. yields blue crystals of $CuI_2.4NH_3.H_2O$. A. Saglier also prepared black crystals of the polyiodide, $2NH_4I.CuI_2.I.2NH_3.12H_2O$, by proceeding as before with a soln. containing in addition a gram eq. of iodine per gram-eq. of ammonium iodide. The dark violet needles or plates decompose in air and water. They dissolve in dil. ammonia water.

A. C. Becquerel prepared white needle-like crystals of *potassium cupro-iodide*, by dipping a copper cathode in a soln. of potassium iodide, and an anode in a soln. of cupric sulphate. The crystals soon decompose into cuprous iodide, etc.

§ 22. Cuprous Sulphide

The action of sulphur on copper was noticed by Geber in his *Summa perfectionis magisterii*, probably written about the thirteenth century. Albertus Magnus,[1] also of the thirteenth century, occupied himself with a study of the action of sulphur on the metals. Copper forms two clearly defined sulphides. This fact was first established by J. L. Proust in 1801. There are a number of other intermediate sulphides and polysulphides whose individuality is not so sharply defined.

In 1546, G. Agricola [2] distinguished the mineral cuprous sulphide from other copper ores, and he likened it to *Kupferglas*. J. G. Wallerius, in 1747, gave it a variety of names, *cuprum vitreum*, *Kupferglaserz*, etc. A. J. Cronstedt referred to it as *cuprum sulphure mineralisatum*. J. von Born called it *cuivre sulfuré*. L. A. Emmerling applied the term *Kupferglanz* as synonymous with *Kupferglas*—hence the terms *copper-glance* and *vitreous copper* now applied to this mineral. F. S. Beudant called it *chalkosine*, which in its English dress is *chalcocite*. J. Nicol called the variety from Redruth (Cornwall), *redruthite*. Other terms have been applied to particular varieties—*Lecherz*, *cupreïn*, *coperite*, *digenite*, *carmenite*, and the mineral *harrisite*. Cuprous sulphide also occurs united or associated with many other sulphides in the copper sulphide ores. The mineral was analyzed by R. Kirwan,[3] M. H. Klaproth, R. Chenevix, and A. Gueniveau.

Cuprous sulphide is formed in a great many reactions and it has been reported in many furnace products. J. F. L. Hausmann,[4] T. Scheerer, P. von Sustschinsky, C. F. Rammelsberg, etc., found it in the slags of copper furnaces ; A. Daubrée, A. Lacroix, C. A. de Gouvenain, E. Priwoznik, etc., detected its crystals on old Roman coins or bronze relics in the neighbourhood of the thermal springs at Bourbonne-les-Bains, and other places with hydrogen sulphide springs. A. Kerner, and W. R. von Haidinger and E. Kögeler found crystals of cuprous sulphide associated with the brass clasps of old books.

The formation and preparation of cuprous sulphide.—Copper and sulphur readily react when heated forming cuprous sulphide, Cu_2S, cupric sulphide, CuS, or a mixture of both. There is also a possible series of higher sulphides, as well as a series of intermediate sulphides ; although some of those which have been reported are in all probability mixtures.

1. *From sulphur and copper or copper oxide.*—Copper foil burns vigorously in sulphur vapour; and when a mixture of copper filings is heated with about one-third of its weight of sulphur, the mixture becomes incandescent, and cuprous sulphide is formed.[5] C. R. Hayward found the product should be broken up, and mixed with more sulphur; he also made cuprous sulphide by boiling sulphur with copper turnings in a large casserole for an hour. To ensure complete conversion to cuprous sulphide, the sulphur was poured off, and the porous mass mixed with 15 per cent. of sulphur and melted for 5 hrs. in a graphite crucible. The same compound is made by the action of hydrogen sulphide or the vapour of sulphur or of some other sulphur compound at a red heat, and cooling the product in the vapour; the excess of sulphur can be removed by heating it with copper. H. Rose, and E. Mitscherlich obtained octahedral crystals of cuprous sulphide by melting together copper and sulphur; and J. Margottet obtained similar crystals by the action of sulphur vapour, carried with a stream of nitrogen, over red-hot copper. Dry sulphur was found by C. Strüver to react very slowly with copper at ordinary temp. G. C. Winkelblech found sulphide is formed when a dry or moist mixture of sulphur and copper is triturated together. According to W. Spring, when a mixture of copper filings and sulphur are subjected a number of times to a press. of 65 atm., cuprous or cupric sulphide can be formed; and with the former the volume decreases from 138 to 100 units. These press. reactions were discussed in an earlier chapter. A. Orlowsky found copper to be blackened by immersion in a soln. of sulphur in carbon disulphide. J. L. Proust prepared cuprous sulphide by calcining the oxide with sulphur. H. Rose also found that cuprous sulphide is formed when copper oxides, oxysulphides, or cupric salts are heated with sulphur. E. Weinschenk obtained octahedral crystals of cuprous sulphide by heating an intimate mixture of cupric oxide, sulphide, and ammonium chloride, until the latter has all sublimed. This method was employed by F. Wöhler with iron oxide.

2. *By displacement with other sulphides.*—The affinity of copper for sulphur is estimated by O. Schumann to be nearly the same as that of copper for oxygen. A. Orlowsky[6] considers that the affinity of copper for sulphur is greater than that of any other metal—excepting, adds E. Schürmann, palladium, mercury, and silver. E. F. Anthon says that this affinity is smaller than that of silver, but greater than that of lead, cadmium, iron, nickel, cobalt, and manganese; to this list E. Schütz added zinc and tin, and placed manganese with silver as possessing a greater affinity than copper for sulphur. F. G. Reichel[7] found that aluminium and magnesium sulphides are reduced at a very high temp. $2Cu+MgS=Cu_2S+Mg$. A. Colson found that little cadmium sulphide is decomposed when it is heated with copper in accord with $2Cu+CdS\rightleftharpoons Cu_2S+Cd$, because the cadmium compound is dissociated below 600°. Sublimed cadmium also collects in the cooler parts of the tube; and he also noted that with iron pyrites and copper in an atm. of carbon dioxide sulphur separates from the pyrites and unites with the copper. E. Schütz observed that at 1195°, copper removed 85·06 per cent. of the sulphur from ferrous sulphide; G. P. Schweder noted that copper removes sulphur from nickel sulphide; K. Heumann found that if mercuric sulphide be boiled under water with copper, it is rapidly decomposed; and G. Strüver found that many dry natural sulphides react with copper at ordinary temp., forming copper sulphide—*e.g.* hauerite acts markedly in about three days, pyrite acts more slowly, marcasite more quickly, and magnetic pyrites more quickly still—no action was observed with arsenical pyrites or cobaltite.

3. *From copper or copper oxide and hydrogen sulphide.*—E. Murmann[8] made cuprous sulphide contaminated with cupric sulphide by the action of hydrogen sulphide on red-hot copper. E. Brunner, L. E. Rivot, and H. Rose prepared cuprous sulphide for weighing in analytical work by heating the precipitated copper sulphide in a crucible to redness in a stream of hydrogen. R. Wegscheider says the temp. should not exceed 600°–700° or some copper is reduced. E. Murmann says that if cuprous sulphide with a fragment of sulphur be repeatedly heated in a stream of hydrogen, the product varies less than ±0·05 per cent. from the theoretical. The

admixture of a little hydrogen sulphide with the hydrogen has also been recommended. When carbon dioxide is employed in the reduction E. Murmann found the results too high. At ordinary temp., dry hydrogen sulphide has very little action on the dry metal, but if oxygen or air be present, the metal is attacked. If hydrogen sulphide be passed through water standing over copper, the metal is scarcely attacked, but if air be present, the metal is quickly blackened. Copper slowly decomposes an aq. soln. of hydrogen sulphide at 200°. Powdered copper very slowly develops hydrogen in an aq. soln. of hydrogen sulphide; if the powdered copper has been calcined it is not so active, but if the powder has been moistened with a soln. of platinic chloride, and ignited, it decomposes hydrogen sulphide more readily than copper alone. An alcoholic soln. of hydrogen sulphide behaves similarly; a soln. in nitrobenzene favours the formation of cuprous sulphide with the simultaneous production of aniline and benzidine. O. Schumann found cuprous sulphide to be formed by the action of hydrogen sulphide on cupric or cuprous oxide. The action takes place in the cold with the development of heat and the formation of water; with cupric oxide, probably cupric sulphide is formed as an intermediate product. C. Doelter heated cupric oxide between 250° and 400° or gently warmed cuprous oxide with hydrogen sulphide, and obtained crystalline cuprous sulphide. J. Milbauer heated to redness a mixture of a cupric oxide and potassium thiocyanate. The reaction is very energetic, the product is washed with hot water and alcohol. If the heating be too protracted $K_2Cu_8S_6$ is formed.

4. *From copper and carbon disulphide.*—A. Cavazzi obtained cuprous sulphide by passing the vapour of carbon disulphide over metallic copper at a high temp.—some graphite is formed at the same time. According to J. Thomsen, if the carbon disulphide is carried along with a stream of nitrogen carbon monosulphide is formed. V. Merz and W. Weith say that at 250° a product with 20 per cent. sulphur (almost the theoretical value for Cu_2S) is formed—the product is admixed with carbon.

5. *The action of hydrogen sulphide on copper salts.*—Hydrogen sulphide gives a precipitate of black cupric sulphide, CuS, from neutral or acid soln.: $CuSO_4+H_2S=CuS+H_2SO_4$. If the soln. be neutral or feebly acid, the precipitate is inclined to form a colloidal soln., and a considerable excess of acid is required to flocculate the sulphide. The precipitate readily oxidizes in air: $CuS+2O_2=CuSO_4$. If the acid soln. be boiling, the sulphide dissolves in hydrochloric acid, forming cupric chloride, which is then reduced to cuprous chloride: $CuS+CuCl_2=2CuCl+S$, and, according to L. L. de Koninck, and T. Kliche, some sulphate is formed at the same time: $CuS+8CuCl_2+4H_2O=CuSO_4+8HCl+8CuCl$. Hydrogen sulphide with acid soln. of cuprous salts gives a precipitate of cuprous sulphide: $Cu_2Cl_2+H_2S=Cu_2S+2HCl$.

The dark greenish-black precipitate obtained by the action of hydrogen sulphide on an excess of a soln. of a cupric salt, and removing the hydrogen sulphide by a current of carbon dioxide, furnishes numbers in agreement with Cu : S=1 : 1. Not all the sulphur, however, is combined—some is free and can be removed by treatment with carbon disulphide or sodium sulphide. The residue contains copper and sulphur in proportions which depend upon the acidity, temp., and concn. of the soln., and on the rate at which the hydrogen sulphide is passed through the soln. The precipitate washed free from uncombined sulphur is thought to be a mixture of cupric and cuprous sulphides containing $n\mathrm{CuS}+m\mathrm{Cu_2S}$. It is supposed that copper behaves like the more negative elements of the analytical group—germanium, tin, arsenic, antimony, molybdenum, tellurium, tungsten, platinum, iridium—and forms an unstable copper thio-salt—*vide* cadmium, mercury, and lead thio-salts—this is then decomposed, forming the two sulphides as symbolized in general terms: $(m+n)\mathrm{Cu}+n\mathrm{S_2Cl_2}=n\mathrm{CuCl_2}+m\mathrm{CuS}+n\mathrm{S}$.

The precipitate is oxidized by air less readily than cupric sulphide. E. Weinschenk made crystals of cuprous sulphide by the action of hydrogen sulphide under pressure on a soln. of cuprous chloride; H. Sommerlad[9] likewise from cuprous chloride and arsenious sulphide; and J. Durocher made six-sided plates by the action of cuprous chloride vapour and hydrogen sulphide at a high temp. P. Sabatier and J. B. Senderens treated $CuNO_2$ with hydrogen sulphide; H. de Sénarmont treated a soln. of a cupric salt with sodium carbonate and hydrogen sulphide or potassium hydrosulphide at 200°; A. Orlowsky boiled a hydrochloric acid soln. of a cuprous salt with sulphur; T. Parkman found sulphur dioxide acts more quickly than milk of sulphur; C. Himley, and G. Vortmann recommended sodium thiosulphate; and F. J. Faktor treated dry cupric chloride with dry sodium thiosulphate.

6. *The action of alkali or ammonium sulphide on copper or copper salts.*—Alkali sulphides act on soln. of cupric salts like hydrogen sulphide: $CuCl_2+K_2S=CuS+2KCl$. J. Pelouze[10] reported that some oxysulphide is formed if the soln. is warm; and T. Kliche found that the precipitate is a mixture of both cupric and cuprous sulphides. Copper is not attacked by a soln. of potassium sulphide in the absence of air or oxygen, but A. Ditte showed that in the presence of air black crystals of cupric sulphide, or of $K_2S.Cu_2S$, are formed and a little passes into soln.; G. Lunge and F. Weibel found that at 20° a soln. of sodium hydrosulphide—about 4 grms. per litre—dissolves 0·6217 grm. of copper in seven days. According to E. Priwoznik, a soln. of potassium hydrosulphide converts copper into crystalline cuprous sulphide, and gas is developed at the same time. He also found that copper reduces the polysulphides of ammonium or the alkalies to the monosulphides, some sulphur may separate, and a brownish-black crust of cupric sulphide is formed on the metal; in a few days this crust is reduced to black cuprous sulphide. Colourless ammonium sulphide in the absence of air produces only a greyish-black film on copper after some months' exposure; if air be present, ammonium hydroxide is obtained. V. Merz and W. Weith noted that a little of the ammonium hydroxide is decomposed furnishing hydrogen. The hydrogen is not developed with dil. soln. A little copper sulphide passes into soln. when a conc. soln. of ammonium monosulphide acts on copper—crystals of cuprous sulphide are simultaneously formed. The copper sulphide which is dissolved is largely precipitated by dilution with water or treatment with hydrochloric acid. According to K. Heumann, the first product of the action of a sat. soln. of sulphur in ammonium monosulphide is a reddish deposit of $(NH_4)_2Cu_2S_7$. V. Merz and W. Weith also found that the reaction with ammonium hydrosulphide is accelerated if platinized copper is used, but even then the action is slow.

7. *The reduction of the oxysulphur compounds by copper.*—J. Uhl[11] found that a mixture of dry sulphur dioxide and air does not form sulphur trioxide, but copper is blackened by the reduction of the sulphur dioxide and the formation of copper sulphide; moist sulphur dioxide was found by H. Causse to give a mixture of cupric sulphite and sulphide, and some hydrosulphurous acid is simultaneously formed. B. D. Steele noted that in the electrolysis of a soln. of potassium iodide in liquid sulphur dioxide with copper electrodes, a black film—presumably cuprous sulphide—is formed. L. Maumené noticed that with conc. sulphuric acid (4 : 5), copper is converted into brown amorphous cuprous sulphide; C. Baskerville found the conversion is quite rapid between 100° and 130°. S. U. Pickering believed that the cuprous sulphide is formed by the direct action of copper on the sulphur of the acid. E. Divers and T. Shimidzu found that reduced spongy copper gives a slight effervescence when placed in fuming sulphuric acid, but the copper soon blackens and the reaction is then very slow. The black film is presumably cuprous sulphide. According to V. Merz and W. Weith, when copper is heated with sodium thiosulphate which has melted in its own water of crystallization, the formation of copper sulphide begins at about 115°, and is completed in about 40 mins. Very little normal sodium sulphite is formed when copper is heated to 120° in aq. soln. of sodium thiosulphate, but at 170° the reaction is rapid. J. Girard noted the formation of cuprous sulphide when a soln. of sodium cuprous thiosulphate is treated with copper.

8. *The reduction of cupric sulphide.*—When dry cupric sulphide is calcined in an open crucible, E. Ulrici[12] found that a mixture of cuprous sulphide and copper

oxide is formed, and W. Hittorf says that some cupric sulphide remains undecomposed even at a white heat. A. Mourlot reduced precipitated and dry cupric sulphide by heating it for 5 mins. with 20 vols. of alcohol; with a long heating, metallic copper is formed. T. Kliche found cupric sulphide is reduced to cuprous sulphide by a conc. hot ammoniacal soln. of a copper salt; A. Ditte says that with potassium monosulphide, cuprous sulphide and then a double salt is formed; R. F. Weinland and L. Storz reduced cupric sulphide with a soln. of sodium arsenite. F. Cornu made crystals of cuprous sulphide by heating covellite in a porcelain crucible out of contact with air; A. Frenzel heated cupric sulphide in a stream of coal gas; E. Weinschenk, and F. Wibel reduced cupric sulphide in a stream of hydrogen. F. Damm and F. Krafft found that cupric sulphide is reduced to cuprous sulphide by exposing it in vacuo at 400° to the cathode light. A. Mourlot reduced cupric sulphide by heating it with a current of 35 amps. and 35 volts—and he adds that it is not decomposed by a current of 300 amps. and 50 volts if it is not in contact with carbon—*vide* cupric sulphide.

9. *From cupric sulphate.*—P. Berthier[13] obtained a mixture of copper and cuprous sulphide by heating cupric sulphate in a carbon crucible to a white heat. C. Brückner heated a mixture of cupric sulphate with sulphur. Pyrites in a soln. of cupric sulphate was found by H. V. Winchell to become slowly covered with a film of cuprous sulphide. P. Hess precipitated a film of cuprous sulphide on iron placed in cupric sulphate soln. and treated with sodium thiosulphate. This protected the iron from oxidation. F. Mylius and O. Fromm found that if a soln. of cupric sulphate with a mixture of a soln. of sulphur in benzene or carbon disulphide be poured on an anodic copper plate at the bottom of a vessel, and a platinum wire cathode be used, a plate of cuprous sulphide is formed at the surface of separation of the two liquids.

C. A. Burghardt supposed that cuprous sulphide has been formed along with hydrogen sulphide, and iron sulphate by the action of steam under press., and over 120°, on cupriferous pyrites. W. Lindgren and W. F. Hillebrand, V. Lewis, H. N. Stokes, and J. F. Kemp seem to regard the mineral as having been originally contained in pyrites from which the ferruginous sulphides have been leached by soln. of cupric sulphate.

The physical properties of cuprous sulphide.—The mineral is greyish-black, blue, green, or violet; and the artificial product is black or bluish-black. Cuprous sulphide is dimorphous. In addition to the methods previously indicated for preparing crystals of cuprous sulphide by E. Weinschenk, J. Margottet, E. Mitscherlich,[14] H. Rose, etc., F. Rössler dissolved the amorphous sulphide in fused lead and obtained octahedral crystals by slowly cooling the soln. The **crystals** of the artificial product are usually octahedra belonging to the cubic system, while the bipyramidal crystals of the natural mineral belongs to the rhombic system and, according to W. H. Miller, it has the axial ratios $a:b:c=0{\cdot}5822:1:0{\cdot}9701$. Both R. J. Haüy and A. Lévy supposed the mineral to belong to the hexagonal system, but F. Mohs showed that this is wrong. The pseudohexagonal symmetry of the mineral, like aragonite and chrysoberyl, is accentuated by its forming twins and triplets about the prism planes.

The cubic crystals appear to be the form stable at a high temp. W. Mönch found both natural and artificial crystals show discontinuous changes in their electrical conductivity at 95° and at 150°. According to M. Bellati and S. Lussana, the first of these changes corresponds with a considerable change in the sp. ht., and they place the transition temp. at 103°, but R. von Sahmen and G. Tammann were unable to detect any discontinuity in the volume-temperature curve. The reported[15] numbers for the **specific gravity** of the artificial product vary from C. F. Rammelsberg's 5·388 to C. J. B. Karsten's 5·9775. The best representative value approaches C. Doelter's 5·80, or W. Herapath's 5·792 (17·7°). The mineralogists give for the sp. gr. of the mineral 5·5 to 5·6. The **hardness** on F. Mohs' scale is 2·5 to 3·0.

C. J. B. Karsten reported that cuprous sulphide melts more readily than copper. H. le Chatelier[16] found the **melting point** to be 1100°; G. Bodländer and K. S. Idaszewsky found 1091°; K. Friedrich gave 1125°–1135° for the f.p. and E. Heyn and O. Bauer, 1127°. Molten cuprous sulphide does not mix in all proportions with copper—the eutectic at about 1070° has, according to G. G. Urazoff, 0·88 per cent. of sulphur, or 4·36 per cent. of Cu_2S, by weight, and from about 9 per cent. to the f.p. of the two layers, the alloy separates into two layers, one rich in cuprous sulphide, and the other rich in copper; the f.p. of the upper layer is 1121°, and of the lower, 1070°. According to G. G. Urazoff, during the cooling of solid soln. of β-Cu_2S rich in copper, the former passes into α-Cu_2S; or cuprous sulphide rich in sulphur remains stable. *Copper moss* grows slowly in cooling soln. by the breaking up of the solid soln. of copper in cuprous sulphide. G. Bodländer and K. S. Idaszewsky found that molten cuprous oxide does not mix in the fluid state with copper, but, when above the m.p., copper is dissolved, and, on cooling, the metal separates out again. When polished surfaces of copper containing cuprous sulphide are etched with ammonium tetrachlorocuprate, $(NH_4)_2CuCl_4$, and with hydrofluoric acid, the red cuprous sulphide remains unchanged. H. Kopp gave 0·120 for the sp. ht. between 19° and 52°. M. Bellati and S. Lussana found the sp. ht. to decrease on a rising temp. up to the transformation temp. 103°; and the sp. ht. at a temp. below 103° is $C=0·10938+0·0002453\theta$; and above 103°, $C=0·16269-0·0000912\theta$; they also give 5·630 Cals. for the **heat of transformation.** J. Thomsen found the **heat of formation** (2Cu, S) to be 20·24 Cals., and (Cu_2O, H_2Saq.), 38·53 Cals. M. Wasjuchnowa gave (2Cu, S)=18·9 Cals., and $\frac{1}{2}$(Cu_2S, S)=2·45 Cals.

A. de Grammont has studied the spark **spectrum** of cuprous sulphide, and found that it gives lines characteristic of sulphur and copper—the presence of iron is also shown spectroscopically by some characteristic lines in the violet. O. Rohde, and K. Herrmann have studied the photoelectric effect of cuprous sulphide.

T. Erhard[17] found that the **electrical conductivity** of copper-glance is virtually nil, and T. W. Case found exposure to light had no perceptible effect on the conductivity of chalcocite; but M. Faraday found that it does conduct if heated to a temp. far below its m.p. W. Hittorf says that it conducts well when it contains copper. G. Bodländer and K. S. Idaszewsky say that cuprous sulphide is an electrolyte and that at a high temp. it is decomposed by the current into copper and non-electrolytic cupric sulphide. According to G. Burckhardt, and T. du Moncel, it conducts like a metal, while W. Hittorf, and R. von Hasslinger find that at 110° or over it conducts like an electrolyte. The latter says that over 500° it conducts both as an electrolyte, and as a metal. W. Mönch also measured the conductivity of the sulphide. S. P. Thompson says that the resistance at 0°, 51°, and 191° is respectively 1130, 120, and 2 units, and W. Kohlrausch adds that if the specific resistance be R, when mercury zero is the unit,

	0°	10°	51°	85°	107°	136°	184°	192°
$R\times10^{-3}$ . .	7430	4470	790	264	62	34	14·5	13 units

S. Bidwell found that precipitated cuprous sulphide pressed between silver and copper plates conducts electrolytically; while F. Streintz found that a rod made by press. from the powder is a worse conductor than cupric sulphide. C. Tubandt found that cubic crystals of cuprous sulphide is an electrolyte with positive cuprous ions. G. Trumpler studied cells of cuprous sulphide, and measured the e.m.f. against soln. of sodium sulphide. According to W. Skey, copper-glance is more electronegative towards a soln. of sodium chloride than is silver; A. Schrauf and E. S. Dana say that it is electropositive towards copper; E. Becquerel observed an e.m.f of 0·28 volt when artificial cuprous sulphide is in contact with nickel silver. E. Hermite and C. F. Cooper proposed to diminish the internal resistance of cuprous sulphide by heating it in the vapour of sulphur, and cooling out of contact with air. For the preparation of thermopiles with cuprous sulphide, see F. Peters' *Thermoelemente und Thermosaulen* (Halle, 1908). C. Tissot and F. Pellin have studied the use of cuprous sulphide for thermoelectric detectors in wireless telegraphy. S. Meyer gave $-0\cdot14\times10^{-6}$ mass units at 17° for the **magnetic susceptibility.**

The chemical reactions of cuprous sulphide.—According to S. U. Pickering,[18] amorphous cuprous sulphide, when dried at 100°, does not oxidize in **air,** although K. Heumann found some samples acquired a steel-blue lustre when exposed to moist air. W. Hittorf found that when heated in the absence of air, cuprous sulphide decomposes into sulphur and cupric sulphide, and A. Mourlot obtained similar results with electrical heating. If heated with a limited access of air, sulphur dioxide, cupric oxide, and sulphate are formed. E. F. Smith effected the complete oxidation of the sulphur by heating the powder on molten potassium hydroxide in a nickel dish which served as an anode for an electric circuit. If heated with **water** vapour, H. V. Regnault, and A. Gautier, found that some is decomposed, at a bright red heat, copper, sulphur dioxide, and hydrogen are produced: $Cu_2S+2H_2O=2Cu+SO_2+2H_2$. The sulphur of hydrogen sulphide may be oxidized by water at a red heat, forming sulphur dioxide and hydrogen along with traces of sulphur, sulphuric and thionic acids. Oxygen is therefore not necessary to account for the presence of sulphur dioxide in volcanic gases. O. Weigel found that water dissolves $3\cdot1\times10^{-6}$ mols of Cu_2S per litre at 18°. W. Hampe found that **hydrogen** slowly and completely reduced cuprous sulphide at a red heat. E. Schütz found that a stream of hydrogen passing at the rate of 0·75 litre per min. reduces 0·75 per cent. of cuprous sulphide heated for 3 hrs. between 600° and 610°, ferrous sulphide under similar conditions lost 3·46 per cent.—J. Uhl, and R. Wegscheider obtained a greater amount of reduction at 800°. According to F. C. Phillips, and A. Liversidge, reduction does take place at 600°, but, added W. M. Hutchings, only when the hydrogen is moist and the effect is then produced by the water vapour. The work of G. P. Schweder, A. Classen, and H. Rose shows that the calcination of cuprous sulphide obtained in analysis, in a stream of hydrogen, does not reduce sufficient cuprous sulphide to interfere with the result, provided the temp. is not over that of the ordinary gas blowpipe flame. A. Ledebur found that some reduction occurs when cuprous sulphide is melted with copper in dry hydrogen. A. T. Weightman, and T. W. Richards showed that if cuprous sulphide be used as cathode in the electrolysis of dil. sulphuric acid, the compound is not reduced so readily as with lead sulphide.

Cuprous sulphide at a dull red heat was found by H. Rose[19] and E. Schäfer to be but slowly decomposed by **chlorine:** and the latter found that under these conditions it is not attacked by **bromine** vapour. J. Lemberg found alkaline lye and bromine forms a skin of cupric oxide on copper-glance. 5*N*-**hydrochloric acid** attacks cuprous sulphide very slowly, but J. Egli found that the action is faster in the presence of chlorine. H. Knop said that dil. hydrochloric acid converts copper glance into cupric sulphide; and K. Heumann found that the boiling conc. acid slowly reacts with cuprous sulphide, forming cuprous chloride and hydrogen sulphide.

E. Priwoznik[20] studied the action of alkali and ammonium sulphides on cuprous sulphide—cuprous sulphide with the **alkali sulphides** forms fusible double sulphides; the alkali polysulphides form products like they do with cupric oxide; K. Heumann studied the action of **ammonium polysulphide,** and obtained a red compound, $(NH_4)_2Cu_2S_7$; K. Friedrich and P. Schön obtained only a single branch in the f.p. curve of mixtures of **zinc sulphide** and cuprous sulphide; if a eutectic is formed it must lie close to the m.p. of cuprous sulphide; K. Friedrich, with mixtures of cuprous sulphide and **lead sulphide,** obtained the typical V-curve with a eutectic at 540° and about 52 per cent. lead sulphide; P. Röntgen obtained indications of the formation of four compounds, $Cu_2S:FeS=3:2$; $1:1$; $2:5$; and $1:2$ on the f.p. curve of mixtures of cuprous sulphide and **ferrous sulphide.**

S. U. Pickering found that with **sulphuric acid,** cuprous sulphide furnishes sulphur dioxide, cupric sulphide and sulphate : $Cu_2S+2H_2SO_4=CuS+CuSO_4+2H_2O+SO_2$; and M. de K. Thompson showed that the action of the dil. acid is very slow in the presence of oxygen. K. Heumann noticed that some varieties of the crystalline sulphide are not attacked by dil. or conc. acid. C. E. Baker and A. W. Burwell found that when **sulphur chloride,** S_2Cl_2, is heated with cuprous sulphide, cupric chloride and sulphur are formed.

According to W. Hampe,[21] and G. P. Schweder, **carbon** has no appreciable reducing action on cuprous sulphide at a red heat ; W. Hampe found that cuprous sulphide is not appreciably reduced by **carbon monoxide** at a red heat; G. P. Schweder found a loss of 0·8 per cent. which W. Hampe attributed to the presence of a little air, for the reducing gases act more rapidly if air is present. When strongly heated in the presence of **carbon dioxide** there is but a slight decomposition and loss of weight. E. Fleischer found that while fusion with **sodium carbonate** has scarcely any action on cuprous sulphide, a mixture of sodium carbonate and hydroxide reduces part of the sulphide to copper ; and P. Berthier, and E. Fleischer noted that a mixture of sodium carbonate and cuprous oxide reduces about half the latter to copper, and the other half forms a compound of sodium and cuprous sulphides ; at a white heat almost all is converted to copper. P. Berthier noted that sodium carbonate with cuprous sulphide and **iron** also furnishes copper. E. Fleischer also fused a mixture of cuprous sulphide, and sodium carbonate and chloride, with **potassium chlorate,** and obtained a more energetic oxidation than occurs with aqua regia. P. Berthier found that a similar action occurs if the sodium carbonate is replaced by **lime** or **baryta,** and double cuprous barium or calcium sulphides are formed.

Cuprous sulphide was found by M. Malzac[22] to be converted by aq. **ammonia,** in the presence of air, into a soln. of a cupric salt. J. Lemberg found that by treating copper-glance with aqua ammonia, and then acidifying the soln. with sulphuric acid, copper is precipitated on the iron. K. Heumann says that cold **nitric acid** gives cupric sulphide and half the copper passes into soln. ; and with warm nitric acid, sulphur is separated ; when fused with **sodium nitrate,** cuprous sulphide furnishes copper. J. Matuschek says that if the copper-glance be too finely powdered cupric oxide may be formed, and that large crystals are scarcely attacked by sodium nitrate, but they are by **potassium nitrate.** H. Rose found **phosphine** slowly decomposes cuprous sulphide, forming hydrogen sulphide and copper phosphide. P. Watts[23] reported that **aluminium** and **calcium carbide** reduce native cuprous sulphide when heated in an electric furnace. C. J. B. Karsten obtained no decomposition by fusing cuprous sulphide with **lead,** although P. Berthier found that when fused with **lead oxide,** there is formed cuprous oxide, lead, and sulphur dioxide: $Cu_2S+3PbO=Cu_2O+3Pb+SO_2$. C. J. B. Karsten, and F. Schweder found that when heated with **iron** there is an incomplete decomposition, forming ferrugineous copper, and cupriferous iron ; E. Schütz found that when the mixture is heated to 1205°, 93·6 per cent. of the sulphur remains with the copper. E. D. Campbell noted the diffusion of cuprous sulphide into cast iron at a red heat. C. J. B. Karsten obtained a slight decomposition of cuprous sulphide by heating it with **ferric oxide,** but none with **ferric silicate.** F. Schweder observed no action when **nickel** is heated with cuprous sulphide. C. J. B. Karsten found that when calcined with **cupric oxide,** sulphur dioxide and copper or cuprous oxide are formed ; the reaction was also studied by E. Heyn and O. Bauer,[24] who found that if reducing agents are present, the sulphur dioxide is partially reduced to sulphur, which re-forms the sulphide. W. Stahl studied the corresponding reaction with **cuprous oxide.** G. Bodländer found cuprous sulphide to be more soluble in **water** than silver sulphide, and more soluble than lead sulphide ; according to O. Weigel, a litre of water dissolved $3{\cdot}1\times10^{-6}$ mol of copper-glance. Cuprous sulphide was found by J. Egli to be slightly soluble in $4{\cdot}5N$-**sodium hydroxide.** E. Berglund says that the precipitated sulphide slowly reduces zinc from a soln. of a **zinc salt ;**

E. Heyn and F. W. Hinrichsen, and O. Bauer studied the action of a soln. of **cadmium acetate** mixed with potassium cyanide on copper containing cuprous sulphide, when alcohol is added, a yellow precipitate occurs. E. Cumenge and R. Wimmer found that when cuprous sulphide is treated with **ferric chloride** soln. cuprous chloride, ferrous chloride, and sulphur are formed ; on the other hand, H. Kammerer showed that when heated in a sealed tube at 120° with ferric chloride, there are formed sulphur and cupric and ferrous chlorides, but not cuprous chloride. Similar results were obtained with a soln. of **ferric sulphate,** and V. Thomas found this last-named solvent readily dissolves copper-glance, forming sulphur and ferrous and cupric sulphates which do not act further on cuprous sulphide. According to T. Kliche, ammoniacal soln. of cupric salts do not attack the sulphide. A boiling conc. soln. of **cupric chloride** in the presence of hydrochloric acid or sodium chloride was found by F. Raschig to decompose cuprous sulphide into cuprous chloride and sulphur; whilst a **cuprous chloride** soln. has no action. M. Vallety, and A. Schneider symbolized the reaction with a soln. of **silver nitrate** : $4AgNO_3+Cu_2S=2Ag+Ag_2S+2Cu(NO_3)_2$. K. Heumann pointed out that the reaction is very slow with the crystalline form of cuprous sulphide. S. Meunier has stated that the metals are precipitated from soln. of the **rare-earth salts** by copper-glance.

§ 23. Cupric Sulphide

The blue *Kupferglas* described by J. C. Freiesleben[1] no doubt referred to the native cupric sulphide; it was named *indigo copper* by C. A. S. Hoffmann and A. Breithaupt. The composition was determined by N. Covelli, and F. S. Beudant named it *covellite*, E. J. Chapman, *breithauptite*.

The formation and preparation of cupric sulphide.—M. Berthelot[2] obtained cupric sulphide by the action of hydrogen sulphide on solid cupric acetate, but not the chloride. A. Ditte obtained crystals of cupric sulphide by the action of a dil. soln. of potassium sulphide on copper when air is excluded. E. Murmann found that cupric sulphide precipitated by alkali sulphides from cupric salt soln. always contains alkali as impurity. E. Priwoznik obtained crystals of cupric sulphide by the action of a soln. of sulphur in aq. ammonium sulphide on copper. K. Heumann noted that when dry cupric oxide is treated with a conc. soln. of ammonium monosulphide, $(NH_4)_2S$, much heat is developed and a violent reaction occurs; a mixture of variable proportions of cuprous and cupric sulphides is formed. F. Cornu evaporated a mixture of malachite and ammonium hydrosulphide to dryness, and extracted the sulphur with carbon disulphide. Crystals of cupric sulphide remained. V. Staněk converted amorphous into crystalline cupric sulphide by heating it for four hours with ammonium sulphide soln. in a sealed tube at 150°–200°; W. Spring heated the amorphous sulphide in vacuo to 150° for about nine days of 7–8 hours' duration. Sodium or ammonium thiosulphate precipitates a mixture of cuprous and cupric sulphide from warm soln. of cupric salts. This reaction has been studied for analytical purposes by A. Carnot, J. Girard, C. Himley, E. Fleischer, H. Nissenson and B. Neumann, A. Orlowsky, G. Vortmann and M. Willenz. E. Priwoznik says a cold soln. of sodium thiosulphate colours copper black in a week's time; a boiling soln. of the salt acts on the finely-divided metal much more rapidly. The same reagent was used by C. Puscher in producing lustre films of the sulphide on copper or its alloys.

F. C. Phillips noted that carbonyl sulphide slowly precipitates cupric sulphide from an aq. soln. of cupric sulphate; and rapidly from an ammoniacal soln.; K. Preis used sodium thioarsenate and boiling soln. J. B. Senderens obtained crystals of cupric sulphide by heating an intimate mixture of sulphur, water, and cupric oxide to 100°. A. Gautier used E. Frémy's process for preparing crystalline metal sulphides in which the vapour of carbon disulphide is passed over the heated oxide. Some cupric sulphide is produced during the action of conc. sulphuric acid on copper (*q.v.*). J. Thomsen[3] showed that the affinity of copper for sulphur is satisfied by the formation of cuprous sulphide, in the sense that no further heat is evolved if the copper takes up no more sulphur, until cupric sulphide is formed. It has hence been argued that the formation of the intermediate sulphides is very doubtful—*e.g.* A. Étard's Cu_3S_2—obtained by the action of hydrogen sulphide at 180° on cuprous sulphite, and supposed to be represented in nature by the minerals *digenite* and *carmenite;* J. Thomsen's Cu_4S_3—obtained by the action of sodium sulphide on cupric sulphate both in very dil. soln.; A. B. Griffiths' Cu_5S_4, a grey mineral which is probably a mixture of copper-glance and indigo-copper. These compounds do not appear on the f.p. curve of binary mixtures of sulphur and copper previously discussed.

The precipitate obtained by the action of hydrogen sulphide on a soln. of a cupric salt is usually regarded as cupric sulphide.[4] According to J. Thomsen, the precipitate is a mixture of the intermediate sulphide Cu_4S_3 with sulphur; A. Ditte does not believe that the precipitate contains cuprous sulphide. B. Brauner found that some free sulphur is present, and when this is removed by digesting the precipitate with carbon disulphide, the product appears to contain variable proportions of cuprous and cupric sulphides. E. Abel believes that the two sulphides are in a state of equilibrium in the solid state. A. Rössing argues that the precipitate is cupric sulphide because it immediately forms silver sulphide, Ag_2S, with silver nitrate soln. J. B. Coppock also says that if a soln. of cupric sulphate freely acidified with nitric acid be poured into an aq. soln. of hydrogen sulphide; washed with acid and water; digested seven days with carbon disulphide; washed with alcohol; and dried in an atm. of carbon dioxide at 100°, the product is cupric sulphide, CuS. W. Antony and A. Lucchesi say that to get pure cupric sulphide the precipitation must be made at 0°, with water sat. with hydrogen sulphide, washed by decantation at 0°, and maintained at this temp. until the precipitate collects at the bottom of the vessel. It is then filtered and washed in an atm. of hydrogen sulphide, and dried in nitrogen at 120°. H. W. F. Wackenroder found that no precipitation occurs if the cupric salt soln. contains potassium cyanide; an excess of ammonia; or tannin. A. Löb, and F. P. Treadwell and G. von Girsewald attribute the non-precipitation of cupric sulphide in these solns. to the formation of complex cupric ions which are not decomposed by the hydrogen sulphide. G. Chesneau has investigated the action of hydrogen sulphide on mixed soln. of lead and cupric nitrates. C. Doelter obtained crystals of cupric sulphide by the action of aq. hydrogen sulphide on copper in a sealed tube at 200°; he also used malachite at 80° in place of metallic copper; E. Weinschenk used a soln. of a cupric sulphate with twice as much ammonium thiocyanate as is needed to convert the copper to the thiosulphite; and with a slight excess of acetic acid. F. von Hochstetter suggested that in some cases cupric sulphide crystals may have been formed in nature by the joint action of calcium sulphate and organic substances on copper or bronze.

B. D. Steele [5] says that cupric sulphide is probably formed during the electrolysis of salt soln. in liquid sulphur dioxide with a copper cathode. A. C. Becquerel says that the crystalline sulphide is formed on the anode during the electrolysis of a soln. of cupric nitrate separated from a soln. of alkali sulphide by a collodion or paper diaphragm.

A. C. Becquerel introduced a cracked test-tube filled with a conc. soln. of copper nitrate into a test-glass containing a soln. of sodium monosulphide, keeping the two liquids at the same level. If the soln. were simply mixed, cupric sulphide and sodium nitrate would be formed, but a brilliant deposit of metallic copper soon appears in the crack, and as the deposit increased, the crack enlarged, and the tube ultimately broke. If the experiment be varied by making a galvanic couple with a copper or platinum wire, copper is deposited on the wire dipping in the cupric salt soln.; no trace of copper appears in the crack, until the wires are removed. A. C. Becquerel then assumed the liquid in the crack plays the part of a solid conductor and electrolysis occurs. Hence, the effects are classed as *electro-capillary* or *chemico-capillary actions.* The chemical effects produced in capillary spaces were studied with other salts—silver, lead, gold, tin, cobalt, and nickel.

The physical properties of cupric sulphide.—Artificial cupric sulphide is usually black, bluish-black, greenish-black, or brown; the native mineral is also black, bluish-black, indigo-blue, dark violet or dark green. A. Lottermoser [6] says that when cupric sulphide is precipitated by hydrogen sulphide from a cold cupric salt soln. it is quite brown and that the product from a hot soln. has a greenish tinge. A. Breithaupt supposed the crystals of covellite belonged to the hexagonal system, and C. A. Kenngott gave the axial ratio $a:c=1:3{\cdot}9720$. According to S. Stevanović, the **crystals** of covellite belong to the monoclinic system with axial ratios $a:b:c=0{\cdot}5746:1:0{\cdot}6168$, and $\beta=90^\circ\ 46'$ although they appear to be pseudohexagonal; he also described various forms, and complicated twins. J. W. Retgers says the crystals are not isomorphous with cinnabar. The reported values [7] for the **specific gravity** range from C. Doelter's 3·9 to S. Stevanović's 4·668. W. F. Hillebrand gives 4·76 at 26°. The mineral covellite has a sp. gr. 4·59–4·64, and its **hardness** is 1 to 2. W. Hittorf [8] converted cuprous to cupric sulphide by heating it up to about 444° with flowers of sulphur; M. Faraday effected the conversion by triturating cuprous sulphide with cold conc. nitric acid. A. Knop treated copper-glance with dil. sulphuric acid, hydrochloric acid, acetic acid, and aq. ammonia, and obtained crystals of cupric sulphide. As previously indicated, W. Spring produced copper sulphide by the action of high press. on mixtures of powdered copper and sulphur. W. Biltz discussed the dissociation of cupric sulphide, and P. W. Bridgman stated that it has a transition point at about 103° similar in character to that exhibited by silver sulphide. A. S. Russell gives the **specific heat** at —135° as 0·0853, and at 25° as 0·1243. K. Bornemann and O. Hengstenberg found the sp. ht. of cupric sulphide rose from 0·1432 at 100° to 0·1690 at 300°, and thereafter diminished to 0·1369 at 1050°. C. H. Lees found the **thermal conductivity** of cupric sulphide to be 0·014 in cals. per cm. M. Icole gave for the conductivity at θ°, $K=0{\cdot}0016+0{\cdot}0_{6}43\theta$. M. Berthelot [9] found that the **heat of formation** ($\frac{1}{2}CuO$, $\frac{1}{2}H_2S$ in 8 litres of water) is 15·8 Cals.; $\{Cu(C_2H_3O_2)_2, NH_4HS\}$, 25·9 Cals.; and with sodium monosulphide, 20·1 Cals. J. Thomsen gives $(Cu, S, nH_2O)=9{\cdot}73$ Cals.; $\{Cu(NO_3)_2aq., H_2Saq.\}=16{\cdot}42$ Cals.; (Cu,S), 9·76 Cals., and $\frac{1}{2}(Cu_2S, S)=0{\cdot}3$ Cal.; while M. Berthelot gives 10·1 Cals., H. von Wartenberg, 11·6 Cals., and M. Wasjuchnowa, (Cu, S)=11·9 Cals.; and $(Cu_2S, S)=4{\cdot}9$ Cals.

A. Verneuil [10] studied the effect of cupric sulphide on the **phosphorescence** of calcium sulphide, and found the colour of the glow is altered a little, but the intensity remains the same. O. Rohde, and K. Herrmann have studied the **photoelectric effect** with cupric sulphide.

According to F. Beijerinck,[11] the **electrical conductivity** of covellite is better than that of copper-glance or, according to W. Hittorf, better than precipitated cuprous sulphide. K. Bädeker gives 0·000125 for the specific resistance of cupric sulphide at ordinary temp. when that of copper is 0·0000017. F. Streintz measured the conductivity of rods prepared by compressing the powder to between 10,000 and 13,000 atm. The resistance remains unchanged at 0·0190 ohm up to 90°; and it decreases slowly to 0·0143 ohm as the temp. rises to 250°; when the mass is cooled, its resistance is smaller than before, *viz.* 0·0023 ohm. G. Bodländer and K. S. Idaszewsky, and W. Hittorf say that it conducts like a metal and not electrolytically. T. W. Case found that exposure to light had no measurable influence on the conductivity of covellite. K. Bädeker found the e.m.f. against copper between 20° and 200° increases 7·33 microvolts per degree. H. Davy found cupric sulphide to be electronegative against copper in potassium hydrosulphide soln. G. Trümpler measured the e.m f. against soln. of sodium sulphide. S. Bidwell observed that the conductivity of cupric sulphide is very small when pressed between silver and copper plates, but if some free sulphur is present, the conductivity is good. W. Spring, and G. Bredig found that when suspended in water, in an electrolytic cell, finely divided, cupric sulphide migrates to the anode. M. Lucas found that when cupric sulphide is suspended in ammonium sulphide soln., only a trace of copper appears on the cathode during electrolysis. E. E. Brooks studied its use as an element in combustion cells; C. Tissot described its use in detecting electric waves; and K. Bädeker found the **thermoelectric force** against copper to be 7·33 microvolts per degree between 0° and 100°. S. Meyer gave $-0{\cdot}16\times10^{-6}$ mass units at 17° for the **magnetic susceptibility**; and E. Wilson gave for copper pyrites $0{\cdot}0102$ to $0{\cdot}0169\times10^{-6}$.

The chemical properties of cupric sulphide.—J. W. Döbereiner,[12] and W. Hittorf found that when cupric sulphide is heated to redness in the absence of air, it is reduced to cuprous sulphide, and the product is then stable over a wide range of temp. Consequently, the high temp. reactions of cupric sulphide are really concerned with cuprous sulphide. A. Mourlot found that in the electric furnace, cupric sulphide is reduced first to cuprous sulphide, and then to the metal. M. Wasjuchnowa investigated the reaction. For the production of moss copper from cupric sulphide, *vide* silver sulphide. F. Damm and F. Kraft found that, in vacuo, it is reduced by the cathode rays even at 400°. Moist cupric sulphide rapidly oxidizes in **air,** and as shown by P. de Clermont and H. Guiot, heat is developed during the oxidation. A. Mailfert found cupric sulphide to be also oxidized by **ozone.** Cupric sulphide is easily reduced by **hydrogen** under atm. press. E. Brunner,[13] S. U. Pickering, and J. Uhl have studied the reduction of cupric sulphide in hydrogen, and find the reduction to copper occurs at 600° in hydrogen, and at 300°–350° in **carbon monoxide**; D. Stickney also found that it is completely reduced in the coal-gas flame. According to K. Heumann, cupric sulphide is reduced by nascent hydrogen; black cuprous sulphide appears to be formed when it is treated with zinc and dil. sulphuric or hydrochloric acid. According to O. Weigel, a litre of **water** dissolves $3{\cdot}51\times10^{-6}$ mol of cupric sulphide; F. Cornu found that the compound is attacked by water, and this is accompanied by some oxidation, but P. de Clermont and M. J. Frommel observed no action at 100°. H. V. Regnault found that when heated to a high temp. with water vapour, copper, sulphur, and much hydrogen are formed.

Gaseous **hydrogen chloride,** and fuming **hydrochloric acid** were found by M. Berthelot[14] to decompose cupric sulphide. According to A. W. Hofmann, it dissolves with difficulty in hot conc. hydrochloric acid with the separation of sulphur, and the formation of hydrogen sulphide and cuprous chloride. W. Antoni and L. Niccoli found hydrochloric acid of medium conc. does not decompose cupric sulphide.

S. E. Linder and H. Picton[15] say that some cupric sulphide is dissolved when it is treated with **hydrogen sulphide.** S. W. Young and N. Preston studied the joint action in sealed tubes of the copper sulphide minerals on liquid hydrogen sulphide and water or dil. sulphuric acid, with and without iron compounds. According to A. Rössing, cupric sulphide is insoluble in a soln. of **sodium monosulphide,** but it is soluble in sodium polysulphide, forming $Na_2Cu_2S_7$; on the contrary, G. F. Becker says it is slowly dissolved by a soln. of sodium monosulphide, in a sat. soln. of hydrosulphide, and in a mixture of hydrosulphide and carbonate. E. Prost and A. van de Casteele examined the solubility of cupric sulphide in potassium polysulphide. J. N. Mukherjee and N. N. Sen found that the stability of a sol of cupric sulphide is increased by dilution irrespective of the nature of the electrolyte. The adsorption theory of coagulation *per simpliciter* predicts that dilution will diminish the stability. A. Lottermoser, and J. N. Mukherjee and N. N. Sen found also that dissolved hydrogen sulphide stabilizes cupric sulphide sol both in aq. and non-aq. media. Potassium and sodium sulphides have a more marked protective action; similarly also with ammonium, potassium, barium, and strontium chlorides, and aluminium sulphate. Alkali hydroxides act similarly, and a trace greatly facilitates the preparation of sols rich in sulphide, and largely increases their stability. A. S. Cushman found cupric sulphide to be soluble in ordinary **ammonium sulphide**; and L. Storch says that it is perceptibly soluble in sodium and ammonium thio-salts of molybdenum, tungsten, arsenic, antimony, vanadium, and tin. A. Guerout says aq. **sulphur dioxide** dissolves it without change. According to S. U. Pickering, conc. **sulphuric acid** decomposes it into cupric sulphate, sulphur dioxide, and sulphur: $CuS+2H_2SO_4=S+CuSO_4+2H_2O+SO_2$. T. Kliche adds that so long as copper is present, cuprous sulphide is formed. A. W. Hofmann says that cupric sulphide is decomposed, but not dissolved by boiling dil. sulphuric acid (1 : 6). G. Gore, and E. C. Franklin and C. A. Kraus find cupric sulphide to be insoluble in liquid **ammonia.** A. W. Hofmann, and W. Antoni and L. Niccoli say that cupric sulphide is decomposed by **nitric acid** with the separation of sulphur and the formation of sulphuric acid. N. D. Costeanu could detect no action when **carbon dioxide** is passed over cuprous sulphide at 550°, but at 760°, a reaction, $Cu_2S+CO_2=Cu_2O+CO+S$, occurs.

According to A. S. Cushman, cupric sulphide is insoluble in a soln. of **potassium hydroxide**; insoluble in an acidified conc. aq. soln. of **alkali chloride** (distinction from cadmium sulphide); and, according to A. L. Flanigen, it is soluble in a soln. of **potassium cyanide,** a reaction which enables it to be separated from cadmium sulphide. M. Ragg found cupric sulphide to be insoluble in an alkaline soln. of **sodium xanthogenate.** E. Cumenge and R. Wimmer say that it is soluble in a soln. of **ferric chloride** with the separation of sulphur; C. F. Mohr says that it is oxidized by a boiling soln. of **ferric sulphate**—J. Hanus adds that the residue probably contains an oxysulphide, and M. de K. Thompson that for the complete soln. of the copper, $CuS+Fe_2(SO_4)_3=CuSO_4+S+2FeSO_4$, air must have free access to the solvent. According to J. Perino, a soln. of **ferric nitrate** at 40°–70° transforms it into cupric sulphate—nitrogen peroxide is first given off, then nitric oxide. In the presence of hydrochloric acid or sodium chloride, a boiling soln. of **cupric chloride** transforms it almost quantitatively into cuprous chloride; and if ammonia is present, much of the sulphur forms sulphuric acid, and, according to J. Pelouze, it forms oxysulphides. According to F. Raschig, very dil. soln. of cupric chloride have very little action, while cuprous chloride acts still less. C. Friedheim says that ammoniacal soln. of cupric salts act very rapidly on cupric sulphide, and cupric oxide separates from the alkaline soln. According to T. Kliche, an ammoniacal soln. of a cupric salt forms cuprous sulphide, and this the more the higher the temp. and the more conc. the soln. The sulphur is oxidized to sulphuric acid, and the cupric oxide reduced to cuprous oxide. Neutral or acid soln. of sulphate, chloride, nitrate, or acetate give the same reactions, but no oxygen is given off; and no oxysulphides are formed. An excess of cupric sulphide was found by E. F. Anthon to give a precipitate when boiled with a soln. of silver nitrate, but not with cobalt or nickel nitrate, cadmium or manganese sulphate, ferric chloride or lead acetate; E. Schürmann also found that when cupric sulphide is added to soln. of silver nitrate or of mercuric or palladious chloride the metal sulphide is precipitated. According to F. Stolle, a litre of a

10 per cent. soln. of **sugar** dissolves 0·5672 (17·5°), 0·3659 (45°), and 1·1345 (75°) grms. of cupric sulphide; while a 30 per cent. soln. dissolves 0·8632 (17·5°), 0·7220 (45°), and 1·2033 (75°) grms.; and a 50 per cent. soln. 0·9076 (17·5°), 1·0589 (45°), and 1·2809 (75°) grms.

Colloidal solutions of copper sulphide.—T. Svedberg[16] prepared an isobutyl-*alcosol of cuprous sulphide* by his process of sparking terminals under the liquid. L. T. Wright found that if precipitated copper sulphide be boiled 10 mins. with an insufficient amount of potassium cyanide soln. for complete soln., and then filtered, the insoluble sulphide immediately passes through the filter paper when the attempt is made to wash it with water. The dark opaque filtrate contains what he called "*colloidal*" *cupric sulphide*, which partially flocculates and settles on standing. W. Spring also made colloidal soln. or *hydrosol of cupric sulphide* by treating a dil. soln. of cupric sulphate with an aq. soln. of hydrogen sulphide. P. Ebell showed that the cupric sulphide colloid is not in a state of true soln., but contains particles in such a fine state of subdivision that they remain in suspension an indefinite time. W. L. Miller and R. H. McPherson found that colloidal copper sulphide does not distribute between aq. alcohol and ether, and therefore argues that the colloidal soln. is far removed from the state of true soln. N. Ljubawin, A. Sabanjéeff, C. Winssinger, S. E. Linder and H. Picton, etc., have further studied these soln.

In place of hydrogen sulphide, J. Thomsen substituted a dil. soln. of sodium sulphide; and in place of cupric sulphate, W. Muthmann and L. Stützel used a dil. soln. of potassium cupric thiosulphate; L. Vanino and F. Hartl, a dil. soln. of potassium cupric cyanide; J. Schröder and A. Neumann, a soln. of cupric chloride in pyridine; and A. Lottermoser, a dil. soln. of a glycosol cupric salt. By working in alcoholic soln., A. Lottermoser also prepared *alcosols of cupric sulphide;* and with aceto-acetic ethereal soln., *etherosols of cupric sulphide.* J. Hausmann studied the periodic or rhythmic precipitation which occurs when a soln. of cupric sulphate is allowed to diffuse into gelatine containing ammonium or sodium sulphide.

S. E. Linder and H. Picton showed that the precipitate obtained by the action of hydrogen sulphide on a dil. soln. of a cupric salt contains an excess of hydrogen sulphide "combined with the freshly precipitated sulphide," and that the proportion of CuS : H_2S depends on the concentration of the soln. They conclude that $7CuS.H_2S$ is first formed, and that this is broken down by the action of acids through successive stages expressible more or less approximately by the formulæ $9CuS.H_2S$ and $22CuS,H_2S$, till there remains a molecule composed of $(CuS)_n$ alone. Here n is possibly a higher multiple than 22CuS. In the light of later work on colloidal chemistry, it is probable that S. E. Linder and H. Picton's cupric hydrosulphides are merely adsorption products of colloidal cupric sulphide and hydrogen sulphide. In the simultaneous precipitation of copper and zinc sulphides, the amount of zinc carried down decreases rapidly with an increase in the conc. of the acid, and when the latter is constant, it also decreases with rise of temp. K. Scheringa concludes that the **zinc sulphide** is not adsorbed superficially, but forms a solid soln. at the moment of precipitation with the cupric sulphide.

The higher cupric sulphides.—J. J. Berzelius, H. Schiff,[17] and H. Peltzer obtained dirty yellow to brown precipitates by treating cupric salt soln. with ammonium or potassium polysulphide, or an ammoniacal soln. of sodium cupric thiosulphate with alcohol. J. J. Berzelius says the precipitate is soluble in an aq. soln. of potassium carbonate, and consists of a mixture of cupric sulphide and pentasulphide, or of cupric di-, tri-, or tetra-sulphides. H. Peltzer said that all the precipitates are soluble in an excess of a soln. of ammonium polysulphide. T. Parkman also obtained what he regarded as a mixture of cupric oxysulphide and polysulphide by boiling sulphur with a soln. of cupric acetate; but J. B. Senderens obtained cupric sulphide from soln. of cupric sulphate or nitrate. H. Debus also prepared what he regarded as a *cupric tetrasulphide*, Cu_2S_4, by the action of cupric acetate on Wackenroder's soln. A. Rössing did not succeed in making the tetrasulphide, Cu_2S_4, nor indeed *cupric pentasulphide*, Cu_2S_5, although F. Bodroux claims to have made it as a reddish-brown mass by pouring an excess of a 1 per cent. soln. of cupric acetate into a dil. soln. of calcium polysulphide, all at 0°. The precipitate was washed with iced water, and with alcohol, and then shaken with cold carbon disulphide. The product was dried at a low temp. in vacuo. The product rapidly decomposes into cupric sulphide and sulphur with a small rise of temp.; it is insoluble in a soln. of alkali sulphide—presumably "colourless," adds A. Rössing.

A. Rössing made **cupric hexasulphide,** Cu_2S_6, mixed with free sulphur by treating a soln. of ammonium or sodium thiocuprate with dil. acids. He also prepared it by fusing a mixture of anhydrous copper sulphate, sodium carbonate, and sulphur, dissolving the fused mass in cold water in an atm. of hydrogen, and precipitating the clear soln. with hydrochloric acid; the orange-red precipitate is dried over sulphuric acid and extracted with carbon disulphide. All operations must be conducted at a low temp. and with the least possible exposure to the air. Analyses deviate within narrow limits from 60·10 per cent. of sulphur, and 39·71 per cent. of copper—theory for Cu_2S_6 is Cu, 39·85; S, 60·15 per cent. A. Rössing believes that the hexasulphide is the anhydride of a dibasic **hydrosulphocupric acid,** $H_2Cu_2.S_7$, with the constitution:

$$\left(\begin{array}{l}HS-Cu-S-S\\HS-Cu-S-S\end{array}>S\right)$$

Hydrosulphocupric acid.

$$\left(S<\begin{array}{l}Cu-S\\Cu-S\end{array}>S\right)$$

Sulphocupric anhydride.

and that the acid forms sulphocuprates (*q.v.*) represented by $(NH_4)_2Cu_2S_7$ prepared by A. G. Bloxam, H. Vohl, K. Heumann, E. Priwoznik, and H. Peltzer. The amorphous powder is orange-red when dry, reddish-brown when moist. When freshly precipitated, it dissolves rapidly in soln. of the alkali or barium polysulphides, and is re-precipitated by carbon dioxide. It is decomposed when warmed, and when treated with colourless soln. of alkali sulphide, forming cupric sulphide; with silver nitrate it forms silver sulphide. **Cupric pentasulphide,** Cu_2S_5, is made by shaking moist cupric hexasulphide, Cu_2S_6, with ammonia. The washed and dried precipitate can be extracted with carbon disulphide. The dark blue amorphous powder is not decomposed at 100°, or by boiling with water. A. Rössing also made **cupric trisulphide,** Cu_2S_3, by heating on a water-bath the dried hexasulphide with carbon disulphide or ether in a flask fitted with a reflux condenser. The insoluble residue was washed with carbon disulphide and dried at ordinary temp. The dark brown amorphous mass is decomposed by boiling alcohol into cupric sulphide. A. Rössing suggests that the formula of this sulphide is:

$$S<\begin{array}{l}Cu-S\\Cu-S\end{array}$$

The state of our knowledge of the cupric sulphides is rather unsatisfactory, because it is not at all convincing to depend upon carbon disulphide or indeed upon other solvents to remove all the free sulphur—if sulphur adsorbed by the colloidal solid be regarded as free, *i.e.* not chemically combined. The fusion curve is indicated in Fig. 6.

Copper oxysulphides.—As indicated above, T. Parkman[18] obtained evidence which he regarded as indicating the formation of an impure oxysulphide in the products obtained by boiling a soln. of cupric acetate with sulphur. In the by-products obtained in the preparation of sulphur dioxide by the action of conc. sulphuric acid on copper, E. J. Maumené stated that brown *cuprous oxydisulphide*, $2Cu_2S.CuO$, is formed when one-fifth the available sulphur dioxide has been evolved; *cupric oxydisulphide*, $2CuS.CuO$, when two-thirds of the available sulphur dioxide has escaped; and the end-product is *cupric oxymonosulphide*, $CuS.CuO$. C. Baskerville also obtained a black oxysulphide by the action of sulphuric acid, sp. gr. 1·84, on copper at 250°. J. Pelouze prepared what he regarded as *cupric oxypentasulphide*, $5CuS.CuO$, by the action of precipitated cupric sulphide on dil. soln. of cupric sulphate; the soln. is gradually decolorized; the action is faster in ammoniacal soln.

If an ammoniacal soln. of a cupric salt at about 75° be just decolorized with sodium sulphide, and the black precipitate washed with air-free water, pressed, and dried in vacuo, its composition is $CuO.5CuS$. These oxysulphides may ultimately prove to be all mixtures of sulphide and oxide. T. Kliche, indeed, says that the products prepared by E. J. Maumené's and J. Pelouze's processes did not contain oxygen, only copper and sulphur, and accordingly *es wären alle Oxysulfide zu streichen.* The action of an ammoniacal soln. of cupric oxide on the sulphide removes sulphur from the sulphide, and with increasing conc., increasing amounts of cuprous sulphide are formed—the sulphur forms sulphuric acid, and the cupric oxide is reduced to cuprous oxide.

Double salts of copper sulphide and the alkali sulphides.—P. Berthier[19] prepared what were thought to be double salts by fusing cupric sulphate, potassium sulphate, and sulphur in a carbon crucible; and L. N. Vauquelin by fusing potassium polysulphide with copper. The composition of the products is rather indefinite.

G. Bodländer and K. S. Idaszewsky[20] found cuprous and sodium sulphides are mutually soluble to a limited extent, and they prepared the **sodium sulphocuprite,** $Na_2S.Cu_2S$, or $NaCuS$, by melting an intimate mixture of equimolecular parts of the component sulphides. Steel-blue needles of the double salt remain when the solid mass is extracted with water. When a fused mixture of the two salts is electrolyzed, copper migrates to the anode as a complex anion, and a little copper appears at the cathode owing to the secondary action of the sodium there formed. The corresponding **potassium sulphocuprite,** $K_2S.Cu_2S$, was also made in a similar manner by fusing the component salts at 800°. By melting proper proportions of cuprous and sodium sulphides, G. Bodländer and K. S. Idaszewsky also prepared crystalline plates of the composition $Na_2S.2Cu_2S$—*sodium trisulphocuprite.* A. Ditte prepared **potassium pentasulphocuprite,** $K_2S.4Cu_2S$, by the action of a conc. cold soln. of potassium monosulphide upon precipitated cupric sulphide. The cupric is reduced to cuprous sulphide. The liquid becomes orange-yellow, and after some hours, the precipitate is converted into a mass of crystals—partly octagonal or quadratic plates, deep red by transmitted light, partly into long slender needles. If the liquid be boiled, bronze-coloured slender needles are formed. All these varieties of crystals have the same composition, $K_2S.4Cu_2S$. If the alkaline soln. be too dil., the cupric sulphide is not affected. Long needles of the same salt were also made by immersing metallic copper in a conc. soln. of the alkali sulphide. If the liquid is exposed to air, the amount of the double compound gradually increases, but if it is contained in a closed vessel, the formation of the double sulphide ceases after a time. The action of the alkaline sulphide on the copper is due to the presence of oxygen, for if the soln. is perfectly free from oxygen and the latter is carefully excluded, the copper is not attacked. The first reaction consists in the formation of potassium hydroxide and cupric sulphide, and the latter as fast as it is formed splits up into cuprous sulphide, which forms the double compound, $K_2S, 4Cu_2S$, and sulphur, which forms polysulphides. A soln. of potassium sulphide too dil. to decompose cupric sulphide attacks metallic copper in presence of air or oxygen, but the product is the simple sulphide CuS.

R. Schneider prepared a sodium salt with a composition corresponding with $Na_2S.Cu_2S.CuS$, $Na_2Cu_3S_3$; and a potassium salt, $K_2S.3Cu_2S.2CuS$, $K_2Cu_8S_6$, by melting the dry alkali carbonate, sulphur, and copper. J. Milbauer also prepared the potassium salt by heating a mixture of cupric oxide with potassium thiocyanate for half an hour. In both cases, the mass was extracted with water, and dark steel-blue crystals remained. The sodium salt forms very dark blue hygroscopic crystals which are attacked by the oxygen and carbon dioxide of the air. They melt below redness in vacuo without decomposition; they deflagrate when heated in air; hydrogen converts them into a mixture of cuprous and sodium sulphide; and they readily dissolve in nitric acid with the separation of sulphur. When the potassium salt is heated, sulphur is given off, and a mixture of cuprous and potassium sulphides remains. When heated in a stream of hydrogen, one-sixth of the sulphur is lost in hydrogen sulphide; it is insoluble in dil. hydrochloric acid, but is attacked by the conc. acid; and with silver nitrate it reacts: $K_2Cu_8S_6+18AgNO_3=8Cu(NO_3)_2+2KNO_3+6Ag_2S+6Ag$. K. A. Hofmann and F. Höchtlen[21] have shown that the compound prepared by H. Peltzer, A. G. Bloxam, A. Gescher, K. Heumann, H. Vohl, and E. Priwoznik is not, as was previously supposed, $(NH_4)_2Cu_2S_7$, $(NH_4)_2S.2CuS_3$, or $(NH_4)_2S_5.2CuS$, but rather **ammonium tetrasulphocuprate,** NH_4CuS_4, the copper ammonium salt of F. W. Küster's hydrogen tetrasulphide, $H.HS_4$. Analyses show that the atomic ratio S : Cu is not 7 : 2 but 4 : 1. H. Peltzer prepared this salt by the action of ammonium polysulphide on sodium copper thiosulphate; K. Heumann, by pouring a soln. of cupric sulphate into a conc. soln. of ammonium pentasulphide; A. Gescher, by the action of a dil. ammoniacal soln. of cupric sulphate on yellow ammonium sulphide; A. G. Bloxam by dissolving freshly precipitated cupric oxide in a sat. soln. of sulphur in ammonium sulphide; H. Vohl, by pouring a soln. of cuprous chloride (free from the cupric salt) in ammonium chloride, or a colourless soln. of cupric chloride in sodium thiosulphate, or an ammoniacal soln. of ammonium sulphicuprite, carefully, with constant stirring, and exclusion of air, into a conc. soln. of ammonium polysulphide; K. Heumann, by the action of yellow ammonium sulphide on freshly precipitated cupric sulphide; and E. Priwoznik, by the action of the same reagent on cuprous sulphide or on cupric or cuprous oxide, or, more slowly, on metallic copper. H. Vohl's process probably gives the purest product. H. Biltz and P. Herms used the following process:

Dil. 200 c.c. conc. (25 per cent.) aq. ammonia with 50 c.c. of water; saturate the soln. with hydrogen sulphide; and saturate half the soln. at 40° with 60 grms. of sulphur; filter this liquid; and mix the two soln. Stir up the liquid with a soln. of 20 grms. crystalline cupric sulphate in 200 c.c. of water; filter rapidly and allow the filtrate to stand overnight while cooled by a freezing mixture. Wash the crystals first with water, then with alcohol, and dry overnight in vacuo over sulphuric acid. Yield 14 grms.

The needle-like crystals have a garnet-red colour; when heated, they lose ammonia and ammonium sulphide, and become brown, but the primitive colour is restored when they are heated in the vapour of ammonium sulphide. The crystals are sparingly soluble in cold water, but they dissolve in warm water leaving a black residue. The yellow soln. on standing becomes dark green and gives a black precipitate with hydrochloric acid. Dil. nitric, sulphuric, or hydrochloric acid has no action on the cold, but when heated with the crystals, gives brown cupric sulphide mixed with sulphur, and gives off hydrogen sulphide, and ammonia—nitric acid oxidizes some of the sulphur. Conc. hydrochloric or sulphuric acid has no action in the cold; and nitric acid causes much effervescence, when nitrous fumes are evolved, and sulphur is separated. The crystals are slightly soluble in alcohol and an aq. soln. of sodium carbonate; but are insoluble in ether.

The crystals of ammonium tetrasulphocuprate are soluble in sodium hydroxide lye, but crystals of the sodium salt have not been obtained; E. Priwoznik prepared a soln. of the sodium salt by the action of a soln. of sodium pentasulphide on cuprous sulphide or cupric oxide. The soln. of the ammonium salt in sodium hydroxide gives precipitates of the potassium, rubidium, or cæsium salts when treated with the corresponding hydroxides. Dark red crystals of **potassium tetrasulphocuprate,** $KCuS_4$, were made by K. Heumann, E. Priwoznik, H. Biltz and P. Herms, by the action of potassium pentasulphide on copper, cupric oxide, sulphide, or other compounds. H. Biltz and P. Herms also used a mixed soln. of sodium pentasulphide and thiosulphate, and they recommend the following process:

A cold soln. of 2 grms. of ammonium tetrasulphocuprate in 6 c.c. of $2N$-NaOH is mixed with 3·5 c.c. of $6N$-KOH in 30 c.c. of alcohol. Filter the soln. rapidly, and stir the filtrate, with twice or three times its volume of alcohol while it is cooled by a freezing mixture. Wash the dark red crystals with alcohol by decantation, and after suction, dry in vacuo over sulphuric acid.

Crystals of **rubidium tetrasulphocuprate,** $RbCuS_4$, were made by H. Biltz and

P. Herms in a similar manner. The dark red crystals have a yellow tinge. Yellowish-red or brick-red prisms of **cæsium tetrasulphocuprate,** $CsCuS_4$, were made by a similar process. These salts are to be regarded as salts of *hydrotetrasulphocupric* acid, $HCuS_4$. H. Biltz and P. Herms say that these salts crystallize in small prisms, and the colour passes from the garnet-red of the ammonium salt to the brownish-red colour of the cæsium salt. The salts are sparingly soluble in cold water and in alcohol. The solubility increases with increasing at. wt. They decompose slowly in air at ordinary room temp. but rapidly when heated; the decomposition is favoured by the presence of moisture, the dry salt may be kept for weeks without appreciable change. Nitric, sulphuric, or hydrochloric acid decomposes the salts very slowly in the cold, but rapidly when boiled. Dil. acids attack the salt more rapidly when hot, cupric sulphide and sulphur separate, and hydrogen sulphide is given off.

H. Biltz and P. Herms obtained small black and prismatic crystals of **potassium decasulphotricuprate,** $K_2Cu_3S_{10}$, or $2KCuS_4.CuS_2$, by shaking a soln. of 2 grms. of ammonium tetrasulphocuprate in 6 c.c. of $2N$-NaOH with 3·5 c.c. of $6N$-KOH, while cooled with ice. Alcohol is carefully added so as to avoid the formation of the red-coloured salt. The crystals are sparingly soluble in alcohol, easily soluble in water. The aq. soln. rapidly decomposes at the ordinary temp. of the room. The soln. gives a brownish-red precipitate with alkali hydroxides, a dirty brown precipitate with potassium monosulphide, and with potassium tetrasulphide in the presence of alcohol, it furnishes potassium tetrasulphocuprate, $KCuS_4$. It is rapidly decomposed by dil. acids, slowly by conc. acids. The corresponding **rubidium decasulphotricuprate,** $Rb_2Cu_3S_{10}$, or $2RbCuS_4.CuS_2$, has also been prepared.

When cuprous oxide or sulphide is dissolved in the pentasulphide soln. at 0°, deep brown-coloured liquids are obtained, from which alcohol throws down yellowish-red prisms of a complex compound, **potassium dioxyenneasulphodicuprate,** $K_3Cu_2O_2S_9$. When freshly precipitated, the crystals dissolve readily in water, and with cæsium hydroxide soln. give a quantitative yield of cæsium copper tetrasulphide.

§ 24. Cuprous Sulphate

Up to 1909, the existence of cuprous sulphate, Cu_2SO_4, was inferred (i) from the existence of certain complex salts like cuprous phenylhydrazine sulphate and cuprous pyridine sulphate prepared by J. Moitessier;[1] cuprous thiourea sulphate prepared by B. Rathke, A. Rosenheim and W. Löwenstamm, and V. Kohlschütter and C. Brittlebank; and hydrated cuprous carbonyl sulphate and cuprous tetramminosulphate, by A. Joannis; and (ii) from certain reactions in aq. soln. Thus, the leaching of roasted cupriferous pyrites with warm water was supposed by C. Bischoff to yield a soln. containing some subsulphate; the dissolution of copper by boiling aq. soln. of cupric sulphate was supposed by C. Soret to be due to the formation of a soluble cuprous sulphate, and H. Rössler showed that when treated with sodium chloride, the green soln. gave a precipitate of cuprous chloride, and when exposed to the air, it became blue.

F. Förster and F. Blankenberg showed that the dissolution of copper by an acid soln. of cupric sulphate proceeds until an equilibrium $2Cu^{\cdot} \rightleftharpoons Cu + Cu^{\cdot\cdot}$ is established, and the same result also obtained in ammoniacal soln. of cupric sulphate decolorized by copper. The appearance of cuprous oxide among the products of the reduction of cupric sulphate soln. by magnesium, zinc, and iron was explained by R. M. Caven by assuming that the cupric salt is reduced by nascent hydrogen; by the direct action of the displacing metal; or by the action of precipitated copper on cupric sulphate, and he favoured both the last-named hypotheses. H. Kiliani also showed that the liquid obtained by the electrolysis of a neutral soln. of cupric sulphate with a copper anode contains cuprous sulphate, for it re-deposits copper during its decomposition. A. Matthiessen and M. von Bose found two decomposition potentials in the electrolysis of cupric salt soln. At cathode potentials below the larger one, F. Förster and G. Coffetti showed that cuprous oxide is deposited from neutral soln., and cuprous sulphate from acid soln. The formation of the cuprous salt is favoured by a rise of temp. and a low current density. A rise of temp. favours the formation of cuprous copper, and F. Förster and O. Seidell found the hot soln. deposits copper on cooling so that the equation: $Cu_2SO_4 \rightleftharpoons Cu + CuSO_4$, or the ionic eq.: $2Cu^{\cdot} \rightleftharpoons Cu^{\cdot\cdot} + Cu$, represents the balanced reaction. In the electrolysis of sulphuric acid with copper anodes, F. Fischer estimates that 50 per cent. of the copper which goes into soln. is univalent. R. Luther computed that at 25°, the conc. of the cuprous sulphate in a $2N$-soln. of cupric sulphate acidified by N-sulphuric acid is $1{\cdot}67 \times 10^{-4}$ mol of Cu_2SO_4; and E. Abel gives at ordinary temp. $[Cu^{\cdot}]/[Cu^{\cdot\cdot}] = 0{\cdot}66 \times 10^{-6}$; and at 25°, a $0{\cdot}0064N$-soln. of cuprous sulphate is in equilibrium with a N-soln. of cupric sulphate.

In neutral soln., say F. Förster and G. Coffetti, cuprous ions are constantly removed by hydrolysis and precipitation of cuprous oxide, and from acid soln. by the oxidation by atm. oxygen. At a copper anode, similarly, the copper dissolves in the cuprous condition until equilibrium is attained, and since the layer of soln. in contact with the anode always contains more cupric sulphate than the body of the soln., a greater number of cuprous ions will be formed there than can exist in the more dil. mass of the liquid, and therefore as the conc. soln. diffuses away from the anode copper must be deposited. This explains the fact that the loss of weight of the anode is greater than the gain of weight of the cathode, and also the presence of copper dust in the anode slime. The conc. of aq. soln. of cuprous sulphate is attended by the hydrolysis and precipitation of cuprous oxide: $Cu_2SO_4+H_2O=Cu_2O+CuSO_4$; or by the deposition of copper: $Cu_2SO_4\rightleftharpoons Cu+CuSO_4$.

A. Recoura has shown that by operating in the absence of water, methyl sulphate and cuprous oxide react to form cuprous sulphate and ether: $Cu_2O+(CH_3)_2SO_4=Cu_2SO_4+(CH_3)_2O$. Ethyl sulphate reacts in a similar manner. Two grams of powdered cuprous oxide are mixed with 20 c.c. of methyl sulphate at 160° until methyl ether ceases to be evolved—about 15 min. The cuprous sulphate, precipitated as a greyish-white powder, is washed with ether while air is carefully excluded, and finally dried in vacuo. The salt is stable in dry air, but is immediately decomposed by moisture: $Cu_2SO_{4\,solid}+Aq.=CuSO_{4\,soln.}+Cu+21$ cals. The development of heat in this decomposition is contrary to the behaviour of other cuprous salts, and explains why cuprous sulphate cannot be prepared in aq. soln. Freshly prepared cuprous sulphate if allowed to oxidize before drying is converted into a soot-black powder, from which cupric sulphate is dissolved by water, leaving an oxide with all the properties of Rose's oxide, Cu_4O. Dry Cu_2SO_4, oxidized at 100°, yields the basic salt, $CuO, CuSO_4$. Cuprous sulphate is soluble in conc. hydrochloric acid, in ammonia, and in glacial acetic acid, the last giving an intensely violet soln.

G. Denigès prepared double compounds of **cuprous hydrosulphate,** $CuHSO_4$, with aniline, toluidine, and *o*-xylidine. F. Förster and O. Seidel prepared yellow amorphous basic cuprous sulphate or **cuprous oxysulphate** by the electrolysis of a $2N$-soln. of cupric sulphate acidified to make the soln. $0{\cdot}01N$-H_2SO_4. Temp. 40°, current density 7·3 amps. per sq. decm., and 1·5 volts.

Cupric sulphate forms complexes in ammoniacal soln. which can be easily reduced to the cuprous state; at the same time, the blue colour of the cupric soln. disappears, forming a colourless liquid. J. Meyer[2] used sodium sulphite for the reduction; A. Bernthsen, and P. Schutzenberger and C. Risler, sodium hyposulphite; J. A. Joannis, carbon monoxide; F. Förster and F. Blankenberg, copper; and F. Ebler, hydrazine sulphate; A. Joannis obtained an ammoniacal soln. of cuprous sulphate by treating cuprous oxide with a soln. of ammonium sulphate in liquid ammonia. P. Schutzenberger and C. Risler found that when shaken with air, an ammoniacal soln. of cuprous sulphate absorbs twice as much oxygen as is needed for the conversion of the cuprous to the cupric salt, and they suggested that half the oxygen is used in forming hydrogen peroxide; C. Engler suggested that a peroxidized body is formed; but J. Meyer found that hydrogen peroxide cannot exist in the presence of cuprous salts even at 0°. According to J. Meyer, an unstable intermediate oxide, Cu_2O_3, may possibly be formed; but the oxidation proceeds on normal lines, in accord with the equation: $2Cu_2O+O_2=4CuO$, and the abnormal result previously obtained is due to the presence of sodium sulphite, which reacts: $Cu_2O+SO_2+O_2=2CuO+SO_3$. The oxidation of ammoniacal cuprous sulphate has been utilized for the measurement of oxygen dissolved in water by P. Schützenberger and C. Risler, F. Tiemann and C. Preusse, J. König and C. Krauch, etc. According to S. L. Bigelow, the reaction occurs in the presence of alcohol.

When hydroxylamine sulphate is added to an alcoholic ammoniacal soln. of cupric sulphate, E. Péchard found that **cuprous tetrammino-sulphate,** $Cu_2(NH_3)_4SO_4$, contaminated with ammonium sulphate is precipitated. He obtained the pure salt by reducing a suspension of basic cupric carbonate, $CuCO_3.Cu(OH)_2$, in dil. ammonia soln. with hydroxylamine sulphate at 80°. Carbon dioxide, nitrogen, and nitrous oxide are evolved, and when alcohol is added to the cooled soln., a heavy white precipitate of the required salt is obtained. A. Angel likewise prepared the same compound by adding hydroxylamine sulphate or hydrazine sulphate to an ammoniacal soln. of cupric formate, and precipitated the salt by the addition of alcohol. A. Bouzat obtained the same salt as a white crystalline powder by adding alcohol to a soln. of cuprous oxide and ammonium sulphate in aq. soln. at 50° in an atm. of hydrogen. According to E. Péchard, the salt forms white hexagonal plates. It is readily oxidized in air, and soluble in aqua ammonia, insoluble in alcohol, and is decomposed by water. When heated to 100°, it does not lose ammonia, but above this temp., it loses ammonia and the residual cuprous sulphate decomposes. A. Bouzat's method of preparation shows that ammoniacal cuprous oxide, like the corresponding cupric compound, is a sufficiently strong base to displace ammonium from its salts. Cuprous tetrammino-sulphate reduces nitric acid with the copious evolution of nitrous fumes. Dil. sulphuric acid precipitates copper from the ammino-sulphate soln., and leaves a soln. of cupric and ammonium sulphates.

F. Förster and F. Blankenberg obtained colourless **monohydrated cuprous tetrammino-sulphate,** $Cu_2(NH_3)_4SO_4.H_2O$, by reducing a soln. of 0·5 mol of cupric sulphate and 8·7 mols of ammonia with copper in an atm. of hydrogen. The prismatic and needle-like crystals which separate are washed with alcohol. They can be kept some weeks in a sealed tube at ordinary temp. Small traces of moisture colour the crystals brown in a few days. When heated in hydrogen to 100°, the crystals lose ammonia, and leave a dark brown-coloured mass containing copper, a cupric salt, ammonia, and water. Dil. sulphuric acid colours the crystals pale red owing to the separation of copper.

A. Joannis found that when carbon monoxide is passed into a soln. of cupric sulphate containing in suspension finely divided copper, or a sheet of platinum coated electrolytically with copper, the gas is slowly absorbed and the liquid becomes colourless. If now the soln. be placed in a vacuum, it loses carbon monoxide (free from carbon dioxide), and when the press. of this gas in the apparatus falls to 2 or 3 mm., a pellicule of copper separates at the surface of the liquid and the liquid becomes blue. If carbon monoxide be again passed into the liquid the copper gradually redissolves and the blue colour disappears. When carbon monoxide is passed into an ammoniacal soln. of cupric sulphate containing finely-divided copper, the soln. becomes colourless, but comparatively little copper dissolves. The whole of the dissolved carbon monoxide cannot be extracted in a vacuum, but part remains in the liquid as ammonium carbonate. There is no separation of metallic copper, and the soln. remains colourless. Even in absence of metallic copper, ammoniacal soln. of cupric sulphate are slowly decolorized by carbon monoxide, and then behave in the manner just described. It would seem that, in these cases, cuprous sulphate exists in the soln. in combination with ammonia, whilst in the cases first described it exists in combination with carbon monoxide. The white crystals have the composition of monohydrated cuprous dicarbonyl-sulphate, $Cu_2SO_4.2CO.H_2O$. They effloresce readily, and under diminished press., the solid and the soln. decompose into copper and cupric sulphate, which suggests that cuprous sulphate cannot exist except in combination with another molecule, such as carbon monoxide or phosphorus hydride. Soln. of cupric nitrate, formate, or acetate, in contact with metallic copper, absorb carbon monoxide and at the same time are decolorized.

§ 25. Cupric Sulphate

Cupric sulphate is known in the anhydrous form, $CuSO_4$, and as the mono-, tri-, and penta-hydrates. The pentahydrated is the usual form. Several other hydrates have been reported—*e.g.* the di-, hexa-, hepta-, and ennea-hydrated sulphates—but their individuality is not well defined. The blue salt which crystallizes from aq. soln. at ordinary temp. is pentahydrated cupric sulphate, $CuSO_4.5H_2O$, and it has been known for many years as *blue vitriol* or *Cyprian vitriol*. There are allusions in Dioscorides and in Pliny to what is thought to be this salt.[1] Geber and Basil Valentine also speak of blue vitriol from Cyprus. The earlier observers confused cupric and ferrous sulphates, since both salts often occur in the same mine waters, and they can crystallize together to form a mixed vitriol—thus Valentine says that "Venus and Mars can be united by soln. and coagulation into a virtuous vitriol." Some of the alchemists sought for the *materia prima* in the mixed vitriols, and Valentine said that "when copper and iron are present, *der Saame des Goldes* will not be far away." *Magistral* is an impure blue vitriol with ferric oxide, sodium sulphate, and chloride, etc., obtained by powdering more or less oxidized cupriferous pyrites. It is used in the amalgamation of silver ores at the Mexican and South American silver mines. A. Libavius described the preparation of *vitriolum veneris* in 1595; J. B. van Helmont prepared the same salt in 1644 from a mixture of copper and sulphur which had been fused together and exposed to rain water.

Several basic sulphates of not very definite composition occur in nature—*brochantite*, $Cu_2SO_4(OH)_2$, is perhaps the most important. C. F. Rammelsberg[2] reported the anhydrous salt in the fumaroles of Vesuvius, and called *idrociano*, that is, *hydrocyanite*, by G. Tschermak, and A. Scacchi. The mineral *chalcanthite*, $CuSO_4.5H_2O$, has been found deposited from cupriferous mine waters either in crystals or in stalactitic formations; and, according to H. Oehmichen, it occurs as a workable ore at Copaquire (Chile), where it has probably been formed by the oxidation of chalcopyrite. The Californian mineral *boothite* is reported by W. T. Schaller to have the composition $CuSO_4.7H_2O$.

The action of sulphuric acid on copper has been previously discussed. The general results show that at ordinary temp. sulphuric acid and copper slowly form cupric sulphate and sulphide. This was early established by the work of J. Davy,[3] and G. Barruel. The latter also showed that dil. sulphuric acid slowly acts on copper if air has access to the liquid, and J. E. Bérard based a process on this reaction for making cupric sulphate on a large scale. G. Barruel obtained cupric sulphate by the joint action of air and sulphurous acid on the metal, and G. de Bechi and H. Gall proposed to make the salt by the action of water vapour, and air, with about 10 per cent. sulphur dioxide on the metal; and E. W. von Siemens and J. G. Halske, by the action of sulphur dioxide and air on cupric oxide, carbonate, or silicate over 500°. Cupric sulphate was made in 1648 by J. R. Glauber, by the action of hot sulphuric acid on the metal. For example, if a mixture of gram-atom of copper be heated with two mols of sulphuric acid, evaporated to dryness, exhausted with hot water, filtered from copper and cupric sulphide, blue crystals of the **pentahydrated cupric sulphate,** $CuSO_4.5H_2O$, separate on cooling. G. E. Stahl in 1723 showed that if nitric acid be mixed with sulphuric acid, the formation of cupric sulphate is facilitated. For example, E. F. Anthon kept a mixture of 100 parts of copper with 150 parts of sulphuric acid and 168 parts of nitric acid (sp. gr. 1·26) in a warm place, and obtained a soln. which when boiled, filtered, and cooled gives crystals of the pentahydrate. The same process was used by W. Hampe. T. Savage recommended using sodium nitrate in place of nitric acid. Cupric sulphate is formed by the electrolysis of dil. sulphuric acid, or soln. of sulphates by means of copper anodes. H. J. U. Palas, F. A. J. Cotta, P. A. Mackay, and E. Gouin have a process for applying this reaction on a large scale.

Perhaps the simplest method of preparing a soln. of cupric sulphate is to dissolve cupric oxide, hydroxide, carbonate, or oxychloride in hot dil. sulphuric acid, and evaporate the liquid for crystallization.[4] On a large scale, cupriferous by-products —roasted copper ores; copper scale; copper-waste or scrap; etc.—are treated with sulphuric acid. Many of these processes are indicated in connection with the extraction of copper. In general, cupriferous pyrites is roasted so that the copper is largely oxidized to the sulphate while the iron is converted into ferric oxide. The hot roasted ore is extracted with water, and the liquid concentrated for crystallization. Cupric sulphate is also a by-product in the extraction of silver from its ores by digesting the roasted ore in sulphuric acid. The lead and gold are precipitated; plates of copper are inserted in the soln. of silver sulphate when silver, arsenic, and antimony are deposited, and copper sulphate passes into soln. This liquid is allowed to crystallize for the required salt. E. V. Zappi discussed the manufacture of copper sulphate from chalcopyrite with 10 per cent. of copper; and H. Suchanek, from old scrap copper; cupriferous residues, slags, and ashes; cupriferous pyrites and poor copper ores; and impure cupriferous liquors.

According to M. de la Source,[5] the pentahydrate is readily converted into **trihydrated cupric sulphate,** $CuSO_4.3H_2O$, for when the powdered salt is dried in a desiccator beside phosphorus pentoxide for about 11 days at 25°–30°, it loses about 14·5 per cent. of water, and it loses no more if kept for a longer time. The product thus contains the amount of water required for the trihydrate. By drying the powdered salt in vacuo beside phosphorus pentoxide, 28·5 per cent. of moisture is lost, and **monohydrated cupric sulphate,** $CuSO_4.H_2O$, is formed. W. Müller-Erzbach obtained the trihydrate by exposing the anhydrous salt to air with moisture eq. to 28 to 30 per cent. of the vap. press. of water; if the air contains 17 per cent. moisture, monohydrated cupric sulphate is formed. T. Graham obtained the monohydrate by warming the pentahydrate in vacuo at 38°—*vide infra*—and W. R. Hodgkinson and co-workers heated the powdered pentahydrate a week at 98°; D. W. Horn and E. D. Taylor heated the pentahydrate to 100° in a current of dry air; and F. Krafft, 60 hrs. over sulphuric acid in vacuo. A. Étard obtained the trihydrate by heating a sat. soln. of cupric sulphate in a sealed tube at 108°–110° for 48 hrs.; and he obtained the monohydrate by heating a soln. of the pentahydrated salt in the smallest possible quantity of water with a great excess of conc. sulphuric acid to 200°, and then cooling the mixture. A. Scacchi and C. F. Rammelsberg crystallized the salt from a sulphuric acid soln. of cupric sulphate. The correct conc. of the acid for producing both the trihydrate and the monohydrate will appear from J. M. Bell and W. C. Taber's study, Fig. 33. C. A. L. de Bruyn found crystals of the trihydrated salt separated from a methyl alcohol soln. of the pentahydrate after some minutes, or immediately on the addition of water, or raising the temp. C. F. Cross boiled the pentahydrated sulphate with absolute alcohol, and finally obtained the monohydrate.

J. L. Proust,[6] and G. Barruel obtained **anhydrous cupric sulphate,** $CuSO_4$, by heating copper with conc. sulphuric acid in a closed vessel. A. Étard crystallized it from a soln. of the pentahydrate in boiling sulphuric acid; and B. Schwalbe, by cooling a sat. soln. of the pentahydrate with solid carbon dioxide. C. Poulenc obtained the anhydrous salt by dissolving cupric fluoride in conc. sulphuric acid, and evaporating the liquid on a sand-bath. The conditions under which the anhydrous sulphate crystallizes from sulphuric acid soln. have been indicated by J. M. Bell and W. C. Taber, Fig. 33. According to P. Latschinoff, when the pentahydrate is heated to 180°, it loses $4{\cdot}75H_2O$, and all passes off at 360°; F. Krafft found all the water is lost from the pentahydrate in vacuo at 250°; and D. W. Horn that all the water is expelled by heating the salt in a stream of air dried by conc. sulphuric acid. The dissociation of hydrated cupric sulphate has also been studied by W. Hampe, H. Lescœur, and D. W. Horn and E. E. Taylor. According to T. W. Richards, 0·042 per cent. of water is retained by the salt heated to 365°, and he dehydrated it by gradually raising the temp. to 400°. T. Klobb prepared the salt by heating ammonium cupric sulphate, $(NH_4)_2SO_4.CuSO_4$, and also by heating a mixture of ammonium sulphate and the pentahydrate in a platinum crucible.

J. M. Bell and W. C. Taber have studied the three-component system $CuO—SO_3—H_2O$. The equilibrium conditions for cupric sulphate, sulphuric acid, and water at 25° are indicated in Table IX and Fig. 33. The penta-, tri-, and monohydrated cupric sulphates were the only hydrates which appeared to be stable. The curve *BE* approaches the side of the triangle, showing that the solubility of cupric sulphate is depressed by the addition of sulphuric acid; and between *B* and *C* the lines joining corresponding points for soln. and residue all meet at the point 5, and hence the solid phase is the pentahydrated salt, $CuSO_4.5H_2O$; from *C* to *D*, the lines meet at the point 3, and this represents the trihydrate, $CuSO_4.3H_2O$; and from *D* to *E*, the corresponding lines meet at the point *I* representing the monohydrate, $CuSO_4.H_2O$. Only one line was determined beyond *E*, and this indicates that the solid phase is the anhydrous sulphate,

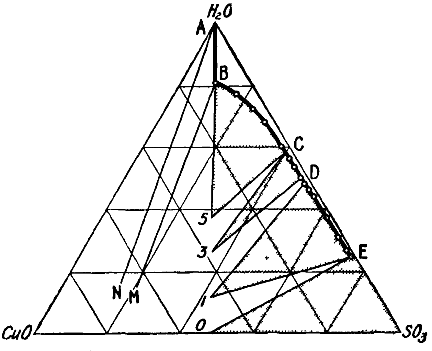

FIG. 33.—Ternary System, $CuO—SO_3—H_2O$, at 25°.

$CuSO_4$. There are two solid phases at *C*, $CuSO_4.5H_2O$ and $CuSO_4.3H_2O$. The exact positions of the points *C* and *D* have not been definitely determined.

The solubility curve of a salt, say, cupric sulphate, with continually increasing amounts of a foreign substance, say, sulphuric acid, will show (i) a varying solubility and constant composition of solid; or (ii) a constant solubility and a varying composition of the solid. In the former case, a pure salt is present, and in the latter, a mechanical mixture of two salts is present. From the results with copper sulphate and water with gradually increasing proportions of sulphuric acid, H. W. Foote showed that at 25° the range of stability of the pentahydrate is from 0 to about 47·66 per cent. of sulphuric acid; of the trihydrate, 50·23 to 54·78 per cent. sulphuric acid; of the monohydrate, 61·79 to 85·46 per cent. sulphuric acid; and of the anhydrous salt, upwards from 86·04 per cent. sulphuric acid. At a lower temp., 12°, the conc. of sulphuric acid required for the dehydration is rather greater. Similar results were obtained by J. Kendall and A. W. Davidson with anhydrous sulphuric acid; cupric sulphate is only slightly soluble in this acid, forming a colourless soln., which becomes bluish-green when heated to the b.p. G. Poma showed that the blue colour of aq. soln. may be due to hydrated $Cu^{\cdot\cdot}$-ions, but not these ions themselves. The colour in the heated soln. would then be due to a loss of sulphur trioxide eq. to the addition of water. No acid salts were observed. F. Bergius made some observations on the solubility of cupric sulphate in sulphuric acid. H. M. Goodwin and W. G. Horsch measured the conductivity of soln. of cupric sulphate in sulphuric acid.

In addition to the penta-, tri-, and mono-hydrates, T. Graham[7] assumed that *dihydrated cupric sulphate*, $CuSO_4.2H_2O$, is formed when the pentahydrate is confined in a dry space for a week at 20°. T. E. Thorpe and J. I. Watts claimed to have made the same salt by mixing a cold sat. soln. of cupric sulphate with an equal vol. of conc. sulphuric acid. M. Berthelot gives the heat of formation from cupric hydroxide as 21 Cals.; J. Thomsen, the heat of soln., +6·09 Cals.; T. E. Thorpe and J. I. Watts, the sp. vol., 67·0. From his measurements of the vap. press., H. Lescœur concluded that no such compound exists, nor do the solubility measurements of J. M. Bell and W. C. Taber lend any support to T. Graham's assumption. R. Dietz and co-workers found evidence of the existence of *enneahydrated cupric sulphate*, $CuSO_4.9H_2O$, at low temp., and of a transformation into *hexahydrated cupric sulphate*, $CuSO_4.6H_2O$, at −20·3°; and in his study of the effect of press. on hydrated cupric sulphate, E. Jänecke found evidence of the existence of *hemihydrated cupric sulphate*, $CuSO_4.\frac{1}{2}H_2O$. L. de Boisbaudran obtained *hexahydrated cupric sulphate*, $CuSO_4.6H_2O$, and *heptahydrated cupric sulphate*, $CuSO_4.7H_2O$, respectively, by adding a small crystal of nickel sulphate, $NiSO_4.6H_2O$, or of ferrous sulphate, $FeSO_4.7H_2O$, to a supersaturated soln. of copper sulphate. Metastable crystals isomorphous with these salts separated, but soon changed into the pentahydrated salt. W. T. Schaller believed that the Californian mineral *boothite* is the heptahydrate. L. de Boisbaudran and J. W. Retgers reported the crystals are monoclinic with $a:b:c=1·1622:1:1·5000$, and $\beta=105° 36'$; the hardness is 2·0 to 2·5, and the sp. gr., 2·1. T. W. Schaller gives 1·944 at 19°. W. Stortenbeker says the solubility cannot be determined. P. A. Favre and C. A. Valson give 2·13 Cals. for the heat of soln. of an eq. of the salt in a litre of water. J. L. Andreae's work on the vap. press. of copper sulphate crystals in various stages of hydration, and J. M. Bell and W. C. Taber's work on the solubility of cupric sulphate in sulphuric acid, show that only the penta-, tri-, and mono-hydrated salts exist under the conditions of their experiments. The hexahydrate is stated by H. Dufet to exist in isomorphous mixtures with nickel sulphate.

The **solubility** of cupric sulphate in water has been measured by many workers—A. Étard,[8] T. Gruner and R. Brandes, E. Cohen, J. E. Trevor, L. C. de Coppet, G. J. Mulder, etc. The best representative values for the solubility expressed in 100 grms. of soln. and 100 grms. of water, are:

	0°	10°	20°	30°	40°	60°	100°	140°	180°.
Soln. . .	12·5	14·8	17·2	20·0	22·5	28·5	43·0	44·5	43·0
Water . .	14·3	17·4	20·7	25·0	28·5	40·0	75·4	80·2	75·4
Solid phases	$CuSO_4.5H_2O$						$3H_2O$	H_2O	

The eutectic at −2° has 16·89 per cent. of the anhydrous salt, so that F. Guthrie's cryohydrate is $CuSO_4+44H_2O$; L. C. de Coppet gives at −166°, 13·5 grms. for

100 grms. of water. According to A. Étard, the solubility S at $\theta°$ referred to the anhydrous salt between $-2°$ and 105° can be represented by two curves $S=11{\cdot}6+0{\cdot}2614\theta$, between $-2°$ and 55°; and $S=26{\cdot}5+0{\cdot}3700\theta$, between 55° and 105°, the subsequent decrease in solubility up to 190° is represented by $S=45{\cdot}0-0{\cdot}0293\theta$. According to E. Cohen, the solubility curve has a break at 56° in consequence of a transformation of the salt into $3CuSO_4.4Cu(OH)_2.8H_2O$. R. Dietz, R. Funk, J. von Wrochem, and F. Mylius give evidence of the transformation $CuSO_4.9H_2O \rightleftharpoons CuSO_4.6H_2O+$sat. soln. at about $-20{\cdot}3°$. E. Jänecke also found that in addition to the three transition points between the 0–$1H_2O$, 1–$3H_2O$ about 130°; and the 3–5 hydrate about 100°; there is evidence of another hydrate, $CuSO_4.\frac{1}{2}H_2O$, because, in agreement with K. Friedrich, there are two clearly defined breaks in the heating curve of monohydrated cupric sulphate—one at 215° and another at 270°. These are interpreted to mean that at 215°, $2(CuSO_4.H_2O) \rightarrow 2CuSO_4.H_2O+H_2O$; and at 270°, $2CuSO_4.H_2O \rightarrow 2CuSO_4+H_2O$. I. Guareschi represents the hemihydrated salt with the doubled formula; graphically:

$$Cu<^{O}_{O}>SO<^{OH}_{—O—}{}^{HO}>SO<^{O}_{O}>Cu$$

H. T. F. Rhodes considers that one water mol. in pentahydrated cupric sulphate differs from the remaining four because when the pentahydrate is treated with ammonia, only four mols. of water are displaced. A. Körbs found the solubility of different faces of a crystal of the pentahydrate in an under-saturated soln. to be different. H. C. Sorby measured the influence of press. on the solubility of the salt.

F. Pfaff measured the influence of a number of salts on the solubility of cupric sulphate. R. Engel found that sulphuric acid and ammonium sulphate depress the solubility. E. Diacon studied the influence of magnesium sulphate; W. Stortenbeker, of zinc and manganese sulphates; F. Rüdorff, of ferrous sulphate—*vide infra*. J. Keppel, and G. Massol and M. Maldès found that with sodium sulphate, a double salt, $CuSO_4.Na_2SO_4.6H_2O$, is formed. J. M. Bell and W. C. Taber say that a sat. soln. of calcium sulphate dissolves as much cupric sulphate as water does. R. Engel measured the solubility of the salt in soln. of ammonium sulphate and found it to be smaller the more conc. the soln. J. Holmes and P. J. Sagemann found that a smaller expansion occurs on mixing soln. of cupric sulphate and sulphuric acid than with the alkali or zinc sulphates and the same acid.

C. A. L. de Bruyn found that 100 grms. of absolute *methyl alcohol* dissolves 1·05 grm. of $CuSO_4$ at 18°, and 15·6 grms. of the pentahydrate at 18°, and 13·4 grms. at 3°; while 100 grms. of 93·5 and 50 per cent. methyl alcohol dissolve respectively 0·93 and 0·40 grm. of the pentahydrate; and A. Klepl, V. Auger, and P. Rohland have also examined the solubility of cupric sulphate in methyl alcohol. R. de Forcrand obtained greenish-blue crystals of a double compound, $CuSO_4.CH_3OH$, by shaking anhydrous cupric sulphate with absolute methyl alcohol. The homologous alcohols do not form similar compounds. 100 grms. of absolute *ethyl alcohol* at 3° dissolve 111 grms. of the pentahydrate. H. Schiff found the solubility in 10, 20, and 40 per cent. alcohol at 15° to be respectively 15·3, 3·2, and 0·25 grms. of the pentahydrate per 100 grms. of solvent. 100 grms. of *glycerol* dissolve 30 grms. of the pentahydrate at 15·5°, and, according to F. Guthrie, the soln. has an emerald-green colour. W. F. C. de Coninck found 100 grms. of a sat. soln. of *glycol* at 14·6° has 7·6 grms. of the pentahydrate. The last-named salt is insoluble in *acetone*, and soluble in the *amines*. H. D. Gibbs found liquid *methylamine* forms an intense blue insoluble mass with cupric sulphate. A. Lieben found *ether* is changed in contact with cold anhydrous cupric sulphate. W. R. Hodgkinson and A. Leahy obtained compounds with *acetic acid* and *benzoic acid*; A. Werner, with amines of the fatty acids, *pyridine*, and *piperidine*; B. Lachowicz, with *quinoline*, *aniline*, *methyl aniline*, and *toluidine*; A. Werner, with *methyl sulphide*.

Anhydrous cupric sulphate forms colourless transparent **crystals,** white prisms, or a white powder which, according to T. Klobb, consists of fine prismatic needles.

The rhombic bipyramidal crystals of anhydrous cupric sulphate (hydrocyanite) were found by A. Scacchi[9] to have the axial ratios $a:b:c=0·7968:1:0·5650$. The monohydrate forms a greenish-white crystalline powder; the trihydrate, a bluish-white crystalline powder; the crystals from the sulphuric acid soln. are monoclinic, and A. Scacchi found the axial ratios to be $a:b:c=0·4321:1:0·5523$, and $\beta=96°\ 25'$. The pentahydrate forms ultramarine-blue crystals belonging to the triclinic system, and, according to A. E. H. Tutton, they have the axial ratios $a:b:c=0·5715:1:0·5575$, and $\alpha=82°\ 16'$, $\beta=107°\ 26'$, $\gamma=102°\ 40'$. G. Boeris found that the crystals from rapidly cooled conc. soln. and slowly cooled more dil. soln. of cupric sulphate exhibited twinning. S. Meyer found no evidence that a magnetic field has any influence on the crystallization. M. Kuhara studied the percussion figures of crystals of cupric sulphate. W. Spring says that the powdered salt under a press. of 6000 atm. forms a homogeneous solid.

The sulphates of the vitriol series form mixed crystals which have been studied by J. W. Retgers, W. Stortenbeker, A. Fock, R. Hollmann, H. W. Foote, etc. There are three types of mixed crystals with zinc and cupric sulphates: (i) *Rhombic*, almost colourless crystals with $7H_2O$; (ii) *Monoclinic*, pale blue crystals with $7H_2O$; and (iii) *Triclinic*, dark blue crystals with $5H_2O$. According to W. Stortenbeker, at 18°, the limits of the crystal phases are, in mol per cent. of copper, *i.e.* 100 mol Cu/(mol Cu+mol Zn):

	Rhombic.	Monoclinic.	Triclinic.
Crystal	0 to 1·97	14·9 to 31·9	82·8 to 100
Soln.	0 to 8·36	8·36 to 21·5	21·5 to 100

The composition of the soln. in equilibrium with the different kinds of crystals is shown in W. Stortenbeker's diagram, Fig. 34; and the relation between the copper in the mixed crystals and in the soln. is indicated in Fig. 35. The dotted lines in both diagrams represent metastable states. Soln. containing between 21·5 and 100 mols per cent. of copper furnish triclinic mixed crystals poor in zinc, and with further concentration monoclinic crystals appear corresponding with soln. containing between 8·36 and 21·5 mols per cent. of copper. Then a mixture of monoclinic and rhombic crystals are formed, and finally soln. with 0 to 8·36 per cent. of copper give rhombic crystals with *F*, Fig. 35, as the end-point of the crystallization. H. W. Foote has investigated the effect of variations of temp. At 40°, the rhombic heptahydrated crystals, $(Cu, Zn)SO_4.7H_2O$, pass into the hexahydrated,

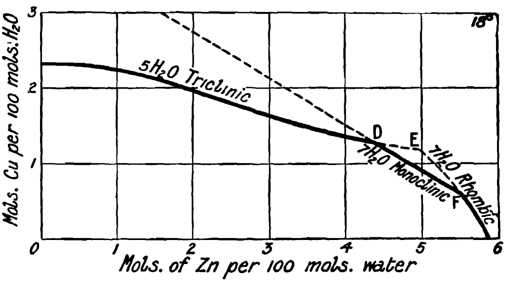

FIG. 34.—Limiting Range in Composition of Soln. for Mixed Crystals of Copper and Zinc Sulphates.

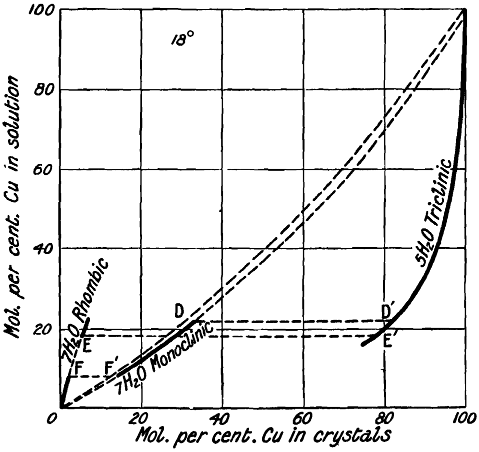

FIG. 35.—Relation between Copper and Zinc in the Mixed Crystals and in the Soln.

(Cu, Zn)$SO_4.6H_2O$. At 45° the monoclinic phase of the heptahydrated crystals disappears. R. Hollmann has investigated the vap. press. of these crystals.

J. W. Retgers and R. Hollmann have likewise investigated mixed crystals of *cupric and magnesium sulphates* and found the composition of the solid phases to be: rhombic: 4·25 per cent. $CuSO_4.7H_2O$; monoclinic: 34·06 and 46·13 per cent. $CuSO_4.7H_2O$; and triclinic: 95·43 per cent. $CuSO_4.5H_2O$. R. Hollmann has measured the vap. press. With mixed crystals of *cupric and cadmium sulphates,* J. W. Retgers found monoclinic crystals with 0·55 parts $CuSO_4.7H_2O$, and triclinic crystals with 98·29 parts $CuSO_4.5H_2O$. J. W. Retgers found mixed crystals of *cupric and ferric sulphates* to be monoclinic between the limits 0 and 53·17 per cent. $CuSO_4.7H_2O$, and triclinic between 94·88 and 100 per cent. of $CuSO_4.5H_2O$. Similar results were obtained with mixed crystals of *cupric and cobalt sulphates.* H. Dufet, A. Fock, and J. W. Retgers have likewise investigated mixed crystals of *cupric and nickel sulphates.* At low temp. there are three series of mixed crystals, rhombic and monoclinic with $7H_2O$, and triclinic with $5H_2O$. Below 33° the nickel sulphate is rhombic, $NiSO_4.7H_2O$; above 33°, it is tetragonal, $NiSO_4.6H_2O$; and over 60°, monoclinic, $NiSO_4.6H_2O$. J. W. Retgers, R. Hollmann, and W. Stortenbeker have likewise studied mixed crystals of *cupric and manganous sulphates.*

The **specific gravity** of crystals of anhydrous cupric sulphate reported by P. I. Bachmetjeff[10] is 3·516 and O. Pettersson gives 3·83 (18°). Several intermediate values have been reported—*e.g.* P. A. Favre and C. A. Valson gave 3·707 (25·3°) and H. Schröder for the salt dehydrated without fusion, 3·640. The best representative value is 3·6—T. E. Thorpe and J. I. Watts found 3·606 at 15°. For the monohydrated salt, the reported values vary from T. E. Thorpe and J. I. Watts' 3·289 at 15°, to H. Schröder's 3·038. The best representative value is 3·20. T. E. Thorpe and J. I. Watts give for the trihydrate 2·663 at 15°. The values for the pentahydrated salt range from J. H. Hassenfratz's 2·1943 to F. Rüdorff's 2·330. The best representative value is 2·27 in agreement with H. Kopp's 2·274 and P. I. Bachmetjeff's 2·276. T. E. Thorpe and J. I. Watts give 44·4 for the **specific** volume of the anhydrous salt; 54·3 for the monohydrate; 80·0 for the trihydrate; and 109·1 for the pentahydrate. W. W. S. Nicol also gives 1863·22 for the mol. vol. of the pentahydrate when 0·5 mol is dissolved in 100 mols. of water at 20° (sp. gr. 1·04268). G. Carrara and M. G. Levi give 48·81 to 46·16 for the mol. vol. of a mol in a soln. of 6·30 to 100·80 litres of methyl alcohol.

P. A. Favre and C. A. Valson[11] measured the contraction which occurs on soln. According to J. G. MacGregor, the volume of the soln. may be smaller than that of the water employed, the maximum contraction occurs with soln. containing 1·34 per cent. $CuSO_4$. The sp. gr. D of a soln. of cupric sulphate is equal to the sp. gr. of the water at the given temp. plus the product $0·0098427w$, where w denotes the per cent. of anhydrous salt in the soln. H. Schiff found the sp. gr. at 18° of soln. with w per cent. of the pentahydrate, $CuSO_4.5H_2O$, and the results are indicated in Table X.

TABLE X.—SPECIFIC GRAVITIES OF SOLUTIONS OF PENTAHYDRATED CUPRIC SULPHATE AT 18° (H. SCHIFF).

	0	1	2	3	4	5	6	7	8	9
0	1·0000	0063	0196	0190	0254	0319	0384	0450	0516	0582
1	1·0649	0716	0785	0854	0923	0993	1063	1135	1208	1281
2	1·1354	1427	1501	1585	1659	1738	1817	1898	1980	2063
3	1·2164									

G. Charpy, J. Delaite, P. A. Favre and C. A. Valson, G. T. Gerlach, J. A. Groshans, R. J. Holland, F. Kohlrausch, J. G. MacGregor, J. C. G. de Marignac, A. Michel and L. Krafft, W. W. J. Nicol, etc., have also determined the sp. gr. of soln. of cupric sulphate. According to E. Irueste, if D and D_0 respectively denote the sp. gr. of soln. and of water at 15°, the conc. per grm. of soln. is $0·95933(D-D_0)-0·43961(D-D_0)^2$. According to J. Thomsen, the soln. contains molecules of $CuSO_4.5H_2O$; R. Luther found the soln. also contains some cuprous sulphate. M. Konowaloff found evidence of the formation of hydrates; H. C. Jones and F. H. Getman, and A. Colson found signs of polymerization in conc. soln. The latter says $(CuSO_4)_2$. A. Hantzsch attributes the constancy of the colour of the soln. to the presence of complexes. J. Traube gives 12·5 for the mol. soln. vol. of a 19·17 per cent. soln., and 102·6 for a 30 per cent. soln. E. Cohen and A. Étard have also studied this subject. S. Lussana represented the influence of press. p atm. on the temp. θ of maximum density of soln. of cupric sulphate, by $\theta=0·0053(p-1)-0·14$.

The **diffusion coefficient** k, in A. Fick's equation, was found by J. Schuhmeister[12] to be 0·21 at 10° for a soln. with 1·25 grm.-eq. per litre; and J. Thovert, at 17°, found for soln. with 1·95, 0·50, and 0·10 grm.-eq. per litre, respectively 0·23, 0·29, and 0·39. Other investigations on this subject have been made by A. Griffiths, G. Bruni and B. L. Vanzetti, H. de Vries, J. C. G. de Marignac, J. H. Long, etc. The **viscosity** of soln. of cupric sulphate has been determined by J. Barnes, S. Arrhenius, and J. Wagner. The latter finds at 25° for N-, $\frac{1}{2}N$-, $\frac{1}{4}N$-, and $\frac{1}{8}N$-soln. the respective values 1·3580, 1·1603, 1·0802, and 1·0384 (water unity). A. Brümmer found a distinct minimum in the **surface tension,** σ, in dynes per cm., and the **capillary constant,** a^2 sq. mm., of soln. of cupric sulphate at 15°, thus:

Per cent. $CuSO_4$	0	5	10	12·5	15	20
a^2	15·43	14·50	13·41	12·77	13·22	13·84
σ	77·1	75·1	71·8	70·8	75·9	81·1

Cupric sulphate does not melt when heated. At 99°, F. Rinne[13] found about a tenth of the water is lost from the pentahydrate and the colour is still dark blue; at 105°, about two-fifths of the water is given off, and the colour paler; at 117°, four-fifths of the water is expelled, and the residue is greenish-white in colour; and all the water is driven off at 258°. I. Guareschi says that over calcium chloride at 21°–23°, the pentahydrate loses only $2H_2O$ and passes into the trihydrate; at 60° it forms the monohydrate. In air, the pentahydrate is not changed at 40°, but loses $2H_2O$ at 45°–50°, and another H_2O at 60°, and the remaining H_2O at 206°. In a current of dry air at 41°–42°, the pentahydrate loses $1·5H_2O$ in 5 hrs., and $0·5H_2O$ more in another 5 hrs.; there is no further loss at 50°–60°, but at 72°, another $2H_2O$ is given off. J. I. Pierre's statement that the pentahydrate crystallized above 25° loses all its water in dry air at 114° is wrong. T. Graham found that the last mol of water is lost at 242°, but, according to T. W. Richards, some water still remains at even higher temp., for the anhydrous salt dried at 255° "loses about 0·17 per cent. of its weight, when heated to 365° . . . and a small amount—about 0·12 per cent.—is held even at 400°." According to D. W. Horn and E. E. Taylor, it is impossible to prepare pure anhydrous or monohydrated cupric sulphate by heating the pentahydrate. The product is brown and the losses in weight are variable even at 220°. In every case the purity of the final product is affected by secondary reactions between the water and the cupric sulphate. This agrees with A. Naumann's observations. J. L. Proust, A. A. B. Bussy, J. L. Gay Lussac, and P. Berthier stated that when heated *au rouge sombre*, the anhydrous salt loses sulphuric anhydride and forms a basic sulphate; if heated to a still higher temp. sulphur trioxide, or sulphur dioxide and oxygen, is given off, and leaves a residue of cupric oxide. R. H. Bradford says that the decomposition begins at 653°, forming a yellow insoluble basic sulphate, and that at 720° it completely decomposes to cupric oxide, etc. S. U. Pickering denied the formation of a basic sulphate, rather is the product a mixture of cupric oxide and undecomposed salt. T. W. Richards found that no acid is lost from anhydrous cupric sulphate heated to 365°. When the temp. of copper sulphate is measured from time to time while the salt is being heated, arrests in the curve occur at about 340°, 380°, 500°, and 620°. These critical temp. correspond with the points at which the salt begins to decompose, or form the basic salts: $8CuO.3SO_3$, and $2CuO.SO_3$. A. Mourlot found that when heated in an electric furnace, cupric sulphate is reduced to the metal. Cupric oxide begins to be formed about 700°.

According to P. I. Bachmetjeff,[14] the **coefficient of thermal expansion** of crystals of anhydrous cupric sulphate is 0·0000245; for the crystalline pentahydrate, 0·000165; and the amorphous salt, —0·000013. C. Forch gives for the volume of a soln. with 0·517 grm. eq. per litre, at $\theta°$ when the volume at 0·01° is unity:

θ .	5·09	10·03	15·03	19·84	25·08	29·79	34·92	39·97
Vol.	1·000301	1·000894	1·001769	1·002856	1·004280	1·005754	1·007565	1·009546

and the expansion coeff. per grm. eq. ($\times 10^6$):

0°–5°	5°–10°	10°–15°	15°–20°	20°–25°	25°–30°	30°–35°	35°–40°
118	169	215	258	302	334	381	410

P. I. Bachmetjeff gives 0·184 for the **specific heat** of the anhydrous salt between 23° and 100°; 0·202 for the monohydrate; and 0·285 for the pentahydrate between 16° and 47°. For soln. of cupric sulphate, $CuSO_4+200H_2O$, J. Thomsen gives 0·953, and for $CuSO_4+nH_2O$ from 18° to 23°. S. Pagliani and J. C. G. de Marignac respectively give for $n=50$, 0·848 and 0·841; for $n=100$, 0·898 and 0·908; for $n=200$, 0·950 and 0·951; and for $n=400$, S. Pagliani gives 0·975. From 22° to 53°, J. C. G. de Marignac gives for $n=50$, 100, and 200, respectively 0·8520, 0·9148, and 0·9528. P. Vaillant, and H. Teudt have also measured the sp. ht. of soln. of this salt. S. Pagliani gives $79+18(n-5)$ for the **molecular heat** for soln. with n mols of water for one mol of $CuSO_4.5H_2O$, when n ranges from 50 to 400; and J. C. G. de Marignac's values for soln. with 50, 100, and 200 eq. of water are respectively 891, 1780, and 3571 between 18° and 23°; and 902, 1792, and 3582 between 22° and 53°. C. Pape, and W. C. Röntgen have measured the **heat conductivity** of the pentahydrated salt. According to the former, the heat conductivity ellipsoid has the axial ratios 0·939 : 0·860 : 1. According to H. F. Weber, the heat conductivity of a soln. of sp. gr. 1·160 is 0·00118 abs. units, or 95·26 (water 100); and G. Jäger found that for each per cent. of cupric sulphate, in the soln., the heat conductivity decreases by 0·00272.

According to M. Berthelot,[15] the **heat of formation** of anhydrous cupric sulphate from its elements is $(Cu, S, O_4)=181·7$ Cals.; J. Thomsen gives 182·6 Cals., and for (Cu, O_2, SO_2), 111·49 Cals. M. Berthelot gives for the heat of formation from cupric oxide, 42·6; and from cupric hydroxide, 22·8 Cals. J. Thomsen gives 56·216 to 55·960 Cals. for the heat of formation of the pentahydrate in aq. soln. $(Cu, S, O_4, aq.)$; P. A. Favre from CuO, 9·711 to 9·814 Cals.; J. Thomsen, $(CuO, SO_3, aq.)$, 18·8 Cals.; and from anhydrous cupric sulphate, 3·41 Cals. (J. Thomsen), or 3·34 Cals. (P. C. F. Frowein). L. and P. Wöhler and W. Plüddemann give 13 cals. for the heat of dissociation of anhydrous cupric sulphate. According to R. Scholz, the **heat of solution** expressed in mean gram-calories for a soln. of a gram of the salt in a n times normal soln.:

n	0·125	0·25	0·50	1·0	2·5
$\frac{1}{2}(CuSO_4.5H_2O)$	13·60	13·38	12·98	12·64	11·48

S. U. Pickering gives 2·465 Cals. for the heat of soln. of the pentahydrate at 15°, —2·762 Cals. at 18°; and J. Thomsen for a mol of $CuSO_4$ in 400 mols of water, 15·8 Cals.; and under similar conditions, for $CuSO_4.H_2O$, 9·33 Cals.; for $CuSO_4.3H_2O$, 2·81 Cals.; and for $CuSO_4.5H_2O$, —2·75 Cals. P. A. Favre gives for the heat of soln. of an eq. of salt in 278 eq. of water, —1315 cals., in the presence of 5 eq. of sulphuric acid, —2555 cals., and 1 eq. of that acid, —1998 cals.; and with 5 and 1 eq. hydrochloric acid under similar conditions, —4484 and —3106 cals. According to J. H. Pollok, if a sat. soln. at 9° be diluted with its own vol. of water.

the temp. rises 0·02°–0·05° ; and J. Thomsen found 41 cals. for the **heat of dilution** of a soln. $CuSO_4+60H_2O$ to $CuSO_4+100H_2O$ and 116 cals. for $CuSO_4+60H_2O$ to $CuSO_4+200H_2O$. The **heat of hydration,** $CuSO_{4solid}+H_2O_{liq.}=6·47$ Cals. ; $CuSO_{4solid}+3H_2O_{liq.}=12·9$ Cals. ; and $CuSO_{4solid}+5H_2O_{liq.}=18·55$ Cals.

According to F. Rüdorff,[16] the **freezing point** of a sat. soln. of cupric sulphate is —2°. F. Guthrie's cryohydrate has been previously indicated. The lowering of the f.p. when a gram of salt is dissolved in 100 grms. of water was found by L. C. de Coppet to be 0·070, and by F. Rüdorff, 0·065—the lowering in the former case is 17·5 per mol. The lowering of the f.p. has been measured by F. M. Raoult, L. Kahlenberg, H. Hausrath, etc. H. C. Jones and F. H. Getman and V. J. Chambers and J. C. W. Frazer found :

Mol $CuSO_4$ per litre	0·072	0·144	0·476	0·595	0·890	1·190
Mol. lowering .	2·33	2·16	1·50	1·45	1·43	1·46

There is some evidence of a minimum. S. U. Pickering measured the lowering of the f.p. of soln. of cupric sulphate, expressed in mols per litre, and the corresponding values calculated from the electrical conductivity agree for soln. up to 0·03 mol per litre, but for more conc. soln. the computed values are greater than the observed. The values of *i* calculated from the f.p. data are here indicated :

Mols $CuSO_4$.	0·0003	0·0028	0·0176	0·0553	0·1658	0·4081	0·7453
Lowering f.p. .	0·0009°	0·0090°	0·0475°	0·1337°	0·3344°	0·7422°	1·3258°
i	1·932	1·681	1·472	1·379	1·293	1·231	1·206

According to T. Griffiths,[17] the **boiling point** of a 45 per cent. soln. is 102·2° and, according to G. T. Gerlach, soln. with 21·3, 63, and 82·2 per cent. of $CuSO_4$, boil respectively at 100·5°, 102·5°, and 104·°2. The raising of the b.p. of soln. of cupric sulphate have been measured by N. Tarugi and G. Bombardini, and L. Kahlenberg. The latter found :

Mols $CuSO_4$ per litre .	0·210	0·489	0·999	2·026	3·583	4·619
Mol. rise	0·43	0·39	0·37	0·43	0·637	0·816

Anhydrous cupric sulphate is very hygroscopic. J. L. Proust[18] noticed that anhydrous cupric sulphate becomes blue when breathed upon, owing to the formation of the blue hydrate. T. Graham found that the hydration of the anhydrous salt raises its temp. 135° ; and, after 3 days' exposure to moist air, R. Brandes found that the pentahydrated salt is formed. C. F. Cross measured the rate of formation of the pentahydrate in moist air ; and P. I. Bachmetjeff, the rate of dehydration of the pentahydrate.

The crystals of the pentahydrate were found by C. Pape to effloresce in dry air ; this phenomenon will in general occur when the vap. press. of the salt is greater than the partial press. of the moisture in the air. H. Lescœur found the dissociation press. for efflorescence at 20° to be 6·0 mm. H. Baubigny reported that if the salt is crystallized from a feebly acid soln , it will effloresce more rapidly than if crystallized from a neutral soln. E. Blasius has studied the corrosion figures produced on the crystals by exposure to the atm. When the pentahydrate is confined over sulphuric acid, P. Latschinoff found it lost two-fifths of its water, and W. Müller-Erzbach, that the finely powdered salt confined over sulphuric acid at 17° scarcely loses any water the first day, the relative vap. press. then rises to 0·04 or 0·05 mm., when it remains constant for a week, and about two-fifths of the combined water is lost. The vap. press. then falls to 0·002 mm. In a month's time a little more than two-fifths of the water remains with the crystals. About 1·66 mol of water per mol of $CuSO_4$ remained after the pentahydrate had been confined in a sealed tube for about ten months. The relative vap. press. of the atm. over the pentahydrate at 44° is over 0·21, and at 41° not over 0·25.

The **vapour pressure** determinations of H. Lescœur confirm the existence of the 1, 3, and 5 hydrates, but not the 2 and 4 hydrates. The dissociation press. at 45° and 78° for a mol of $CuSO_4$ with nH_2O are :

45°	nH_2O	4·85	4·64	3·87	2·37	1·06	0·98
	Vap. press.	30	30	30	10	15	<1 mm.
		3–5H_2O			1–3H_2O		

78°	nH_2O	4·13	3·71	3·41	2·61	2·10	1·75	1·00
	Vap. press.	234	238	232	142	145	148	<10 mm.
		3–5H_2O			1–3H_2O			

The constant vap. press. correspond with the univariant systems containing the 3–5 hydrates and vapour, the 1–3 hydrates and vapour, or the 0–1 hydrates and vapour. A. Naumann was unable to get constant vap. press. for definite temp., and G. Wiedemann attributed this to adsorbed air and water imprisoned in the crystals ; A. W. C. Menzies has also studied this question. The vap. press. at different temp. are :

	10°	30°	60°	80°	100°	163°	186·5°	206°	220°
3–5H_2O	2·8	12·5	72	263	668				
1–3H_2O	—	5	45	168	525				
0–1H_2O	—	—	—	—	—	11	44	143	666

P. C. F. Frowein has made determinations for the 3–5H_2O system, which W. Müller-Erzbach believes are rather low. J. L. Andreæ found the changes from one system to the other are abrupt. According to W. Müller-Erzbach, the dissociation press. of the 0–1H_2O system is less than 0·3 mm. of mercury ; with the 1–3 system at 14·5°, the press. is 0·19 mm., and 0·30 mm. at 17·8° ; and with the 3–5H_2O system, it is 0·31 mm. at 17·5°. Observations have been made by A. H. Pareau, J. R. Partington, R. E. Wilson, A. A. Noyes and L. R. Westbrook, H. Schottky, etc. *Vide* 1. 9, 11 ; and for the action of heat on the anhydrous salt, *vide* basic cupric sulphates.

J. Moser found that the vap. press. of water was lowered 12 mm. by the soln. of 25 grms. of the pentahydrate in 100 grms. of water at 30°. J. H. Schüller found the lowering of the vap. press. to be proportional to the quantity of salt dissolved, and he found it to be 0·022 for one per cent. of salt—the value calculated by Helmholtz's formula is 0·0212. H. Sentis has examined the effect of surface tension on the phenomenon.

According to A. Lavenir,[19] the **index of refraction** of cupric sulphate for sodium light is α=1·51408, β=1·53684, γ=1·54345. M. le Blanc gives for the corresponding molecular refractions 56·33, 58·89, and 59·64 respectively. C. Chéneveau, and M le Blanc have studied the index of refraction of soln. of cupric sulphate ; the latter finds for 5·58, 15·05, and 16·79 per cent. soln. the respective sp. grs. 1·05874, 1·16936, and 1·19125, the respective indices of refraction 1·34376, 1·36260, and 1·36613, and the respective molecular refractions 28·69, 28·55, and 28·48. The optical constants have been measured by C. Pape, F. Kohlrausch, etc. C. Pape also found the crystals of the pentahydrate to have a negative double refraction. D. Gerney found the crystals to be triboluminescent ; and P. Gaubert found that the adsorption of methylene blue makes them polychroic. The adsorption of radiant energy by soln. of cupric sulphate has been studied by P. Desains. The absorption spectra have been discussed in connection with cupric chloride. M. Kofler has investigated the absorption of radium emanation by soln. of cupric sulphate.

According to T. Gross,[20] solid anhydrous cupric sulphate conducts the electric current, so also does the solid pentahydrate. The subject has been studied by P. Vaillant. A great many observations have been made of the **electrical conductivity** of aq. soln. of cupric sulphate by W. C. D. Whetham, J. G. McGregor and E. H. Archibald, F. Kohlrausch, N. Tarugi and G. Bombardini, T. C. Fitzpatrick, J. H. Long, F. B. de Lenaizan and L. Maury, L. Kahlenberg, etc. The following may be regarded as selected representative values of the eq. conductivity λ at 0° and 18°. The conc. C is in gram-eq. per 1000 grms. of soln.:

C	0·00001	0·0001	0·001	0·01	0·1	1·0	2·0
λ at 0°	69·6	67·4	60·2	44·5	28·2	16·0	13·5
λ at 18°	—	109·9	98·6	71·7	43·8	25·8	20·1
α at 0°	99·8	96·7	86·3	63·8	—	—	—

P. Sack, F. Kohlrausch, and S. Arrhenius have calculated the **temperature coefficient** of the conductivity. The **degrees of ionization** expressed in percentages in the above data have been studied by A. Bouzat, W. C. D. Whetham, N. Tarugi and G. Bombardini, G. N. Lewis and M. Randall, etc. A. A. Noyes and K. G. Falk gave 0·629 for the degree of ionization of 0·01 molar soln., computed from λ/λ_∞; G. N. Lewis and G. A. Linhart introduced some correction terms and obtained 0·290. S. Arrhenius calculated the **heat of ionization** to be —1566 cals. at —35°. G. Carrara and G. B. Vespignani calculate the **degree of hydrolysis** of a $\frac{1}{5}N$-soln. to be 0·057 per cent. at 25°. The **transport numbers** of anions and cations have been determined by many observers.[21] H. Jahn found an apparent maximum for the anion at 15°; thus, with soln. containing 0·032 per cent. of copper, the values at 1° and 15° are respectively 0·615 and 0·633; with 30 per cent. of copper, 0·611 at 0° and 0·607 at 50°; and with 0·73 per cent. of copper, 0·632 at 15° and 0·622 at 76° H. Jahn has for the cation at room temp. and soln. with a mol dissolved in v litres:

v	4·08	7·92	12·20	16·00	32·00	65·44	94·51
	0·328	0·328	0·366	0·373	0·376	0·375	0·375

A. Campetti found the values to increase with rise of temp. J. Dowling and K. M. Preston studied the high frequency resistance of glycerol soln. of cupric sulphate; and A. Gilmour examined soln. of cupric sulphate in glycerol as a source of high resistance of small inductance; and N. Isgarischeff, the polarization of soln. of cupric sulphate in the presence of gelatin, gum, and sucrose.

S. H. Freeman[22] has studied the production of a current during the evaporation of a soln. of cupric sulphate. A. Hollard, and H. M. Goodwin and W. G. Horsch measured the conductivity of soln. of cupric sulphate with different proportions of sulphuric acid; J. L. Hoorweg noted that cooling occurs when a current passes from sulphuric acid to cupric sulphate, and cooling produces a current from the acid to the salt. J. T. Barker has measured the effect of glycocol on the conductivity of soln. of cupric sulphate; T. C. Fitzpatrick, the effect of alcohol; and A. Gilmour, the effect of glycerol. The **potential difference** of copper in soln. of cupric sulphate has been measured by J. von Hepperger, S. Lussana, F. Paschen, etc.; of soln. of cupric sulphate and other soln. by E. Bichat and R. Blondlot, S. Pagliani, H. Bagard, A. Hagenbach, J. Miesler, etc. C. W. Bennett found that in the electrolysis of a soln. of acid copper sulphate, with a rotating copper cathode, the potential drop across the cell, with constant current, increases with the speed of rotation. Since the rotation of the electrode would give an efficient stirring of the soln., and lessen conc. differences, it might be anticipated that a fall of potential would occur. C. W. Bennett and C. O. Brown explained the increase in the potential as an effect of the formation of cuprous ions. As the rotation increases, the stirring becomes more efficient, and the cuprous ions are removed, so that the rate of soln. of the copper is increased, and the voltage is increased. With nitric acid, the potential decreases with increasing speed of rotation because the film of nitrous acid is removed from the copper; this decreases the speed of soln. of the copper and lowers the potential. The **decomposition potential** of soln. of copper sulphate has been studied by J. Moser, C. Truchot, etc., *vide* copper.

The **magnetic susceptibility** of anhydrous cupric sulphate has been observed by H. W. March[23] to be $10{\cdot}47\times10^{-6}$ mass units, in agreement with observations by G. Quincke, O. Liebknecht and A. P. Wills, S. Meyer, and J. Königsberger.

G. Chéneveau gave for the crystalline salt $6{\cdot}5\times10^{-6}$ mass units. C. K. Studley also measured this constant for soln. of cupric sulphate, and found $10{\cdot}4D(w/100)-0{\cdot}80D(1-w/100)^2$, when w represents the per cent. of water-free salt in the soln., and D the sp. gr. A. Heydweiller found the **dielectric constant** per mol of water of crystallization in hydrated cupric sulphate to be 6·22, showing that the water is profoundly modified in crystals. For the anhydrous salt respectively powdered and compact, the values are 2·36 and 10·31; and for the pentahydrate respectively 3·44 and 7·84 for $\lambda=478$ cm. R. T. Lattey found the dielectric constants of 0·00114*N*-, 0·00228*N*-, and 0·00456*N*-soln. to be respectively 75·2 (15·1°), 78·2 (13·2°), and 73·9 (14·8°).

According to A. Leighton, the decomposition voltage of a soln. of cupric sulphate between platinum electrodes is not appreciably affected when the anode is illuminated with a mercury lamp, but it is increased when the cathode is so illuminated. J. A. Arfvedson[24] found that heated soln. of cupric sulphate is reduced by **hydrogen**; and J. L. Gay Lussac that it is reduced by **carbon.** A 2*N*-soln. of the salt absorbs carbon dioxide —0·0751 grm. per 75 c.c. of soln. at 15°, and 720 mm., but there is no perceptible chemical action.

According to M. C. Lea,[25] A. Colson, and R. M. Caven soln. of cupric sulphate made with cold air-free **water** are feebly acid, for they redden blue litmus. F. Clowes, and D. W. Horn and E. E. Taylor say that while a cold soln. is acid towards litmus, it is practically neutral towards methyl orange; R. M. Caven found a dil. cold air-free soln., which has been boiled, gives a precipitate of basic cupric sulphate, and the soln. reacts acid to methyl orange; on the other hand, a conc. soln. of cupric sulphate does not give a precipitate on boiling, nor does such a soln., after boiling, affect methyl orange. The formation of the basic salt, and the development of acidity towards methyl orange are co-related; the one is not produced without the other. The phenomena occur only in dil. soln., and, as shown by D. Tommasi, and E. Divers, they are the result of the **hydrolysis** of cupric sulphate by the mass action of hot water. The amount of sulphuric acid produced by hydrolysis in cold soln. is very small. J. H. Long has compared the hydrolysis in dil. aq. soln. of cupric sulphate and potash alum. The latter alone, in cold soln., affects the colour of methyl orange. After maintaining the two soln., each mixed with saccharose, for 6 hrs. between 50° and 60°, during which no basic salt was precipitated, J. H. Long found that there was an appreciable reduction with the alum soln., and a barely perceptible reduction with the cupric sulphate soln. Hence, it was inferred that only an infinitesimal amount of free sulphuric acid is present in soln. of cupric sulphate from which no basic salt has been precipitated. E. J. Houston noticed that the soln. is green when boiled, and it becomes blue when cold, and a still deeper blue if more strongly cooled. J. L. Andreæ found that if evaporated in a sealed tube, the penta- and tri-hydrated salts are formed, and if the water be removed, the trihydrate, and finally the monohydrate, is formed. R. C. Tichborne also studied the dehydration of soln. of cupric sulphate when heated in sealed tubes.

R. Kane found that if **hydrogen chloride** be passed over powdered pentahydrated cupric sulphate, the gas is absorbed, heat is developed, and over two-fifths of the water is set free. When the grass-green product is heated, a brown mass is formed, and hydrogen chloride is given off. P. Latschinoff likewise found that when hydrogen chloride is passed over pentahydrated cupric sulphate, at room temp., the gas is absorbed, forming a product, $CuSO_4.5H_2O.3HCl$, and this then breaks down into $CuSO_4.2H_2O.2HCl$. When air is passed over the latter compound a complex product, $CuSO_4.H_2O.\frac{1}{8}HCl$, is obtained from which the hydrogen chloride cannot be removed by a stream of air. C. Hensgen found that if dry hydrogen chloride be passed over the salt, it is completely converted into grass-green needle-like crystals of cupric chloride, $CuCl_2.2H_2O$. According to A. Colson, hydrogen chloride converts the anhydrous sulphate partially into chloride. Pentahydrated cupric sulphate dissolves in **hydrochloric acid,** and the temp. is at the same time lowered about 17°, forming a green liquid. If about two mols of HCl are present per mol of $CuSO_4$, crystals of cupric chloride, $CuCl_2.2H_2O$, are formed when the soln. is evaporated and cooled; if the crystals remain in the mother-liquid, crystals of $CuSO_4.5H_2O$ are formed. A. B. Prescott found that if a soln. of a gram of the salt with 3·5 c.c. of hydrochloric acid of sp. gr. 1·153, be evaporated to dryness on a water-bath, about 3·6 per cent. of the copper is converted into cupric chloride. The transformation with the anhydrous sulphate is not complete although brownish-yellow cupric chloride, $CuCl_2$, is formed. With anhydrous chloride under similar conditions, about two mols of hydrogen chloride are absorbed with the evolution of much heat. A dark brown mass is formed which loses its hydrogen chloride when heated, or which, on soln. in water furnishes crystals of cupric chloride. According to J. Löwe, when a soln. of cupric sulphate is treated with **zinc** and sulphuric acid, some hydrogen sulphide is formed, and, according to T. Leykauf, and L. Meyer, copper and basic zinc sulphate are precipitated, and zinc sulphate passes into soln. The action of **magnesium** on soln. of cupric sulphate is attended by the precipitation of cuprous oxide and the evolution of hydrogen. The reaction has been studied by F. Clowes, R. M. Caven, S. Kern, A. Commaille, E. Divers, and D. Vitali. F. Clowes showed that the change is not due to an impurity in the copper salt, and he suggests the reaction, $2Mg+2CuSO_4+H_2O=2MgSO_4+Cu_2O+H_2$. E. Divers believes that the evolution of hydrogen is due to the free sulphuric acid formed by the hydrolysis of the cupric sulphate; cuprous sulphate is formed: $2CuSO_4+Mg=Cu_2SO_4+MgSO_4$, and the cuprous sulphate is then converted into cuprous oxide—*vide* the metallic precipitation of copper. K. Griessbach studied the action of **ammonium and alkali hydroxides and carbonates** on soln. of cupric sulphate.

According to A. Vogel,[26] and C. J. B. Karsten, a soln. of cupric sulphate forms cupric and ammonium sulphates and cupric chloride when treated with **ammonium chloride;** and, according to J. B. J. D. Boussingault, an analogous change occurs with **sodium chloride.** H. Rose,[27] A. Joannis, and J. Riban have studied the action of **phosphine.** C. F. Rammelsberg found that when boiled with **antimony pentasulphide,** a soln. of cupric sulphate furnishes black cupric thioantimoniate, antimonic oxide, and sulphur trioxide. H. Quantin noted the reduction of a soln. of 0·5 grm. of cupric sulphate per litre by alcoholic ferment, whereby cupric sulphide is formed. J. F. Persoz found glacial **acetic acid** precipitates the pentahydrate, $CuSO_4.5H_2O$; and L. de Bouquet found that **alkali thiocarbonates** give carbon disulphide. A. Gawalowsky showed that a white precipitate—said to be *cuprous sulphate*—is formed by the action of **potassium permanganate** on cupric sulphate soln. which results in the evolution of oxygen; with nitric oxide, the white precipitate gives copper and cupric sulphate.

Ordinary cupric sulphate is used as the starting-point in the preparation of many compounds of copper; in dyeing; in electroplating; in making galvanic cells; etc. It is also used as an antiseptic, and in making preparations for protecting plants from fungoid and other diseases.

§ 26. Cupric Ammino-Sulphates. Double Cupric Sulphates

G. Gore,[1] and E. C. Franklin and C. A. Kraus found anhydrous cupric sulphate to be insoluble in liquid ammonia. According to W. R. Hodgkinson and C. C. Trench, both anhydrous and hydrated cupric sulphates absorb much ammonia gas. H. Rose found 53·97 per cent. to be absorbed by the anhydrous salt, forming a blue powder. According to A. Bouzat, the reaction is at first very vigorous and the white salt becomes blue; later, the absorption is slow, and the reaction continues for 16 hrs. if the cupric sulphate contains a perceptible quantity of iron. The product is taken to be anhydrous **cupric pentammino-sulphate,** $Cu(NH_3)_5SO_4$; which, according to A. Bouzat, is best prepared by allowing ammonia gas, thoroughly dried by fused potassium hydroxide, to act on cold dry cupric sulphate. According to D. I. Mendeléeff, the compound gives off no ammonia when confined over sulphuric acid, but, according to D. W. Horn, it slowly loses ammonia on standing; for example, a specimen lost 0·12 mol in 6·5 hrs. and 1·42 mol in 2064 hrs. In moist air, water replaces the ammonia molecule by molecule, forming, according to D. I. Mendeléeff, $Cu(NH_3)_4SO_4.H_2O$, and then $Cu(NH_3)_2SO_4.3H_2O$; and, according to A. Bouzat, and F. Ephraim, it is stable up to 99°, but when heated between 99° and 141°, it forms anhydrous cupric tetrammino-sulphate, $Cu(NH_3)_4SO_4$. P. Latschinoff found that all the ammonia is expelled at 360°, but about one-fourth of a mol is retained at 320°. The product melts below 200°, turns black, and as the temp. rises, it appears to boil, and near 400° begins to decompose, leaving almost pure metallic copper. According to H. Rose and A. Bouzat, the product is soluble in water, forming an ultramarine blue soln. which deposits a basic salt when diluted.

A. Bouzat found that anhydrous **cupric tetrammino-sulphate,** $Cu(NH_3)_4SO_4$, indicated above, is obtained by passing ammonia gas over anhydrous cupric sulphate between 90° and 150°, and D. W. Horn made it by keeping the pentammino-sulphate in a desiccator over sulphuric acid of sp. gr. 1·84. The bluish-violet powder is stated by A. Bouzat to dissociate into **cupric diammino-sulphate,** $Cu(NH_3)_2SO_4$, and ammonia when heated over 150°. It is soluble in a little water, but more water precipitates a basic salt. F. Ephraim found it to be stable up to 141·5°. Both compounds are insoluble in liquid ammonia.

Cupric sulphate dissolves in an excess of aq. ammonia, forming a deep blue liquid, called *eau céleste,* which has been the subject of many investigations. The general results show, as C. Immerwahr found, the simple $Cu^{\cdot\cdot}$ cations are to a large extent replaced by more complex ones ; and that a complex cupric ammino-sulphate is formed, containing not more than four molecules of ammonia to one of copper. A. Reychler showed that the addition of this proportion of ammonia to a soln. of cupric sulphate made very little difference to the lowering of the f.p. of the soln., presumably because the complex $Cu(NH_3)_4SO_4$ acts as a molecule like $CuSO_4$. D. P. Konowaloff found that for each mol of cupric sulphate in dil. soln., from 3·4 to 4·04 mols of ammonia were absorbed according to the conc. W. Gaus investigated the lowering of the vap. press of ammoniacal soln. produced by the addition of cupric sulphate, and, assuming that ammonia soln. follow Henry's rule, the vap. press. of a normal soln. of ammonia is 13·45 mm., the ratio of the ammonia to the copper is given by the equation :

$$\frac{\text{Lowering of vap. press.}}{13\cdot45[\text{Cu}]}=\text{Number of molecules } NH_3 \text{ in complex.}$$

When 0·0491 and 0·0982 mol of copper, [Cu], are present in a litre of soln. the vap. press. was lowered 2·49 and 5·02 mm. respectively. Hence, although the conc. of copper are widely different, the two determinations give 3·77 and 3·80 mols of NH_3 in the complex. W. Gaus' results were to a certain extent confirmed by J. Locke and J. Forssall. The distribution ratio of ammoniacal soln. containing varying quantities of copper and ammonia between water and chloroform, was compared by H. M. Dawson and J. McCrae with the distribution ratio for ammonia alone. Selecting the extreme determinations from their list,

Mols Cu	Cu : total NH_3	Cu : Combined NH_3
0·05	1 : 5	1 : 3·14
0·05	1 : 10	1 : 3·76
0·025	1 : 6	1 : 3·16
0·025	1 : 16	1 : 3·96

The ratio gradually increases as the proportion of ammonia increases, and this is thought to mean that more than one complex is formed. The ratio of copper to combined ammonia, in soln. with 0·0235 and 0·0470 mol Cu per litre, was claimed by J. Locke and J. Forssall to be satisfactorily constant, and in agreement with the assumption that all the copper passes into the complex $Cu(NH_3)_4SO_4$, but H. M. Dawson does not agree. The values of the ratio NH_3 : Cu were smaller than 4, and this was attributed by J. Locke and J. Forssall to the lower solubility of ammonia in cupric sulphate soln. than in water. With soln. above 0·1175 mol per litre, there is evidence of the formation of a higher complex $Cu(NH_3)_4SO_4$ or $Cu(NH_3)_6SO_4$ with higher conc. of ammonia. D. W. Horn, however, says that more than 5 mols of NH_3 cannot be added to a mol of $CuSO_4$ at press. not greater than one atm., and between —30° and 20°.

H. M. Dawson believes that J. Locke and J. Forssall's conclusion is ill-founded. It was shown that the ratio of combined ammonia to the copper, for a given conc. of copper increases with the quantity of ammonia present ; and with a fixed proportion of total ammonia to copper, the molecular ratio of combined ammonia to metal increases with the absolute conc. This indicates that dissociation phenomena are involved. The changes which occur when ammonia is gradually added to a soln. of cupric sulphate can be symbolized : $CuSO_4+2NH_4OH=Cu(OH)_2$

$+(NH_4)_2SO_4$, and $Cu(OH)_2+nNH_3\rightleftharpoons Cu(NH_3)_n(OH)_2$; as well as $Cu(NH_3)_n(OH)_2+(NH_4)_2SO_4\rightleftharpoons Cu(NH_3)_4SO_4+(n-2)NH_3+2H_2O$, where n is less than 4 and probably equal to 2. An ammoniacal soln. of cupric sulphate represents a complex system in which copper is present in the form of three different ions: $Cu(NH_3)_4^{\cdot\cdot}$, $Cu(NH_3)_n^{\cdot\cdot}$. and $Cu^{\cdot\cdot}$, in proportions dependent on the conc. of the soln., and the relative proportions of ammonia and copper salt. A. A. Blanchard studied the evidence from the viscosity data; W. Bonsdorff and D. P. Konowaloff, the electrical conductivity data; W. Gaus, the vap. press. data; A. Bouzat, the thermal data; A. Reychler, the f.p. data; and H. M. Dawson and J. McCrae, the partition coeff.

A compound of ammonia and cupric sulphate was prepared by J. A. Stisser[2] in 1693, and from an analysis by J. J. Berzelius, it was probably **monohydrated cupric tetrammino-sulphate,** $Cu(NH_3)_4SO_4.H_2O$. A. Bouzat's opinion is that the formula should be $Cu(NH_3)_4SO_4.1\frac{1}{2}H_2O$, but D. W. Horn and E. E. Taylor have shown that A. Bouzat is probably wrong and J. J. Berzelius right. The last-named recommended treating an aq. soln. of cupric sulphate with an excess of ammonia water and adding alcohol to the purple soln. If the alcohol be carefully poured on the purple soln., crystals of the salt separate at the surface of contact of the two liquids; while if the alcohol be added slowly and mixed with the purple soln. the salt separates in pulverulent crystals. The salt so prepared is very unstable, and only small quantities can be dried between filter-paper or on porous tiles without considerable decomposition—evidenced by the smell of ammonia. A. Bouzat cooled a hot conc. soln. of the salt, and quickly dried the crystals between filter-paper. A. Mallaert prepared the salt by the action of ammonia gas on the powdered solid pentahydrate, and D. W. Horn and E. E. Taylor found that the product is a mixture containing basic salts or cupric oxide. G. André prepared the salt by passing ammonia gas into a soln. of cupric sulphate. Fine crystals of the required salt are precipitated as the conc. of the ammonia in the soln. increases. D. W. Horn and E. E. Taylor, and H. M. Dawson recommend this process. The crystals are dried over lime. The product $4CuO.5SO_4.16NH_3$, obtained by S. U. Pickering by adding aq. ammonia to an almost sat. soln. of cupric sulphate until the precipitate first formed had almost redissolved, and allowing the soln. to stand for some time. This is probably the tetrammino-salt contaminated with cupric and ammonium sulphates.

Monohydrated cupric tetrammino-sulphate forms dark ultramarine blue prismatic or needle-like crystals, which are rhombic bipyramids possessing, according to J. C. G. de Marignac, and A. Johnsen, the axial ratios $a:b:c=0·5903:1:0·8893$. A. Johnsen found the sp. gr. to be 1·81. According to D. W. Horn and E. E. Taylor, the dry salt has no smell, and it is stable when kept over lime in a closed vessel; but not so in vacuo, or when kept over sulphuric acid, phosphorus pentoxide, or calcium chloride. It loses ammonia in moist air, and forms a green powder, which, according to O. B. Kühn, is a mixture of ammonium sulphate and basic cupric sulphate $CuSO_4.3CuO$. H. M. Dawson and J. McCrae found the compound is not much affected by temp. up to 30°. L. Sabbatani said that between 100° and 125° the compound loses all its water and half its ammonia. According to R. Kane, when heated to a temp. not exceeding 149°, it forms an apple-green powder which, when analyzed, led him to say: "By the first action of heat all the water and half the ammonia is driven off, and the green residue consists of copper sulphate united with one equivalent of ammonia. . . . I have tried to separate the water, without loss of ammonia by the most careful management of the flame, but could not." He added that when the temp. is raised to 205° half the remaining ammonia is expelled, and at 260° all the ammonia is given off, leaving anhydrous cupric sulphate. If the powder be suddenly heated, J. J. Berzelius said that ammonium sulphite, and R. Kane that ammonium sulphate is given off, leaving a residue of cuprous oxide and cupric sulphate. In opposition to R. Kane, and L. Sabbatani, D. W. Horn and E. E. Taylor found that when monohydrated cupric tetrammino-sulphate is heated in dry air at 100°, 125°, 149°, 203°, and 260°, no definite compound, but rather a mixed product is obtained, a result which is characteristic of salts containing copper sulphate combined with water, for such salts cannot change without secondary reactions between the water and copper sulphate. In illustration, they found it impossible to prepare pure monohydrated or anhydrous cupric sulphate by heating the pentahydrate in air; and the mixed product obtained with monohydrated cupric tetrammino-sulphate at 260° is brown, and not, as R. Kane stated, anhydrous cupric sulphate. If mono- or di-ammino-sulphate is formed at all it is mixed with other products. E. Rosenbohm found the magnetic susceptibility of the ammino-sulphate to be $+5{\cdot}71\times10^{-6}$ vol. units, and $+1403\times10^{-6}$ mass units.

The solubility of monohydrated cupric tetrammino-sulphate, according to D. W. Horn and E. E. Taylor, is 18·05 grms. of salt per 100 grms. of solvent between 21° and 22°. The salt is decomposed by water with the partial separation of ammonia. This decomposition is probably an hydrolysis, and proceeds as far as the formation and precipitation of basic salts. These changes occur even with an excess of ammonia, and extend over a long period of time. They are hastened by the removal of ammonia, and by great dilution. "The salt gives a clear soln. when water is poured gradually upon it, but if the addition of water is continued, a permanent precipitate is formed at about 0·05 to 0·04-molar conc. When a soln. of the salt is dropped into water, a permanent precipitate is formed at once. A $\frac{1}{10}$-molar soln., after standing a couple of days in a tightly closed vessel, begins to deposit a crystalline blue solid; this continues for weeks." According to G. André, if the salt is heated with ten times its weight of water for 5 hrs. at 200° in a sealed tube, small crystals of cupric oxide collect on the walls of the tube; similar crystals are formed in small quantities when a soln. of cupric sulphate in aq. ammonia is evaporated in air. A $\frac{1}{10}N$-soln. of $Cu(NH_3)_4SO_4.H_2O$ behaves differently from a soln. of the same conc. made by adding the calculated quantity of ammonia to a $\frac{1}{10}N$-soln. of copper sulphate. H. M. Dawson found no evidence of this; and D. W. Horn added that a soln., made by adding ammonia to copper sulphate soln., which has a conc. $\frac{1}{10}N$- with respect to copper sulphate and $0{\cdot}4N$- with respect to ammonia, may be left in a stoppered bottle for a year without visible change. If, however, a soln. of the salt $CuSO_4.4NH_3.H_2O$ of conc. $\frac{1}{10}N$- with respect to copper, is kept under the same conditions, a blue, crystalline substance is gradually deposited, although the dry salt is very stable. This change begins directly the salt is dissolved and continues for some time, crystals becoming visible in about thirty-two hours. The crystalline substance has the composition $4CuO.SO_3.2\frac{2}{3}NH_3.4\frac{1}{3}H_2O$. On adding alcohol to the clear soln. from which the basic salt had separated, a compound was obtained in lilac-blue needles which had the composition of ordinary cuprammonium sulphate, $CuSO_4.4NH_3.H_2O$. The changes occurring are expressed by the equations: $36(CuSO_4.4NH_3.H_2O) + H_2O = 12CuO.3SO_3.8NH_3.13H_2O + 24(CuSO_4.4NH_4.H_2O)$ (precipitated by alcohol)$+9(NH_4)_2SO_4+22NH_3$. These results show that the behaviour of a freshly prepared $\frac{1}{10}N$-soln. of cuprammonium sulphate differs from that of a soln. of the same strength prepared from copper sulphate and ammonia.

V. Schwarzenbach[3] says that an explosion occurs when alcohol is poured over an intimate mixture of a mol of the salt with seven gram-atoms of iodine. When alcohol is added to a hot soln. of the tetrammino-salt, the precipitate is not a diammino-compound, but rather is the product a mixture of ammonium sulphate, etc. E. Sommerfeldt, and A. Johnsen have also studied this reaction. According to G. André, the salt is insoluble in conc. aq. ammonia, but it becomes more and more soluble as the conc. of the ammonia decreases. A. Bouzat found that when ammonia is passed into soln. of the salt cooled to —15°, higher compounds are not formed, while H. M. Dawson and J. McCrae say that more ammonia is taken up by the salt at low than at high temp. P. Latschinoff stated that in an atm. of dry ammonia, the molecule of water in $Cu(NH_3)_4SO_4.H_2O$ is replaced by a molecule of ammonia; D. W. Horn and E. E. Taylor say that the salt takes up ammonia when confined over sticks of potassium hydroxide and a little ammonia water in a desiccator. The ammonia displaced part of the water, but " the reaction is not a clean one, resulting in the formation of $Cu(NH_3)_5SO_4$, but one giving rise to mixed products containing basic salts or cupric oxide."

According to A. Destrem, zinc precipitates copper from the aq. soln. of the salt; and, according to N. W. Fischer, cadmium and lead precipitate copper slowly and imperfectly; arsenic forms copper arsenite; while antimony, bismuth, tin, and iron have no action. H. Schiff could not make double salts with the ammino-salts of copper.

T. Klobb[4] prepared **ammonium trisulphato-cuprate,** or *ammonium dicupric sulphate*, $(NH_4)_2SO_4.2CuSO_4$, by melting pentahydrated cupric sulphate with three times its weight of ammonium sulphate at about 300°. It forms pale green transparent prismatic crystals of sp. gr. 2·85; is soluble in water; almost insoluble in alcohol at 90°, but slowly colours the latter solvent blue. The crystals soon become blue and opaque on exposure to air and about 42 per cent. of water is absorbed. Dissociation commences at ordinary temp. in vacuo, for the salt loses $\frac{1}{1000}$th of its weight in 24 hrs. The salt shows signs of melting at about 200°; and at 350°, it decomposes, leaving a residue of cupric sulphate. D. M. Torrance and N. Knight found evidence of the dissociation of the complex into its component salts, when the diffusion of aq. soln. is measured.

Cupric sulphate unites with the sulphates of potassium, rubidium, cæsium, or with ammonium, forming a group of double salts, $CuSO_4.R_2SO_4.6H_2O$, which form pale blue monoclinic prisms. The double sodium salt is not isomorphous with its series. F. A. H. Schreinemakers studied the ternary system, $CuSO_4$—$(NH_4)_2SO_4$—H_2O, at 30°, and his results are indicated in Fig. 36. With the regular conventions, the curve *BC* represents the solubility with the solid phase $CuSO_4.5H_2O$; *CE*, with the solid phase $CuSO_4.(NH_4)_2SO_4.6H_2O$; and *EF*, with the solid phase $(NH_4)_2SO_4$. There are no other double salts stable in the soln. at this temp. J. J. Berzelius, E. Barchet, etc., prepared **ammonium disulphato-cuprate** or *ammonium cupric sulphate*, $(NH_4)_2SO_4.CuSO_4.6H_2O$, by crystallization from soln. of equimolecular parts of the component salts; A. Vogel obtained it from a mixed soln. of ammonium chloride and cupric sulphate; and A. Bouzat, from the soln. obtained by treating cupric tetrammino-sulphate with sulphuric acid. The pale blue monoclinic prisms were found by W. H. Miller to have the axial ratios $a:b:c=0·7433:1:0·4838$, and $\beta=106°\ 6'$. According to E. Mitscherlich, the crystals are isomorphous with the corresponding magnesium salt, and with many other salts with the alkali and heavy metals in place of ammonium. H. Kopp's value for the sp. gr. is 1·757; J. P. Joule and L. Playfair's, 1·894 at 3·9°; and H. Schiff's, 1·931. According to H. Schröder, the anhydrous salt has a sp. gr. 2·348. W. Beetz found the heat conductivity of aq. soln. sp. gr. 1·086 to be about 1·6 times that of water. P. A. Favre found the heat of soln. of an eq. of the salt at 8·1° in 71 eq. of water to be 5203 cals.; in 77 eq., 5441 cals.; and in 464 eq., 5622 cals. P. A. Favre and C. A. Valson found the heat of soln. of the single salt to be 2191 cals. A. Bouzat gives 9·85 Cals. for the heat of soln. of the anhydrous salt at 14°.

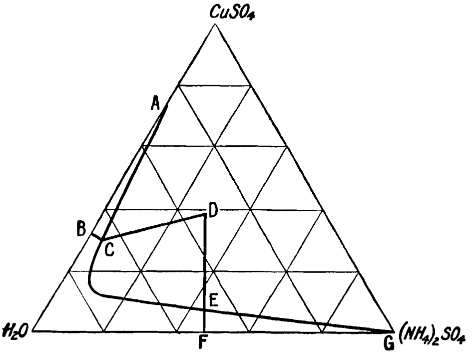

FIG. 36.—Equilibrium Curves in the Ternary System, $CuSO_4$—$(NH_4)_2SO_4$—H_2O, at 30°.

According to A. Vogel, the crystals effloresce in dry air; according to H. Rheineck, and A. Bouzat, they lose about 27·5 per cent. of water at 120° or 130°, and become white. At a higher temp. the crystals become green and melt, giving off water and ammonium sulphate. H. Rheineck found that during calcination at a low temp. the salt lost 39·1 per cent. weight, and gave a residue of cupric sulphate; K. Klüss found cuprous oxide was formed at a higher temp. A. Vogel found that 100 parts of boiling water dissolve 66·7 parts of the salt, most of which separates out on cooling. H. C. Jones and B. P. Caldwell observed that the salt is not all dissociated in aq. soln. even when the conc. is less than 0·0005*N*-; R. Engel found that a sat. soln. of ammonium sulphate at 0° can remain in contact with the double salt without acquiring more than a scarcely appreciable blue coloration.

Anhydrous copper sulphate and hydroxylamine, NH_2OH, in methyl alcohol soln. at—10°, furnish pale green crystals of **cupric hydroxylamine sulphate,** $CuSO_4.NH_2OH$, when the copper sulphate is in excess; and **cupric dihydroxylamine sulphate,** $CuSO_4.2NH_2OH$, when the hydroxylamine is in excess, and if in very large excess violet crystals of **cupric pentahydroxylamine sulphate,** $CuSO_4.5NH_2OH$. The latter compound is not very stable; the others are stable when dry or in water, alcohol, or ether at 0°. When warmed with water containing a drop of alkali cuprous oxide is precipitated. Cupric hydroxide and hydroxylamine sulphate, or a cold aq. soln. of hydroxylamine with $CuSO_4.2NH_2OH$, furnishes the basic salt $Cu_2OSO_4.2NH_2OH$. T. Curtius and F. Schrader prepared pale blue prismatic or tabular crystals of **cupric hydrazine sulphate,** $CuSO_4.(N_2H_5)_2SO_4$, from a mixed soln. of the component salts. A litre of water at 10° dissolves 0·871 grm. of the salt. They are decomposed with the evolution of gas by conc. nitric acid, hot conc. sulphuric acid, sodium hydroxide, and aq. ammonia.

C. F. Rammelsberg[5] believed that **lithium sulphato-cuprate** does not exist. F. A. H. Schreinemakers has studied the behaviour of the quaternary system, $CuSO_4—Li_2SO_4—(NH_4)_2SO_4.H_2O$, at 30°. F. A. H. Schreinemakers' study of the ternary system, $CuSO_4—Li_2SO_4—H_2O$, at 30°, also confirms this. As illustrated in the diagram, the curve *AB* represents the solubility of pentahydrated cupric sulphate, and *BC* of the hydrated lithium sulphate, $Li_2SO_4.H_2O$. No double salt appears. In addition to the three sulphates just indicated, there are two solid complexes involved in the equilibria, hexahydrated ammonium disulphato-cuprate, $(NH_4)_2.SO_4.CuSO_4.6H_2O$, and ammonium sulphato-lithiate, $(NH_4)_2SO_4.Li_2SO_4$.

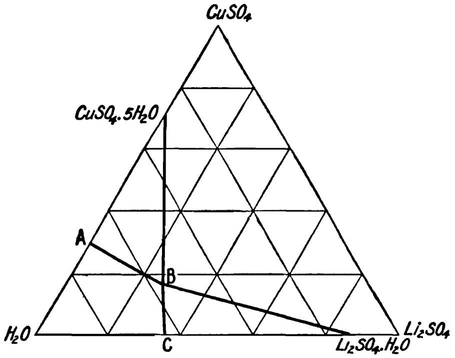

FIG. 37.—Equilibrium Curves of the Ternary System, $Li_2SO_4—CuSO_4—H_2O$, at 30°.

The mineral *kröhnkite* occurs in Bolivia and Peru,[6] its composition corresponds with $Na_2SO_4.CuSO_4.2H_2O$, or dihydrated **sodium disulphato-cuprate,** or *sodium cupric sulphate.* T. Graham[7] crystallized this salt from soln. of the component salts. He said that like other double salts of sodium sulphate it cannot be formed directly because it is decomposed by water, and this even when it is attempted to form it by double decomposition from sodium hydrosulphate; in general, a large quantity of the components are separately deposited before the double salt appears. The range of stability of the salt in soln. of different composition is indicated in Table X. F. Rüdorff, and G. Massol and M. Maldès made a few measurements of the solubility of cupric and sodium sulphates in water; and J. Koppel's results for the mol. proportions of $CuSO_4$ and of Na_2SO_4 in 100 mols of water at different temp. are indicated in Table XI. H. W. Foote also studied the ternary system, $Na_2SO_4—CuSO_4—H_2O$, at 12° and 25°, and at the lower temp. he found but one univariant system when the two single salts are present; at the higher temp., he found two univariant systems with solid phases double salt and cupric sulphate, and double salt and sodium sulphate.

	Solid phases	Per cent. H_2SO_4	Per cent. $CuSO_4$
12°	$Na_2SO_4.10H_2O$	9·54	none
	$Na_2SO_4.10H_2O+CuSO_4.5H_2O$	10·44	14·65
	$CuSO_4.5H_2O$	none	16·15
25°	$Na_2SO_4.10H_2O$	21·90	none
	$Na_2SO_4.10H_2O+Na_2Cu(SO_4)_2.2H_2O$	21·20	6·28
	$CuSO_4.5H_2O+Na_2Cu(SO_4)_2.2H_2O$	10·95	16·85
	$CuSO_4.5H_2O$	none	18·47

H. W. Foote has also investigated the quaternary system, $Na_2SO_4-CuSO_4-H_2SO_4-H_2O$, at 12° and at 25°, but found no other double salts than those here indicated. A. Massink studied the ternary system, $Na_2SO_4-CuSO_4-H_2O$, at 20° and 35°, and found the region of stability of the double salt, $Na_2Cu(SO_4)_2.2H_2O$.

TABLE XI.—MUTUAL SOLUBILITY OF SODIUM AND CUPRIC SULPHATES.

$CuSO_4.5H_2O+Na_2SO_4.10H_2O$			$Na_2Cu(SO_4)_2.2H_2O$			Double salt$+CuSO_4.5H_2O$			Double salt$+Na_2SO_4.10H_2O$		
	$CuSO_4$	Na_2SO_4		$CuSO_4$	Na_2SO_4		$CuSO_4$	Na_2SO_4		$CuSO_4$	Na_2SO_4

The salt forms pale turquoise-blue crystals in octahedral prisms, or needles. They belong to the monoclinic system, and, according to L. Darapsky, and C. Palache and C. H. Warren, the axial ratios are $a:b:c=0·4463:1:0·4353$, and $\beta=107° 19'$. L. Darapsky gives 3 for the hardness and 2·061 (4°) for the sp. gr. of the mineral. J. Koppel found that the salt loses no water at 100°, but after some hours at 160°, it becomes green and anhydrous. The anhydride again takes up water with the development of much heat. The salt melts below a red heat without decomposition, forming a dark green liquid; it loses sulphur trioxide at a red heat. C. Palache and C. H. Warren found *kröhnkite* loses most of its water at 150°, and the rest at 350°. T. Graham found the salt deliquesces slowly in air, and is decomposed into its component salts by water. P. Rohland gives 21° for the transition point: $CuSO_4.5H_2O+Na_2SO_4.10H_2O \rightleftharpoons Na_2Cu(SO_4)_2.2H_2O+13H_2O$; and J. Koppel gives 16·7°, and he adds that 17·7° is the lowest temp. at which the pure double salt is stable in contact with the soln. C. Palache and C. H. Warren considered the emerald-green monoclinic pyramidal crystals of *natrochalcite* to be a basic *sodium hydroxy-sulphato-cuprate*, $Na_2SO_4.Cu(OH)_2.3CuSO_4.3H_2O$. This mineral has the axial ratios $a:b:c=1·423:1:1·214$, and $\beta=118° 42·5'$; the hardness is 4·5, and the sp. gr. 2·33. It loses water slowly at 150°, and between 350° and 520° it decomposes, giving off sulphur trioxide. It is sparingly soluble in water, easily soluble in acids.

T. Graham [8] found **potassium disulphato-cuprate,** $K_2SO_4.CuSO_4.6H_2O$, to be formed by crystallization from a soln. of cupric sulphate and potassium sulphate or hydrosulphate in equimolecular proportions. R. Böttger, and J. I. Pierre also obtained this salt by crystallization from a soln. of cupric oxide or carbonate in an aq. soln. of potassium hydroxide. A. E H. Tutton obtained the best crystals by the slow evaporation of soln. containing the two constituent sulphates in equi-molecular proportions. J. E. Trevor added a crystal of one component to a sat. soln. of the double salt, and the latter separated out until the soln. was in equilibrium. J. I. Pierre believed the salt was a heptahydrate, not a hexahydrate. D. M. Torrance and N. Knight found evidence of the dissociation of the complex salt in aq. soln. into its component salts, when the diffusion coeff. was measured. Crystals of hexahydrated **rubidium disulphato-cuprate,** $Rb_2Cu(SO_4)_2.6H_2O$, are obtained in a similar manner and more readily than is the case with the potassium salt. The crystals of hexahydrated **cæsium disulphato-cuprate,** $Cs_2Cu(SO_4)_2.6H_2O$, were even more readily obtained than the rubidium salt. G. Brügelmann obtained the potassium salt by crystallization from mixed cold sat. soln. of potassium dichromate and cupric sulphate. A. Scacchi found hexahydrated potassium disulphato-cuprate in the lava of Vesuvius, and he called it *cyanochroite*.

According to A. E. H. Tutton, the light greenish-blue crystals of all three salts are isomorphous and crystallize in the monoclinic system; the habit of the potassium salt is more or less tabular, that of the rubidium salt is tabular or prismatic; and that of the cæsium salt is more or less pyramidal. The axial ratios of the potassium salt are $a:b:c=0·7490:1:0·5088$, with $\beta=75°\ 32'$; those of the rubidium salt, $a:b:c=0·7490:1:0·5029$, with $\beta=74°\ 42'$; and those of the cæsium salt, $a:b:c=0·7429:1:0·4946$, with $\beta=73°\ 50'$. According to E. Mitscherlich, the crystals are also isomorphous with those of the corresponding ammonium magnesium salt, $(NH_4)_2SO_4.MgSO_4.6H_2O$. The reported values of the sp. gr. of the potassium salt—by H. Kopp, H. Schiff, P. A. Favre and C. A. Valson, J. P. Joule and L. Playfair, and H. Schröder—vary from 2·137 to 2·224. A. E. H. Tutton's value 2·2239 (20°/4°) is probably the best representative value. F. L. Pérrot's value for the sp. gr. of the rubidium salt is 2·58 (15°), A. E. H. Tutton's value 2·5699 (20°/4°); and the latter gives 2·8540 (20°/4°) for the cæsium salt. A. E. H. Tutton's values for the mol. volume of potassium disulphato-cuprate is 199·4; of the rubidium salt, 207·9; and of the cæsium salt, 219·3. According to T. Graham, the potassium salt loses nearly half its water of crystallization when heated to 100° in air; at a higher temp., T. Graham, E. Böttger, and J. I. Pierre found the anhydrous salt as a pale green almost colourless powder, which was observed by F. C. Vogel to lose some acid when melted. S. U. Pickering says:

> When heated at 100°, this hydrated salt parted quickly with the whole of its water, leaving the anhydrous salt in the form of a blue powder as dark in colour as the hydrated substance itself: when, however, this blue salt was heated to a temp. of 150°–200°, it was found to lose its colour and become white, or very nearly white; this white modification in its turn underwent a change when the temp. was further raised to about 300° or 400°, and became again blue or bluish-green. This third modification remained apparently unchanged by any additional increment of temp. till the m.p. of the salt was reached at a low red heat. The molten salt forms an opaque green liquid, which solidifies to form a glassy mass; as soon, however. as the temp. falls sufficiently low, this glass crumbles into an opaque blue powder resembling in every respect the blue modification obtained at 400°.

S. U. Pickering adds that at 18·25°, the heat of the formation of the α-salt is $K_2SO_4+CuSO_4=\alpha\ K_2Cu(SO_4)_2-571$ cals. (endothermal); similarly for the β-salt, 2649 cals. (exothermal); and for the γ-salt, 731 cals. (exothermal). The heat of transformation of the α- to the β-salt is 3220 cals. (exothermal), and of the β- to the γ-salt, —1918 cals. (endothermal). According to P. A. Favre, the sp. gr. of the anhydrous salt is 2·784 (20·5°), and, according to H. Schröder, the salt which has been melted, solidified, and ground, has a sp. gr. 2·754 to 2·789. The anhydrous salt in moist air becomes blue.

The three alkali copper sulphates are readily soluble in water. F. S. Locke gives for the solubility of the potassium salt in a litre of water at 25°, 116·9 grms. or 0·354 mol. of the anhydrous salt; the corresponding numbers for the rubidium salt are 102·8 grms. or 0·241 mol.; and for the cæsium salt, 460·0 grms. or 0·882 mol. P. A. Favre and C. A. Valson give 1·0713 (20·2°) for the sp. gr. of a normal soln. of the potassium salt; and the contraction in the joint vol. of the solvent and the anhydrous salt is 18·5 c.c. per litre; and of the hydrated salt, 6·1 c.c. F. M. Raoult gives for the mol. lowering of the f.p. of the soln., ±58. T. Griffiths gives 102·8° for the b.p. of a 40 per cent. soln. According to J. Thomsen, the heat of formation, $CuSO_4+K_2SO_4=CuK_2(SO_4)_2+20$ Cals.; and $CuSO_4+K_2SO_4+6H_2O=CuK_2(SO_4)_2.6H_2O+22·99$ Cals. S. U. Pickering gives 9709 cals. for the heat of soln. of a mol of the α-salt at 18·25° in 800 mols of water; 6489 cals. for the β-salt; and 8407 cals. for the γ-salt. The respective mol. sp. hts. of the α-, β-, and γ-soln. are 56·025, 51·240, and 58·735. The heat of soln. of the hexahydrated salt at 18° is —13738 cals., and for the anhydrous salt, 9709 cals. P. A. Favre and C. A. Valson obtained rather lower values. S. U. Pickering found the heat of hydration for each mol of water to be 2330 cals., and J. Thomsen gives for the heat of soln. of $K_2Cu(SO_4)_2$ with nH_2O :

n . .	0	1	2	3	4	5	6
Cals. .	+9396	+4102	+1210	—4295	—7197	—10460	—13570
Diff. .		5294	5312	3085	2902	3263	3110

so that if the results be plotted there is a break for $n=2$, corresponding with a possible dihydrated salt, $K_2Cu(SO_4)_2.2H_2O$.

A. E. H. Tutton's mean values for the indices of refraction of the potassium, rubidium, and cæsium salts for the different rays are :

	Li-line	*C*-line	*Na*-line	*Tl*-line	*F*-line	*G*-line
K . .	1·4834	1·4838	1·4864	1·4889	1·4922	1·4975
Rb . .	1·4878	1·4882	1·4906	1·4933	1·4966	1·5013
Cs . .	1·5032	1·5036	1·5061	1·5089	1·5123	1·5174

The mol. refractions of the hexahydrated potassium disulphato-cuprates are respectively 97·29, 102·54, and 111·80. The specific refractions and specific dispersions, by Lorenz and Lorentz's formula, are :

	C-ray.			*G*-ray.			Dispersion.		
	α	β	γ	α	β	γ	α	β	γ
K .	0·1282	0·1295	0·1325	0·1305	0·1322	0·1354	0·0027	0·0027	0·0029
Rb .	0·1148	0·1122	0·1147	0·1143	0·1148	0·1174	0·0025	0·0026	0·0027
Cs .	0·1035	0·1037	0·1053	0·1059	0·1061	0·1077	0·0024	0·0024	0·0024

According to E. Rieger, a part of the copper is present in the soln. as a complex salt, which, according to J. H. van der Waals, is dissociated into its component simple salts, and J. E. Trevor found that the potassium salt diffused more rapidly through a dialyzer than the cupric salt. E. Rieger found the specific electrical conductivity of aq. soln. at 18° to be 515×10^{-4} for 0·291 mol of the salt per litre ; and 378×10^{-4} for 0·191 mol of the salt per litre. J. Trötsch has also measured the conductivity of soln. of the potassium salt. The transport numbers of the potassium salt were measured by J. F. Daniell and W. A. Miller, and E. Rieger.

H. Schiff believed that he had made *ammonium potassium disulphato-cuprate*, $K(NH_4)SO_4.CuSO_46H_2O$; and E. Sommerfeldt obtained a bluish-green product by adding ammonia to a mixed soln. of potassium and cupric sulphates, which is probably mixed crystals of potassium sulphate with cupric tetrammino-sulphate. According to T. Graham and C. Brunner, when the aq. soln. of potassium disulphato-cuprate is heated between 60° and 100°, a pale green crystalline *trihydrated potassium hydroxy-tetrasulphato-cuprate*, $K_2SO_4.Cu(OH)_2.3CuSO_4.3H_2O$, separates out, and is not again dissolved. J. F. Persoz and F. Reindel say different basic cupric sulphates are formed when a soln. of potassium disulphato-cuprate is repeatedly boiled—the former says $3CuO.SO_3.2H_2O$; the latter, $7CuO.2SO_3.7H_2O$. F. L. Pérrot says that no basic salt is formed if the rubidium salt is boiled with water.

§ 27. The Basic Cupric Sulphates

Several basic cupric sulphates have been reported. Various hydrated or anhydrous forms of products with the ratio $CuO : SO_3$ as 10 : 1, 5 : 1, 4 : 1, 7 : 2, 3 : 1, 11 : 4, 8 : 3, 5 : 2, 7 : 3, and 2 : 1 have been reported. The best defined of these are possibly the salts with $CuO : SO_3$ as 2 : 1 ; 4 : 1 aq. ; 5 : 2 aq. ; and 8 : 3 aq., although all are possibly mixtures or solid soln. of cupric oxide or hydroxide, cupric sulphate, and water. For example, in their study of the ternary system, $CuO—SO_3—H_2O$, J. M. Bell and W. C. Tabor digested ignited copper oxide or cupric hydroxide with sulphuric acid in order to find if basic sulphates are formed. The line *AB*, Fig. 33, represents the composition of the residue in equilibrium with the soln. The lines joining corresponding points of soln. and residue fall between *NA* and *MB* ; they do not meet in a point within the triangle. The points *M* and *N* represent the two basic sulphates which have the best status in literature, namely $5CuO.2SO_3.5H_2O$, and $4CuO.SO_3.4H_2O$. This indicates that the solid phases consist of a series of solid soln. of cupric oxide, sulphur trioxide, and possibly water ; but there is nothing to show that definite basic compounds are formed. The soln. which exist in equilibrium with the solid soln. range from pure water to a sat. soln. of cupric sulphate. The composition of the soln. containing sulphuric acid, water, and copper sulphate, in equilibrium with the solid phase, is represented by *BE*, Fig. 33, which is plotted from the data indicated in Table VIII. The weakness of the evidence for the hypothesis, based largely on analysis, that the basic cupric sulphates are definite compounds, will be emphasized best by a review of their modes of preparation. K. Griessbach has also studied this subject.

S. U. Pickering prepared a blue product of the composition *cupric enneaoxysulphate*, $10CuO.SO_3$, that is $CuSO_4.9CuO$, by the action of 0·9*N*-alkali on a dil. soln. of cupric sulphate. He says : " When an alkali is added gradually to a weak soln. of copper sulphate, a point is reached when the liquid begins to show a slight alkaline reaction, but this reaction is temporary, and more alkali must be added before a permanent alkalinity is obtained. The gradual absorption of alkali after the first temporary alkalinity occurs extends over two or three days. The eq. of alkali required to produce the initial and permanent alkaline reaction, together with the eq. required to precipitate the copper completely, were found to be :

	Precipitation complete.	Initial alkalinity.	Permanent alkalinity.
BaO	—	0·903	0·903
CaO	0·752	0·870	0·908
Na_2O	0·766	0·842	0·901
Li_2O	—	0·808	0·903
K_2O	(0·75)	0·805	0·893

The precipitation of the metal is complete when the alkali reaches 0·75 eq., an amount showing that the basic sulphate then formed must have the formula $4CuO.SO_3$. This sulphate is evidently converted into a more basic one by further addition of alkali, and permanent alkalinity is reached in all five cases when the amount added amounts to 0·9 eq. This represents the formation of $10CuO.SO_3$. In only one instance, that of baryta, is the point of initial alkalinity identical with that of permanent alkalinity, an exception probably connected with the insolubility of barium sulphate. With lithia and potash, initial alkalinity occurs with 0·8 eq., but with soda and lime the values are higher. It seems most probable, however, that in all cases the point of initial alkalinity indicates the existence of a basic sulphate intermediate between the first and final products, although in some cases it may be impossible to obtain this intermediate compound unmixed with a certain amount of the final product, and hence the quantity of alkali absorbed is abnormally large." The basic copper sulphates have been in use since 1883 as a fungicide under the name Bordeaux mixture or *bouillie bordelaise.* S. U. Pickering adds:

> The discovery of its value was accidental. It had been the practice in the vineyards in the neighbourhood of Bordeaux to sprinkle those vines which were near a road with verdigris in order to give them the appearance of having been poisoned, and so to prevent depredations. A mixture of lime and copper sulphate was soon substituted for the verdigris, being cheaper, and, when the downy mildew of America (*Peronospora viticola*) made its appearance in Europe, it was noticed (1882) that those vines which had received the copper dressing were those which kept their leaves longest, and were least affected by the disease.

The so-called "normal" or "1·6" mixture is made by adding 1·1 parts of lime made into milk of lime to 1·6 parts of crystallized cupric sulphate dissolved in 100 parts of water. Occasionally, stronger or weaker mixtures are used, and sometimes the proportion of lime is increased so as to equal that of the copper sulphate. For complete decomposition, the crystallized sulphate requires one-fifth of its weight of pure lime; consequently, the lime used in practice is in considerable excess of that required for complete decomposition even when an allowance is made for impurities. G. Tripodi, and L. Sostegni found Bordeaux mixture to be stable in air, and not affected by atm. carbon dioxide, but it is converted by aq. ammonia or ammonium nitrate into $4CuO.SO_3$.—*vide* cupric calcium sulphate. R. Kane[1] prepared what he regarded as $8CuO.SO_3.12H_2O$ by precipitating copper from a soln. of the sulphate, and stopping just short of the point where the liquid becomes alkaline. S. U. Pickering also prepared a similar apple-green substance by the action of 9 mols of Na_2O in the form of sodium hydroxide on 10 mols of cupric sulphate. D. Smith failed to confirm the existence of R. Kane's product, and he recorded the formation of pale blue *cupric tetroxysulphate,* $5CuO.SO_3.6H_2O$, or $CuSO_4.4CuO.6H_2O$, or $CuSO_4.4Cu(OH)_2.2H_2O$. S. U. Pickering obtained a similar precipitate by the action of alkali eq. to 0·8 mol of Na_2O on 10 mols of cupric sulphate. The colour obtained has different tints of blue, according as CaO, K_2O, or Li_2O is the alkali used.

Trioxysulphates with 2, $2\frac{1}{2}$, 3, $3\frac{1}{2}$, 4, 5, and $16H_2O$ as well as the anhydrous salt have been reported. S. U. Pickering precipitated a product, *cupric trioxysulphate,* $4CuO.SO_3$, that is $CuSO_4.3CuO$, by the action of 134 c.c. of lime water on a soln. of a gram of crystallized cupric sulphate. He also used soln. containing 0·75 eq. of BaO, CaO, Li_2O, Na_2O, or K_2O in place of lime water. D. W. Horn and E. E. Taylor obtained it by the action of a soln. of sodium carbonate on one of cupric tetrammino-sulphate; and A. Recoura, by the action of a cold or hot soln. of cupric sulphate on freshly precipitated cupric hydroxide. S. U. Pickering obtained a blue flocculent precipitate of $4CuO.SO_3.2H_2O$, by the action of a cold or hot soln. of sodium acetate on cupric sulphate; the precipitate is not changed by heating it in air at 100°. D. Smith obtained $4CuO.SO_3.3H_2O$ by the action of just enough potassium hydroxide on a soln. of copper sulphate to ensure that no copper remains in soln., by the incomplete precipitation of cupric sulphate from a soln. of cupric sulphate by sodium carbonate, and by heating $4CuO.SO_3.5H_2O$ between 200° and 240° when two-fifths of the water is expelled; C. Roucher digested finely-powdered $2CuO.SO_3$ in cold water, and separated the basic salt from the soln. of cupric sulphate by filtration. S. U. Pickering heated $4CuO.SO_3.2NH_3.5H_2O$ to 100° for 20 hours; L. Sabbatani boiled cupric tetrammino-sulphate with water; and W. Hampe boiled a neutral soln. of cupric sulphate. It is not definitely settled whether the mineral *brochantite* is $4CuO.SO_3.3H_2O$ or $7CuO.2SO_3.5H_2O$. It crystallizes in rhombic pyramids, and A. Werner suggests that it is a hexol-compound, $[Cu\{Cu(OH)_2\}_3]SO_4$.

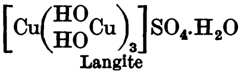
W. Casselmann reported the formation of $4CuO.SO_3.3\frac{1}{2}H_2O$ when a dil. soln. of cupric sulphate is boiled with acetate of potassium, sodium, ammonium, magnesium, manganese, cobalt, nickel, zinc, or cadmium; $6CH_3COONa+4CuSO_4+3H_2O=3Na_2SO_4+4CuO.SO_3+6CH_3COOH$. Sodium formate, propionate, or valerate may be used instead of the acetate. He also made it by the action of sulphates of calcium, strontium, silver, and those previously enumerated on cupric acetate. K. Klüss prepared the same salt by the action of an aq. soln. of cupric sulphate, $CuSO_4.5H_2O$ (24 grms. per litre), on a soln. of sodium acetate (16 grms. per litre). G. André described the product $4CuO.SO_3.16H_2O$, which he obtained by saturating a hot soln. of ammonium sulphate with cupric oxide, and pouring the liquid into water.

J. L. Proust (1800), and F. Field (1862) made a bright green powder, $4CuO.SO_3.4H_2O$, by the incomplete precipitation of a soln. of cupric sulphate with potassium hydroxide. The product was washed with water. J. Kühn recommended adding insufficient of the alkali to make the soln. react alkaline; and S. U. Pickering used less than $1\frac{1}{2}$ mols of potassium hydroxide to one of cupric sulphate in the cold. A. Vogel and C. Reischauer recommended the use of aqua ammonia, and add that if too much is employed, some cupric hydroxide is formed which later causes the precipitate to blacken. S. U. Pickering also digested the precipitate obtained by adding an excess of potassium hydroxide to a soln. of cupric sulphate for some hours in the cold with a 10 per cent. soln. of cupric sulphate; and J. L. Proust digested cupric hydroxide dried at 100° under similar conditions—cupric oxide does not react in this way. P. Sabatier made prismatic crystals of this product by digesting copper oxide, or hydroxide, or $4CuO.H_2O$, or $Cu(OH)_2.3CuO$, with a conc. soln. of cupric sulphate. E. C. Sullivan obtained a precipitate analogous to langite or brochantite by the action of natural potassium, sodium, or magnesium silicate on a soln. of cupric sulphate. A. Mailhe digested cupric sulphate with nickel oxide, hydroxide, or carbonate. R. Kane obtained the same product by washing with water the green powder obtained by heating cupric ammino-sulphate. S. U. Pickering boils the dark blue precipitate obtained by adding water to an ammoniacal soln. of cupric sulphate with a conc. soln. of cupric sulphate for 10 minutes; but if the soln. is cold, the product has the composition $6CuO.2SO_3.5H_2O$. A. Vogel and C. Reischauer say that the product obtained by digesting metallic copper with ammonium sulphate soln. in air is $4CuO.SO_3.4H_2O$ contaminated with cupric hydroxide. J. Tüttscheff boiled cupric oxide with a soln. of ammonium sulphate; and evaporated nearly to dryness; and washed with water. The apple-green product was dried at 110°.

According to A. H. Church, P. Berthier, F. Pisani, A. Foullon, F. A. Genth, and C. F. Rammelsberg, this hydrated basic sulphate corresponds with the mineral *langite*, $4CuO.SO_3.4H_2O$, or $CuSO_4.3CuO.4H_2O$, or $CuSO_4.3Cu(OH)_2.H_2O$, or $Cu_4(OH)_6SO_4.H_2O$. According to N. S. Maskelyne, the blue or greenish-blue mineral crystallizes in the rhombic system, and has the axial ratios $a:b:c=0{\cdot}5347:1:0{\cdot}6346$, hardness 2·5, and sp. gr. 3·48 to 3·50. G. Tschermak applies the term *devilline* to a mineral which is probably a mixture containing langite. According to J. Kühn, and J. Tüttscheff, the artificial product does not lose water between 150° and 180°, but when heated for a long time at 180°, it loses 1·22 per cent., and with a stronger heat, both water and sulphur trioxide are given off. S. U. Pickering said that 100 c.c. of cold water dissolve 0·0017 grm. of the salt, and that it is not blackened when heated for a long time with water; while J. Tüttscheff, and P. Sabatier say that it is insoluble and unchanged in cold water. A. Werner regards langite as a hexol-sulphate:

$$\left[\mathrm{Cu}\left(\begin{matrix}\mathrm{HO}\\ \mathrm{HO}\end{matrix}\mathrm{Cu}\right)_3\right]\mathrm{SO_4}$$

Brochantite



$$\left[\mathrm{Cu}\left(\begin{matrix}\mathrm{HO}\\ \mathrm{HO}\end{matrix}\mathrm{Cu}\right)_3\right]\mathrm{SO_4.H_2O}$$

Langite

When $CuSO_4.CuO.4H_2O$ is treated with a sat. soln. of cupric sulphate, P. Sabatier found that the basic sulphate passes into green-coloured $5CuO.2SO_3.5H_2O$, which loses cupric sulphate when treated with water, and forms langite. J. M. Bell and W. C. Tabor's study of the ternary system, $CuO—SO_3—H_2O$, lent no support to the hypothesis that any definite basic compound is formed; the reported products are members of a series of solid soln. ranging between $5CuO.2SO_3.5H_2O$ and

$8CuO.SO_3,12H_2O$. Three hydrates of *cupric heptoxydisulphate*, $CuO : SO_3=7 : 2$, have been reported with respectively 5, 6, and $7H_2O$. According to J. L. Proust, cupric hydroxide or freshly-precipitated carbonate passes into the heptahydrated salt, $7CuO.2SO_3.7H_2O$, or $2CuSO_4.5Cu(OH)_2.2H_2O$, or $2CuSO_4.5CuO.7H_2O$, when digested with a soln. of cupric sulphate, and he also made it by the action of aq. potassium hydroxide or aq. ammonia on an excess of cupric sulphate. Similar methods were employed by D. Smith, J. J. Berzelius, M. le Blanc, L. Hünefeld, T. Thomson, and C. Roucher. According to T. Graham, the precipitate carries down with it some potassium sulphate which cannot be removed by washing. E. Brunner used zinc oxide in place of potassium hydroxide, and found the precipitate to be free from zinc. F. Reindel and E. Brunner treated the double salt, $K_2SO_4.CuSO_4$, with hot water, or boiled cupric sulphate with potassium sulphate. G. André digested cupric tetrammino-sulphate with water and metallic copper until the black mass became apple-green; the decanted liquid was treated anew with metallic copper; he also heated cupric oxide with a soln. of ammonium sulphate in a sealed tube at 200°; and he mixed equal volumes of sat. soln. of cupric sulphate and tetrammino-sulphate, or else heated the mixture in a sealed tube at 150°. The product is a pale-green or bluish-green powder. F. Reindel, and T. Graham found that at 120°, the product loses only 1 or 2 per cent. of hygroscopic moisture, nothing is lost at 200°, and 2 mols of water are lost at 250°; when further heated, the salt is so changed that cupric sulphate can be extracted with boiling water, but, according to J. L. Proust, if the salt be left to stand for some time, the constituents recombine. The salt is not changed when washed with cold water, it dissolves in boiling water and in acids; according to G. André, the salt is partially soluble in aq. ammonium sulphate; J. Habermann obtained a bluish-green micro-crystalline powder of the hexahydrated salt, $7CuO.2SO_3.6H_2O$, or $2CuSO_4.5CuO.6H_2O$, or $2CuSO_4.5Cu(OH)_2.H_2O$, by dropping a conc. soln. of ammonia or sodium carbonate, with constant agitation, into a conc. boiling soln. of cupric sulphate. The product is insoluble in cold or hot water; it does not lose water at 100° in vacuo; when heated to 190° it loses one per cent. of water without perceptible colour change; between 280° and 290°, it suffers a continuous loss of weight and changes its colour; at 320° the colour changes to a dirty green; and at a dark red heat it becomes black. The salt loses its water at a dark red heat, forming an anhydrous product, $7CuO.2SO_3$, or $2CuSO_4.5CuO$. A. C. Becquerel obtained crystals of the pentahydrated salt, $7CuO.2SO_3.5H_2O$, or $2CuSO_4.5Cu(OH)_2$, by allowing porous limestone to stand in a soln. of cupric sulphate; S. Meunier used freshly precipitated cupric carbonate in place of limestone; he also used pieces of galena, when the time occupied is 11 months; and L. Grimbert and M. Barré used spring water with calcium bicarbonate in soln. L. Bourgeois heated a soln. of urea in a sealed tube at 130°; J. Habermann and R. Ehrenfeld added 50 c.c. of $2N$-sodium hydroxide to a soln. of 5 grms. of crystalline cupric sulphate in 200 c.c. of water, washed the product in cold water, alcohol, and ether, and dried the mass at 100°; and S. Meunier allowed an ammoniacal soln. of cupric sulphate to stand for a long time exposed to the air. G. Rousseau and G. Tité found that with water and magnesium carbonate at 240° or 250° the product gives cupric oxide pseudomorphic after bronchantite.

This compound is supposed to be represented in nature by the mineral *brochantite*. This view is based on the analyses of P. Berthier, A. H. Chester, I. Domeyko, F. Field, G. Forchhammer, E. Ludwig, W. Lindgren and W. F. Hillebrand, F. von Kobell, N. S. Maskelyne, F. Pisani, F. Sandberger, G. Tschermak, and R. Warington. It occurs in dark green or emerald-green prismatic crystals belonging to the rhombic system, and with the axial ratios $a : b : c=0·7739 : 1 : 0·4871$. The hardness ranges between 3·5 and 4·0; and the sp. gr. 3·78 to 3·90. Several other formulæ have been ascribed to this mineral, $4CuO.SO_3.3H_2O$, *vide supra*; $7CuO.2SO_3.6H_2O$; $3CuO.SO_3.2H_2O$, *vide infra*; $3CuO.SO_3.3H_2O$, *vide infra*.

Five hydrated forms of *cupric dioxysulphate*, $3CuO.SO_3$, or $CuSO_4.2CuO$, have been reported respectively with $1\frac{1}{2}$, 2, $2\frac{1}{2}$, 3, and $4H_2O$. According to A. Brĕzina, the composition of the mineral *urvölgyite*, or *herrengrundite*, $3CuO.SO_3.4H_2O$, corresponds with that of a basic cupric sulphate; others like C. F. Rammelsberg, and B. von Schenck[2] believe it to be a cupric calcium sulphate, $CaSO_4.3Cu(OH)_2.CuSO_4.3H_2O$, or $CaSO_4.4CuO.SO_3.6H_2O$. J. J. Berzelius and F. Wibel prepared grass-green crystals corresponding with $3CuO.SO_3.3H_2O$ by treating cupric sulphate with not quite sufficient ammonia for complete precipitation, washing and drying the product, and then heating it in a retort. F. Wibel also heated in a sealed tube at 210° a soln. of cupric sulphate with finely divided silicates, anthophyllite, or hornblende, and he attributes this formula to the mineral brochantite. S. U. Pickering obtained a bluish-green product, $3CuO.SO_3.1\frac{1}{2}H_2O$, by boiling a neutral aq. soln. of cupric sulphate; and C. Roucher by exposing the $CuSO_4.CuO$ to moist air. F. Reindel treated an excess of a boiling soln. of cupric sulphate with ammonia, and well washed the product with water; J. Habermann used sodium carbonate for the precipitation; while L. Marchlewsky and J. Sachs heated on a water-bath a sat. soln. of cupric sulphate with an excess of dimethyl or diethyl-aniline, washed with cold water, alcohol, and ether, and dried the bluish-green mass in a desiccator. The product does not decompose below 270°, but does so above that temp. It is very soluble in hydrochloric acid.

W. A. Shenstone, and S. U. Pickering prepared the dihydrated salt, $3CuO.SO_3.2H_2O$, that is, $CuSO_4.2Cu(OH)_2$, by heating cupric sulphate with water in a sealed tube at 200°, and washed the resulting solid with water; N. Athanasescu added a little cupric oxide to the tube before sealing it up; and C. L. Berthollet, E. Brunner, D. Smith, and F. Reindel used zinc oxide. C. Roucher heated $2CuO.SO_3$ with boiling water; F. Reindel precipitated an excess of a boiling soln. of cupric sulphate with sodium or ammonium carbonate, or basic magnesium carbonate; W. Spring and M. Lucion treated cupric hydroxide with a soln. of magnesium or manganese sulphate; and J. F. Persoz believed that the process employed by F. Reindel and E. Brunner furnished this salt, and not $7CuO.2SO_3.7H_2O$, as was supposed—he stated that this is confirmed by the work of C. Freese on basic cupric chromate. It has been suggested that the emerald-green mineral *brochantite* has this composition, and F. W. Hillebrand gave the name *antlerite* to a variety of this mineral from Arizona. According to H. A. Miers, the mineral *stelznerite* occurs in bipyramids belonging to the rhombic system with axial ratios $a:b:c=0·4971:1:0·6881$. A. Arzruni obtained similar numbers. The sp. gr. is 3·884 (4°). According to F. Reindel, the product is stable at 270°, and loses water slowly at 357°, and all the water is lost at 448°. According to W. Spring and M. Lucion, the product decomposes at 15° in 600 to 648 hrs., at 30° in 57 hrs., and at 45° in 29 to 33 hrs. It is insoluble in water, and soluble in dil. sulphuric acid. According to W. A. Shenstone, it redissolves in a few weeks in its own mother liquid. A. Steinmann, and V. Merz and W. Weith prepared bright green microscopic crystals of $3CuSO_4.SO_3.1\frac{1}{2}H_2O$ by heating a cold sat. soln. of cupric sulphate in a paraffin bath between 200° and 250°. The product decomposes readily, is insoluble in water, but very soluble in warm acids.

According to F. Clowes and R. M. Caven,[3] the basic sulphate which S. U. Pickering formed by boiling a soln. of cupric sulphate, and thought to be $6CuO.2SO_3.5H_2O$, has the composition *cupric heptoxy-tetrasulphate*, $4CuSO_4.7Cu(OH)_2.H_2O$, or $11CuO.4SO_3.8H_2O$. R. Schütze reported the formation of *octahydrated cupric trioxy-trisulphate*, $8CuO.3SO_3,8H_2O$, in green needles by boiling a conc. soln. of cupric sulphate; and L. Marchlewsky and J. Sachs, the green decahydrated salt, $8CuO.3SO_3.10H_2O$, by the action of an excess of quinoline on a sat. soln. of cupric sulphate. This salt decomposes at 200°. F. Wibel heated 7 grms. of wollestonite with 30 c.c. of cupric sulphate soln. (1·965 grms. copper) to 100° in a sealed tube, and obtained what he regarded as *trihydrated cupric trioxy-disulphate*, $5CuO.2SO_3.3H_2O$, or $2CuSO_4.3Cu(OH)_2$. P. Sabatier obtained green crystals of the pentahydrated salt, $5CuO.2SO_3.5H_2O$, by the action of a conc. soln. of cupric sulphate on $4CuO.SO_3.4H_2O$; the latter is reformed by the action of cold water on $5CuO.2SO_3.5H_2O$. E. Weinschenk made $5CuO.2SO_3.6H_2O$ by the action of an excess of ammoniacal cupric sulphate on iron wire in a sealed tube at 150°. The composition of the crystals was determined by A. Weisbach. Green microscopic crystals of this product occur in nature as *arnimite*, and when mixed with calcium sulphate, the mineral is called *herrengrundite—vide supra*. A. Étard obtained a green crystalline powder of *cupric heptoxy-trisulphate* with the composition $7CuO.3SO_3.12H_2O$, or $2CuSO_4.4Cu(OH)_2.8H_2O$, by heating the preceding salt in a muffle between 55° and 105°. C. Roucher, and T. Klobb, prepared an amorphous orange-yellow powder of *cupric oxysulphate*, $2CuO.SO_3$, or $CuSO_4.CuO$, by heating cupric sulphate to dull redness in a platinum crucible; and K. Klüss similarly treated basic cupric dithionate, $CuS_2O_6.3CuO.4H_2O$. L. and P. Wöhler and W. Plüddemann heated cupric sulphate to 800° in a stream of sulphur dioxide. T. Thomson, and L. Gmelin made the same product by digesting cupric oxide with an aq. soln. of the sulphate; and A. Recoura prepared $CuSO_4.CuO$ by the oxidation of dry cuprous sulphate at 200°. According to J. E. Strandmark, the salt was found by A. Scacchi in the ejecta of Vesuvius, as the mineral *dolerophanite* described by J. E. Strandmark, and G. Tschermak. It forms monoclinic prisms with the axial ratios $a : b : c = 1{\cdot}323 : 1 : 1{\cdot}203$. The orange-yellow or yellowish-brown powder is said to be isomorphous with cupric sulphate. It is not changed in dry air, but readily decomposes in moist air. L. and P. Wöhler and W. Plüddemann give for the vap. press. 92 mm. at 650°; 122 mm. at 685°; 168 mm. at 725°; 256 mm. at 763°; and 454 mm. at 800°. The composition has been graphically symbolized:

$$O<\begin{matrix}Cu—O\\Cu—O\end{matrix}>SO_2$$

§ 28. Copper Carbonates

Normal cuprous or cupric carbonate has not yet been isolated, although R. Wagner[1] says a carbonate probably exists in aq. soln. to the extent of one in 4000–5000 parts of aq. carbonic acid under a press. of several thousand atm. J. L. Gay Lussac also believed that the black mineral *mysorine* is the normal carbonate, but this is now known to be a basic salt. P. Carles noted the formation of scales on copper exposed to the joint action of air and ammonia on copper. The scales were blue on the outer surface, reddish-yellow in contact with the metal, and malachite green in the interior. In time the blue becomes green, and finally all becomes reddish-yellow. The product is stable, and it dissolves in acids with effervescence. It is assumed some *cuprous carbonate* is present. The soln. in hydrochloric acid gives a white precipitate when diluted with water.

P. N. Raikow says that when freshly precipitated cuprous hydroxide, suspended in water, is treated with carbon dioxide, with the exclusion of air, a *cuprous hydrocarbonate*, $Cu_3H(CO_3)_2$, is precipitated, and this is soon decomposed into cuprous hydroxide and carbon dioxide. The orange-yellow precipitate produced by adding sodium carbonate to a soln. of cuprous chloride in hydrochloric acid assumes a brick-red colour when washed with cold water and is stated by L. Gmelin to be hydrated cuprous oxide, free from carbon dioxide.

According to F. Förster and F. Blankenberg, the colourless or blue soln. which has been used in gas analysis for the absorption of carbon monoxide, contains *cuprous ammino-carbonate;* the soln. precipitates some copper when sulphuric acid is added. Double salts of the normal cuprous and cupric carbonates with ammonium or the other metal carbonates have been prepared. Basic cupric carbonates have been reported with $CuO : CO_2 : H_2O$ in the ratios 10 : 1 : 6, 8 : 1 : 5, 6 : 1 : 0, 3 : 1 : 2, 8 : 3 : 6, 5 : 2 : 6, 2 : 0 : 1, 2 : 1 : (1 or 2), 5 : 3 : 0, 8 : 5 : 7, and 3 : 2 : 1. Several of these occur as minerals, and from the analyses on which the formulæ are based there is nothing to indicate which are chemical individuals and which are solid soln. The mixture obtained by adding sodium carbonate to copper sulphate is used as a fungicide—the mixture is known as *soda Bordeaux*. S. U. Pickering says that the ordinary cupric carbonate of commerce approximates to $2CuO.CO_2.H_2O$, the formula for malachite with 71·94 per cent. of CuO, but H. B. Dunnicliff and S. Lal found that the average of thirteen samples from different Indian and European sources approximated more to azurite—the extremes were 66·16 to 78·60 per cent. CuO.

On adding copper sulphate to a large excess of a soln. of sodium carbonate, no precipitate is formed until a considerable quantity of the copper salt has been added, since the small amount of precipitate formed at first dissolves on warming.

A bright blue soln. results. When the soln. is boiled, a green granular precipitate is formed, while the soln. remains a bright blue. After prolonged ebullition, the precipitate is dense black. The green precipitate has a composition analogous with malachite; the black precipitate is largely cupric oxide.

Precipitates from soln. of copper salts and soluble carbonates are invariably basic, and the degree of basicity depends upon the conditions under which the precipitation is made. H. Kühn thus obtained precipitates with the ratio $CuO : CO_2$ varying from 6 : 1 to 5 : 3. A bulky blue precipitate is thrown down when soln. of sodium carbonate and cupric sulphate are mixed, and some carbon dioxide is evolved. S. U. Pickering working with dil. soln. found that alkalinity is attained when 1·61 mols of sodium carbonate have been added for each mol of copper sulphate. He also found that precipitation is practically complete when 1·6 mols of the carbonate have been added per mol of copper sulphate. He therefore infers that the reaction is a simple one and does not occur in two stages, as when an alkali hydroxide is added to copper sulphate, in which case the whole of the metal is first precipitated to form one basic sulphate, and this reacts with a further addition of alkali to form a more basic one before the liquid finally becomes alkaline. The precipitate was found to contain no traces of sulphate unless the copper was only partly precipitated, and then only in minute quantities; its formula, therefore, is, presumably, hydrated $5CuO.2CO_2$, its formation being represented by the equation: $5CuSO_4+3H_2O+8Na_2CO_3=5CuO.2CO_2+5Na_2SO_4+6NaHCO_3$. The precipitation is never absolutely complete, because the basic carbonate dissolves in the sodium hydrogen carbonate formed in the reaction; but the quantity present when dealing with very dil. soln. is barely recognizable. Where more than 1·6 mols of sodium carbonate are added, the amount of copper dissolved becomes more considerable, and with stronger soln. the liquid becomes quite blue. Exposure to the air, by increasing the proportion of acid carbonate present, increases the amount of copper dissolved.

M. Gröger regards the bluish-green precipitate first obtained by mixing soln. of sodium carbonate and cupric sulphate as a colloidal copper carbonate associated with an indefinite amount of water, and if eq. quantities of the two soln. are employed, the mol. ratio of $CuO : CO_2$ is as 2 : 1. The precipitate immediately begins to coagulate and to lose carbon dioxide. S. U. Pickering found that hydrated **cupric trioxy-dicarbonate,** $5CuO.2CO_2.nH_2O$, or $2CuCO_3.3CuO.nH_2O$, decomposes when in a moist condition, but it can be dried over sulphuric acid, when it contracts to a brittle blue mass; it may likewise be heated to 100° without decomposition. It is then dark green and contains $5CuO.2CO_2.3H_2O$, but regains its blue colour on exposure to moist air. H. Struve gave $5CuO.2CO_2.6H_2O$ for the composition of the insoluble residue obtained by washing the double salt $Na_2CO_3.CuCO_3.3H_2O$ with water. When the blue precipitate is left in contact with a cold sat. soln. of sodium carbonate for some days or weeks, according to the temp., it loses carbon dioxide and forms cupric hydroxide; on the other hand, if left in contact with a soln. of sodium hydrocarbonate, or its own mother liquid, it takes up carbon dioxide and forms green pulverulent malachite. If the precipitated $5CuO.2CO_2.nH_2O$ is washed on a filter with well-boiled distilled water, or with a N-soln. of sodium carbonate, it loses no copper, but it does so if washed with aq. carbonic acid, or with a soln. of sodium hydrocarbonate, forming malachite.

With conc. soln. of sodium carbonate and cupric sulphate, the precipitate soon blackens, and contains only traces of carbonate, and, according to F. Field, if boiling soln. be used, the precipitate has the composition of *cupric pentoxycarbonate,* $6CuO.CO_2$, or $CuCO_3.5CuO$, or, according to H. St. C. Deville, *cupric heptoxycarbonate,* $8CuO.CO_2.5H_2O$, or $CuCO_3.7CuO.5H_2O$. S. U. Pickering found that the products obtained by F. Field, and H. St. C. Deville are stages in the continuous decomposition of the basic carbonate first precipitated, and that even more basic carbonates are produced. For example, the brown powder obtained in the preparation of sodium cupric carbonate, $Na_2Cu(CO_3)_2.3H_2O$, is thought by M. Gröger to be

$10CuO.CO_2.6H_2O$. D. Strömholm obtained no definite compound by precipitation with a mixture of sodium hydroxide, carbonate, and hydrocarbonate.

According to S. U. Pickering, when a dil. soln. of cupric sulphate is mixed with one of sodium hydrocarbonate, a light blue finely-divided precipitate is slowly formed, and considerable quantities of carbon dioxide are evolved; with conc. soln. of the two salts:

> The light blue precipitate first formed re-dissolved, producing a deep blue liquid; warming increases the amount of copper which can thus be dissolved, but on boiling, or before, the substance in soln. decomposes rather suddenly, forming a green precipitate of malachite, and leaving the liquid only slightly blue. This decomposition often takes place during, or after, filtering; but, if it does not do so then, the dark blue soln. decomposes in another manner, depositing gradually throughout twenty-four hours, or more, fairly light blue crystals of the double salt, $CuCO_3.Na_2CO_3.3H_2O$, and leaving the liquid with often only a trace of copper in it.

The precipitation of the copper is never complete, but reaches a maximum of 92–93 per cent. when three mols of sodium hydrocarbonate, or more, are present for every mol of copper sulphate. The amount of acid carbonate used up for the copper precipitated is always more than two eq., and is practically constant at about 2·15 mols of sodium hydrocarbonate for every mol of copper sulphate. The only way in which more than two mols of sodium hydrocarbonate can be used up is by the precipitate combining with additional sodium carbonate, but the compound is decomposed at once on washing. According to M. Gröger, the precipitate obtained from sodium hydrocarbonate and cupric sulphate at a low temp. is colloidal, and has the ratio $CuO : CO_2$ as 8 : 5. The complex is not altered by drying, and when dried over sulphuric acid has the composition of $8CuO.5CO_2.7H_2O$, or $5CuCO_3.3CuO.7H_2O$. S. U. Pickering considers that the ratio $CuO : CO_2$ in the washed precipitate corresponds with *cupric dioxy-tricarbonate*, $5CuO.3CO_2.nH_2O$, or $3CuCO_3.2CuO.nH_2O$, and when dried at 100°, $n=7$. This basic carbonate dissolves in aq. carbonic acid, but is insoluble in water and in soln. of the normal carbonate.

If the double salt, $CuCO_3.Na_2CO_3.3H_2O$, be washed with water, the whole of the sodium carbonate, but no copper, is removed, and the dark blue residue, when dried at 100°, becomes green. S. U. Pickering's analyses give for the composition: $8CuO.3CO_2.6H_2O$, corresponding with *cupric pentoxy-tricarbonate*, $3CuCO_3.5CuO.6H_2O$. P. A. Favre stated that he obtained a basic cupric salt, $3CuO.CO_2.3H_2O$, or *cupric dioxycarbonate*, $CuCO_3.2CuO.3H_2O$, by the hydrolysis of cupric ammonium carbonate with an excess of water; but S. U. Pickering failed to verify this preparation. He digested malachite for two days at 25° with a conc. soln. of ammonium carbonate; but the deep purple liquid thus obtained gave no precipitate at all on dilution. On adding alcohol, a few small crystals of a purple colour, very soluble in water, were obtained on one occasion, these evidently being a cuprammonium salt; on another occasion a good crop of shining, purple, crystalline plates was obtained. These were quite insoluble in water, and consisted apparently of a basic cuprammonium carbonate. H. B. Dunnicliff and S. Lal failed to make a carbonate of constant composition by adding a soln. containing 5 per cent. each of sodium carbonate and hydrocarbonate, to a soln. of cupric sulphate sat. at 14·5° and diluted with its own vol. of water. The precipitate after standing in its mother liquid for about a day was filtered, washed free from sulphate, and dried 6 hrs. in a steam oven. The product had a fairly constant composition corresponding with **cupric pentahydroxydicarbonate,** $2CuCO_3.5Cu(OH)_2$, or $7CuO.2CO_2.5H_2O$.

The 2 : 1 : 0 basic carbonate is represented by the mineral *mysorine*, from Mysore, analyzed by R. D. Thomson [2] in 1836: CuO, 60·75; CO_2, 16·70; Fe_2O_3, 19·50; and SiO_2, 2·10 per cent. F. R. Mallet's analysis led him to regard mysorine as a mixture of malachite with calcite, chrysocolla, barytes, chalcocite, and ferric oxide. L. Franchet's observations on samples from the Urals confirm R. D. Thomson's conclusion that mysorine is a definite mineral species of hardness 5·5; and sp. gr. 4·398. The attempts of J. L. Gay Lussac, F. Field, H. Rose, and J. J. Colin and M. Taillefert to prepare mysorine artificially were not successful. F. S. Beudant's statement that when malachite is heated it forms a product with the characters of mysorine is not confirmed by L. Franchet, for he found that the water and carbon dioxide are simultaneously evolved, and friable black cupric oxide remains. It will be observed that if the formula $2CuO.CO_2$, or $CuCO_3.CuO$, **cupric oxycarbonate,** correctly represents the composition of this basic carbonate the mineral can be regarded as representing **cupric ortho-carbonate,** Cu_2CO_4 :

$$\begin{matrix}HO\\HO\end{matrix}>C<\begin{matrix}OH\\OH\end{matrix}$$

Orthocarbonic acid

$$Cu<\begin{matrix}O\\O\end{matrix}>C<\begin{matrix}O\\O\end{matrix}>Cu$$

Cupric orthocarbonate

The hydrated forms of this mineral are represented by *malachite*—from μαλάχη, a mallow, in allusion to its green colour. The χρυσόκολλα and the false emerald of Theophrastus and Dioscorides were possibly malachite. The mineral is mentioned by Pliny, by G. Agricola, and by J. G. Wallerius. It is the *cuivre carbonaté vert* of L'Abbé Fontana. Malachite, $Cu_2(OH)_2CO_3$, and the related mineral *azurite*, $Cu_3(OH)_2(CO_3)_2$, are common secondary minerals formed in the upper portions of ores deposited by the action of carbonate waters on copper ores, or by reactions between cupriferous waters and limestones. The basic carbonates are also found in the patina of ancient bronzes, *vide* copper. Malachite has been also called *copper rust, noble green-span, verdigris, aerugo nobilis,* etc. The terms *copper-green* and *mineral-green* are also used, but mainly for the artificial product. L. N. Vauquelin, R. Phillips, H. Struve, A. E. Nordenskiöld, J. L. Smith, E. Stöhr, T. Haege, M. H. Klaproth, J. Macadam, P. Berthier, A. Gawalowsky, J. Tüttscheff, etc., have analyzed this mineral. These analyses are in general agreement with the formula $2CuO.CO_2,H_2O$, or $CuCO_3.Cu(OH)_2$, **cupric hydroxycarbonate.** The constitution is unknown. G. Tschermak represents it as a monohydrated cupric orthocarbonate, $Cu_2CO_4.H_2O$, or as $CuCO_3.Cu(OH)_2$, and P. Groth as a normal carbonate of the base CuOH′, namely $(CuOH)_2CO_3$.

The preparation of malachite.—J. L. Proust observed that malachite is slowly formed when moist cupric hydroxide is exposed to the air, and more rapidly when carbon dioxide is passed through water holding cupric hydroxide in suspension, and P. N. Raikow added that the presence of air favours the reaction. J. Tüttscheff warmed precipitated cupric oxide with a soln. of commercial ammonium carbonate, and found that ammonia is given off, and the liquid becomes blue; at the same time, part of the cupric oxide is transformed into a green powder, which when washed with water and dried over sulphuric acid, has a composition like that of malachite. O. Kühling suspended freshly precipitated cupric oxide in a soln. of sodium chloride in one case, and of sodium nitrate in the second, and treated the mixture with a stream of carbon dioxide during from two to five days. The bright green amorphous powders obtained had the constitutions represented by the formulæ, $OH{\cdot}CuCl{\cdot}CuCl_2{\cdot}5Cu(OH)_2$, and $OH{\cdot}Cu{\cdot}O{\cdot}CO{\cdot}O{\cdot}Cu{\cdot}OH$. R. Wagner treated basic cupric carbonate suspended in water with carbon dioxide under 6 atm. press., and found the undissolved basic salt was transformed into crystals of malachite. A. de Schulten also allowed a soln. of basic cupric carbonate in carbonic acid to stand at ordinary temp. for some time, when crystals of malachite were formed. According to L. Bourgeois, amorphous precipitated malachite can be crystallized by heating it with water and ammonium nitrate or chloride, or urea in a sealed tube at 140°.

Many experiments have been made on the synthesis of malachite by the action of potassium or sodium carbonate on a soln. of a cupric salt. H. Rose, for example, used a cold dil. or conc. soln. containing equi-molecular proportions of the alkali carbonate and cupric sulphate. Hot soln. gave black precipitates containing sulphuric acid. E. Chuard, M. Gröger, and S. U. Pickering precipitated a soln. of cupric sulphate with an equi-molecular proportion or an excess of alkali carbonate, and allowed the blue precipitate to remain in contact with the alkaline mother liquid until it had acquired a green colour. Modifications in procedure have been devised by J. A. Crowther, H. Struve, etc.

In illustration, F. Field added sodium hydrocarbonate to a soln. of cupric sulphate so long as no precipitate was formed; on heating the soln. to its b.p., a granular precipitate of the composition of malachite was formed. H. St. C. Deville said that the crystals are sodium cupric carbonate, but F Field could not confirm this. W. C. Reynolds heated to 100° a soln. of potassium carbonate with a great excess of cupric acetate. E. E. Free mixed eq. proportions of $\frac{1}{2}N$-Na_2CO_3 and $\frac{1}{2}N$-$CuSO_4$ at 50°, and allowed the mixture to stand overnight. The precipitate was filtered, washed, and suspended in water, and treated for three days with carbon dioxide under a press. slightly greater than that of the atm. A. de Schulten prepared crystals of malachite by heating on a water-bath for eight days, a soln. of precipitated copper carbonate in ammonium carbonate in flasks filled up to the neck. The water was renewed as it evaporated. As the ammonium carbonate volatilizes, green crystals of malachite appear on the sides of the flask. F. Millosevitch spread a gram of dihydrated cupric chloride on the bottom of a glass tube, then a cm. thick layer of china clay, then two grams of decahydrated sodium carbonate, and sealed up the tube. When the tube was heated to 70°–85° he obtained crystals of malachite. H. de Sénarmont and V. Karavodine treated a soluble cupric salt with sodium carbonate or hydrocarbonate between 150° and 225° in a sealed tube. Some preparations have been reported with more water than corresponds with $CuCO_3.Cu(OH)_2$. Thus, E. Rubénovitch said that the precipitate agreed with $CuCO_3.Cu(OH)_2.1\frac{1}{2}H_2O$. E. Brunner, and J. J. Colin and M. Taillefert dried the washed precipitate at 20°–30°, and obtained analyses in agreement with $CuCO_3.Cu(OH)_2.2H_2O$. E. Chuard's, P. A. Favre's, and M. Gröger's precipitates also contained more water than is required for malachite. This is in agreement with what would be anticipated if the precipitate formed is colloidal.

H. de Sénarmont, and A. C. Becquerel heated a soln. of cupric chloride with calcium carbonate in a sealed tube between 150° and 225°; F. Wibel likewise heated a soln. of cupric sulphate with calc-spar, in a sealed tube for 24 hrs. at 150°–170°. A crust of malachite is formed near the calc-spar; calcium sulphate dissolves. At a high temp. the reaction is considered to be: $2CuSO_4+2CaCO_3+H_2O \rightarrow CuCO_3.Cu(OH)_2+2CaSO_4+CO_2$; and at a lower temp., the malachite loses water and takes up carbon dioxide: $3Cu_2(OH)_2CO_3+CO_2 \rightarrow H_2O+2Cu_3(OH)_2(CO_3)_2$, *i.e.* azurite. F. Millosevitch kept a mixture of marble with water sat. with carbon dioxide and a dil. soln. of cupric sulphate (5 grms. per litre) for some hours at 10°, and obtained crystals of malachite; and by using a more dil. soln. of cupric sulphate ($2\frac{1}{2}$ grms. per litre), crystals of azurite were obtained. He added: "A greater excess of calcium carbonate to the cupric salt is necessary for the formation of the more basic copper carbonate, azurite. The carbon dioxide is needed for the dissolution of the calcium carbonate to enable it to react readily with the copper salt." A. C. Becquerel placed a piece of porous limestone in a soln. of cupric nitrate of sp. gr. 1·091–1·116, and, after some basic nitrate had been formed, he added a soln. of sodium hydrocarbonate of sp. gr. 1·040, and in some days crystals of malachite appeared.

A. C. Becquerel covered a copper plate with crystals of sodium cupric carbonate, dipped the plate in water, and made it the positive pole of a galvanic circuit. Crystals of malachite were then formed on the metal plate. C. Luckow electrolyzed a 1·5 per cent. soln. of sodium chloride and carbonate in the respective proportions 4 : 1, between copper electrodes with a current density of 0·5 amp. per sq. dcm., and 2 volts; the feeble alkalinity of the electrolyte was maintained and carbon dioxide and water introduced. E. Gunther, G. Kroupa, A. Lismann, etc., have also prepared malachite by the electrolysis of dil. soln. of carbonate with a copper anode. According to J. Errera, on electrolyzing with a copper anode, a soln. of an alkali hydrocarbonate, free from chlorine, a film of cuprous oxide is formed on the copper, and, on top of this, a layer of a green, insoluble, basic carbonate, $2CuCO_3.2Cu(OH)_2.H_2O$, is gradually built up, while a certain amount of copper dissolves as $Na_2CO_3.CuCO_3.3H_2O$. No azurite is formed; but, with high current densities, there is formed a black cathode deposit of copper, which changes to the ordinary form on treatment with acids.

The properties of malachite.—Malachite usually occurs in nature as earthy or compact nodular masses, sometimes with a fibrous structure. A. Wieler[3] found a sample with a honeycomb structure. The harder varieties of green malachite have been cut, and polished into table tops, vases, etc.—*e.g.* the mantelpieces, etc., in the Grand Trianon, Versailles. Good crystals are rare. A. Lacroix has described some needle-like crystals. The crystals are usually thin prisms with well-defined twinning. According to V. von Lang, F. Hessenberg, etc., prismatic monoclinic **crystals** have axial ratios $a:b:c=0\cdot8809:1:0\cdot4012$, and $\beta=118°\ 10'$. The colour ranges from emerald-green to grass-green. The **specific gravity** has been determined by A. Breithaupt, H. Schröder, V. von Zepharovitch, F. S. Beudant, J. L. Smith, etc. The numbers range from 3·3572 to 4·033. The best representative value is 3·9, the **hardness** is 3½. W. Spring compressed the powder to a glass-like mass under great press.

Malachite decomposes and melts in the blowpipe flame. According to H. Rose, a sample of malachite from the Urals began to decompose at 220°, when it turned brown and black. When a sample, dried at 100°, was heated for a long time at 220°, it lost 0·76 per cent. in weight; at 230°, 1·22 per cent.; at 250°, 2·16 per cent.; and at 300°, 27·71 per cent. The residue then contained 98·74 per cent. of cupric oxide and 1·26 per cent. of water. Precipitated malachite lost 25·12 per cent. by weight at 200°, and contained 96·55 per cent. of cupric oxide, and 3·45 per cent. of water; and at 300° it still retained 0·63 per cent. of water. According to J. L. Gay Lussac, malachite loses carbon dioxide and blackens when boiled with water at 100°. P. E. W. Oeberg found 0·1763 for the **specific heat** of a sample of malachite from the Urals; and J. Joly, 0·1766.

A. Heiduschka says that the green colour persists unchanged at the temp. of liquid air. G. Césaro found that the crystals have a negative double refraction, and they are pleochroic. A. Voller and B. Walter investigated the **absorption of X-rays** by malachite. E. Dorn found the **electrical conductivity** of compressed malachite powder to be $3\cdot4\times10^{-6}$, and, after warming 2½ hrs. at 140°, $2\cdot8\times10^{-6}$. K. Zenghelis measured the e.m.f. of precipitated malachite towards copper.

The **solubility** of malachite in water, indeed, the solubilities of all the basic cupric carbonates in this menstruum, is very small; the moistened mineral, according to A. Kenngott,[4] does not react alkaline. J. L. Lassaigne found malachite to be soluble in water containing carbon dioxide in soln.; 100 parts of water sat. with carbon dioxide dissolve 0·03 part of malachite after 12 hrs. action at 10°, and 755 mm. press. R. Wagner gives 0·0213 part of malachite per 100 parts of water after many months' action at 6 atm. press. The solubility of malachite in aq. soln. of carbon dioxide has also been measured by H. Jahn, P. A. Favre, and E. E. Free. The last-named found the solubility of precipitated malachite increases with the conc. of the carbonic acid. Expressing the results in parts of copper dissolved per million parts of water with carbon dioxide in soln.:

CO_2 . . .	0	157	348	859	1158	1224	1549
Cu . . .	1·5	8·3	17·0	28·0	33·7	34·8	39·7

The last-named soln. was sat. at a little above atm. press. The presence of small amounts of sodium chloride or sulphate or calcium sulphate have no marked effect on the solubility, but when the conc. of the salt attains about 500 parts per million, the solubility of the basic carbonate is augmented. For example, with carbon dioxide approximately 1200 parts per million:

NaCl . .	0	10	50	100	500	10,000
CO_2 . .	1268	1404	1158	1326	1255	1276
Cu . .	35	38	35	36	39	58

The data for sodium and calcium carbonates are nearly the same:

Na_2CO_3 . .	0	100	10,000
Cu . . .	35	10	0·7

$CaCO_3$ . .	0	100	1125
Cu . . .	35	7	1·4

C. A. Seyler explains the phenomena by assuming that when a soln. of a copper salt is treated with sodium carbonate, $CuCO_3.Cu(OH)_2$ is precipitated and copper passes into soln. as hydrocarbonate: $CuCO_3.Cu(OH)_2+3H_2CO_3 \rightleftharpoons 2H_2O+2Cu(HCO_3)_2$. The active mass of the solid basic carbonate and the water can be regarded as virtually constant, and, therefore, for equilibrium, $[Cu]^2[HCO_3]^4/[H_2CO_3]^3=K$. Consequently, when no other salt is present the conc. of the $Cu^{\cdot}$-ions is always half as great as that of the $HCO_3{}'$-ions, and, consequently, small quantities of calcium sulphate, sodium sulphate, or sodium chloride have but little influence; on the other hand, salts which furnish analogous ions—$Cu^{\cdot}$ or $HCO_3{}'$—for example, sodium or calcium hydrocarbonate, must lower the solubility.

E. E. Free also found that a precipitate of basic copper carbonate changes its nature under the influence of carbon dioxide and water, whereby its solubility in dil. carbonic acid decreases. The solubility of different precipitates in aq. carbonic acid ranged from 52 to 107 parts of copper per million in soln. of 0·12 per cent. CO_2. After 4 or 5 days' treatment with dil. carbonic acid, the solubility of all the precipitates was approximately 35 parts per million. The explanation depends either on the transient high solubility with a fine-grained precipitate, or there is a chemical change from a substance with a variable to one of constant composition —but a little more basic.

Malachite is readily soluble with effervescence in *acids*. According to W. Spring, if the speed of dissolution of calcspar in hydrochloric or nitric acid at 15° is unity, that of malachite is 0·231. E. Landrin, and E. Murmann found malachite to be soluble in soln. of *ammonium salts—e.g.* ammonium citrate, which forms a crystalline double salt. G. Gore, and E. C. Franklin and C. A. Kraus found malachite to be insoluble in liquid *ammonia;* J. Schröder and A. Naumann found it to be insoluble in *pyridine.* A. Callegari found that when a suspension of cupric hydroxide in water is poured into a conc. soln. of *hydrazine carbonate*, a violet coloration appears which is assumed to be produced by an hypothetical *cupric hydrazine carbonate* which has not been isolated. J. Lemberg found malachite to be soluble in *potassium cyanide* soln.; J. Peschier in soln. of cane sugar; Kalle & Co., in soln. of alkali salts of the *peptones.* The copper is not precipitated from the soln. with *cane sugar* by alkali carbonates, but it is by ammonium hydrosulphide, and potassium ferrocyanide. According to C. Hassack, malachite is superficially coloured pale grey by *sodium hydroxide* soln., and in the presence of nascent *hydrogen*, it forms a brownish-black mass. D. Tommasi found the moistened salt reacts with *alkali chlorides.* F. C. Phillips noted that artificial malachite is rapidly converted by *methyl hydrosulphide* into a yellow powder. L. Loock found that patina is converted by *sulphur dioxide* or *sulphuric acid*, or organic matters from the atm. into a soluble form. According to A. C. Becquerel, the electrolysis of water with malachite in suspension reduces the copper salt by the agency of the hydrogen at the cathode.

The soln. of cupric hydroxide or of basic cupric carbonate in potassium hydrocarbonate was introduced by A. Soldiani (1876) as a substitute for H. von Fehling's soln. in sugar analysis; H. Ost also recommended the soln., and it is sometimes called *Ost's solution.* This liquid has an intense colour, and, since R. Luther and B. Krsnjavy found it to diffuse readily through parchment, they infer that it is not colloidal. During electrolysis the metal migrates to the anode, and it is assumed to form a complex of ion—say, $[Cu(HCO_3)_2]$ of *hydrocupricarbonic acid*, $HCu(HCO_3)_2$, and the soln. may therefore contain the salt, $KCu(HCO_3)_2$. G. Weltzlar found iron precipitates copper from the soln. only in the presence of ammonium or sodium chloride, or potassium nitrate or sulphate. J. W. Döbereiner obtained octahedral crystals from the soln. According to H. Jahn, and R. Wagner, cupric hydrocarbonate, $Cu(HCO_3)_2$, may also be formed by the soln. of basic cupric carbonate in water containing carbon dioxide.

The transformations of malachite and azurite have been studied mineralogically by W. Haidinger, and many others.[5] S. F. Glinka [6] found a mineral near Atai, with monoclinic crystals and yellow and green pleochroism. Its composition corresponded with $2CuCO_3.PbCO_3\,Cu(OH)_2$, and it was hence called *lead malachite*, or *plumbomalachite*. C. F. Zinken found a bluish-green mineral which contained copper and calcium carbonates, and was hence called *calciomalachite* or *lime-malachite*. It is probably a mixture of several minerals. A. Damour also shows that A. Raimondi's *cuprocalcite* is probably a mixture of calcite and cuprite.

The basic carbonate, $3CuO.2CO_2.H_2O$, or $2CuCO_3.Cu(OH)_2$, **cupric hydroxydicarbonate,** occurs as a mineral *chessylite*—French *azurite*, German *Kupferlasur*. The English name is derived from Chessy near Lyons, where the finest crystals have been obtained. This mineral was recognized by J. F. W. Widenmann[7] in 1791, as a *himmelblau Fossil* from Styria. It was later called *smalt blue, native smalt, blue felspar, mollite, blue spar, Berlin blue,* etc. A. Stütz called it *unächter Lasurstein,* or false lapis-lazuli; M. H. Klaproth called it *lasurite,* or *lazulite;* F. S. Beudant, *Klaprothite;* etc. Analyses were made by M. H. Klaproth, J. N. von Fuchs, R. Brandes, C. F. Rammelsberg, J. L. Smith and G. J. Brush, L. J. Igelström, L. N. Vauquelin, R. Phillips, F. Wibel, A. H. Church, etc. The corresponding chemical formula, by C. F. Rammelsberg, is $2CuCO_3.Cu(OH)_2$, or, by G. Tschermak, $(CuOH)_2Cu(CO_3)_2$. According to the latter, therefore, malachite and azurite are related as

$$\begin{array}{l}HO.Cu\\HO.Cu\end{array}\!\!>CO_3$$

Malachite, $Cu(OH)_2.CuCO_3$

$$\begin{array}{l}HO.Cu—CO_3\\HO.Cu—CO_3\end{array}\!\!>Cu$$

Azurite, $Cu(OH)_2.2CuCO_3$

Several modes of preparing azurite have been indicated in connection with malachite; and many properties of the same mineral have been there indicated. Azurite readily passes into malachite by the loss of carbon dioxide and the gain of water, and conversely. The two minerals are usually associated together, and sometimes crystals of azurite from Chessy are transformed at one end into malachite. H. Debray[8] did not succeed in making azurite by the action of carbon dioxide under a press. of 10 to 14 atm. on malachite, or precipitated basic carbonate; but he did prepare crystals of azurite by enclosing crystals of cupric nitrate with pieces of chalk (in excess) with a little water in a glass tube, so that the press. of the carbon dioxide was kept at 3–4 atm. A basic nitrate was first formed, and this slowly passed into azurite. Potassium carbonate will not serve in place of the calcium carbonate. A. C. Becquerel found a mixture of cupric nitrate, chalk, and sodium hydrocarbonate in the cold furnished crystals of azurite; and he also heated to 125° a soln. of cupric chloride with pieces of limestone, under press. L. M. Michel kept a soln. of cupric sulphate for many years in contact with pieces of Iceland spar at ordinary temp. and obtained a crystalline crust of azurite; F. Millosevitch used pieces of Portland cement in place of Iceland spar; F. Wibel and E. Tüngel heated a soln. of cupric sulphate with pieces of marble in a sealed tube at 200° for a month. A. C. Becquerel found that azurite formed on the walls of collodion or parchment paper separating a soln. of cupric nitrate from one of potassium carbonate or hydrocarbonate. R. Phillips, and F. Fouqué and A. Michel-Lévy have described processes for making azurite for use as a pigment.

Azurite occurs both as an earth and in a crystalline form. The crystals are deep blue, the earth is a lighter blue. The crystals are monoclinic prisms, with axial ratios $a:b:c=0{\cdot}8501:1:1{\cdot}7614$, and $\beta=92°\ 24'$. H. Schröder[9] gives 3·710 to 3·770 for the sp. gr. of the crystals; J. L. Smith gives 3·88. The hardness is 4. The crystals have a positive double refraction. V. Agafonoff showed that azurite has isolated absorption bands in the red, yellow, orange, green, and greenish-blue; in general, only the blue and bluish-green rays traverse places 1½ mm. thick. R. Handmann showed that the mineral is phosphorescent.

The mineral decomposes and melts in the blowpipe flame. Powdered azurite from Chessy was found by H. Rose to begin to lose weight when heated to 220°, and little volatile matter remains when the temp. reaches 250°; the colour is then greyish-brown; at 300° the product is cupric oxide with a very little water.

When azurite is boiled with water, carbon dioxide is evolved more copiously than with malachite, and the powder is blackened. Azurite is not changed when allowed to stand for three months in water at ordinary temp. or between 60° and 80°. Azurite is soluble in aqua ammonia, forming a dark blue soln.; it is also soluble in a hot conc. soln. of sodium hydroxide, and, according to F. Field, when boiled, the liquid precipitates green malachite.

The transformation products have been studied mineralogically by G. Sillem,[10] L. Buchrucker, E. Döll, R. Blum, W. S. Yeates, etc. A. Breithaupt's deep blue crystalline mineral *zinc-azurite* is probably a mixture of zinc sulphate and azurite; and his *atlasite* is probably a mixture of atacamite and azurite or malachite.

According to E. J. Maumené, aq. ammonia free from ammonium salts does not dissolve either cupric hydroxide or cupric oxide. C. Bischof[11] dissolved with access of air copper filings, or cupric oxide, hydroxide or carbonate, in an aq. soln. of ammonium carbonate, and obtained an azure-blue liquor—he found that 100 parts of ammonium hydrocarbonate in 1440 parts of water dissolved in 24 hrs., 2·38 parts of cupric oxide, or 17·03 parts of the hydroxide. P. A. Favre showed that this soln. furnishes crystals of **cupric diammino-carbonate,** $Cu(NH_3)_2CO_3$, when treated with alcohol. According to E. J. Maumené, freshly precipitated copper carbonate dissolves in aq. ammonia in the presence of ammonium carbonate, forming a compound $CuO.3CO_2.4NH_3$. D. W. Horn prepared cupric diammino-carbonate by saturating purified cupric carbonate of commerce, $CuCO_3.Cu(OH)_2$, with a mixture of 50 c.c. of a cold sat. soln. of the solid ammonium carbonate of commerce and 10 c.c. of aqua ammonia of sp. gr. 0·9. About 6 grms. of the basic carbonate were employed; 95 per cent. alcohol was slowly added to the filtered soln., and the mixture shaken. Fine crystals of the diammino-salt separated out, these were pressed between filter paper and dried over potassium hydroxide. P. Cazeneuve prepared the same salt by treating a soln. of cupric oxalate with an equal vol. of alcoholic ammonia. F. Ephraim showed that at room temp. cupric carbonate yields only the diammino-salt, although cupric pentammino-carbonate, $CuCO_3.5NH_3$, formed at $-18°$, does not decompose until 37°; above this temp., the pentammine slowly passes into the diammine, which is stable at 170°, and above 170° it decomposes completely.

According to C. F. Bucholz, the azure-blue soln. gives off ammonium carbonate when heated, and deposits nearly all the copper in bluish-green crusts which contain ammonia; a similar crust is obtained by the slow evaporation of the soln. D. W. Horn stated that the diammine salt behaves like a sat. compound towards ammonia, for liquid ammonia may be boiled from it for a period of at least an hour, and the salt remains entirely unchanged. According to P. A. Favre, the crystals are insoluble in alcohol and ether, they are decomposed by water with the separation of a basic carbonate, $2CuO.CO_2.2H_2O$. When rapidly heated in carbon dioxide decomposition occurs, ammonium carbonate sublimes, and metallic copper remains. H. Rose found that by boiling the soln. with potassium hydroxide, cupric oxide is precipitated. According to E. Bronnert, M. Frémery, and J. Urban, the soln. dissolves cellulose, forming a more stable liquid than when cupric tetra-ammino-oxide is employed. The soln. is used in the manufacture of artificial silk; and a soln. of copper carbonate in aq. ammonia or ammonium carbonate has been used for many years as a fungicide.

According to J. J. Berzelius,[12] when sodium carbonate is heated with cupric oxide before the blowpipe, a glass is formed which is green while hot, and opaque and white when cold. A. C. Becquerel filled a porous pot with a soln. of sodium hydrocarbonate, and immersed it in a soln. of cupric sulphate. Copper electrodes dipping in each liquid were connected electrically, copper is deposited on the electrode in the cupric sulphate soln., and bluish-green silky needles of a double sodium cupric carbonate are deposited on the other electrode. H. Debray mixed basic cupric nitrate or carbonate with an excess of sodium hydrocarbonate with a little water so as to form a slurry, and heated the mixture in a sealed tube to 160°, and obtained blue crystals of anhydrous **disodium cupric dicarbonate**, $Na_2CO_3.CuCO_3$. The crystals were not decomposed by water.

H. St. C. Deville described the deep blue soln. obtained by dissolving a basic copper carbonate in conc. soln. of mixed alkali carbonate and normal carbonate. With the sodium salts the soln. furnishes light blue crystals of **trihydrated disodium cupric dicarbonate**, $CuCO_3.Na_2CO_3.3H_2O$, leaving the liquid slightly coloured.

The salt was made by A. C. Becquerel by the prolonged action of an aq. soln. of sodium hydrocarbonate on basic cupric nitrate. H. Struve and J. G. Gentele prepared the salt more or less contaminated with cupric carbonate by a process similar to that used by H. St. C. Deville. M. Gröger recommended mixing a soln. of 20 grms. normal sodium carbonate and 50 grms. of the hydrocarbonate in 700 grms. of cold water with a soln. of 8 grms. of hydrocarbonate in 700 grms. of cold water and a soln. of 8 grms. of pentahydrated cupric sulphate in 20 grms. of water, and allowing the precipitate to stand in contact with the mother liquid. W. C. Reynolds ground solid copper acetate with a conc. soln. of sodium carbonate. M. P. Applebey, and K. W. Lane employed a process similar to that recommended by M. Gröger, using cupric acetate in place of the sulphate.

The change in colour which accompanies crystallization is supposed to indicate that the liquid cannot be a mere soln. of the crystals ; and, as M. Gröger has shown, the crystals do not readily dissolve in the mother liquor, and they are decomposed by water ; but, according to M. P. Applebey and K. W. Lake, the crystals dissolve in and can be recrystallized from a conc. soln. of sodium carbonate containing hydrocarbonate. W. C. Reynolds, and T. B. Wood and H. O. Jones proved that the liquid contains highly-coloured anions, and that on electrolysis, copper is deposited on both electrodes. Hence, the soln. probably contains both copper cations and carbonato-cupric- or cupricarbonate anions: $Na_2Cu(CO_3)_2=2Na^{\cdot}+Cu(CO_3)_2''$, and $Cu(CO_3)_2''=Cu^{\cdot\cdot}+2CO_3''$. In the one case copper is basic or electropositive, and in the other acidic or electronegative. The cupricarbonates give a clear yellow colour with potassium ferrocyanide, but as the change between them and copper carbonate is a reversible one, the red colour of copper ferrocyanide gradually appears on standing—the actual time depends on the conc. and temp. of the soln. The cupricarbonate has the power of oxidizing dextrose with the precipitation of cuprous oxide. This action takes place in the cold, or, more rapidly, on heating, and is preceded by the formation of some soluble compound of the cupricarbonate with the sugar, for the amount of copper passing into soln. at first is greatly increased by the sugar. No such action, nor any precipitation of cuprous oxide, occurs when the soluble compound present is that containing electropositive copper.

S. U. Pickering determined the percentage of copper in soln. containing different proportions of sodium carbonate and hydrocarbonate when the total mol. proportion of the two carbonates was 5·6 and 2·24 times that of the cupric sulphate. The results are shown in Fig. 38, where the dotted lines represent electronegative copper, and the continuous line electropositive copper. The variation in amount of copper passing into soln. is continuous throughout, and shows no abrupt change when electropositive copper gives way to electronegative copper. S. U. Pickering thus explains the reactions which occur when a conc. soln. of copper sulphate is added to one of sodium hydrocarbonate :

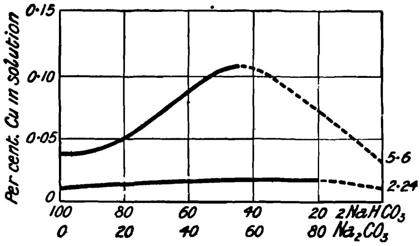

FIG. 38.—Per cent. of + and − Copper in Solutions of the Two Sodium Carbonates.

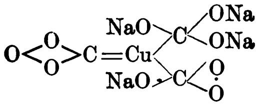
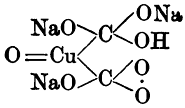
The basic carbonate, $5CuO.3CO_2$, is first precipitated, and then gradually absorbs carbon dioxide from the sodium hydrocarbonate present, passing into soln. as the normal copper carbonate, or, rather, as a double carbonate of copper and sodium, forming a deep blue liquid wherein the copper is electropositive. On standing, this soluble compound gives rise either to the crystalline double carbonate, or else decomposes into malachite, nearly all the copper going out of soln. On heating to the b.p., the change into malachite always takes place if the soln. contains much copper. If the light blue liquid and the malachite resulting from this change are boiled together for some time, the proportion of normal sodium carbonate in the liquid is increased, and the precipitate gradually redissolves, forming again a deep blue liquid, in the form of cupricarbonate, and not malachite. The change from the soluble compound with electronegative copper, is a reversible one. On taking a rather weak soln. of the former and heating it to boiling, it becomes darker, and the copper no longer reacts with ferrocyanide; but, on cooling, it becomes lighter again, and responds to the ferrocyanide test.

The double carbonate is a light blue salt, which, according to C. F. Rammelsberg and P. Groth, belongs to the monoclinic system, and has the axial ratios $a:b:c = 1·5827:1:2·2665$. and $\beta=91° 52'$. The salt cannot be crystallized from water without decomposition. The salt is considered by S. U. Pickering to be a molecular compound of the two carbonates in which the copper is electronegative. In the presence of an excess of normal sodium carbonate, the copper becomes electronegative and it is then a complex which S. U. Pickering calls **sodium α-cupricarbonate,** consisting of $Na_2Cu(CO_3)_2$ united with Na_2CO_3, but in which the copper is joined directly to the carbon atoms, and is in a tetrad condition. It oxidizes dextrose, and the constitution suggested represents the presence of a loosely combined oxygen atom explaining such a reaction. Excess of sodium hydroxide decomposes it, but a greater excess dissolves the basic carbonate thrown down, to form a deep violet-blue soln. of **sodium β-cupricarbonate,** which consists of $Na_2Cu(CO_3)_2$ united with one or two molecules of sodium hydroxide. This, too, oxidizes dextrose, and also combines with cellulose. It is stable in the presence of excess of alkali, whereas the α-compound gradually decomposes, either into the crystalline double salt or into malachite. Sodium cupric carbonate decomposes in a similar manner, but generally into malachite. S. U. Pickering suggested constitutional formula for the α- and β-cupricarbonates, on the assumption that copper is quadrivalent:



Sodium α-cupricarbonate.



Sodium β-cupricarbonate.

M. P. Applebey and K. W. Lane made a partial examination of the solubility equilibria in the case of Na_2CO_3—$Na_2Cu(CO_3)_2$—$CuCO_3$, at 18°, and, expressing the conc. in grams per litre, found in the soln.:

	Na_2CO_3	$NaHCO_3$	Cu
Solid phases: $Na_2Cu(CO_3)_2.3H_2O+NaHCO_3$	9·27	87·79	—
	11·08	86·45	0·0509
	168·75	53·60	0·1553

When the results are represented graphically along with H. N. McCoy and C. D. Test's determinations of the solubility of mixtures of sodium carbonate and hydrocarbonate at 25°, the trona breaks in the curve at 25° do not appear in the curve at 18° in the presence of the cupric salt, possibly because trona dissociates between these two temps. The solubility curves of copper carbonate and the double salt appear to intersect when the conc. of the copper is about 0·045 grm. per litre. Instead of the solubility of each component being depressed by the presence of the other, there is a steady increase, possibly because of the formation of the complex. Unlike the normal behaviour of soln. sat. with double salts, M. P. Applebey and K. W. Lane say that "the increase of conc. of one component brings about an increase in the conc. of the other, the curve apparently rising throughout its whole course." This abnormal behaviour must, as in the case of the solubility of copper carbonate itself, be occasioned by the formation of a new constituent in the soln. which removes copper from the soln. equilibrium of the double salt, and so leads to an increase in its apparent solubility. The increasing solubility of the double salt with rising conc. of sodium carbonate thus constitutes a direct experimental proof of the view held by H. St. C. Deville that the copper in these soln. was largely present in some form chemically different from the salt which crystallizes out. It is shown that a large proportion of the copper in the soln. is a colloidal substance—either the normal or the basic carbonate. J. M. Haussmann[13] observed that an aq. soln. of potassium carbonate dissolves basic copper carbonate forming a deep blue liquid. According to H. Ost, the carbonate is not so soluble in a soln. of potassium hydrocarbonate, but is freely soluble in a cold conc. soln. of the normal carbonate. The soln. contains a readily soluble double salt which crystallizes out in needles; when heated, a basic copper carbonate or black oxide is precipitated, but if the soln. contains sufficient potassium hydrocarbonate, it is quite stable even at its b.p. As indicated above, when the soln. is electrolyzed, T. B. Wood and H. O. Jones obtained copper at both electrodes, and J. W. Turrentine says that during the electrolysis, " reduction occurs at the anode due to the formation there of percarbonates, which, breaking down in aq. soln., yield as a product hydrogen peroxide. This acts as a reducing agent."

In 1851, H. St. C. Deville obtained a crystalline mass with the composition $K_2CO_3.5CuO.4CO_2.10H_2O$, by allowing the deep blue soln., obtained by mixing sat. soln. of cupric sulphate and potassium hydrocarbonate, to stand for some hours. H. Debray likewise obtained a potassium cupric carbonate by heating basic cupric nitrate with potassium hydrocarbonate with a little water in a sealed tube. According to M. Gröger, the products are contaminated by basic cupric carbonate. The last named prepared a product of the composition $2K_2CO_3.8CuO.7CO_2.17H_2O$, by dissolving 20 grms. of potassium hydrocarbonate in 50 c.c. of cold water, and dropping the soln. slowly into 20 c.c. of a *N*-soln. of cupric sulphate. The precipitate was pressed on porous tiles, and dried in air. T. B. Wood and H. O. Jones believe that M. Gröger's salt is a mixture.

W. C. Reynolds prepared **potassium cupric carbonate,** $K_2CO_3.CuCO_3$, by adding 13 grms. of finely powdered cupric acetate to 70 c.c. of a conc. soln. of potassium carbonate of sp. gr. 1·35 at 65°. The mixture was rapidly filtered through glass wool, and the filtrate set aside. In about 48 hrs., the crystals were drained by suction on toughened filter paper on a Buchner's filter plate; washed with a mixture of alcohol with half its vol. of glycerol (which floats on the salt soln. without mixing with it); when all the mother liquid is displaced, the washing is completed with alcohol alone until the glycerol is all removed; the crystals are then dried in vacuo over sulphuric acid. The product contains three kinds of crystals (i) dark blue six-sided plates of the anhydrous salt; (ii) light blue silky needles of the monohydrate, $K_2Cu(CO_3)_2.H_2O$; and (iii) large greenish-blue square plates of the tetrahydrate, $K_2Cu(CO_3)_2.4H_2O$. The last-named crystals can be separated by hand. The anhydrous and monohydrated forms appear to be deposited indifferently from soln. of the same conc. and temp. The copper soln. decomposes slowly when heated to 65°, and rather quickly at 85°, cupric oxide being precipitated; if, however, a large quantity of the acetate is added, no black precipitate forms even at 100°, but a green powder of the composition, $Cu_2(OH)_2CO_3$. According to T. B. Wood and H. O. Jones, the same potassium cupric carbonate is obtained by shaking for several days a soln. of 100 grms. of potassium carbonate in 100 c.c. of water with a mixture of the basic copper carbonate, $CuCO_3.Cu(OH)_2.2H_2O$, potassium carbonate, and hydrocarbonate in the proportions required by the equation: $CuCO_3.Cu(OH)_2.2H_2O+2KHCO_3+K_2CO_3=2(CuCO_3.K_2CO_3)+4H_2O$. The double salt decomposes in contact with water, with the production of basic copper carbonate. A soln. of potassium carbonate containing 85 grms. to 100 c.c. of water dissolves the double carbonate, forming a deep blue soln., which, if not sat. with copper carbonate, does not change on boiling.

§ 29. Copper Nitrates

In his *Furnis novis philosophicis* (Amstelodami, 1648), J. R. Glauber described a dark green mass which he prepared by evaporating a soln. of copper in nitric acid. R. Boyle [1] also described the crystals which he obtained in a similar manner, and in 1685, he noticed that the soln. coloured a flame blue and green. F. Förster and F. Blankenberg found that an ammoniacal soln. of cupric nitrate is reduced by copper almost completely to the cuprous salt, when air is excluded. There is probably a state of equilibrium between cupric and cuprous ammino-nitrates. According to J. Sloan, when a soln. of cupric nitrate in liquid ammonia is left in contact with copper foil until the soln. becomes colourless, the salt, **cuprous ammino-nitrate,** $CuNO_3.2NH_3$, is formed. F. Ephraim[2] also prepared this salt and noted that while the cuprous halides form triammines, the nitrate and thiocyanate form diammines, and cuprous cyanide only forms a monammine. If the ammonia is allowed to evaporate gradually, **cuprous nitrate,** $CuNO_3$, mixed with a little cupric nitrate is formed. Cuprous nitrate rapidly oxidizes when exposed to air. The action of nitric acid on copper has been discussed in connection with the metal. A soln of the nitrate is best made by the action of dil. nitric acid on the metal, on the oxide, hydroxide, or carbonate. According to W. Jäger, a litre of N-HNO_3 dissolves 0·4802 gram-atom of copper, forming the nitrate. According to T. Graham, a basic nitrate is formed when cupric oxide is drenched with conc. nitric acid, even though the acid be in excess. The resulting green powder is to a large extent insoluble in water. With nitric acid of sp. gr. 1·42, cupric oxide is wholly converted into the nitrate. W. N. Hartley made a soln. of cupric nitrate for his spectroscopic work, by digesting 100 c.c. of $2N$-HNO_3 with cupric carbonate for two or three days. When the soln. neutral to litmus was diluted to 200 c.c. with distilled water, and allowed to stand for some months, a deposit of either the hydroxide or carbonate is formed—most probably the former.

According to T. Graham, the soln. of copper in dil. nitric acid is at first green, but it changes to a blue colour when it has stood for some time—possibly owing to the formation of a higher hydrate. When the soln. is conc. by evaporation, T. Graham noted that dark blue prismatic crystals of **trihydrated cupric nitrate,** $Cu(NO_3)_2.3H_2O$, and paler blue rhomboidal plates of **hexahydrated cupric nitrate,** $Cu(NO_3)_2.6H_2O$, are formed. R. Funk also prepared crystals of **enneahydrated cupric nitrate,** $Cu(NO_3)_2.9H_2O$. The temp. range of stability of these three hydrates is indicated in Fig. 39. The trihydrated salt was prepared by J. H. Gladstone, H. C. Jones and H. P. Bassett, and C. F. Gerhardt. The latter thought that the salt was tetrahydrated, but T. Graham's analyses showed that, owing to the hygroscopicity of the salt, high results were obtained in the determination of the combined water. J. Ordway, and R. Funk showed that the trihydrated salt is obtained when the salt is allowed to crystallize from its soln at a temp. over 26°. A. Ditte obtained the same salt by heating the hexahydrated salt until red fumes appear, and then crystallizing the product from a hot soln. in fuming nitric acid; H. Lescœur heated the hexahydrate to 65°—J. Ordway says 26·4°; T. Graham converted the hexahydrate to the trihydrate by keeping the former in vacuo over sulphuric acid for a night; if kept longer, more water is slowly given off. According to E. Mitscherlich, the trihydrate is precipitated as a crystalline powder when nitric acid of sp. gr. 1·522 is added to a sat. aq. soln. The hexahydrated salt was prepared by J. L. Proust, T. Graham, H. Lescœur, and by H. C. Jones and H. P. Bassett—the latter by cooling a soln. of the salt between 0° and —10°; and they also obtained the enneahydrate by cooling the soln. between —20° and —24°. R. Funk showed that the enneahydrate is obtained by suction from the melting cryohydrate which freezes at —24°. According to A. Ditte, anhydrous cupric nitrate, $Cu(NO_3)_2$, can be obtained by cooling a soln. of the hydrated salt in hot fuming nitric acid which has

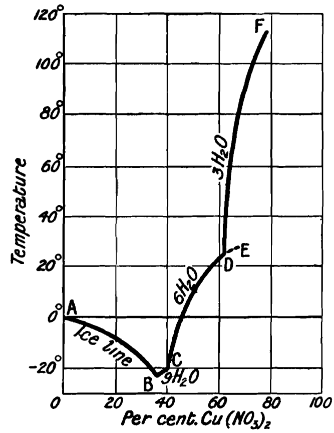

FIG. 39.—Solubility Curve of Cupric Nitrate.

been heated until red fumes appear. A. Guntz and M. Martin used a similar process. Anhydrous nitrates of the heavy metals—manganese, copper, nickel, cobalt, etc.—have been prepared by the action of nitric anhydride or of a soln. of this compound in nitric acid, upon the hydrated salts of the metals. The product is white with a green or blue tinge.

L. Playfair and J. P. Joule found the sp. gr. of the trihydrate is 2·047 (3·9°). The cryohydric point is —24° ; the transformation temp. of the ennea- to the hexahydrate is —20·5° ; of the hexa- to the tri-hydrate about 24·5° ; and the metastable m.p. of the hexahydrate, 26·4°. A. Guntz and M. Martin say the anhydrous salt begins to decompose between 155° and 160°. According to J. Ordway, the trihydrate melts at 114·49°, freezes at 95·56°, and boils at 170°, with the evolution of nitric acid, and the formation of a basic salt; T. Graham noted the formation of a basic salt at 65°. The trihydrate has a caustic metallic taste and cauterizes the skin. According to J. L. Proust, the hexahydrate melts at 38° ; R. Funk, and J. Ordway give 26·4°, at which temp. the salt decomposes into the trihydrate and water. According to T. Graham, the hexahydrate rapidly loses half of its combined water in vacuo over sulphuric acid ; the remaining water is retained more strongly because only a small proportion is lost in two days. According to P. Sabatier, the hexahydrate can form the trihydrate by efflorescence in air. The vap. press. of a soln. sat. at 20° is 7·9 mm. The cupric nitrates are all deliquescent. J. Thomsen found the heat of soln. of the hexahydrate in 400 mols of water is —10·71 Cals. P. Sabatier gives —10·5 Cals. ; he also gives for the heat of soln. of the trihydrate —2·5 Cals. at about 15° ; and for the heat of hydration $Cu(NO_3)_2.3H_2O_{solid} + 3H_2O_{solid} = Cu(NO_3)_2.6H_2O_{solid} + 3·9$ Cals. or 1·3 Cals. per mol of water. A. Guntz and M. Martin give 10·47 cals. for the heat of soln. of the anhydrous salt. J. Thomsen found the heat of formation of the salt in aq. soln. is given as $(Cu, O, N_2O_{5aq.}) = 52·41$ Cals. and $(Cu, 2N, 6O, 6H_2O) = 92·9$ Cals. J. Thomsen found the heat of dilution of a soln. of a mol of cupric nitrate in 10 mols of water with *n* more mols of water :

n . . .	12	15	20	50	100	200
Cals. . . .	474	744	940	904	776	729

R. Funk's values for the **solubility** *S* of the ennea- and hexa-hydrates, expressed in per cent. $Cu(NO_3)_2$, are :

	−23°	−21°	−20°	−21°	−10°	0°	10°	20°	26·4°
S . .	36·08	37·38	40·92	39·52	42·08	45·00	48·79	55·58	63·39
Solids	$\underbrace{\qquad}_{Cu(NO_3)_2.9H_2O}$			$\underbrace{\qquad}_{Cu(NO_3)_2.6H_2O}$					

These results are plotted in Fig. 39. The corresponding numbers for the trihydrate are :

	25°	30°	40°	50°	60°	70°	80°	114·5°
S . .	60·01	60·44	61·51	62·62	64·17	65·79	67·51	77·59

E. Mitscherlich found the salt to be soluble in nitric acid, but it is precipitated from its sat. soln. by nitric acid, as indicated above. F. Palm has also studied the reaction. According to A. A. Noyes and A. A. Blanchard, a soln. of 48 grms. of the salt in 10 c.c. of alcohol is pale blue, and green when diluted with five times its vol. of water.

The **specific gravity** of soln. of cupric nitrate has been determined by B. Franz[3] at 17·5° ; C. Bender at 15° ; by J. H. Hassenfratz at 12·5° ; by H. C. Jones and H. P. Bassett at 0° ; and H. C. Jones and J. N. Pearce at 0°. The results by J. H. Hassenfratz are :

Per cent. $Cu(NO_3)_2$.	1	5	10	20	30	40	50	56
Sp. gr. . . .	1·0059	1·0320	1·0655	1·1350	1·2320	1·3320	1·4440	1·5205

E. Irueste found that if D and D_0 respectively denote the sp. gr. of a soln. of cupric nitrate, and of water, at 15°, the conc. of a gram of the soln. is $1·12679(D-D_0)$

—0·25321$(D-D_0)^2$. J. Traube calculated the **molecular solution volume** from F. Kohlrausch's measurements of the sp. gr. (15°/4°), where for soln. with 5, 25, and 35 per cent. of $Cu(NO_3)_2$, the sp. gr. was respectively 1·043, 1·248, and 1·377, and the mol. soln. vol., 29·8, 38·0, 40·5. M. Simon found the capillary rise for a sat. soln. to be 1·012 (water unity). S. Arrhenius has measured the **viscosity** of aq. soln. of cupric nitrate, and J. Wagner found at 25° of N-, $\frac{1}{2}N$-, $\frac{1}{4}N$-, and $\frac{1}{8}N$-soln. to be respectively 1·1792, 1·0802, 1·0400, and 1·0179 (water unity). J. C. G. de Marignac found the **specific heat** of soln., between 18° and 50°, with 187·3 gram-eq. of the salt in 50, 100, and 200 c.c. of water, is respectively 0·8256, 0·9475, and 0·9882; and the **molecular heat,** 898, 1788, and 3588. W. Beetz found the **heat conductivity** between 8° and 14° for soln. of sp. gr. 1·187 and 1·455 to be respectively 1·0242 and 0·9782 (water unity); and between 28° and 38°, for soln. of sp. gr. 1·197 and 1·455, respectively 1·0000 and 0·8504 (water unity). F. Rüdorff, H. C. Jones with F. H. Getman, H. P. Bassett, and J. N. Pearce have measured the **lowering of the freezing point.** For soln. of 0·0591 mol per litre, the mol. depression is 5·52; and for soln. with 2·3630 mols per litre, 9·26. A. J. Rossi found the **osmotic pressure** of soln. with 0·5 mol per litre to be greater than with calcium or strontium nitrates.

C. Chéneveau, and H. C. Jones and F. H. Getman have measured the **index of refraction** of soln. of cupric nitrate; the latter find for soln. with 0·0591, 0·4726, and 1·1815 mol per litre, these indices are respectively 1·32751, 1·32979, and 1·35961. The **absorption spectra** of soln. of cupric nitrate have been studied by T. Ewan—*vide* cupric chloride. According to E. Franke, conc. aq. soln. of the salt are much more ionized than corresponding soln. of cupric sulphate. The **electrical conductivity** has been measured by H. C. Jones with F. H. Getman, A. P. West, H. P. Bassett, J. N. Pearce, E. Franke, A. C. Becquerel, and E. Bouty. For soln. with a mol. of the salt in v litres, the molecular conductivities μ at 0° and 35°, and the **degrees of ionization** α, are:

	v	2	8	16	32	128	512	1024
0°	μ	69·38	86·48	93·0	99·15	109·0	117·7	119·8
	α	57·9	72·2	77·6	82·8	91·0	98·2	100·0
35°	μ	147·1	188·5	204·0	219·9	245·0	266·6	271·7
	α	54·1	69·4	75·1	80·9	90·2	98·0	100·0

The corresponding **temperature coefficients** have also been calculated. H. Herwig found that raising the *pressure* did not affect the resistance of soln. of cupric nitrate. The **transport numbers** have been measured by G. Wiedemann, A. Chassy, and by G. Carrara. According to H. C. Jones and J. N. Pearce if n mols of $Cu(NO_3)_2$ are dissolved in a litre of water, there will be m mols of solvate water per mol of the salt:

n	0·025	0·05	0·25	0·5	0·75	0·935	1·5	2·0
m	195·2	48·7	22·4	22·5	22·15	21·3	18·38	17·32

A. Renard, and H. Jahn have studied the electrolysis of soln. of cupric nitrate. C. W. Bennett and C. O. Brown studied the potential of cells with a rotating anode—*vide* cupric sulphate. O. Liebknecht and A. P. Wills,[4] and G. Chéneveau respectively found the **magnetic susceptibility** to be $8{\cdot}7\times10^{-6}$ and $9{\cdot}1\times10^{-6}$ mass units.

The salt has strong oxidizing properties which are dependent on the ease with which it is decomposed. It is accordingly used as an oxidizing agent in dyeing and in calico printing.[5] L. V. Brugnatelli noted that when cupric nitrate is projected on red-hot charcoal there is a feeble detonation; and B. Higgins found that if some crystals are wrapped in tin foil, and rubbed, decomposition sets in and the accompanying rise of temp. may suffice to cause the emission of sparks. J. Priestley mentioned that paper soaked in the salt and dried readily inflames. According to I. Corne, cupric nitrate oxidizes phosphorus to hypophosphoric acid, $H_4P_2O_6$.

According to N. P. Wassilieff, cupric nitrate reacts very slowly with benzene at 100°, but faster at a higher temp. B. Lachowicz found that cupric nitrate readily unites with ammonia, and with the amines of the fatty acids, pyridine, piperidine, quinoline, aniline, and toluidine; and not so readily with dimethyl aniline, and methylaniline. A. W. Speransky and E. G. Goldberg studied the electrolysis of pyridine soln.

E. C. Franklin and C. A. Kraus[6] studied the electrical conductivity of soln. of the salt in liquid ammonia. J. J. Berzelius, R. Kane, and P. Pudschies prepared **cupric tetrammino-nitrate,** $Cu(NO_3)_2.4NH_3$, by saturating a soln. of cupric nitrate with ammonia. The precipitate which is at first formed redissolves, and the liquid deposits crystals of the salt on cooling. D. W. Horn recommended mixing a hot soln. of 10 grms. of hexahydrated cupric nitrate with 8 c.c. of water and 25 c.c. of aqua ammonia, of sp. gr. 0·9, and shaking the mixture till all is dissolved. On cooling, the crystals which separate are dried by press. between filter paper, and standing in a desiccator over potassium hydroxide. The blue needle-like crystals belong to the rhombic system, and J. C. G. de Marignac found the axial ratios $a : b : c = 0·5475 : 1 : 0·6350$. R. Kane showed that when the crystals are heated, they lose traces of ammonia but no water, and the angles may have blackened tips due to the formation of cupric oxide. The crystals are readily soluble in water from which J. J. Berzelius crystallized the salt unchanged. According to F. Ephraim, the deep blue tetrammino-salt is converted into a similarly coloured hexammino-salt below 15°, and decomposes above 205° into indefinite products. E. Rosenbohm found the magnetic susceptibility of the crystals of the tetrammino-nitrate to be $5·51 \times 10^{-6}$ vol. units, and 1409×10^{-6} mass units. According to D. W. Horn, the crystals of the tetrammino-nitrate are soluble in approximately their own weight of liquid ammonia, forming **cupric pentammino-nitrate,** $Cu(NO_3)_2.5NH_3$, which decomposes: $Cu(NO_3)_2.5NH_3 = NH_3 + Cu(NO_3)_2.4NH_3$ between 15·30° and 15·32° at 760 mm. press. D. W. Horn also prepared a still more complex salt $4Cu(NO_3)_2.23NH_3$—possibly *cupric hexammino-nitrate,* $Cu(NO_3)_2.6NH_3$—by the action of liquid ammonia on the tetrammino-salt. It rapidly loses ammonia when exposed to air, and its dissociation temp. is 15° at 760 mm. press. If a mixed soln. of cupric and ammonium nitrates be evaporated, decomposition attended by violent detonation occurs at a certain stage of the conc. F. Förster and F. Blankenberg found that cupric nitrate, in ammoniacal soln., is reduced to cuprous nitrate by copper.

J. Priestley[7] mentioned the formation of a blue precipitate when a soln. of cupric nitrate is heated, and the redissolution of the precipitate when the mixture is allowed to stand in the cold; the precipitate appeared again as at first by re-heating the soln. J. L. Proust obtained a similar crystalline precipitate of the composition $67CuO.16N_2O_5.17H_2O$—possibly $4CuO.N_2O_5.H_2O$ or $Cu_4N_2O_9.3H_2O$, or $Cu(NO_3)_2.3Cu(OH)_2$, because L. Bourgeois found that bluish-green crystals of **cupric trihydroxy-nitrate** are formed by evaporating an aq. soln. of cupric nitrate on a water-bath, and washing out the soluble matter with water. A basic cupric nitrate was prepared by J. L. Proust, C. F. Gerhardt, T. Graham, and L. Grünhut by heating cupric nitrate to about 170°, and extracting the mass with water. In all these cases the hydrolysis of an aq. soln. of cupric nitrate occurs, which is more marked the higher the temp.

J. L. Proust, F. Field, and E. Reindel prepared basic cupric nitrate by treating a soln. of cupric nitrate with alkali hydroxide insufficient for complete precipitation; C. F. Gerhardt and H. Kühn used ammonium hydroxide, and J. Habermann considered that the pale blue granular product obtained by dropping dil. aq. ammonia into a boiling conc. soln. of cupric nitrate, cooling the mixture, washing the precipitate by suction with cold water before blackening begins, and drying in a desiccator over quicklime, has the composition $Cu(NO_3)_2.Cu(OH)_2.CuO$, but it is usually regarded as **cupric trihydroxy-nitrate,** $Cu(NO_3)_2.3Cu(OH)_2$. L. Bourgeois heated a soln. of cupric nitrate with urea in a sealed tube at 130°. J. H. Gladstone prepared the basic nitrate as an amorphous mass by treating cupric nitrate with the hydroxide; while P. Sabatier used $4CuO.H_2O$ (cupric oxide would not do), and obtained a green micaceous powder. N. Athanasescu boiled a conc. aq.

soln. of cupric nitrate for several hours with cupric carbonate, and then heated the mixture in a sealed tube for several hours at 300° and obtained small emerald-green crystals of the basic nitrate. L. Bourgeois, and H. L. Wells and S. L. Penfield prepared a variety of the basic salt $Cu_4N_2O_9.3H_2O$ in dark green monoclinic plates by boiling a soln. of cupric nitrate with copper, or by heating the mixture in a sealed tube at 150°. A. Mailhe found that the same basic salt could be obtained by heating a soln. of cupric nitrate with nickel oxide, hydroxide, or carbonate.

W. Spring and M. Lucion found that when cupric hydroxide is kept in contact with a soln. of potassium nitrate at 15°, basic cupric nitrate is formed which decomposes at 30°. J. Tüttscheff, and D. Strömholm boiled a soln. of ammonium nitrate with precipitated cupric oxide and obtained what they regarded as basic nitrate of the composition $12CuO.2N_2O_5.12H_2O$, that is, $2Cu(NO_3)_2.10Cu(OH)_2.5H_2O$. A. Vogel and C. Reischauer passed nitrous fumes, N_2O_3, into water with cupric hydroxide in suspension, and they also boiled a mixed soln. of cupric nitrate and potassium nitrate, and obtained greenish-blue plates in both cases. F. P. Dewey treated cuprous oxide with an excess of a cold soln. of silver nitrate, and obtained the basic nitrate $Cu(NO_3)_2.3Cu(OH)_2$, *i.e.* $Cu_4N_2O_9.3H_2O$—H. Rose used a similar process, and C. F. Rammelsberg believed that the product had the composition $3Cu(NO_3)_2.7CuO$, or $Cu_{10}N_6O_{25}$, but H. L. Wells and S. L. Penfield regarded the product as a mixture. G. Rousseau obtained bluish-green thin plates of basic nitrate by heating trihydrated or hexahydrated cupric nitrate between 180° and 330° with marble in a sealed tube for 24–49 hrs.; and L. Michel found that a film of crystals of this same salt are formed on the surface of Iceland spar which has been lying for a few years in a soln. of cupric nitrate. A. Casselmann, J. M. van Bemmelen, and K. Klüss obtained the basic nitrate by heating a boiling dil. soln. of cupric nitrate with formate of sodium, calcium, barium, or lead; with the acetate of potassium, sodium, copper, silver, calcium, barium, magnesium, zinc, cadmium, manganese, nickel, cobalt, or lead; or with sodium and barium propionates; or with sodium valeriate. Conversely, the same product is obtained by treating cupric acetate, propionate, or valerianate with the nitrates of the above metals excepting silver and strontium.

Cupric trihydroxynitrate, $Cu(NO_3)_2.3Cu(OH)_2$, occurs as a mineral in the copper mines at Jerome (Arizona), etc., and it was named *gerhardtite*, in honour of C. F. Gerhardt; and W. Lindgren and W. F. Hillebrand regard it as a product of the action of water on cupriferous porphyry. Some analyses correspond with the composition: $Cu(NO_3)_2.3CuO.H_2O$, instead of $Cu(NO_3)_2.3CuO.3H_2O$, as indicated above. H. L. Wells and S. L. Penfield assume it to be the hydrate of an hypothetical nitric acid, H_3NO_4, $H(CuOH)_2NO_4$, as indicated above. J. P. Cooke gives without any satisfactory evidence $(HO)_3(CuOH)_3.CuO_2.N_2O$; N. Athanasescu, and A. Werner respectively, give

$$\begin{matrix}O\\HO\end{matrix}\!>\!N\!<\!\begin{matrix}O.CuOH\\O.CuOH\end{matrix}$$

$$\left[Cu\left(\begin{matrix}HO\\HO\end{matrix}Cu\right)_3\right](NO_3)_2$$

The latter thus regards the basic salt as a hexol-cupric salt.

This basic salt is dark green, emerald green, or bluish-green in colour. H. L. Wells and S. L. Penfield regard the mineral as belonging to the rhombic system with axial ratios $a:b:c=0{\cdot}92175:1:1{\cdot}56117$, and, as indicated above, they prepared a monoclinic variety; the hardness is 2, and the sp. gr. 3·41–3·426; L. Bourgeois gives 3·41. According to T. Graham, very little decomposition occurs at the m.p. of lead; at higher temp. nitrogen oxides, oxygen, and water are given off. N. Athanesescu says that water begins to come off at 160°–165°, and nitric oxide at 175°; at the same time the salt begins to blacken. L. Grünhut found that a prolonged heating at 200° gives cupric oxide. The basic salt is stable in air; insoluble in water; and soluble in dil. acids. A. Casselmann found that the precipitated salt slowly becomes brown on standing under water, and finally black; and J. M. van Bemmelen noted that the basic salt becomes grey when boiled with water. G. Rousseau and G. Tité heated the salt with water in a sealed tube at 160° for 20 hrs., and found it decomposes completely into cupric oxide and nitric acid. J. M. van Bemmelen decomposed the salt into cupric hydroxide by treating it with alkali hydroxide. G. Rousseau and G. Tité say that the temp. of decomposition is lower than the temp. of formation, and that the heat of formation is over 10·5 Cals., while the heat of soln. of the solid nitrate in an excess of water is 10·8 Cals. at about 100°; but P. Sabatier gives for the heat of formation $Cu(NO_3)_2.3H_2O_{solid} + 3CuO_{dry} = 12{\cdot}1$ Cals. The crystals of gerhardtite have a strong negative double refraction; they have a marked pleochroism, being blue in the direction of the *c*-axis, and green in the direction of the other two axes.

A. Massink studied the ternary system, $Cu(NO_3)_2$—$NaNO_3$—H_2O, at 20°, and the ternary system, $Cu(NO_3)_2$—$CuSO_4$—H_2O, at 20° and 35°, but obtained no double salts; he also investigated the quaternary system, Na_2SO_4—$NaNO_3$—$Cu(NO_3)_2$—$CuSO_4$, at 20°, but obtained no new complex salts. K. A. Hofmann and E. C. Marburg reported the preparation of bluish green **cupric hydrazine nitrate,** $Cu(N_2H_4)(NO_3)_2$, which explodes when heated or on detonation.

§ 30. Copper Phosphates

No one has yet prepared *cuprous orthophosphate*, Cu_3PO_4, although E. Péchard obtained what he regarded as *ammonium cuprous orthophosphate*, or **ammonium phosphato-cuprite,** by adding hydroxylamine to cupric sulphate until the soln. was decolorized, and then treating the mixture with a soln. of ammonium dihydrophosphate. V. Auger also claims to have made **cuprous metaphosphate** by adding metaphosphoric acid at a dull red heat to an excess of copper turnings contained in a platinum capsule provided with a lid and heated to a similar temp.; the copper dissolves with the evolution of hydrogen and the mass becomes brown. The latter is immediately oxidized by air, but if the mass is poured off from the unattacked copper into a platinum crucible and protected from air, on cooling it deposits lamellæ of copper in weight equal to that subsequently found in the residual mass in the form of cupric phosphate. The cuprous metaphosphate formed is thus stable at a red heat, but decomposes on cooling into cupric metaphosphate and copper. If the fused mass of cuprous metaphosphate dissolved in excess of metaphosphoric acid is allowed to fall in small drops into methyl chloride, transparent, vitreous, pale yellow beads of cuprous metaphosphate dissolved in excess of metaphosphoric acid are obtained. These can be kept in a sealed tube for some days, but gradually become reddish-brown and opaque. The change occurs immediately on warming.

E. Mitscherlich [1] obtained normal **cupric orthophosphate,** $Cu_3(PO_4)_2.3H_2O$, as a bluish-green amorphous precipitate by adding an amount of diammonium, or dipotassium hydrophosphate, insufficient for complete precipitation, to the soln. of a cupric salt. J. Steinschneider used a great excess of cupric sulphate or nitrate. From the work of C. F. Rammelsberg and R. A. Metzner, the composition of the precipitate depends upon the proportions and conc. of the soln. employed.

J. Steinschneider found that in preparing cupric phosphate by the action of disodium hydrophosphate on cupric sulphate the following phosphates are formed: By employing an *excess of copper sulphate*, a double salt of the formula $3Cu_3P_2O_8.NaH_2PO_4$ is formed; if the copper sulphate be present in very large excess, C. F. Rammelsberg's normal phosphate, $Cu_3P_2O_8$, is formed. Both these salts, if subjected to protracted washing under press., are converted into the compound $4CuO.P_2O_5$, already described by H. Debray, and C. Friedel and E. Sarasin. Sodium acetate precipitates the double salt $3Cu_3P_2O_8.NaC_2H_3O_2$ from the filtrate. By employing an *excess of sodium phosphate*, two double salts are formed, namely, $2Cu_3P_2O_8.Na_2HPO_4$ and $3Cu_3P_2O_8.Na_2HPO_4$; the former is formed first and is converted into the latter by continued washing. By the action of disodium hydrogen phosphate on cupric chloride, the following phosphates are formed: When an *excess of cupric chloride* is employed, the double salt $3Cu_3P_2O_8.2NaCl$ is principally formed, although sometimes it is mixed with the phosphate, $4CuO.P_2O_5$, and the oxychloride, $CuO.CuCl_2$; in one case the salt had the formula $5Cu_3P_2O_8.3NaCl$. If an *excess of the sodium phosphate* is employed, the same phosphate, $3Cu_3P_2O_8.2NaCl$, is formed as in the case of employing an excess of cupric chloride. By the action of the sodium phosphate on cupric nitrate, the following phosphates are obtained: By employing a slight *excess of the cupric nitrate*, the double salt $Cu_3P_2O_8.NaH_2PO_4$ is formed, whilst if the cupric nitrate is present in very large excess, the normal phosphate, $Cu_3P_2O_8$, together with a small quantity of basic cupric nitrate, is obtained. If an *excess of the sodium phosphate* is employed, a double salt of the formula $18CuO.3Na_2O.8P_2O_5$, is formed, which is decomposed by washing.

H. Rose said that if two mols of the disodium salt are used with three mols of cupric sulphate, the salt $2CuHPO_4.3H_2O$ or $4CuHPO_4.CuH_4(PO_4)_2$ is precipitated, but the work of C. F. Rammelsberg renders this doubtful. J. Weineck's analysis makes the product a mixture and not a definite compound. A. Breithaupt and C. F. Plattner say that the emerald-green amorphous mineral *thrombolite* has the composition $2CuHPO_4.3H_2O$, hardness 3 to 4, and sp. gr. 3·4; while A. Schrauf regards this mineral as an arsenate. H. Debray prepared the normal phosphate as a crystalline powder by dissolving the carbonate in dil. phosphoric acid, and heated the soln. to 70°; he also heated cupric nitrate with calcium hydrophosphate below 100°. V. Augur heated cuprous chloride with phosphoric acid to 180°. It is questionable if the pure salt has yet been made.

According to H. Debray, the salt loses water and becomes brown when it is heated. According to A. Barillé, cupric phosphate is insoluble in water, but soluble in water with carbon dioxide in soln. R. M. Caven and A. Hill found that in washing the precipitate with water, the salt is hydrolyzed, and a marked hydrolysis occurs with hot water. H. Debray found the salt is rapidly hydrolyzed when heated with water in a sealed tube, forming basic phosphates several of which have been examined by J. Steinschneider, A. Reynoso, etc. According to J. Moser, cupric phosphate is soluble in nitric acid; according to H. Debray, in phosphoric acid, acetic acid, and, as B. W. Gerland also found, sulphurous acid, without forming cuprous oxide. C. Lory uses a soln. in hydrochloric acid in his process for determining bicarbonates; H. Debray also found the phosphate to be perceptibly soluble in soln. of ammonium salts; and R. M. Caven and A. Hill in soln. of cupric chloride or sulphate. It is also dissolved by a soln. of sodium thiosulphate. W. Skey and L. Grandeau obtained double phosphates by treating cupric phosphate with a soln. of potassium or ammonium magnesium phosphate. According to R. M. Caven and A. Hill, a cold soln. of potassium hydroxide produces no perceptible change, but on boiling, the precipitate becomes dark coloured, and is completely converted into cupric oxide. Cupric phosphate was found by H. Debray to be reduced to the phosphide when heated with carbon. H. N. Warren electrolyzed a soln. of cupric phosphate in phosphoric acid, and so obtained an acid of any desired sp. gr. The evaporation of a soln. of cupric phosphate furnishes a green sticky mass of uncertain composition, and labelled, according to the older chemistry books, "acid cupric phosphate," that is, *cupric hydrogen phosphate*. C. Luckow, and W. Borchers obtained a basic cupric phosphate of unknown composition by electrolyzing soln. of sodium phosphate between copper electrodes; and when the phosphate is precipitated electrolytically in a porous cell, H. N. Morse found it to form a semipermeable membrane. L. T. Wright found cupric phosphate absorbs hydrogen sulphide, and A. Colson found that the absorption by the dry salt at 0° is slow but continuous; the rate of absorption is reduced by lowering the press. and accelerated by raising the temp. J. Steinschneider found that cupric orthophosphate is decomposed quantitatively when boiled with a soln. of silver nitrate, forming cupric nitrate and silver phosphate.

It might be anticipated from the slow hydrolysis of cupric phosphate in contact with water, that many different *basic cupric phosphates* would have been reported by the early chemists who had no criterion other than analysis and the stoichio-metrical laws for recognizing chemical compounds. The phase rule test has not yet been applied. Hence, as might be anticipated, quite a number of basic cupric phosphates have been reported, and a number occur in nature as minerals, where the ratio $CuO : P_2O_5 : H_2O$ is 6 : 1 : 3; 5 : 1 : 2; 5 : 1 : 3; 4 : 1 : 1; 4 : 1 : 2; and 4 : 1 : 3.

Many are probably solid soln.; all are more or less hydrated. Perhaps the most important basic phosphate approximates in composition to **cupric hydroxyorthophosphate,** $4CuO.P_2O_5.H_2O$, or $Cu_3(PO_4)_2.Cu(OH)_2$, and its natural representative is the mineral *libethenite.* It was prepared by C. Friedel and E. Sarasin in octahedral crystals by heating cupric carbonate or cupric phosphate with dil. phosphoric acid in a sealed tube at 180°; H. Debray heated cupric phosphate with water in a sealed tube; the formation of libethenite occurs at 100° if cupric nitrate or sulphate be also present—to get fine crystals, however, 150° is recommended—and a rather higher temp., 200°, is necessary if cupric chloride be used; and he found that libethenite is formed by heating a mixture of cupric nitrate and calcium hydrophosphate to 100°. J. Steinschneider, and R. M. Caven and A. Hill found that the same basic phosphate is obtained by boiling the normal phosphate with water, or by the prolonged washing of this salt with water at 100° until its composition is constant, and then drying the mass at 100°.

The crystals of libethenite are rhombic bipyramids, and the measurements of W. T. Schaller, and G. Melczer correspond with axial ratios $a:b:c=0·9605:1:0·7020$. The analyses of C. F. Rammelsberg, H. Kühn, F. Field, R. Hermann, and C. Bergemann are in the main in agreement with the formula, $4CuO.P_2O_5.H_2O$, or $Cu_3(PO_4)_2.Cu(OH)_2$; which P. Groth reduces to $Cu(CuOH)PO_4$, and thus regards libethenite as a basic cupric phosphate free from water. There are two more hydrated forms; one, which C. F. Rammelsberg designated *pseudo-libethenite,* has the composition $4CuO.P_2O_5.2H_2O$, or $Cu_3(PO_4)_2.Cu(OH)_2.H_2O$, in accord with the analyses of C. Berthier, and R. Rhodius. The other hydrate is called *tagilite,* and, according to A. Breithaupt, occurs in monoclinic crystals, and has the composition $4CuO.P_2O_5.3H_2O$, or $Cu_3(PO_4)_2.Cu(OH)_2.2H_2O$, in accord with the analyses of R. Hermann and F. Field. R. Hermann found the sp. gr. of libethenite to range from 3·6 to 3·8, and that of tagilite to be 3·50; A. Breithaupt gave 4·076 for crystalline tagilite, and 3·5 for the amorphous mineral. The hardness of libethenite is 4, that of tagilite a little less. A. des Cloizeaux has measured the optical properties; the double refraction is negative. H. Debray found that water attacks the mineral with difficulty, and G. Rousseau and G. Tité that three days' heating in a sealed tube at 275° had no perceptible effect. R. M. Caven and A. Hill add that "the tenacity with which the single molecule of water remains in combination with the basic phosphate is remarkable, since a dull red heat is necessary for its elimination. The ignited precipitate, consisting of $Cu_3(PO_4)_2.CuO$, was olive green in colour." It is soluble in acids and in aq. ammonia or ammonium carbonate, in a soln. of sodium hyposulphite. J. Steinschneider observed no alteration when the mineral is boiled with a soln. of silver nitrate.

There is a group of naturally occurring basic cupric phosphates called *lunnites,* which A. Schrauf has shown can all be regarded as containing varying proportions of one or more of the three minerals: *dihydrite,* $5CuO.P_2O_5.2H_2O$; *ehlite,* $5CuO.P_2O_5.H_2O$; and *phosphochalcite,* $6CuO.P_2O_5.3H_2O$. The formula for dihydrite is based on the analyses of R. Hermann, J. A. Arfvedson, H. Kühn, and A. Schrauf. The latter says the doubly refracting, dark green crystals are triclinic with axial ratios $a:b:c=2·8252:1:1·53394$, and $\alpha=89° 29'$; $\beta=91° 0·5'$; and $\gamma=90° 39'$; the hardness is approximately 5; the sp. gr. 4·4. The formula for ehlite is based on the analyses of A. Schrauf, who regards ehlite as a transformation product of dihydrite. The formula of phosphorochalcite is based on the analyses of R. Hermann, H. Kühn, C. F. Rammelsberg, C. Bergemann, M. F. Heddle, A. H. Church, A. Schrauf, N. Story-Maskelyne and W. Flight, R. Rhodius, etc. The hardness is 4·5 to 5, and the sp. gr. 4·4. It loses no water at 200°. The variety called *pseudomalachite* has a sp. gr. 4·2, and suffers an appreciable loss of water at 200°. A. Hutchinson and A. M. Macgregor found the *cornetite* from Mkubwa (Rhodesia) has a composition approximating $Cu_3(PO_4)_2.3Cu(OH)_2$. The rhombic crystals have the axial ratios $a:b:c=0·9855:1:0·7591$; sp. gr. 4·10; and hardness 4 to 5. The optical properties agree with a mineral containing a little cobalt (Co,Cu)(OH)(PO_4), named cornetite by H. Buttgenbach, and obtained from Katanga (Congo). G. Césaro found the axial ratios $a:b:c=0.9844:1:0.7679$.

H. Schiff[2] found freshly precipitated and moist cupric phosphate dissolved slowly but completely in aq. ammonia, forming a dark blue liquid from which alcohol precipitates a dark blue syrup which soon forms greenish-blue anhydrous crystals of **cupric tetrammino-orthophosphate,** $Cu_3(PO_4)_2.4NH_3$. The salt can also be obtained directly by the use of alcoholic ammonia. Cupric tetrammino-orthophosphate is sparingly soluble in water; it dissolves in aqua ammonia, possibly forming, according to H. Schiff, a hexammino-complex, although only the tetrammino-salt has been isolated. R. A. Metzner obtained monoclinic prismatic crystals of a complex by similarly treating a sat. soln. of the basic phosphate in aq. ammonia. Analyses correspond with $2CuO.3P_2O_5.20NH_3.21H_2O$. R. A. Metzner also obtained monoclinic crystals of the complex $Cu(NH_4)_7(PO_4)_3(NH_3)_3.7H_2O$ by adding alcoholic ammonia to a soln. of an acid cupric phosphate in ammonia. E. J. Maumené claimed to have made $2CuO.P_2O_5.8NH_3$ from an ammoniacal soln. of cupric phosphate.

According to J. Weineck,[3] the well-washed precipitate obtained by mixing hot soln. of two mols of cupric sulphate with three of disodium hydrophosphate, when dried between 100° and 110°, has a composition corresponding with $2Na_2O.4P_2O_5.9CuO$, and is probably a mixture of two or more salts. J. J. Berzelius and others have noted that beads of microcosmic salt, when sat. with various metallic salts, become opaque on cooling, owing to the separation of minute crystals of sodium phosphate and the metal phosphate. K. A. Wallroth has isolated these salts by dissolving metallic oxides in microcosmic salt or sodium metaphosphate at a bright red heat, and maintaining the glass in a fused condition until the crystals separate out. On cooling, the mass is digested with water, and then with dil. hydrochloric acid. With copper, a blue crystalline powder of **sodium phosphatocuprate,** or sodium cupric phosphate, is formed, $Na_6Cu_3(PO_4)_4$, or $2Na_3PO_4.Cu_3(PO_4)_2$, which melts to a green transparent glass. L. Ouvrard obtained the same salt in dichroic prisms, probably monoclinic. If an excess of cupric oxide or sodium pyrophosphate be used, prismatic crystals of **sodium cupric phosphate,** $NaCu(PO_4)$, with an oblique extinction, are formed. If sodium orthophosphate be employed as flux, a mixture of cupric and cuprous oxides, with some amorphous matter, is produced. C. Raspe also prepared a soluble double phosphate by melting disodium hydrophosphate with cupric and phosphoric oxides.

L. Ouvrard prepared what are said to be pale blue triclinic crystals of **potassium cupric phosphate,** $KCuPO_4$, by a method similar to that which he employed for the sodium salt. The crystals were similar to those of the sodium salt. L. Grandeau also reported the formation of a bluish-green crystalline powder of the same compound made up of small plates, by melting cupric phosphate with an excess of dipotassium hydrophosphate. L. Ouvrard also made greenish-blue monoclinic lamellæ of **potassium triphosphatotetracuprate,** of $KCuPO_4.Cu_3(PO_4)_2$, by fusing cupric oxide or carbonate with potassium metaphosphate. As previously indicated, J. Steinschneider prepared salts with $Cu_3(PO_4)_2:Na_2HPO_4$ in the ratios 3 : 1, 2 : 1, and 1 : 1; and also two *sodium cupric chlorophosphates* with $Cu_3(PO_4)_2$: NaCl in the ratios 3 : 2 and 5 : 3, but there is nothing to show if these are really double salts, or mixed crystals (solid soln.).

Cupric pyrophosphates.—A. Schwarzenberg,[4] A. Pahl, and J. H. Gladstone obtained blue amorphous cupric pyrophosphate—either $Cu_2P_2O_7.2H_2O$ or $Cu_2P_2O_7.2\frac{1}{2}H_2O$—by adding an excess of sodium pyrophosphate to a soln. of a cupric salt; it becomes crystalline when boiled with sulphurous acid, or when precipitated from its soln. in aqua ammonia by the addition of sulphurous acid. No reduction occurs in either case. A. Pahl also precipitated the same salt from a soln. of the double sodium and cupric pyrophosphate by the addition of sulphuric or hydrochloric acid. The compound loses half its combined water at 150°, and when heated in a stream of hydrogen, it gives a sublimate of phosphorus trioxide, and gives off phosphine and water. The residue is cupric phosphide. The salt is soluble in aqua ammonia, mineral acids, and in a soln. of sodium pyrophosphate. The deep blue colour of the ammoniacal soln. is bleached by grape sugar. According to A. Colson, the salt is decomposed by hydrogen sulphide liberating 50 Cals. of heat. A. Schwarzenberg found a boiling soln. of potassium hydroxide forms cupric oxide and potassium phosphate, while A. Stromeyer found a boiling soln. of disodium hydrophosphate forms sodium pyrophosphate and cupric orthophosphate. According to A. Pahl, if a soln. of this salt in sulphurous acid be evaporated over sulphuric acid, it forms blue crystals of the pentahydrate, $Cu_2P_2O_7.5H_2O$; and, according to A. Wiesler, the same salt is made by mixing soln. of 15 grms. of pentahydrated cupric sulphate with one of 5 grms. sodium trimetaphosphate, evaporating in vacuo, and washing and drying the product. The salt is sparingly soluble in water, soluble in dil. acids, and when heated it becomes green without melting. According to F. W. Clarke and J. S. Diller, Mexican turquoises may be regarded as mixtures of different proportions of pentahydrated cupric pyrophosphate, $Cu_2P_2O_7.5H_2O$, and aluminium phosphate, $2Al_2O_3.P_2O_5.5H_2O$. J. H. Gladstone obtained evidence of the formation of an allotropic form. According to A. Schwarzenberg, when the hydrate is heated, it forms the anhydrous salt. G. Tammann also made the anhydrous salt by melting equi-molecular parts of cupric sulphate and microcosmic salt, or phosphoric acid and cupric sulphate. The pale blue salt is readily soluble in hot hydrochloric or nitric acid ; and it is converted into sodium pyrophosphate and cupric sulphide by the action of a soln. of sodium sulphide.

A. Schwarzenberg found that when a soln. of cupric pyrophosphate in aqua ammonia is treated with alcohol, a **cupric ammino-pyrophosphate,** $8CuO.3P_2O_5.8NH_3.8H_2O$, is formed. The salt is slightly soluble in water, and when heated it becomes brown. According to H. Schiff, if a soln. of cupric pyrophosphate in aqua ammonia be exposed to the air, it gradually loses ammonia, and gives green crystals of the monohydrated **cupric tetramminopyrophosphate,** $2CuO.P_2O_5.4NH_3.H_2O$, that is, $Cu_2P_2O_7.4NH_3.H_2O$, which, when heated, form a bluish-white mass easily soluble in acids and aqua ammonia. When further heated, it forms white anhydrous cupric pyrophosphate. T. Fleitmann and W. Henneberg digested cupric hydroxide with a soln. of sodium pyrophosphate in excess ; and they also boiled freshly precipitated cupric pyrophosphate with a soln. of sodium pyrophosphate, filtered the hot soln., and cooled the mixture. The white crystals have a composition corresponding with $Na_4P_2O_7.3Cu_2P_2O_7.7H_2O$, that is, $Na_2CuP_2O_7.Cu_2P_2O_7.3\frac{1}{2}H_2O$, **tricupric disodium dipyrophosphate,** $Na_2Cu_3(P_2O_7)_2.3\frac{1}{2}H_2O$ The crystals are insoluble in water. A similar salt, $Na_2CuP_2O_7.Cu_2P_2O_7.10H_2O$, or $Na_2CuP_2O_7.3Cu_2P_2O_7.20H_2O$, was prepared by M. Stange by mixing a soln. of sodium triphosphate with cupric sulphate until a permanent precipitate is obtained. The white crystalline powder is quite insoluble in water, and when heated, it becomes blue, green, and yellowish-green ; it sinters at a high temp. After heating, it is still soluble in nitric and hydrochloric acids. A. Pahl had previously reported the preparation of minute pale blue rhombic plates of $Na_4P_2O_7.Cu_2P_2O_7.10\frac{1}{2}H_2O$, or $Na_4P_2O_7.3Cu_2P_2O_7.21H_2O$. He said the salt melted when heated and freezes to a pale blue crystalline mass ; and that it is soluble in a soln. of the salt, $3Na_4P_2O_7.Cu_2P_2O_7$. When this salt is heated to 100°, and then extracted with water, A. Pahl found that the soln. on evaporation furnished a bluish-green crystalline mass of the composition, $4CuO.P_2O_5.5H_2O$, or $2Cu(OH)_2.Cu_2P_2O_7.3H_2O$, **cupric hydroxypyrophosphate.** This basic salt melts when heated and forms on cooling a green glass. It is soluble in a soln. of sodium pyrophosphate, with the separation of cupric oxide.

When the mother liquid remaining after the preparation of the preceding salt is slowly evaporated, J. F. Persoz found that pale blue crystals of **cupric disodium dipyrophosphate,** $CuNa_2P_2O_7.6H_2O$, or $Na_4P_2O_7.Cu_2P_2O_7.12H_2O$, are formed. A. Pahl's and T. Fleitmann and W. Henneberg's analyses of the salt, crystallized respectively at 40° and 100°, correspond with $Na_4P_2O_7.Cu_2P_2O_7.1\frac{1}{3}H_2O$. The salt is sparingly soluble in water; melts when heated and freezes to a pale blue glass or, if slowly cooled, to a pale blue crystalline mass. T. Fleitmann and W. Henneberg and A. Pahl found that spontaneous evaporation of the syrupy mother liquid from the preparation of the preceding salt gives blue crystals of the composition: $3Na_4P_2O_7.Cu_2P_2O_7.24$(or 32)$H_2O$, that is, $Na_4P_2O_7,Na_2CuP_2O_7.12$(or 16)$H_2O$, corresponding with **hexasodium cupric dipyrophosphate,** $Na_6Cu(P_2O_7)_2.12$(or 16)H_2O. J. F. Persoz's analysis gave the lower proportion of water, A. Pahl's the higher; when dried at 100°, T. Fleitmann and W. Henneberg found the salt has the composition $Na_6Cu(P_2O_7)_2.2H_2O$. The latter also stated that the crystals are triclinic prisms, easily soluble in water, which sinter about 100°, and melt when heated to a higher temp. The alkali cupric pyrophosphates want studying in the light of the phase rule. A. Pahl and J. F. Persoz obtained a pale blue mass of the composition **cupric dipotassium pyrophosphate,** $K_2P_2O_7.Cu_2P_2O_7.1\frac{1}{3}H_2O$, or $K_2CuP_2O_7.\frac{1}{3}H_2O$. The salt melts when heated, and freezes to a glassy mass. The salt is very soluble in water; zinc does not precipitate the copper, but iron does so in a few days.

F. Schwarz prepared what he regarded as **cupric triphosphate,** $5CuO.3P_2O_5.13H_2O$, by precipitation from the sodium salt soln. with a conc. soln. of cupric sulphate; but M. Stange expressed his doubts about the homogeneity of this product. F. Schwarz and M. Stange obtained prismatic crystals of **sodium cupric trimetaphosphate,** $Na_3CuP_3O_{10}.12H_2O$, from a not too dil. soln. of a gram of sodium triphosphate, $3Na_2O.P_2O_5$, and 0·486 grm. of pentahydrated cupric sulphate. When heated the salt melts in its water of crystallization; when further heated, the water is expelled; and at a red heat, it melts to a yellow liquid, which on cooling forms a bluish-green glass. It is sparingly soluble in water, easily soluble in acids.

Copper metaphosphates.—T. Fleitmann,[5] and R. Maddrell prepared anhydrous **cupric dimetaphosphate,** CuP_2O_6, by mixing cupric nitrate with a dil. soln. of orthophosphoric acid, evaporating to dryness, and heating the product to 316°. F. Warschauer, and A. Glatzel prepared this salt by dissolving cupric oxide in phosphoric acid of sp. gr. 1·68 to 1·75, so that the acid is about 5 per cent. in excess. The dissolution is assisted by heating first on a water-bath and then on a sand-bath gradually to 400°. The powdered mixture was washed with dil. nitric acid. According to G. Tammann, the insoluble form of sodium metaphosphate dissolves slowly in a conc. soln. of cupric sulphate. A rise of temp. hastens the rate of dissolution, and J. Müller obtained some copper metaphosphate from the soln. G. Tammann also obtained cupric dimetaphosphate by adding cupric sulphate to a soln. of silver metaphosphate; and he found ammonium metaphosphate swells up in a soln. of cupric sulphate, forming a mass soluble in excess; the soln. does not give a precipitate on dilution with water.

Cupric dimetaphosphate so prepared was regarded by F. Warschauer as a tetrametaphosphate. The salt is so sparingly soluble in water that R. Maddrell supposed it to be insoluble; T. Fleitmann found the salt to be almost insoluble in alkalies, easily soluble in aq. ammonia. According to A. Glatzel, some remains insoluble when the salt is extracted with boiling aqua ammonia. G. Gore says the salt is insoluble in liquid ammonia. A. Glatzel says the salt is almost insoluble in most acids. The salt was found by T. Fleitmann to be decomposed by soln. of alkali sulphides, but to be scarcely affected by hydrogen sulphide. T. Fleitmann obtained a dark blue crystalline powder of tetrahydrated salt, $CuP_2O_6.4H_2O$, by the mixing soln. of cupric salts and alkali dimetaphosphates. The salt does not lose its water of crystallization at 100°, but it does so at a dull red heat with the simultaneous volatilization of phosphorus pentoxide. The salt melts when heated to a higher temp. and forms on slow cooling the tetrametaphosphate, $Cu_2P_4O_{12}$. T. Fleitmann said the salt is insoluble in water, but A. Glatzel found 100 parts of water dissolve 1·3 parts of the salt, and it is easily decomposed by hot. conc. sulphuric acid.

T. Fleitmann, and A. Glatzel obtained dark blue crystals of **ammonium**

cupric dimetaphosphate, $(NH_4)_2Cu(P_2O_6)_2.4H_2O$, by mixing conc. soln. of two mols of ammonium dimetaphosphate with one mol of cupric chloride. By using a great excess of the former salt, T. Fleitmann found the dihydrated salt, $(NH_4)_2Cu(P_2O_6)_2.2H_2O$, is formed, but A. Glatzel could not verify this. The compound dissolves sparingly in water, for 100 parts of water dissolve two parts of salt. All the water is expelled from the salt at 150°. Acids attack it with difficulty, it is readily decomposed by boiling conc. sulphuric acid.

G. Tammann obtained what was considered to be **cupric trimetaphosphate,** $Cu_3(P_3O_9)_2.9H_2O$, by mixing soln. of the sodium salt and cupric sulphate. The precipitate separates with difficulty, and by mixing cupric sulphate with the barium salt, a liquid is obtained which does not crystallize. The salt is said to be sparingly soluble in water, 0·04 grm. dissolving in a litre at 20°; the salt melts at a white heat. A. Wieslar and C. G. Lindboom obtained only cupric pyrosulphate by G. Tammann's process of preparation.

A. Glatzel obtained what he regarded as anhydrous **cupric tetrametaphosphate,** $Cu_2P_4O_{12}$, by the process indicated above for the dimetaphosphate (*q.v.*). The octahydrated salt, $Cu_2P_4O_{12}.8H_2O$, was also obtained by A. Glatzel in pale blue crystals by treating a dil. soln. of ammonium tetrametaphosphate with an excess of cupric sulphate. The water of crystallization can be all expelled by heat, and the anhydrous salt is formed when the mass fuses. The octahydrate is very sparingly soluble in water; acids, other than sulphuric acid, attack the salt with difficulty. T. Fleitmann, and A. Glatzel prepared anhydrous bluish-white crystalline **disodium cupric tetrametaphosphate,** $Na_2CuP_4O_{12}$, by mixing cupric dimetaphosphate with more than an equi-molecular part of sodium dimetaphosphate. The dried salt is heated to 300°. According to A. Glatzel, other metaphosphates are always present. The salt is decomposed by sodium sulphide soln., forming sodium tetrametaphosphate. A. Glatzel also prepared blue crystals of the tetrahydrate $Na_2CuP_4O_{12}.4H_2O$, by mixing conc. soln. of sodium dimetaphosphate and cupric chloride, and evaporating. The water of crystallization is expelled between 150° and 200°, and 100 parts of water dissolve 2·2 parts of the salt. A. Glatzel prepared tetrahydrated **dipotassium cupric tetrametaphosphate,** $K_2CuP_4O_{12}.4H_2O$, in a similar way. The properties of this salt resemble those of the sodium salt. 100 parts of water dissolve 1·72 parts of the salt. Conc. sulphuric acid readily decomposes the salt; boiling acids attack the salt particularly if it has been previously calcined. Alkali sulphide soln. decompose the salts.

G. Tammann reported the formation of **cupric pentametaphosphate,** $Cu_5(P_5O_{15})_2$ by mixing soln. of cupric sulphate and of ammonium pentametaphosphate. H. Lüdert precipitated bluish-white **cupric hexametaphosphate,** $Cu_3P_6O_{18}$, by mixing sat. soln. of cupric chloride, and sodium hexametaphosphate. The precipitate is soluble in an excess of either reagent. H. Rose says that no precipitate is obtained if cupric sulphate be used. The precipitate is sometimes a pale green oily liquid which dries on a glass plate to a brittle glass. The oil dries to a sticky mass at 100°. The salt is sparingly soluble in water, easily soluble in acids. H. Lüdert obtained evidence of the formation of **sodium cupric hexametaphosphate,** $Na_6P_6O_{18}.Cu_3P_6O_{18}$, by adding alcohol to the soln. remaining after the separation of the preceding salt.

CHAPTER XXII

SILVER

§ 1. The History of Gold and Silver

> No one ever yet has had so much silver as not to desire more ; and if people have a superabundance, they hoard it, and are not less delighted with so doing than with putting it to use.—XENOPHON (*c.* 353 B.C.).

PREHISTORIC man probably discovered silver some time after gold, and gold possibly before copper. Native silver is not nearly so common as gold, and it is not likely to have attracted attention so early. Pliny writes in his *Historia naturalis* (**33.** 31) that silver " is never found but in shafts sunk deep in the ground, and there are no shining spangles to raise hopes of its existence as in the case of gold." Silver was not known to the Aryans before the linguistic separation, since the Latin, Greek, and Sanskrit names were formed independently. The philologists[1] tell us that the Latin *argentum* is derived from the Aryan root *radj* or *arg*, meaning white, bright, or shining ; the Greek term is ἄργυρος, and both the Greek and Sanskrit terms have the same root with a different suffix ; the Gothic *silubr*—Icelandic *silfr*, English *silver*, Hollandic *zilver*, Swedish *silfver*, Danish *sölv*, German *silber*—is believed to be a loan-word from the Assyrian *sarpu*, and to indicate that the term travelled to the Baltic nations from the Euxine along the trade route *viâ* the river Dnieper. The Celtic *argat* (Old Irish) shows that the Celts probably obtained the term when they invaded Italy about 390 B.C.

Silver occurs native in Spain and Armenia, and silver ornaments have been found in Spain in tombs of the early bronze age. The Phœnician traders probably carried silver from the Spanish mines to Greece between the twelfth and tenth centuries B.C., since the metal is not found in the oldest Phœnician style of tomb in Greece of the twelfth century, but is found in the more recent tombs at Mycenæ—earlier than the tenth century. Silver is not found in the Italian pile dwellings of the bronze age, but appears in those of a later date—400–500 B.C. There were mines in Persia, India, and China.

In his *Historia naturalis* (**33.** 31), Pliny gives an account of silver ore *quæ sequens insania est*—the next folly of mankind after gold ; and he describes a process of fusion and cupellation with lead for isolating the silver. Strabo, also, in his *Geographia* (**3.** 2) describes the process of extracting silver from the ore at Carthagena. The ore was washed and sieved five times ; fused with lead ; and then cupelled for *argentum purum*.

Gold and copper were probably the first metals to be worked by primitive man and the evidence shows that both metals were known to the early Egyptians and Babylonians as far back as history goes. Both metals are fairly widely distributed, and the glittering yellow metal, gold, in the sandy beds of so many rivers, must have attracted man's attention at very early periods, and it is mentioned in the earliest writings of civilized man. Representations of quartz-crushing and gold-refining processes have been found on the rock carvings of Upper Egypt, the earliest of which is supposed to date back 2500 B.C.—*cf.* Fig. 1, Cap. I. In the code of Menes, who is supposed to have reigned in Egypt 3500 B.C.—about 200 years before Moses—it is decreed that gold is equal in value to two and a half parts of silver.

This code is probably related with the Hindu *Manu*, the Thibetan *Mani*, the Lydian *Manes*, the Phrygian *Manis*, and the Cretan *Minos*. It is accordingly thought to be probable that gold and silver were used as money in all countries between the Indus and the Nile many centuries before Christ—some estimate twenty-eight centuries B.C.[2] Silver coinage was probably used as early as that of gold. There are numerous references to these metals in the Pentateuch.[3] According to W. Herapath,[4] there is some evidence that the early Egyptians used argentine soln. for marking linen—*vide* nitric acid.

The absence of any common word for gold among the descendants of the Aryan peoples is taken to show that the Aryans paid no particular attention to this metal before the linguistic separation. The scholars say that the Greek term for gold, χρυσός, is a loan-word derived from the Semitic *chārutz*—Hebrew *tzanab*, to shine. The gold objects found at Attica, Thera, Mycenæ, etc., in tombs ornamented in the style of Phœnician art, are believed to date from about the twelfth century B.C.; and it is thought to be improbable that gold was known in Greece before it was brought there by the Phœnicians about this time. Similarly, gold was probably unknown in Italy before the eleventh century B.C., because neither gold nor silver has been found in the pile dwellings of Emilia, where bronze was plentiful. Gold was probably brought to Italy by the Phœnicians and Greeks about the ninth century B.C. The scholars [5] also tell us that the Latin term for gold, *aurum*, and the earlier Sabine *ausum*, are words of Italian origin related to *aurora*, meaning the morning glow, or the shining dawn. The Celtic terms *ór* (Old Irish) and *awr* (Cymric) appear to have been borrowed from the Latin *aurum* about the time of the Gallic invasion of Italy—390 B.C. The old German *ausis* shows that the word was obtained from Italy before the change from *ausum* to *aurum*. The term *gold* is supposed to be derived from the Sanskrit *jvalita* derived from *jval*, to shine. The Teutonic *gulth*—the glowing or shining metal—was passed on to the Esthonians and Lapps, where it assumed the forms *kuld* and *golle* respectively. The terms for gold in the various Hindu and Iranian families are derived from the Sanskrit *hiranya*.

Most of the gold in ancient times was largely derived from Siberia (Bactria), Nubia, Greece, and India. Xenophon in his Πόροι, written about 353 B.C., says that "no one ever pretended from tradition or the earliest accounts of time, to determine when the Grecian mines began to be worked, and this is a proof of their antiquity." The Nubian mines were worked extensively by the early Egyptians, and a kind of map showing the gold-mining region about 1350–1330 B.C. has been found in an Egyptian tomb. Diodorus' account (*c.* 50 B.C.) of the African mines makes sorry reading:

> On the confines of Egypt and the neighbouring countries there are parts full of gold mines, from whence, with the cost and pains of many labourers, much gold is dug. The soil is naturally black, but in the body of the earth there are many veins. shining with white marble, and glittering with all sorts of bright metals, out of which those appointed to be overseers cause the gold to be dug by the labour of a vast multitude of people. For the kings of Egypt condemn to these mines not only notorious criminals, captives taken in war, persons falsely accused, and those with whom the king is offended, but also all their kindred and relations. These are sent to this work either as punishment, or that the profit and gain of the king may be increased by their labours. There are thus infinite numbers thrust into these mines, all bound in fetters, kept at work day and night, and so strictly guarded that there is no possibility of their effecting an escape. They are guarded by mercenary soldiers of various barbarous nations, whose language is foreign to them and to each other, so that there are no means either of forming conspiracies or of corrupting those who are set to watch them; they are kept to incessant work by the nod of the overseer, who, besides, lashes them severely. Not the least care is taken of the bodies of these poor creatures; they have not a rag to cover their nakedness; and whoever sees them must compassionate their melancholy and deplorable condition, for though they may be sick, or maimed, or lame, no rest nor any intermission of labour is allowed them. Neither the weakness of old age nor the infirmities of females excuse any from that work to which all are driven by blows and cudgels, till at length, borne down by the intolerable weight of their misery, many fall dead in the midst of their insufferable labours. Thus these miserable creatures, being destitute of all hope, expect their future days to be worse than the present, and long for death as more desirable than life.

There are several accounts in the Bible of the quest for the precious metals in patriarchial days.[6] The extravagant splendour of the royal palace and the holy temple erected by Solomon, is recorded in the first book of *Kings*, and the second book of *Chronicles ;* while in the book of *Daniel* there is a description of an immense golden image erected by Nebuchadnezzar on the plain of Dura. The ancient historians—Herodotus and Diodorus—relate prodigies which, though they be exaggerations, yet indicate that a vast quantity of the precious metals had been collected in those early days. The wealth of Crœsus, who reigned as King of Lydia some 540 years before Christ, is proverbial. The profuse and lavish decoration of the palaces and temples of the cities of Tyre, Nineveh, and Babylon, over 1000 B.C., are but a few examples of the ornate display of the precious metals which history recounts, and which in this modern age seem almost fabulous. In any case, this ostentatious wealth displayed so gorgeously excited the cupidity of neighbouring nations, with disastrous results to the exhibitor in virtually every case.

There can be little doubt that the expeditions of Jason of Phœnicia, Darius of Persia, Alexander of Greece, Cæsar of Rome, Columbus of Genoa, as well as the marauds of the Huns, the Goths, and the Vandals, were little more than rapacious forays for gold, silver, or slaves. Plunder, not political supremacy, was the real object of these and many other ventures recorded in history. As W. Jacob puts it, the leaders of these historical expeditions " sought the precious metals not by exploring the bowels of the earth, but by the more summary process of conquest, tribute, and plunder." In many cases they left behind a ghastly trail of cruel wickedness, inhuman lust, and wanton brutality. The letter of Ferdinand, King of Spain, to his colonists in Hispaniola (America), July 25, 1511, is thus paraphrased by A. Helps : [7] " Get gold ; humanely if you can ; but at all hazards get gold." The greed of the Spaniards was so exorbitant that the natives of America were impressed with the idea that gold was the white man's god, the god whom they sought and served. In the words of Timon of Athens : " Gold ! yellow, glittering precious gold ! . . . Much of this will make black, white ; foul, fair ; wrong, right ; base, noble ; old, young ; coward, valiant."

The circle was used by the early Egyptians as the symbol for divinity and perfection, and the same symbol was chosen by them for the sun ; gold, the most perfect of metals, was also designated by the circle. The alchemists called gold *Sol* (the sun) or Apollo, and represented it by the symbol of perfection ⊙, or by the sun (or Apollo) with a crown of rays, ☼, not altogether on account of its appearance, but because they considered it to be the most perfect of the then known noble metals—the *metallum rex*, the very king or Apollo of metals. Silver approaching nearest to gold was represented by the Egyptians by a semicircle, (. The alchemists termed silver *Luna* or *Diana*, and represented it by the symbol for the crescent moon ☾, possibly because of the pale silvery colour, which, the poets say, is characteristic of moonlight.

§ 2. The Occurrence and Distribution of Silver

Silver is fairly widely distributed in various minerals in quantities less than one per cent. The disposition of the principal silver deposits are indicated on the map, Fig. 1. Few gold ores are quite free from silver, and silver is almost invariably found in the sulphide ores of lead, copper, and zinc. The lead-silver ores form an important class; and a comparatively large proportion of the world's silver is extracted from the base metals—lead and copper. Of 92 ores examined spectroscopically by W. N. Hartley and H. Ramage,[1] only four were found to be free from silver, and this element was detected in all manganese ores and bauxites examined. L. Wagoner estimated that granitic rocks contain on the average 6·15 parts of silver per million; sandstones, 0·44; and marble, 0·21 part per million. In 1787, J. L. Proust noted the occurrence of silver in sea-water, and it was estimated by F. J. Malaguti and J. Durocher, that sea-water contains one mgrm. of silver per 100 litres, and that the total quantity of silver in sea-water was two million tonnes. A. Liversidge estimated that sea-water contained one to two grains per ton; the water in the Christiania Fjord (Norway) is estimated to contain 0·005 part of silver per million; the water of the San Francisco Bay, 0·011; and the water in the depths of the Atlantic Ocean, 0·015 to 0·267 part per million.[2] According to F. Field, the copper sheathing of ships gradually becomes richer in silver. Of 54 samples of spring waters in France, J. Bardet found that 34 contained silver when examined spectroscopically. F. Field also detected silver in the ashes of seaweeds, *e.g.* the fucus serratus and the fucus ceranoïdes had 0·00001 per cent. F. J. Malaguti and co-workers found silver in the ashes of land plants; rock salt; coal ash; and in the blood of herbivora; G. Forchhammer found silver and lead in corals; J. W. Mallet reported silver in volcanic ash.

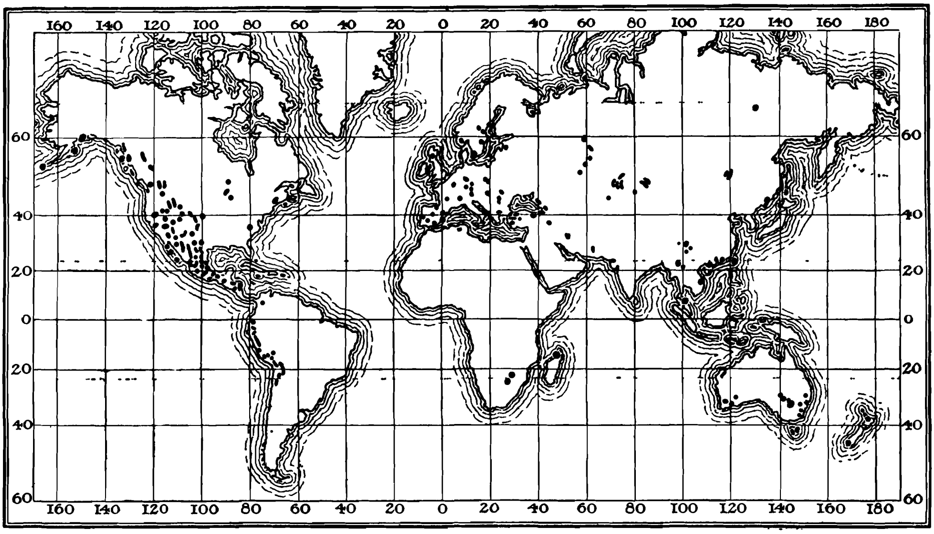

Fig. 1.—The Geographical Distribution of the Chief Deposits of Silver Ores.

Most of the silver extracted in **Europe** is derived from galena or lead ores. In Great Britain, argentiferous ores have been obtained from Helston, Liskeard, Redmor, Tamor (Cornwall); Ochil Hills (Stirlingshire); Hilderstone Hills (Linlithgowshire), Leadhills and Wanlockhead; the Isle of Man; etc.; and at Wicklow, Ballycorn, etc., in Ireland. France obtained argentiferous ores, etc., from Pontgibaud (Pay-de-Dôme), Bormettes (Var), Peyrebrune (Tarn), and in the departments of Loire, Haute Saône, Isère, etc. The chief centres furnishing silver in Germany are Nassau, Westphalia, Saxony, Hartz, Silesia, etc. The argentiferous copper of Rammelsberg, near Goslar, has been exploited for silver since 968 A.D. In Czecho-Slovakia, the chief centre is at Przibram in Bohemia. The silver mines at Joachimsthal (Bohemia) were flourishing at the beginning of the sixteenth century, and in 1516 employed nearly 8000 miners; the mines at Schneeberg (Saxony) were worked in 1471, and yielded about 160 tons of silver per annum in 1500. A concession to reopen the old mines at Przibram was granted in 1527. There are also argentiferous deposits at Erzgebirge, Kremnitz, Schemnitz, Tyrol, etc. In Spain silver ores are obtained in Gaudalaxara, Almeria, etc. The Spanish mines were exploited by the Phœnicians, and Pliny, *Historia naturalis* (**33.** 31), stated that silver was found in the mountains of nearly all the Roman provinces, and that the richest of all were to be found in Spain; Strabo, *Geographia* (**3.** 2), also notes the richness of the Spanish mines. Italy has centres in Tuscany, Sardinia, etc. Argentiferous ores are also obtained in the Laurium of Greece; Karassou (Ismidt) and Kassandra (Salonica) of Turkey; Fahlum and Sala, in Sweden; Kemi in Finland; and in the Urals of Russia. Native silver is mined in Kongsberg, Norway. In **Asia**, argentiferous minerals are obtained in Siberia; in Thibet; Kervan in Persia; the province of Fo-Kien in China; in Japan; Formosa; etc. **Africa.**—The old Egyptians obtained silver from Nubia and Ethiopia. The more important silver mines are in Algeria, Transvaal, Madagascar, etc. **Australasia.**—Silver is obtained from Broken Hill in New South Wales; Wilson's Reef in Victoria; Tasmania; Thames District, New Zealand; etc. In South **America** a great deal of silver has been obtained from mines in Chili, Bolivia, Peru, Argentine, etc. Native silver is obtained at Huantaya (Peru). Mexico in North America appears to be extraordinarily rich in silver ores. The Spaniards commenced silver mining at Tasco (Mexico) in 1522, and these mines, with those at Pachuca, are considered to be the oldest in Mexico, for they appear to have been worked by the Aztecs before the advent of the Spaniards. The more important sources of silver in the United States are in the Colorado, Montana, Utah, Idaho, Nevada, California, Texas, Washington, Dakota, New Mexico, Alaska, Oregon, Kansas, Michigan, Carolina, Tennessee, and Virginia. In Canada there are mines at Cobalt, Ontario; British Columbia; etc.

The world's production of silver[3] was estimated in troy ozs. to be, in 1920:

	Troy ozs.		Troy ozs.
Mexico	66,200,000	Japan	4,500,000
United States	56,564,000	China	60,000
S. America	15,500,000	Dutch East Indies	1,300,000
Canada	13,500,000	Transvaal and Rhodesia	950,000
Central America	3,000,000	Rest of Africa	200,000
British India	180,000	Spain and rest of Europe	5,000,000
Burma	2,000,000	Australasia	3,500,000
Total	171,200,000 Troy ozs.		

and the totals for the years:

1493–1520	1601–1620	1701–1720	1801–1810	1876	1886	1908	1918
1,511,050	13,576,235	11,452,540	51,641,172	74,709,494	93,317,452	203,131,404	197,394,900

The minimum and maximum prices in 1909 were respectively $23\frac{1}{16}$ and 24*d.* per oz.; 1913, $25\frac{15}{16}$ and $29\frac{3}{8}$*d.*; in 1916, $26\frac{11}{16}$ and $37\frac{1}{8}$*d.*; in 1917, $35\frac{11}{16}$ and 55*d.*; and in 1919, $47\frac{7}{8}$ and $79\frac{1}{8}$*d.* The average in 1920 was $61\frac{9}{16}$*d.*; and in February, 1921, the price of silver had dropped to $35\frac{1}{2}$*d.*

Native silver occurs in crystals belonging to the cubic system—the largest crystals, cubes of 2·3 cms. side, come from Kongsberg (Norway); a mass of silver, weighing 697 kilograms, has been found in the same locality. The crystals are often twinned or distorted. The metal also occurs in dendritic masses, in filaments, and in sheets. Native silver is sometimes almost pure, but more usually it is alloyed with some copper, mercury, arsenic, antimony, tellurium, bismuth, iron, gold, or platinum. D. Forbes' analysis[4] of a sample from Chuquiaguillo (Peru) gave: Silver, 97·98; gold, 0·22 per cent.—sp. gr. 10·77; G. Fordyce's analysis of a sample from Norway gave 28 per cent. of gold with the silver; and samples from the same country have been reported with but 0·0019 per cent. of gold. In some cases the analyses correspond by chance with chemical formulæ: $AuAg_2$, AuAg, etc., but there is no evidence of chemical combination—see electrum. P. Berthier[5] reported a sample of silver from Curcy (France) with 10 per cent. of copper; H. J. Burkart one from Chilances (France) with 8 to 12 per cent. of antimony; and J. Domeyko one from Bolivia with 0·53 per cent. of antimony, and 0·015 per cent.

of arsenic. *Amalgam*, a native alloy of silver and mercury, crystallizes in the cubic system. The crystals are silvery-white; rather brittle; and with a bright metallic lustre. T. Scheerer reported a sample with 2 per cent. of mercury; F. Pisani, samples with 4·74 to 5·06 per cent.; and H. J. Burkart, samples with 18 to 26 per cent. Some specimens have a composition in agreement with chemical formulæ: Ag_2Hg_3, AgHg, etc. A sample from Arqueros (Chili) corresponds with $Ag_{12}Hg$, and is called *acquerite*.

Besides occurring native, silver is found as sulphide, arsenide, antimonide, telluride, bismuthide, halides, and various sulpho-salts. **Argentite,** *glance ore,* or *silver glance,* in its purer forms contains the eq. of 12·9 per cent. of sulphur, and corresponds with the formula Ag_2S. It crystallizes in the cubic system; the colour varies from a leaden grey to black, and the surface becomes dull and acquires a sooty coating on exposure to air and light. The mineral is called by the Hungarian miners: *soft ore;* the old name *glass ore—Glaserz* —of Agricola is inappropriate since it has no resemblance to glass. Argentite is often contaminated with native silver. It is soluble in nitric acid. A variety with copper approaching $(AgCu)_2S$ is called **jalpaite.** The so-called *ruby silvers* are of two kinds: (i) **Proustite,** or *light red silver ore,* or *arsenical silver blende,* approximates in composition with $3Ag_2S.As_2S_3$, or Ag_3AsS_3. It crystallizes in the rhombohedral system; it has a cochineal-red colour, and is slightly translucent. The rare mineral **xanthoconite** is a dimorphic variety which crystallizes in the monoclinic system. (ii) **Pyrargyrite,** or *dark red silver ore* or *antimonial silver blende,* also crystallizes in the rhombohedral system. Its composition approximates with $3Ag_2S.Sb_2S_3$, or Ag_3SbS_3. This mineral has a dark red colour. There is a rare variety called **pyrostilpnite,** or *fire blende,* which crystallizes in the monoclinic system. The mineral **stephanite,** also called *black silver ore,* or *brittle silver ore,* approximates in composition with $5Ag_2S.Sb_2S_3$. It crystallizes in the rhombic system, and is of a dark grey colour. **Polybasite** is a complex sulphide of copper, silver, antimony, and arsenic approximating in composition with $(Ag_2S,CuS)_9.Sb_2S_3.As_2S_3$, and crystallizing in the rhombic system. It is almost black in colour. **Argyrodite** is a rare mineral, almost black in colour, with a violet tinge. It crystallizes in the cubic system, and its composition approaches Ag_8GeS_6. **Dyscrasite,** or *antimonial silver,* is a silver antimonide. The relative proportions of the two elements are variable—for instance, the silver may vary from 72 to 84 per cent., thus corresponding with Ag_3Sb contaminated with more or less silver. The mineral crystallizes in the rhombic system; and its colour is silver-white; on exposure to air and light, it acquires a dull grey or yellow colour. This is not an important ore of silver. **Hessite** approaches silver telluride, Ag_2Te, in composition. Its colour is steel-grey or lead-grey. A variety with gold is called *petzite* $(AgAu)_2Te$ (*q.v.*). **Naumannite** approaches silver selenide, Ag_2Se, in composition. It is almost black in colour. A variety with copper, approximating $(AgCu)_2Se$, is called **eucairite;** and one with sulphur, approximating $Ag_2(SSe)$, is called **aguilarite.** A mineral corresponding with silver chloride is called **kerargyrite** or *cerargyrite.* This mineral is comparatively soft, and can be cut like horn, and resembles horn in lustre and colour—hence the name *horn silver.* Cerargyrite is pale grey—sometimes tinged blue or green—and on exposure to light, it becomes brown and dull. A piece of iron is silvered when rubbed with this mineral. Bromine or iodine is sometimes present. To distinguish the different halides, the chloride is sometimes called **chloroargyrite;** the bromide, **bromoargyrite;** the iodide, **iodoargyrite;** and the mixture of the chloride and bromide, **embolite.**

§ 3. The Extraction of Silver from its Ores

Of all the branches of metallurgy, that of which silver forms the subject is the most extensive, the most varied, and the most complicated.—J. PERCY (1880).

The extraction of silver from its ores[1] is usually effected by one of three processes: (1) An alloy of silver with lead or with copper is prepared in a smelting furnace, and the silver subsequently recovered from the base metal—*dry process;* (2) The silver is first amalgamated with mercury, and the mercury removed by distillation—*amalgamation process;* or (3) The ore, suitably prepared, is leached with a suitable solvent, and the silver subsequently precipitated—*wet process.* It will be observed that in all three processes, the silver is collected or extracted from its ore by a suitable solvent—lead, copper, mercury, cyanide-lye, brine, etc. In another variation of the wet process, the silver is converted into an insoluble form, and the copper into a form soluble in dil. sulphuric acid.

Dry processes for the extraction of silver.—The dry process is used where the silver ores contain enough lead to enable them to be smelted for the latter metal (*q.v.*); sufficient lead must be present to dissolve and retain in soln. the whole of the silver in the ore. The reaction is symbolized: $Ag_2S+nPb=PbS+[2Ag+(n-1)Pb]$. If the ore does not contain enough lead, either lead or galena, or a suitable plumbiferous mineral, is mixed with it, and the smelting is conducted as before. This process can be economically applied when cheap fuel is available. The resulting lead is subsequently desilvered by cupellation or otherwise. This process is sometimes called the **lead smelting process** in contradistinction to the **matte smelting process,** which is applied when the silver ore contains insufficient lead for the lead smelting process, and in districts where plumbiferous minerals are not prevalent, and where cupriferous minerals are abundant or where the silver ore is naturally mixed with enough cupriferous pyrites. The mixture of silver ore and cupriferous pyrites can then be smelted for matte as in the case of copper ores. The matte is bessemerized for copper, and the copper refined by electrolytic processes where the precious metals are obtained as a by-product. The Ziervogel leaching process (*vide infra*) was once used for extracting silver from the matte, but the electrolytic process gives better results. The copper matte acts like lead, in the lead smelting process, and collects the precious metals—silver and gold. A highly siliceous slag is desirable, and the amount of zinc impurity in the ore should be low. Under these conditions, there is very little loss of the precious metal in the slag. Argentiferous pyrites containing as low as 2 or 3 per cent. of copper can be profitably treated by this process under conditions where it would not pay to treat the ore for copper alone. Pyrites free from copper does not appear to collect the precious metals very well, but if as little as one-half or two-thirds of one per cent. of copper be present in the ore, the gold and silver are satisfactorily collected by the matte, and not lost in the slag.

The ancients extracted silver and gold from their ores by alloying them with lead, and oxidizing the product, when the precious metals remain alone unoxidized in the metallic state. The facts must have been known from very early times. The Jewish prophets Jeremiah (**6.** 29) and Ezekiel (**22.** 20–22), about 590 B.C., refer to the purification of the precious metals from the base metals by exposing mixtures of the two to a " trial by fire." The base metals are alone " consumed " or drossed, while pure silver and gold pass unscathed through the ordeal. Diodorus Siculus (*c.* 50 B.C.), quoting from a lost book by Agarthides of Cnidos, says that gold was purified by mixing it with lead, salt, and some barley husks, enclosing the mixture in a crucible with a luted lid, and heating the crucible and contents for five days and nights in a furnace. On cooling, purified gold remained in the crucible. Gold purified by this operation was called *aurum obryzum* (obrizum or obrussum), and the operation itself *obrussa*—from the Greek *ὄβρυζον*, meaning pure gold.

The base metals would be oxidized and absorbed by the pot; the silver would be chlorinated by the salt, and also absorbed into the pot as fused silver chloride; and the bran would prevent the base metals from being oxidized too rapidly. As previously indicated, near the beginning of the first century, both Pliny, in his *Historia naturalis* (**33.** 31), and Strabo, in his *Geographia* (**3.** 2), refer to the purification of silver by cupellation with lead. In the sixteenth century, V. Biringucci, in his *De la pirotecnica* (Venezia, 1540), stated that "if we had not lead, we should work in vain for the precious metals, for without its aid, silver and gold could not be extracted from the ores containing them." The method was also described by L. Ercher in his book *Beschrieibung aller fürnemsten mineralischen Ertzt und Berckwercksarten* (Prag, 1574); [2] and numerous later writers.

Cupellation.—In the modern operation, the alloy of lead with the precious metals to be cupelled is melted on the hearth of a reverberatory furnace. The hearth is made of bone-ash, calcareous clay (marl), magnesia, or other suitable earth which will resist the corrosive action of the lead oxide. The hearth is either covered by a movable hood, as in the so-called German cupellation furnace, or the hearth is movable and the hood is fixed as in the so-called English cupellation furnace. In both furnaces, a current of air impinges on the surface of the molten metal; litharge is formed, and the base metals simultaneously oxidized are dissolved in the litharge which accumulates about the edges of the metal and is removed periodically, or continuously. The first drawings of litharge consist largely of arseniates and antimoniates of lead; a more pure litharge then commences to form; bismuth persistently remains unoxidized until near the end of the operation, when it, too, is attacked. Hence, in some works, with alloys containing appreciable amounts of bismuth, the litharge which is formed towards the end of the operation is collected separately and the bismuth recovered. Finally, the precious metals, sometimes as much as 99·7 or 99·8 per cent. purity, remain on the hearth unoxidized.

The **English cupellation furnace** has undergone more or less modification in different localities. It is virtually a reverberatory furnace with a firemouth very large in proportion to the size of the hearth, Fig. 2. The hearth or *test* is oval or oblong—about 4 ft. by 2½ ft.—and is supported on a carriage which can be removed. The pig-lead to be desilvered is charged into openings in the sides of the furnace; the litharge as it is formed is carried along by the blast, and runs over a notch in the hearth into a conical iron pot below. The silver is concentrated to 50–70 per cent. silver, and then ladelled or poured into moulds, and the furnace is re-charged. The molten metal is finished in another cupellation furnace. In the **German cupellation furnace**, the hearth or test is built *in situ*, and is circular or elliptical, 9 to 11 ft. in diameter. The roof can be raised or lowered and luted to the body of the furnace with clay. The English furnace is used for the cupellation of alloys richer in lead than those usually treated in the German furnace. The litharge from the English furnace usually contains too much silver to be sold without further purification; the litharge from the German furnace is comparatively pure, and is ready for the market. The English furnace is continuous, and the German furnace is intermittent in that it is allowed to cool after each charge of ore has been treated.

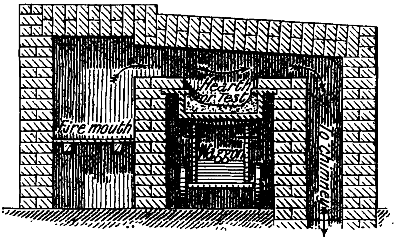

Fig. 2.—Diagrammatic Section of the English Cupellation Furnace.

Cupellation is now an auxiliary to the desilverization of lead or base-bullion—the name commonly applied to lead containing silver by Parkes' or Pattinson's process—though formerly all the silver extracted from lead was effected by the cupellation process. Cupellation is sometimes an independent process when litharge is to be manufactured, but in competition with Parkes' or Pattinson's process cupellation is profitable only when the lead contains considerable amounts of silver. The final separation, however, whether Parkes' or Pattinson's process has been employed, is effected by cupellation.

Amalgamation process for the extraction of silver.—The use of mercury for the extraction of silver and gold is probably very old. True, the first known mention of mercury occurs in Theophrastus' Περὶ Λιθῶν, about 300 B.C., but neither he nor Diodorus the Sicilian, who wrote about 30 B.C., mentioned the use of mercury in this connection, although Diodorus wrote at some length on the process for the extraction of gold from quartz in Upper Egypt. Vitruvius, about 13 B.C., described the use of mercury for the recovery of gold from the cloth in which it was interwoven; and Pliny, in his *Historia naturalis* (**30.** 32), about 77 A.D., spoke of the amalgamation process as if it were very well known.

> Everything excepting gold floats on quicksilver; gold alone is attracted by mercury, and therefore that metal is best cleansed by mercury, for the impurities are expelled from gold by repeatedly shaking it with mercury in earthen vessels. The product (gold amalgam) is poured into skins, which are then squeezed, the mercury exudes like sweat, and leaves behind the pure gold.

The gold is not pure, but is rather a solid amalgam. There is nothing in Pliny's account to show that silver could be so treated; his method would be effective only with simple gold-silver ores, but from this, a process was developed capable of extracting the metal from more complex ores. The early European process was described by V. Biringucci, in his *De la pirotecnica* (Venezia, 1540), as if it were a secret art, although it must have been used at an earlier date; it is mentioned by R. Theophilus, a writer of the eleventh century. In this early *European amalgamation process*, the ore was ground in a stone mill with water, mercury, salt, and some copper compound. It is sometimes said that the extraction of the precious metals by amalgamation was invented by the Spaniards in Mexico, about 1557, but, according to F. A. Schmid's edition (Freyberg, 1806) of G. Agricola's *Bermannus sive de re metallica* (Basil, 1530), the process was more probably introduced at Pachuca, in Mexico, by Bartolomé Medina, in 1552, who doubtless learned about it in Europe.[3] According to F. Xavier de Sarria, and J. Garces y Eguia, the first printed treatise on the amalgamation process is A. A. Barba's *Arte de los metales* (Madrid, 1640). In B. Medina's *Mexican amalgamation process*—usually known as the **patio process**—the general principles of the European process were modified to suit the special conditions which prevailed in Mexico. In both processes, mercury is used in conjunction with common salt and a salt of copper, without the use of fuel except for expelling mercury from the solid amalgam. Horses and mules were introduced into Mexico about 1793 for mixing the *pulp*, mercury, etc. Previous to this time, the mixing was done by hand. It is said a saving of 757 per cent. on the cost of mixing was thereby effected. Very few improvements have been made on the original process during the 360 years it has been used in Mexico, but it is now almost entirely superseded by the cyanide process which is capable of giving a higher yield of the precious metal and at a less cost. Hence, the patio process promises very soon to be of little more than historical interest. The amalgamation process for extracting the previous metals from their ores soon travelled from Mexico to Peru, and in 1640, A. A. Barba described the *cazo process*—*cazo*, a small pan (*vide supra*). In this process, said to have been worked by Barba at Potosi (Bolivia) in 1590, the ground ore was stirred with water, mercury, and salt in copper cauldrons heated over a fireplace. The reaction is symbolized: $2AgCl+Cu+nHg=2Ag+nHg+CuCl_2$; and $CuCl_2+Cu=2CuCl$. The cazo process was used in Mexico and South America for some years, and about 1800 it developed into the *fondon process*—*fondon*, ground—in which a larger vessel with a copper bottom and wooden sides was employed, and the stirring was done by mule power.

The Mexican ore contains metallic silver, silver sulphide, and silver chloride, etc., distributed in a large quantity of gangue. The ore is first crushed in stamp mills, and ground to powder between porphyry blocks fixed on an axis turned by horses or mules. The work has to be done in a country where water for washing the ore is not available, while neither steam nor water power is practicable; the powdered ore, moistened with water, is thoroughly incorporated with a little sodium chloride. In about a day, mercury is added along with some roasted pyrites containing a mixture of iron and copper sulphates and oxides, and called *magistral*. The whole is most intimately mixed, and more mercury is added from time to time. The mixing is done on stone-paved areas—called *patios*—by being treaded by horses or mules as illustrated in Fig. 3. The mixture which is trodden by the mules or horses is called a *torta*, and a torta has to be treated from a fortnight to a month according to circumstances.

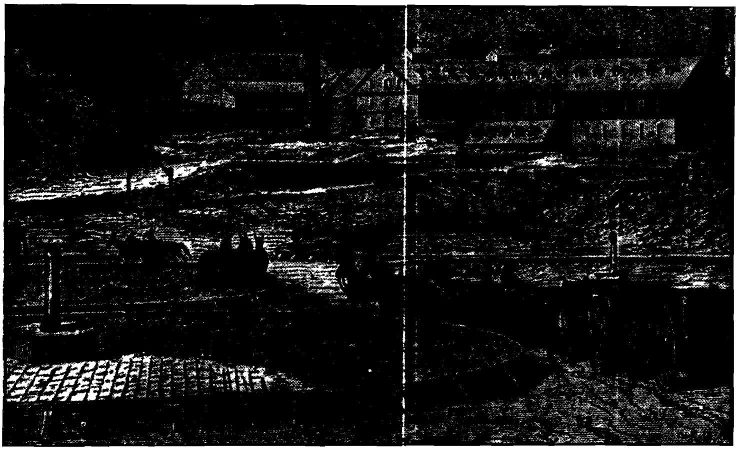

FIG. 3.—The Patio Process for the Extraction of Silver.

It is probable that cupric chloride is first formed:[4] $2NaCl+CuSO_4=Na_2SO_4+CuCl_2$, and this reacts with the silver sulphide, forming cuprous and silver chlorides: $CuCl_2+Ag_2S=2AgCl+CuS$; $CuCl_2+CuS=2CuCl+S$; and $2CuCl+Ag_2S=2AgCl+Cu_2S$. The complex sulphides are likewise decomposed: $2Ag_3SbS_3+3CuCl_2=6AgCl+3CuS+Sb_2S_3$, and similarly with the arsenic compound Ag_3AsS_3. Ferric chloride also reacts with the silver sulphide: $2FeCl_3+Ag_2S=S+2AgCl+2FeCl_2$. The silver chloride dissolves in the brine, and it is then immediately reduced and dissolved by the mercury: $AgCl+Hg=Ag+HgCl$. There are many other side reactions: $CuCl_2+Hg=CuCl+HgCl$, and $CuCl_2+Ag=CuCl+AgCl$, but the loss of mercury as mercurous chloride, HgCl, which occurs in practice is not great enough to give these reactions any significance. The actual consumption of mercury is but 85 per cent. of that required by the equation: $Hg+AgCl=Ag+HgCl$.

The silver amalgam is separated from the mud by washing and settling; the excess of mercury is squeezed through canvas; the solid amalgam in the bags is pressed into cakes and heated in retorts—mercury distils over, and the silver which remains in the retort has a white frosted appearance and is called *plata pina*. The silver is then fused and cast into ingots. The mercury used in the amalgamation process is said to be more active if it has about one per cent. of sodium in soln.[5]

Various modifications of the amalgamation process have been tried in different localities. In the so-called *Boss process*, the ore passes continuously from the stampers through the amalgamating pans, and is not collected from the stamps and charged into the amalgamating pans at intervals. The chloridizing roast for silver ores was introduced by I. de Born[6] in combination with the cazo process at Schemnitz (Hungary), and in conjunction with barrel amalgamation at Freiburg in 1790. The amalgamation was adapted to the special conditions in the Washoe district, U.S.A., in 1860, and it was called the *Washoe process*. In the Washoe process, the ore is usually crushed wet, and amalgamated in pans without previous roasting. The richer ores are roasted with salt and then amalgamated in barrels ; the poorer ores are treated in the stamp mill and ground in cast-iron pans, with mercury and hot water—with or without the addition of salt and copper sulphate. The presence of copper sulphate is not so important as in the Mexican process because the ore contains more free silver, and under the influence of heat the mercury and iron are able to deal with the silver. After the amalgamation, the process is similar to the Mexican. Amalgamation in conjunction with cyanide soln.[7] was tried successfully in 1911, in the so-called Batopilas and the Nipissing processes.

Wet processes for the extraction of silver.—Numerous wet processes have been proposed for the extraction of silver from its ores, copper mattes, speise, and metallic copper. There are four types of process :

I. The ore is roasted so that the copper is oxidized to cupric oxide and the silver sulphide is converted into metallic silver. The copper oxide is extracted with sulphuric acid, and crystallized from the soln. as copper sulphate or blue vitriol ; the residue, containing silver and gold, is smelted with lead by the dry process. Any iron oxide which may be dissolved by the acid crystallizes, as an impurity, with the copper sulphate. The process [8] is called the **Freiberg vitriolization process,** because it was developed at Freiberg in Saxony. In a modification, called the **Hofmann's vitriolization process,** the iron is separated by treating the hot neutral soln. of copper sulphate with roasted copper mattes—mainly cupric oxide—and forcing air through the liquid ; ferric oxide is precipitated : $4FeSO_4+O_2+4CuO=2Fe_2O_3+4CuSO_4$. Basic copper sulphate may also be precipitated with the iron oxide, and recovered by treatment with 2·5 or 3 per cent. sulphuric acid, which dissolves the copper but not the iron.

II. The sulphide ores are fractionally roasted so as to convert most of the iron and copper sulphides into oxides, and the silver sulphide into silver sulphate. The mass is then leached with water. Silver and copper sulphates dissolve. The silver is precipitated from the soln. by scrap copper ; the copper is afterwards precipitated by scrap iron—**Ziervogel's process.**[9]

III. The sulphide ores are roasted with salt whereby the silver sulphide is converted into chloride, and the mass is then leached with a suitable solvent.

(*a*) The chloride is extracted with a sat. soln. of sodium chloride at about 80°, and the silver precipitated by scrap copper—**Augustin's process.**[10]

(*b*) The chloride is extracted with sodium thiosulphate soln., the silver precipitated as sulphide, and reduced to the metal by calcination in a roasting furnace—**Patera's process.**

IV. The ore—which may or may not be calcined—is treated with a soln. of alkali cyanide—**cyanide process.** The cyanide reacts with the silver sulphide : $Ag_2S+4NaCy=2NaAgCy_2+Na_2S$. The accumulation of sodium sulphide in the soln. stops the reaction. When the soln. is exposed to the air, however, the sodium sulphide is oxidized to sodium thiosulphate and sulphur. The reaction then progresses as indicated in the equation from left to right. Thus, the free access of air to the cyanide soln. is an important factor in promoting the dissolution of the silver. Silver and gold are also dissolved by the cyanide soln. as indicated in the discussion on the cyanide process under gold. The silver is recovered from the cyanide soln. by precipitation with zinc or aluminium.[11] The cyanide process has almost ousted the other lixiviation processes—*vide* gold. Augustin's process was used at Mansfield (Germany) between 1840 and 1842 ; at Freiberg between 1848 and 1862 ; and for a time at a few other places.[12] The failure of Augustin's process is mainly due to the comparatively low solubility of silver chloride in the brine which necessitates handling large volumes of liquid ; and to the imperfect oxidation of silver in the presence of arsenic, antimony, and zinc.[13] In the Patera process, the thiosulphate not only removes the silver chloride, but silver arseniate and antimoniate, and to some extent metallic silver and gold, are dissolved. Lead sulphate also, if present, is also dissolved. Consequently, the precipitate from the thiosulphate soln. contains silver, gold, copper, lead, and small quantities of other metals. The use of sodium thiosulphate for the extraction of silver was indicated by A. Hauch in 1846, and by J. Percy in 1850. The solvent action is due to the formation of a soluble double thiosulphate of silver and sodium: $Na_2S_2O_3.Ag_2S_2O_3$. The process was applied industrially by A. Patera at Joachimsthal (Bohemia) in 1858, and the silver was precipitated by sodium or calcium sulphide: $Ag_2S_2O_3.Na_2S_2O_3+Na_2S=Ag_2S+2Na_2S_2O_3$, so that with sodium sulphide as precipitant, the thiosulphate can be used again. In 1860, M. Kiss proposed to substitute calcium thiosulphate for the sodium salt as the leaching liquid—**Kiss' process**; and if calcium sulphide is used as the precipitating agent, the calcium thiosulphate is regenerated. He claimed that the calcium salt is a more effective solvent—particularly for gold—than the sodium salt; but the claim has not been established. In 1884, E. H. Russell[14] introduced a soln. of sodium cuprous thiosulphate which was claimed to exert a more energetic solvent action on metallic silver, silver sulphide, and the arsenical and antimonial sulphides, and other silver minerals. In **Russell's process,** the chloridized ore is leached first with sodium thiosulphate, and subsequently with sodium cuprous thiosulphate—the latter is called the *extra solution*—and it is supposed to extract an additional amount of silver which would otherwise escape in the tailings, and to require a less careful chloridizing roast. E. H. Russell also showed that lead can be removed from the thiosulphate extract by treatment with sodium carbonate; and the copper and silver in the remaining soln. precipitated as in the original thiosulphate process. The advantages claimed for the Russell process over the Patera process have not been generally established in that the extra cost is not always compensated by the increased yield of precious metal—particularly if the chloridizing roast be efficiently performed.

Roasting sulphide ores for sulphates—sulphatizing roast.—The sulphatizing roast has been mentioned in connection with the extraction of copper (*q.v.*). Suppose an ore containing iron, copper, and silver sulphides be roasted in a furnace where the temp. is gradually rising. The iron sulphide begins to oxidize just over 300°, and the sulphur di- and tri-oxides which are formed are swept along with the furnace gases. Ferric oxide is produced: $4FeS_2+11O_2=2Fe_2O_3+8SO_2$. The condition of equilibrium between the two sulphur oxides: $2SO_3=2SO_2+O_2$, in the presence of the catalytic agent, ferric oxide, is discussed in connection with these gases. As the temp. rises, the partial press. of sulphur trioxide increases because the gases become more and more charged with sulphur oxide. The iron sulphate formed at a lower temp. begins to decompose between 550° and 600°; and the copper sulphate begins to decompose slowly at about 650°, and the decomposition is complete at about 850°.

The relation between the partial press. and temp. of ferric and cupric oxides and sulphur trioxide, for equilibrium,[15] is indicated in Table I.

TABLE I.—EQUILIBRIUM CONDITIONS FOR IRON AND COPPER SULPHATES.

$Fe_2(SO_4)_3 \rightleftharpoons Fe_2O_3+3SO_3$		$2CuSO_4 \rightleftharpoons 2CuO.SO_3+SO_3$		$2CuO.SO_3 \rightleftharpoons 2CuO+SO_3$	
Temp.	Press., mm.	Temp.	Press., mm.	Temp.	Press., mm.
553	23	546	43	600	62
592	45	588	55	653	98
614	70	615	70	686	123
650	149	642	98	705	139
660	182	665	130	728	173
680	286	700	233	745	209
690	401	725	460	775	298
707	715	731	647	805	542

If the partial press. of the sulphur trioxide in the atm. of the furnace be greater than the equilibrium value for that temp. the corresponding sulphate will be formed;

and conversely, if less, sulphate will be decomposed. The partial press. of sulphur trioxide necessary for the formation of iron and copper sulphates are indicated in Table II.

TABLE II.—PARTIAL PRESSURES OF SULPHUR TRIOXIDE NECESSARY FOR THE FORMATION OF IRON AND COPPER SULPHATES.

Temp.	Partial press. of SO_3 in mm. of mercury.		
	$Fe_2(SO_4)_3$	$CuSO_4$.	$(CuO)_2SO_3$
550	12	27	—
600	22·5	29	29
650	61·5	40	33
700	244·0	99	35

At 650°, the partial press. of sulphur trioxide necessary for the formation of ferric sulphate is 61·5 mm.; and for copper sulphate, 40 mm. Consequently, if the stream of gases passing through the furnace has sulphur trioxide eq. to a partial press. of 50 mm., copper sulphate will be formed, and ferric sulphate decomposed. When the temp. rises still higher, and the partial press. of the sulphur trioxide required for the formation of copper sulphate is not high enough, copper sulphate will be decomposed. Silver oxide dissociates about 130°, but precisely similar relations obtain between silver or silver sulphide and sulphur trioxide as those between cupric oxide and the same gas. The dissociation[16] of silver sulphate is very slow at 750°, and rapid at 917°. If the temp. of the furnace exceeds this limit, the sulphates are all decomposed into ferric and cupric oxides, and metallic silver; and if the temp. exceeds 1020°, or if reducing gases be present, some of the cupric oxide will be reduced to cuprous oxide, and ferric oxide to ferrosoferric oxide, Fe_3O_4. The reactions are more complex still with natural ores; for instance, if arsenic and antimony are present, and have not been volatilized early, arsenate and antimoniate of silver will be formed, and thus introduce losses because these salts do not dissolve when the sulphate is extracted with water. The apparently simple operation of roasting, said W. C. Roberts-Austen,[17] demands the exercise of the utmost skill, care, and patience. The main reactions begin at about 500° and end at about 700°, that is, within a range of 200°. "It would be difficult to appreciate too highly the delicacy of touch and sight which enables an operator to judge by the aid of rough tests, but mainly from the tint of the streak revealed when the mass is rabbled, whether any particular stage has or has not been reached."

Roasting sulphide ores for chlorides—chloridizing roast.—The aim of the chloridizing roast is to convert certain constituents of an ore into chlorides, and thus make them amenable to solvents. Certain volatile chlorides are incidentally formed, and these may or may not be recovered. The chloridizing roast is employed in W. Longmaid and W. Henderson's process for copper ores (*q.v.*); in Stahl's process for nickel ores; and in A. Patera's process for silver ores. In chloridizing roasting the crushed ore is usually mixed with about 10 per cent. of sodium chloride, and the mixture heated to 800° or 900° in a reverberatory furnace. The sulphates formed by the oxidation of the sulphides, react with the salt, forming chlorine and hydrogen chloride. These gases convert silver, silver sulphide, thioarsenides, and thioantimonides into silver chloride. The reactions are somewhat complicated. The salt may react directly with the sulphate, forming chlorine: $4NaCl+4FeSO_4+O_2=2Na_2SO_4+2Fe_2O_3+2SO_2+2Cl_2$; and simultaneously, the ferric and copper sulphates decompose, forming sulphur trioxide, which reacts with the salt, forming chlorine: $2SO_3+2NaCl=SO_2+Na_2SO_4+Cl_2$. In the main reaction, the chlorine acts directly on the silver compounds converting them into silver chloride: *e.g.* $Ag_2S+O_2+Cl_2=SO_2+2AgCl$. Hydrogen chloride is formed by the action of steam and sulphur trioxide on sodium chloride: $2NaCl+SO_3+H_2O=2HCl+Na_2SO_4$, and by the silica present in the ores: $2NaCl+SiO_2+H_2O=Na_2SiO_3+2HCl$. The hydrogen chloride acts on the oxidized silver ores converting them into silver chloride. Among the numerous side reactions which simultaneously occur: Copper sulphate is decomposed by sodium chloride, forming cupric chloride: $CuSO_4+2NaCl=Na_2SO_4+CuCl_2$; and silver sulphate reacts similarly: $Ag_2SO_4+2NaCl=Na_2SO_4+2AgCl$. Silver sulphate—formed by the direct oxidation of the sulphide or by a reaction symbolized: $Ag_2S+4SO_3=Ag_2SO_4+4SO_2$—may react with cupric chloride: $Ag_2SO_4+CuCl_2=2AgCl+CuSO_4$. Some arsenic and antimony are volatilized in the oxidizing roast, and also as chlorides. If the temperature be too high, appreciable quantities of silver chloride may be volatilized.

Electrolytic processes for the extraction or refining of silver.—The electrolytic process employed in the refining of copper is used for the separation of silver from argentiferous copper, and it would be difficult to find a more remarkable application of the electric current than in the purification of metals by transferring the impure metal from the anode to pure metal at the cathode. In **Moebius' process,**[18] the electrolyte is a mixture of silver and copper nitrates acidified with nitric acid. A slab of impure silver is used as anode, and a plate of pure silver as cathode. Silver and copper are dissolved at the anodes and the silver is deposited on the cathodes. The gold, if present, remains undissolved as slime below the anode. The anodes are sometimes enclosed in filter bags to facilitate the collection of the *anode mud*. The composition and concentration of the solution as well as the current density, are carefully regulated on account of the danger of depositing copper with the silver.

The preparation of highly purified silver.—Silver should be fairly pure when it is required for cupellation assays, volumetric analysis, etc., and such silver may be obtained by dissolving the metal in nitric acid, diluting the solution with water, and allowing the soln. to settle so that gold, tin and antimony oxides, basic bismuth nitrate, silver sulphide, etc., may coagulate, and permit the solution to be filtered. Silver chloride is precipitated from the filtered solution by the addition of hydrochloric acid. If sodium chloride be used for the precipitation, basic bismuth and antimony chlorides, if present, would be precipitated. The silver chloride is boiled with hydrochloric acid, and washed with hot distilled water until free from acid. The silver chloride can be reduced to metal by boiling it with invert sugar and sodium hydroxide; by the addition of an aqueous solution of formaldehyde, ammonium formate, etc. The precipitate in any case is thoroughly washed, and if desired, it can be fused to a button in a crucible under borax. The chloride can also be reduced by fusion with about half its weight of sodium carbonate and one-sixth its weight of potassium nitrate in a porcelain crucible. The so-called *molecular silver*,[19] used in organic chemistry, is a grey powder which acquires a metallic lustre when rubbed under a burnisher, or heated to redness. It is prepared by washing silver chloride, precipitated in the cold, until it is nearly free from acid, and then bringing it in contact with a sheet of zinc for some hours. The silver chloride is reduced. The product is washed with dilute hydrochloric acid, then with water, and dried on paper in air, and finally heated to 140° or 150°.

It is a custom in atomic weight determinations to take the utmost precautions to eliminate every impurity. The materials used in preparing highly purified materials must themselves be of an exceptional degree of purity. The preparation of absolutely pure substances is an extremely difficult, if not an impossible task. Liquids, said T. W. Richards,[20] often attack the containing vessels and absorb gases, crystals include and occlude solvents, precipitates carry down polluting impurities, dried substances cling to water, and solids, even at high temperatures, often fail to discharge their imprisoned contaminations. Every substance, added T. W. Richards, must be assumed impure until proof to the contrary can be obtained.

J. S. Stas, in his celebrated investigation on the atomic weight of silver, prepared highly purified silver by boiling the chloride with sodium hydroxide and sugar; by reducing the nitrate with ammonium formate and acetate, although, as T. W. Richards has shown, the formate alone is better since it introduces less carbon as impurity in the pores of the crystals. J. S. Stas also reduced the silver with ammonium sulphite.

(1) *J. S. Stas' process.*—In one process, J. S. Stas started from samples of silver containing copper as the chief impurity. Dissolve the metal in dilute boiling nitric acid; evaporate to dryness; heat the residue until it fuses so as to decompose any platinum nitrate which may be present. Dissolve the cold mass in dilute ammonia, and after standing 24 hrs, filter through a double filter paper, and dilute the ammoniacal solution of silver and copper nitrates until it contains the equivalent of about 2 per cent. of silver. Add enough of a soln. of ammonium sulphite to precipitate the whole of the silver—the exact amount is determined by a preliminary trial by running the ammoniacal silver soln. from a burette into a definite volume of ammonium sulphite soln. until the liquid above the precipitate appears faintly blue. The ammoniacal copper nitrate solution appears blue only when the silver nitrate has been all reduced. About one-third of the total silver will be found to have precipitated when the liquid has stood 24 hrs. in a closed vessel. Decant the blue liquid from the precipitate and warm the soln. to about 60° or 70° when the whole of the silver will be precipitated. Wash the two portions of precipitated silver with ammoniacal water by decantation until the wash-liquid shows no trace of a blue colour on standing. After standing some days in contact with concentrated ammonia, wash the precipitate with water until all trace of ammonia has been removed. To convert the precipitated silver into bars, J. S. Stas mixed the precipitate with 5 per cent. of its weight of previously calcined borax, and 0·5 per cent. of sodium nitrate, and fused it in a porcelain crucible. The metal was cast in moulds made from a mixture of calcined and uncalcined china clay. The cold bars were cleaned with fine sand, and heated with purified potash lye in order to remove the last traces of clay from the bars. If the bars are cut with a chisel for use, the pieces must be warmed with concentrated hydrochloric acid, washed with ammonia, and then with water. J. S. Stas freed the silver from traces of absorbed gas by distilling the metal in an apparatus resembling Fig. 6.

(2) *T. W. Richards and R. C. Wells' process.*—According to T. W. Richards and R. C. Wells,[21] Stas' silver was probably contaminated with occluded oxygen, alkalies, etc., derived from the vessels used in the operations. T. W. Richards and R. C. Wells, in consequence, used vessels of porcelain or quartz instead of glass. G. P. Baxter and co-workers have described modifications of the process.

A dilute soln. of recrystallized silver nitrate was precipitated as chloride by means of hydrochloric acid, and well washed. The silver chloride in a silver dish was converted into metallic silver by treatment with invert sugar and sodium hydroxide which had been previously purified by electrolysis until all the iron had been deposited. The precipitated silver was fused to a button on a block of lime while exposed to the reducing flame of a blast gas-blowpipe. This silver was found to be extremely pure for it contained but 0·001 per cent. of impurity derived from the sulphur and carbon of the coal gas-flame, a trace of unreduced silver chloride, and possibly some cavities or pores holding gas. To purify further the silver, T. W. Richards and R. C. Wells placed the button of silver on a watch glass, and wholly submerged the two in a conc. soln. of silver nitrate prepared from the same silver. The button of silver was made the anode, and the cathode was a piece of highly purified silver. On electrolysis,[22] a fine crystalline powder of electrolytic silver was obtained. In order to exclude contamination, no metal but silver was allowed to come in contact with the electrolyte. The crystals of silver were probably contaminated with the mother liquid from which they were deposited, and from which they were freed by fusion in an atmosphere of hydrogen on a boat of lime, heated to bright redness in a porcelain tube. Spectroscopic tests, capable of detecting 0·0001 per cent. of lime, failed to detect calcium in the metal. The silver was freed from adherent lime by scrubbing the piece with hard sand, and by successive treatment with dilute nitric acid, ammonia, and water. The little bars were finally dried at about 400° in vacuo.

For **colloidal silver,** *vide* gold.

§ 4. The Desilverization of Lead

Galena usually contains a little silver, and most of the silver follows the lead during its extraction. In some cases, the silver is even more valuable than the lead itself—*e.g.* at Freiberg, Colorado, and Broken Hill. The lead from furnaces often contains sufficient silver to pay for its extraction ; the lead at Freiberg, for instance, contains about 96·67 per cent. of lead and 0·55 per cent. of silver. The lead is usually desilverized by Pattinson's or Parkes' process, and in rarer cases, by cupellation or electrolysis. The choice of the process is determined by local conditions. Other things being equal, it is reported that at Ems :[1]

	Cupellation.	Pattinson's process.	Parkes' process.
Cost of treatment	3	1·5	1 unit.
Percentage recovery of silver and lead .	0·94	0·98	0·99 unit.

The first operation in desilvering lead by Pattinson's or Parkes' process is to soften the so-called *hard-lead—Hartblei*—from the blast-furnace, by melting it in a reverberatory furnace with a shallow bed, and with the walls cooled by a water-jacket where they are most likely to be attacked by the metallic oxides formed in the operation. The metal is melted at a low heat and stirred ; most of the copper rises to the surface and is skimmed off as dross ; at a rather higher temp., much tin is removed ; and at a still higher temp., arsenic, antimony, and many other metal impurities are removed as oxides with some litharge. The hard-lead, thus freed by liquation and oxidation from the impurities which make it hard and brittle, is called *soft-lead—Weichblei.*

Pattinson's process for desilvering lead.—In 1833, H. L. Pattinson[2] noticed that on heating a bar of lead containing a small proportion of silver, the first drops which oozed out were richer in silver than the residual lead ; and conversely, with bars of lead with a relatively high proportion of silver, the first drops of metal which oozed out contained less silver than the residual lead. These phenomena were generalized only when the laws of soln. had been elucidated further than was the case in Pattinson's day ; but the facts sufficed for the development of a highly ingenious process for the desilverization of lead.

Molten lead and silver mix together in all proportions, and the m.p. of all possible alloys of the two metals, with less than 10 per cent. of silver, are indicated in Fig. 4. There is a eutectic temp. at 303°, when the molten lead contains 2·4 per cent. of silver. The part of the curve on the lead side of the eutectic is alone concerned in Pattinson's process. If a molten mixture of lead with, say, 50 per cent. of silver be allowed to cool, when the temp. reaches 648°, some silver (contaminated with a little lead) will separate from the soln. The remaining fluid is richer in lead than it was before, and consequently remains fluid, but as the temp. falls, more silver will separate from the soln. and the mother liquid will continually get poorer and poorer in silver until but 2·4 per cent. remains. The whole will then freeze *en bloc* at 303°. If the molten mass contains less than 2·4 per cent. of silver, it will freeze somewhere between 327° and 303°, and lead (contaminated with a little silver) will separate from the soln., and continue separating until the mother liquid has 2·4 per cent. of silver, when all the remaining silver and lead will freeze *en masse.* In Pattinson's process, the softened lead is melted, and the molten mixture, containing less than 2·4 per cent. of silver, is allowed to cool slowly. The crystals of lead which separate from the cooling soln. contain more lead than the original soln., and form a kind of mush. The crystals are ladled with perforated ladles into a neighbouring pot on the right until one-eighth to one-third of the liquid remains.[3] The enriched alloy, remaining in the pot, is ladled to a pot on the left. The operations are repeated on both fractions time and again, until the enriched lead contains about 1 per cent. of silver, and the desilvered lead contains but 0·001–0·002 per cent. of silver—in practice, the desilvered lead has about

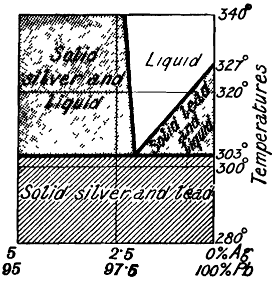

Fig. 4.—The Eutectic Portion of Freezing Curve of Silver-Lead Alloys.

10 dwts. or less of silver per ton. In practice, the enriched lead has 300–500 ozs. of silver per ton. When the ladling from kettle to kettle is done by hand, there may be a row of eight to sixteen pots; the last pot on the right is the *market-pot*, and it contains the desilvered lead. The impurities, antimony, bismuth, and nickel, associated with the soft lead follow the silver, and at Freiberg, the bismuth is recovered from the litharge formed during the cupellation. Arsenic follows the lead, and the copper remains equally distributed with both fractions.[4] The market lead produced by Pattinson's process is soft and fairly pure.

In a modification of Pattinson's process—called **Rozan's process**[5]—the base-bullion is melted in tilting kettles which discharge into a crystallizing kettle; steam is then blown through the latter until about two-thirds of the lead has crystallized, and the enriched portion is removed by tapping. The process is repeated until the lead is sufficiently desilverized.

Parkes' process for the desilverization of lead.—In 1842, C. J. B. Karsten[6] discovered that argentiferous lead could be desilverized by means of zinc, but the process was not practicable until A. Parkes developed the subject about 1850. If 1 to 2 per cent. of zinc be stirred into argentiferous lead, just above its m.p., it appears as if the affinity of silver for zinc is greater than it is for lead, because the zinc deprives the lead of its silver and floats as an alloy on the molten lead. The surface crust of the zinc-silver alloy freezes before the lead, and the two can be separated by skimming the surface of the molten metal. In practice, the zinc added to the lead is kept between 0·8 and 1·5 per cent., and the composition of the zinc-silver crystals ladled off, is dependent upon the temp., and on the relative proportions of the two metals present. Gold in the argentiferous lead passes with the silver to the zinc; arsenic, antimony, and bismuth, for the main part, follow the lead; platinum, palladium, cobalt, and nickel follow the zinc.[7] Consequently, the lead from Parkes' process is not freed from bismuth during the operation as is the case with Pattinson's process. To avoid an undue consumption of zinc, it is necessary to soften the lead by a preliminary purification as in the case of Pattinson's process. Usually, the zincing of the lead is performed two, three, or more times, the temp. being raised each time. Finally, the desilvered lead contains but 0·0005 per cent. of silver. The desilverization can be carried much further by this process than is practicable with Pattinson's. The mixture of zinc, lead, and the precious metals is liquated by heating it on an inclined surface hot enough to melt the lead, but not the zinc alloy; or else it is subjected to press. as it is lifted from the kettles containing the molten alloy. In either case, the lead flows away, and the enriched scum remains. The zinc can be separated from the silver, gold, and lead by distillation from plumbago retorts; the residue in the retort is cupelled, and, if necessary, parted, as described for gold. The solubility of lead in zinc varies considerably with temp. At 540°, silver is about 300 times more soluble in zinc than in lead, and at 358°, about 3000 times more soluble. Above 940°, the two metals are mutually soluble in all proportions, below that temp., the liquid separates into two layers—the lower layer represents a soln. of zinc. in lead, and the upper layer a soln. of lead in zinc. The two solubility curves meet at about 940°, forming a closed curve as illustrated in Fig. 5. The temp. 940° is the critical soln. temp. If from 1 to 2 per cent. of zinc be stirred into molten lead, the liquid separates into two layers, the lighter zinciferous alloy floats on the surface of the heavier plumbiferous alloy. If silver be present in the lead, it will divide itself between the two layers so that a considerably larger proportion of the silver accumulates with the lighter layer. C. R. A Wright and C. Thompson[8] determined the composition of the two layers with varying proportions of the three

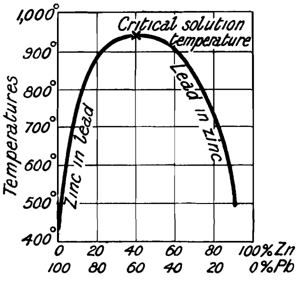

FIG. 5.—Mutual Solubility of Lead and Zinc.

metals after they had stood for 8 hrs. between 750° and 850°; a selection from their results is indicated in Table III. G. N. Potdar [9] measured the partition coeff. of silver between the lead and zinc, but the numbers are not altogether satisfactory, although the partition coeff. was nearly constant for the more dil. soln. up to about 6 per cent. of silver, *e.g.*:

TABLE III.—THE DISTRIBUTION OF SILVER BETWEEN ZINC AND LEAD.

Heavier layer.			Lighter layer.

0 0226	0·9646	0·0128	0·4893	0·0382	0·4725
0·1075	0·8695	0·0230	0·6193	0·1028	0·2779

Silver in light layer . . .	0·75	0·99	2·14	4·43	5·42	6·26
Silver in heavy layer . . .	0·0030	0·0037	0·0096	0·0198	0·0169	0·0197
Partition coeff.	250	267	223	226	320	317

The many compounds of zinc and silver, contrasted with the failure of silver and lead to form any compound, show the greater affinity between zinc and silver, than between silver and lead; this may also have some connection with the fact, indicated above, that at about 540°, silver is 300 times more soluble in zinc than in lead. F. Rössler recommended the addition of 0·5 per cent. of aluminium to the zinc so as to give it a greater resistance to oxidation.

Electrolytic process for desilverization of lead.—Lead has also been desilvered electrolytically. Base-bullion is used for the anodes; sheets of highly purified lead are used for the cathodes; and a soln. of lead fluosilicate is used as electrolyte. Otherwise, the process is analogous with the refining of copper by electrolysis. Gold, silver, and bismuth are recovered from the anode slime.[10]

§ 5. The Purification of Silver ; and the Separation of the Metal from its Compounds

Commercial electrolytic silver may contain 0·5 per cent. of impurities, and silver prepared in the dry way is of a still lower degree of purity. The impurities which have been reported include lead, copper, gold, bismuth, antimony, arsenic, platinum, palladium, selenium, sulphur, etc. A common method of purifying the silver is to dissolve it in dil. nitric acid and precipitate the silver from the soln. of the nitrate, or precipitate the silver as chloride, and subsequently reduce the chloride to the metal. Silver is readily reduced from most of its compounds. V. Kohlschütter and E. Eydmann [1] reduced silver oxide, nitride, hyponitrite, nitrite, carbonate, and oxalate by the mere application of heat ; and also by warming the oxide in hydrogen or carbon monoxide. P. Laur found that hydrogen developed in a liquid in which silver sulphide, chloride, bromide, or iodide is suspended reduces these salts to the metal ; and A. Jaques that a soln. of silver acetate is reduced by hydrogen ; and H. Vogel that the same soln. is reduced slowly when boiled.

F. Mohr [2] reduced the chloride by mixing it with one-third its weight of resin, and gradually raising its temp. ; when the resin is burned away, some borax is added and the mixture heated to the m.p. of the metal. The process is very messy. G. C. Wittstein used wood charcoal in place of resin. The reduction is ascribed wholly to the hydrogen of the charcoal, for (*a*) no chlorine is evolved, but hydrogen chloride alone is given off, and (*b*) no reduction occurs if pure carbon be substituted for the charcoal. J. S. Stas recommended re-melting the metal with 5 per cent. of borax, and ½ per cent. of soda nitre in an unglazed porcelain crucible. J. Thallwitz mixed wood charcoal and sodium dioxide with the silver chloride in a clay crucible. In a short time a vigorous reaction spontaneously occurs, and a button of silver is formed. J. L. Gay Lussac reduced silver chloride by heating it with a mixture of calcium oxide and charcoal; but, according to J. B. Trommsdorff, and P. T. Meissner, the reaction is incomplete. J. E. F. Giese, E. Mohr, etc., fused silver chloride with alkali carbonate, but J. L. Proust found that the reaction is incomplete since some decomposed silver chloride remains as a residue when the silver is dissolved in nitric acid.

Silver chloride is reduced to the oxide when boiled with a conc. soln. of potassium or sodium hydroxide. The oxide is washed, and heated until it decomposes and melts ; if any undecomposed chloride is still present, a little alkali carbonate is added. According to W. Gregory,[3] there is no fear of the loss of silver chloride by its sinking into the crucible, or spitting. Silver chloride is reduced to the metal when boiled with a soln. of alkali hydroxide or carbonate mixed with a suitable reducing agent. A. Levol, J. L. Casaseca, and F. Mohr used sugar ; H. Vogel and J. S. Stas used lactose ; P. A. Bolley used sugar, glycerin, or honey—it is probable that the reaction is not always complete ; R. Böttger and E. Brunner, and C. A. Müller used dextrose ; T. W. Richards and R. C. Wells, G. P. Baxter and H. C. Chapin, and W. Wicke used invert sugar ; L. Vanino, and V. Kohlschütter and E. Eydmann used formaldehyde ; G. D. Buckner and G. A. Hulett. ammonium formate. J. Guareschi reduced silver bromide by warming it with chromic anhydride ; E. H. Booth reduced an ammoniacal soln. of silver chloride with sodium dioxide ; F. Mawrow and G. Mollow found that silver chloride is slowly and quantitatively reduced by hypophosphorous acid.

Moist silver chloride is reduced to the metal when placed in contact with iron or zinc ; a little dil. sulphuric or hydrochloric acid hastens the reaction. The reduced silver is washed with dil. acid, then with the hot water, and dried. It then appears as a soft grey powder ; it is then mixed with borax and then a little nitre, and fused. According to F. Mohr, and W. Gregory, the reaction is incomplete, and the washing with acid does not remove all the zinc or iron from the silver. A. Gawalowsky also studied the reduction of silver chloride by zinc. M. Gräger reduced a soln. of the silver chloride in aq. ammonia with zinc, and found that the silver is simultaneously separated from copper—if that element be present. The silver chloride can also be triturated with an excess of mercury; a silver amalgam is formed from which the mercury can be separated by distillation, as in the amalgamation process—*vide infra.* E. Vigouroux used aluminium in the presence of 10 per cent. hydrochloric acid; the acid can be replaced by ammonia, and the water by benzene, ether, or chloroform.

N. W. Fischer,[4] and J. E. F. Giese placed silver chloride with water in a glass cylinder closed at one end by a membrane; the cylinder rested on a zinc plate immersed in water, and electrical connection with the water in the cylinder was made by means of a platinum or silver wire. The chloride was reduced in about a week's time. E. Brunner, F. Wandesleben, and O. Pfeiffer covered a platinum, silver, or copper dish with wax, leaving a round patch of the metal exposed on the bottom. The dish was placed on a disc of amalgamated zinc resting in a larger dish. Sulphuric acid was poured into the vessel so that the smaller dish containing silver chloride was wholly immersed. The silver chloride was reduced in about 24 hrs. Any of the halide not reduced was removed by washing with aqua ammonia. J. E. F. Giese, N. Gräger, W. Gregory, P. A. Bolley, R. Böttger, C. A. Müller, and O. Kühn have used modifications of the process. J. Nicklès, and J. S. Stas obtained silver of a high degree of purity by the electrolysis of a soln. of silver chloride in potassium cyanide. L. Kahlenberg electrolyzed a soln. of silver nitrate in pyridine. R. Lorenz and A. Helfenstein electrolyzed fused silver chloride; and T. W. Richards and W. N. Stull electrolyzed a soln. of silver nitrate in a molten mixture of sodium and potassium nitrates.

According to A. Vogel,[5] *sulphurous acid* gives a white precipitate with soln. of silver salts which turns grey on boiling, the mother liquid retains silver, and it becomes turbid when allowed to stand for some time. A. Pleischl said that sulphurous acid gives white flakes which turn yellow, then brown, and then contain silver sulphide. He also found that *ammonium sulphite* precipitates white silver sulphite which becomes covered with a shining film of metal—slowly at ordinary temp., rapidly when heated. The reaction of *potassium sulphite*, said A. Pleischl, resembles that of sulphurous acid. H. Rose found *cuprous oxide* precipitates from silver nitrate soln. a grey-coloured mixture of silver and basic cupric nitrate, and a mechanical mixture of copper and cupric oxide was found to act in a similar manner. P. Sabatier found the reaction is exothermal, and with a mol of silver in two litres of water the precipitate has the composition $6Ag+3CuO.Cu(NO_3)_2.3H_2O$. The precipitate from a boiling soln. has virtually the same composition. J. H. Gladstone, and A. Geuther observed that a warm soln. of silver nitrate dissolves cuprous oxide and at the same time crystals of silver are formed. R. Heumann and R. Schneider obtained a mixture of metallic silver and silver sulphide by the action of *cuprous sulphide* on a soln. of silver nitrate. K. Emszt obtained silver and silver chloride by acting on silver nitrate with *cuprous chloride;* N. A. E. Millon and A. Commaille reduced ammoniacal soln. of silver salts with an ammoniacal soln. of cuprous chloride; and J. S. Stas utilized the reaction in the preparation of silver from the ammoniacal soln. of a silver salt contaminated with copper. When ammonium sulphite is added, the copper is reduced to the cuprous form, and that reduces the silver to the metal which is precipitated in a finely-divided condition. A. Geuther mixed the soln. of silver with ammonium chloride and treated it with an alkaline soln. of *sodium hypophosphate,* whereupon silver is precipitated and any copper present remains in soln.

According to H. Rose, a soln. of *stannous chloride* in small quantity gives a white precipitate of silver chloride, while an excess of the tin salt gives a brownish-black precipitate of metallic silver. When the soln. of silver nitrate and stannous chloride are very dil., J. Percy obtained a rich yellowish-brown liquid, probably colloidal silver. The colour resembles that of glass stained with silver, for " the silver-stain of glass may be due to metallic silver in an extremely fine state of division." H. Schulz obtained a colour analogous to that of purple of Cassius by stirring stannous hydroxide with water and a neutral soln. of silver nitrate and then gradually warming the mixture. Here again the colour of the *silver purple of Cassius* is probably a kind of lake in which stannic oxide is tinted with the finely-divided metal, just as M. Faraday could say, "I believe the purple of Cassius to be essentially finely-divided gold associated with more or less oxide of tin." H. Rose also found that a soln. of *stannous sulphate* produces a precipitate which is at first white, but soon becomes black or brownish-black, and retains this colour on boiling; and when this precipitate is heated with hydrochloric acid, metallic silver remains. F. Gutzkow, and L. Berlandt treated a hot soln. of silver nitrate or sulphate with one of *ferrous sulphate*, silver is precipitated, copper remains in soln. The reaction was noted by J. Keir, and, according to J. L. Proust and C. F. Bucholz, the precipitated silver may redissolve in the soln. of ferric sulphate when boiled. With silver nitrate the reaction is symbolized: $3AgNO_3+3FeSO_4=Fe_2(SO_4)_3+Fe(NO_3)_3+3Ag$. G. Wetzlar, J. E. F. Giese, and A. Vogel found that silver so obtained is contaminated with some iron, particularly if the soln. be dil., presumably owing to the simultaneous precipitation of a basic ferric salt. According to H. Rose, if the soln. of silver nitrate be mixed with ferrous chloride, the addition of ferrous sulphate precipitates silver chloride not the metal, and he added:

> If moist oxide of silver be added in sufficient quantity to a soln. of ferrous sulphate, the former becomes deep black, but is still converted into silver after some time, and only acquires greater stability when the quantity of silver oxide is very predominant: the filtered liquid then contains no iron, but only silver sulphate. The black compound is obtained most readily and of the greatest stability, when a soln. of silver nitrate is mixed with so much ammonia that the small quantity of silver oxide separated is redissolved, and an excess of this soln. is dropped into a soln. of ferrous sulphate. A deep black precipitate is then formed immediately, which has so remarkably strong a colouring power that the smallest quantity of ferrous or argentic oxide may be thereby detected. In the first case, the slightly ammoniacal soln. of silver oxide is as sensitive a reagent as the soln. of potassium ferrocyanide and ammonium sulphide. The black precipitate is very stable, and undergoes no change in the air. At a dull red heat it only loses water, but it is not otherwise changed in composition; at a stronger red heat it is converted into silver and ferric oxide. By trituration in an agate mortar, it acquires a metallic lustre. It is changed by dil. hydrochloric acid into silver chloride, silver, and ferric chloride; but the quantity of silver separated is not very considerable: it is greater when the substance is treated with dil. acetic acid. By nitric acid, ferric oxide is first separated, whilst silver dissolves with evolution of gas; complete soln. takes place on the application of heat. When treated with a soln. of auric perchloride, silver chloride is formed and gold separated. The compound when variously prepared has the same composition: it consists of $AgO+2FeO+Fe_2O_3$, where the ferric oxide acts as an acid towards the two bases. A compound of $AgO+Fe_2O_3$, without ferrous oxide, may be obtained by dissolving silver oxide in ammonia-water and adding thereto a soln. of ferrous sulphate, the former soln. being in great excess. When ferrous and silver oxides are combined with weak acids, the soln. of these neutral compounds form the black precipitate of silver oxide, without the addition of ammonia or any other base. If ferrous and silver acetates be used, the black compound is immediately produced, but under the influence of the free acids becomes white of itself in course of time, changing into silver. A far greater quantity of the compound of silver oxide is, however, produced when the free acids are sat. by a small quantity of a base.

J. Seymour showed that the reaction between ferrous sulphate and silver nitrate occurs in darkness as well as in light. The action of ferrous sulphate on silver salts has been also studied by V. Kohlschütter and E. Fischmann, H. Vogel, etc. L. Pissarjewsky obtained indications of what he regarded as two different modifications of silver by reduction with ferrous salts—*vide* allotropic and colloidal silver. F. Kessler reduced a neutral soln. of a silver salt with a mixture of sodium and *ferrous acetate*. C. Palmer and E. S. Bastin found some natural *sulphides* of copper, cobalt, and nickel precipitated silver from dil. soln. of the sulphate; pyrite and galena were inactive. J. M. Eder found potassium ferrous oxalate reduces silver nitrate to the metal. There is no decomposition when a soln. of manganous sulphate is added to one of silver nitrate, although a black precipitate may appear after a very long time; but, according to L. Schnaubert, and F. Wöhler, when alkalies are added to a mixed soln.

of a silver and a *manganous salt*, a black mixture of silver and manganese dioxide is precipitated. J. J. Ebelmen found *uranous oxide* decomposes silver nitrate without any evolution of gas producing metallic silver and uranic nitrate. According to R. A. Wawrinsky, when a mixed soln. of copper and silver nitrates is treated with *magnesium carbonate*, the copper carbonate is precipitated between 40° and 50°, and silver carbonate over 60°.

According to V. Kohlschütter and E. Fischmann, *hydrazine hydrate* precipitates silver from the ammoniacal soln. of a silver salt. R. Fresenius and H. Neubauer[6] found a dil. soln. of silver nitrate is more rapidly reduced by *phosphorus* than a conc. soln. Finely-divided phosphorus, observed J. S. Stas, slowly reduces a 1 per cent. soln. of silver nitrate to the metal. With a conc. soln. of the nitrate and yellow phosphorus, T. Poleck and K. Thümmel obtained first a yellow liquid owing to the formation of $Ag_3P.3AgNO_3$, which is then reduced to silver phosphide, and W. Wicke found that a conc. soln. slowly deposits crystalline silver on the phosphorus. J. Phillip obtained silver phosphate as well as phosphoric and phosphorous acids by warming a nitric acid soln. of silver nitrate with phosphorus. J. B. Senderens represents the reaction with red phosphorus: $10AgNO_3+2P+8H_2O=10Ag+2H_3PO_4+10HNO_3$. The reduction of silver nitrate soln. by phosphorus is utilized in electro-plating.

According to G. Shaw, the article to be plated is cleaned and dried, and then dipped in a soln. of phosphorus in twelve times its weight of carbon disulphide As the solvent evaporates, a film of finely divided phosphorus remains on the surface. The article is then immersed in a soln. of silver nitrate. In this manner, the most delicate objects, such as lace, feathers, insects, and fruit, indeed, anything which will bear immersion in liquid, may be coated with a film of silver. Mrs. Fulhame used a similar process in 1794.

According to C. J. D. von Grotthuss, characters written on paper with a soln. of silver nitrate, and placed in a bottle containing phosphorus and atm. air, are blackened owing to the reduction of the nitrate to the metal. According to W. Herapath, the early Egyptians marked linen with a soln. of a silver salt. F. Mawrow and G. Mollow quantitatively reduced silver chloride to the metal by treating it with *hypophosphorous acid*. A. Wurtz reduced silver nitrate with the same agent. The brown precipitate produced by *phosphine* in a soln. of silver nitrate or sulphate consists of metallic silver, *vide* silver nitrate. P. Pascal found that *alkali ferropyrophosphate*, $M_8Fe_2(P_2O_7)_3$, reduces silver nitrate to the metal. E. Soubeiran, and J. L. Lassaigne reduced dil. soln. of silver nitrate to the metal by treatment with *arsine;* with conc. soln. a double compound is formed. Z. Pozzi, and H. Reckleben and co-workers found arsine reduced ammoniacal soln. of silver salts. H. Reckleben and A. Güttich found *stibine* behaved like arsine. According to T. Poleck and K. Thümmel, when finely-divided *arsenic* is added to a neutral conc. soln. of silver nitrate, a yellow colour is developed, and the soln. reacts acid; nitric and arsenious acids are formed, and silver is precipitated. N. W. Fischer found that arsenic reduces aq. or alcoholic soln. of silver nitrate, forming, according to J. B. Senderens, arsenious oxide; *antimony* reduces the aq. nitrate or carbonate suspended in water, but it does not reduce the aq. sulphate or alcoholic nitrate; T. Poleck and K. Thümmel found that if precipitated antimony be added to a very conc. soln. of silver nitrate, a black precipitate of presumably silver antimonide is formed, and the soln. reacts acid; with the addition of more antimony a grey substance is precipitated, oxides of nitrogen are evolved, the soln. becomes warm, and the acidity disappears. The grey substance is presumably a mixture of antimony trioxide and silver. Black silver antimonide is precipitated from dil. soln. of silver nitrate (1 : 80) and the soln. becomes warm; J. B. Senderens says the precipitate is metallic silver; and R. Bartels, that a vigorous evolution of gas occurs. According to J. B. Senderens, no gas is developed with $\frac{1}{20}N$-$AgNO_3$, and the reduction is incomplete because a protective crust of antimony oxynitrate is formed, but from a $\frac{1}{4}N$- or $\frac{1}{2}N$-soln. the silver is quantitatively precipitated, some free nitric acid is formed and very little ammonium nitrite. According to N. W. Fischer, *bismuth* reduces the aq. or alcoholic nitrate; and the carbonate suspended in water; but not the aq. sulphate. C. H. Palmer and E. S. Bastin found that the arsenides of copper, cobalt, and nickel reduce a dil. soln. of silver sulphate to the metal.

The metallic precipitation of silver.—In his memoir *Das Verhältniss der chemischen Verwandschaft zur galvanischen Electricität, in Versuchen dargestellt* (Berlin, 1830), N. W. Fischer [7] showed that silver is precipitated in the metallic state from aq. soln. of the nitrate by metallic lead, zinc, cadmium, mercury, tin, iron, copper, bismuth, antimony, and arsenic. The time required for the precipitation varies with the kind of metal employed. It is shortest with the first two elements, and the others require a longer and longer time and that in the order named. Excluding antimony, the reduction of silver from alcoholic soln. of silver nitrate is likewise affected by these metals. The metal is also reduced from the ammoniacal soln. of the nitrate quickly and completely by zinc, cadmium, copper, and arsenic; slowly by cobalt, mercury, and antimony; and not all by iron, manganese, nickel, or bismuth. Silver is also reduced from the molten nitrate by zinc, cadmium, tin, and copper, though not all, or very slowly, by certain other metals. J. B. Senderens studied metallic precipitation with the object of testing Richter's law, but he found that with silver nitrate, the law does not describe the facts because the displacement of the silver is always accompanied by a reduction of some of the nitric acid. According to A. Guntz and F. Martin, finely-divided manganese, nickel, cobalt, and copper, reduce silver nitrate dissolved in strongly ionizing, non-aqueous solvents. Thus, in liquid ammonia these metals form ammino-salts of the type $M(NO_3)_2.nNH_3$; similar remarks apply more or less to soln. in acetone and benzonitrile.

A. Chevallier found that dry silver nitrate is reduced to the metal by **copper.** As just indicated, N. W. Fischer found silver to be precipitated by copper from aq. or alcoholic soln. of the nitrate, and from the molten salt. According to J. L. Gay Lussac, the silver precipitated from aq. soln. of the nitrate is at first fairly pure but that later deposited is mixed with copper which dissolves out when the contaminated metal is immersed in a soln. of silver nitrate. J. B. Senderens found that only 65 to 68 per cent. of the silver can be displaced by copper from the nitrate; some ammonium nitrite is produced, and the presence of air leads to the deposition of some basic cupric salt. W. Hampe observed that with a cold soln. of silver nitrate, copper first gives nitric oxide and then forms some cupric oxide, which is decomposed by the excess of silver nitrate; the precipitated silver contains traces of copper. The phenomenon has been also studied by M. Lucas, and L. Vignon.

J. H. Gladstone and A. Tribe found that if a plate of copper be suspended in a soln. of silver nitrate, so that the suspended metal reaches neither to the top nor the bottom of the liquid, and if the percentage conc. of the salt C be expressed by series of powers of 2, the rate of chemical action V will be expressed by the corresponding powers of 3, such that for conc. represented by 1, 2, 4, 8, . . ., the rate of chemical action will be 1, 3, 9, 27. . . . The mathematical expression of what they called a new *law in chemical dynamics*, is: $V=k(\log 3-\log 2)c$, where k is a constant. Two currents are set up during the precipitation, a light blue ascending stream of silver and copper nitrates, and a deep blue descending stream of copper nitrate containing about three times as much nitric acid as the main soln. J. W. Langley showed that the true law of chemical action: "the rate of total chemical action varies directly as the mass of the reacting body in soln.," is here obscured by the effects of gravitation, for the access of fresh silver nitrate to the copper depends on the rate at which cupric nitrate soln. is removed from the copper plate, and this in turn depends on the density of the copper nitrate soln. Gladstone and Tribe's "2–3 law" is not therefore a general law of chemical dynamics, but a case where the law of mass action is obscured by the conditions of the experiment.

The action of **silver** on a conc. soln. of silver nitrate has already been described. According to N. W. Fischer, **zinc** reduces silver from aq. or alcoholic soln. of silver nitrate, and also from the fused salt; it also reduces aq. soln. of the sulphate, and suspensions of the carbonate or phosphate in water. According to G. Wetzlar, if zinc be placed in a slightly acidulated soln. of silver nitrate, from the beginning to the end of the precipitation, there is formed a black moss-like growth of silver contaminated with zinc. The deposit assumes a lighter colour towards the edges, and portions detached from the mass part with the contained zinc and become white—the dark colour is restored by bringing a whitened portion in contact with the zinc. He added that with a neutral soln. of silver nitrate only the metal first precipitated is black, the metal subsequently deposited is white. N. W. Fischer, on the contrary, maintains that neutral soln. give alloys from the beginning to the end of the precipitation, while acidulated soln. give alloys only towards the end of the deposition. If the silver nitrate soln. contains some copper nitrate, N. W. Fischer observed that the silver is all precipitated before the deposition of copper begins. According to the last-named authority, **cadmium** behaves like zinc. J. B. Senderens says some cadmium nitrite is formed; and with the zinc reduction, nitric oxide, ammonia, and zinc hydroxide are formed. According to E. G. Bryant, **magnesium** acts very much like zinc, and J. W. Dodson obtained finely divided crystalline silver by the action of magnesium on a soln. of silver nitrate.

In the fifteenth century, P. Eck de Sultzbach, in his *Clavis philosophorum*, 1489, mentioned arborescent crystals of silver which are produced by the action of mercury on a soln. of silver nitrate. The product of the reaction was soon after called *arbor Dianæ*—or the tree of Diana—*e.g.* in J. B. Porta's *Magia naturalis* (Naples, 1558). The precipitation of silver by mercury was mentioned by R. Boyle in his paper *On the mechanical causes of chemical precipitation* (London, 1675), and in many later writings; by J. von Löwenstein Kunckel in his *Vollstantiges Laboratorium chymicum* (Berlin, 1767), etc. N. W. Fischer observed that when **mercury** is immersed in a soln. of silver nitrate, or sulphate, silver amalgam is formed, and a black powder said to contain silver suboxide is deposited from alcoholic soln.; mercury also exerts a slight action on silver phosphate and carbonate. According to A. Ogg, equilibrium in the reaction between mercury and a soln. of silver nitrate is attained between silver and mercurous nitrates and the amalgam. The conc. of the mercury may be regarded as constant, and if a be the eq. conc. of the silver nitrate, b that of mercurous nitrate, and c that of the silver in the amalgam, a/bc is a constant if the mercury ions are equivalent, and $a/cb^{\frac{1}{2}}$ if the mercury ions are bivalent. C. Barfoed found silver nitrate is reduced by the vapour of mercury.

N. W. Fischer found that black metallic silver is precipitated by **tin** from a soln. of silver nitrate or sulphate, a brown powder is formed at the same time, and the liquid is tinted brown. Tin precipitates but a little silver from an alcoholic soln. of the nitrate, and this only when the metal is first immersed. Tin also reduces dry silver nitrate, and the carbonate or phosphate when suspended in water. According to J. B. Senderens, the reduction of aq. soln. of the nitrate is attended by the formation of stannous oxide, and ammonium nitrate. N. W. Fischer found that **lead** precipitates silver from aq. soln. of the nitrate, and, with alcoholic soln., it behaves like tin. J. B. Senderens found that 2 gram-atoms of lead are required to displace the silver in two mols of silver nitrate, and that lead nitroso-nitrate, $NO_2Pb—O—PbNO_3$, is simultaneously formed. A soln. of silver nitrate was found by N. W. Fischer to be completely reduced by brass, and alloys of silver with zinc, tin, or lead; **manganese** exerts but a slight action, and **palladium** none. J. B. Senderens found **aluminium** to act very much like zinc, and the speed of the reduction increases with the conc. of the soln. N. W. Fischer says that **iron** causes no reduction either in an aq. or alcoholic soln. of silver nitrate, provided the soln. is perfectly neutral and there is no access of air; and none occurs so long as the metal is kept under the soln. If, on the contrary, the soln. is not neutral, but is diluted to a certain degree and contains free acid, or, if the iron projects out of the soln. and is exposed to atm. air, reduction always follows in a longer or shorter time, which depends partly on the degree of dilution of the soln., as also upon the quantity of free acid, and partly upon the quality of the iron itself. However, under favourable conditions, complete reduction of the silver hardly occurs even after a very long time. According to H. Rose, and P. Sabatier, neutral soln. of above $\frac{1}{30}N$-$AgNO_3$ are not attacked by iron, but silver is deposited if the dilution be greater than is represented by $\frac{1}{50}N$-$AgNO_3$. In acid soln. of silver nitrate, the iron becomes passive. F. Brandenberg stated that silver nitrate may be melted in iron vessels without change provided water be absent. According to J. B. Senderens, **nickel** has no action on soln. of silver nitrate, and **cobalt** acts like copper.

§ 6. The Physical Properties of Silver

Silver *en masse* is the whitest of metals, although the colour of some of the metals —*e.g.* tin, cadmium, indium, and lithium—approximates to that of silver. The silver reduced by the metals from the halides appears as a grey spongy mass, more or less granular and earth-like, but it immediately acquires the characteristic lustre of the metal when the burnisher is applied. Very thin layers of the metal on glass have a violet, blue, or bluish-green colour in transmitted light. According to F. Bothe,[1] a film of silver deposited on glass by J. von Liebig's process is so thin that when held up to bright sunlight it appears transparent and of a beautiful deep blue colour; L. Foucault showed that the blue colour is not due to porosity, but is an effect of the passage of light through the solid metal. A. K. Christomanos added that the colour of that portion of light transmitted by very thin layers of silver is bluish-green, and by somewhat thicker layers, yellow or yellowish-brown. H. Ambronn prepared films but a few millionths of a millimetre thick. The colloidal metal—*vide infra*—appears in various shades of red, yellow, green, blue, or violet. According to W. C. Roberts-Austen and J. N. Lockyer, "the vapour of silver when condensed into fine particles escaping into an atm. of hydrogen, is blue by reflected light." According to J. S. Stas, the vapour of silver produced by the oxyhydrogen flame has a pale blue colour, slightly inclining to purple, and is not green. The green tint which has been reported is due to the presence of a trace of copper.

J. B. L. Romé de l'Isle [2] first showed that the **crystals** of the metal belong to the cubic system, and they occur in the form of cubes, octahedra, hexahedra, dodecahedra, hexakis-octahedra, etc. R. J. Haüy, F. Mohs, G. Rose, etc., confirmed this observation, and J. F. L. Hausmann found sharply defined octahedra in the solidified silver hanging on the sides of a crucible from which the molten metal had been poured. V. Kohlschütter and E. Eydmann obtained well-defined crystals by heating the amorphous powder for some hours under molten silver nitrate; and E. Giurgea placed a copper rod in a soln. of silver nitrate in a porous cell, and obtained a crystalline deposit on the cell walls. G. W. A. Kahlbaum, K. Roth, and P. Siedler obtained microscopic octahedra and hexahedra by subliming the metal in vacuo. W. Haidinger obtained crystals by the fusion and slow cooling of the metal. Electro-deposited silver may appear as a black or dark grey powder in which six-sided stellate crystals can be recognized under the microscope. This subject has been studied by H. Dauber, G. vom Rath, M. Kirmis, U. Behn, R. C. Snowdon, etc. According to E. B. Rosa, G. W. Vinal and A. S. McDaniel, electrolytic silver obtained from purified substances consists of microscopic cubes with sharp corners and angles. An acidulated electrolyte gives smaller and more numerous crystals—cupric nitrate or sulphate soln. act similarly. The presence of colloidal substances interferes with the formation of crystals. In general, the form of the deposit depends on the current density, the conc. of the soln., the voltage, etc. A. H. W. Aten and L. M. Boerlage have studied the crystallization of metals by electrical precipitation. M. Ettisch and co-workers say that the crystallites in soft wires are arranged irregularly, those in hard drawn wires, regularly. Z. Jeffries and R. S. Archer give 200° as the lowest temp. at which the recrystallization of the cold-worked metal has been observed. Filamentary and dendritic forms of silver occur in nature. **Filiform, moss, or hair silver** can be made artificially by reducing the sulphide in a current of steam; by reducing the sulphide, selenide, or telluride in a current of hydrogen—the sulphide at 400°. The temp. should suffice to agglutinate the sulphide, but be below the m.p. of the silver. J. Percy said:

> This beautiful experiment may be made in a glass tube through which a current of the gas is passed. Long delicate fibres of silver may be seen protruding from minute rounded masses of the sulphide; and as they are produced while these masses are in a soft state and lying free in the tube, the idea that they result from the application of external mechanical press., in a similar manner to maccaroni, can hardly be entertained. There seems to be some force in operation at the base of each filament, which causes the particles of silver at the moment of liberation to successively arrange themselves in one continuous fibre, or series of fibres; or, in other words, each filament grows, as it were, from a root embedded in sulphide of silver.

O. Ohmann made what he called *silver-wool.* Filiform silver has been studied by J. Margottet, C. Bischoff, H. Vogel, W. M. Hutchings, A. Gurlt, A. Liversidge, C. Winkler, O. Mügge, K. Friedrich and A. Leroux, L. Opificius, and particularly by V. Kohlschütter and E. Eydmann, and A. Beutell. J. Percy said:

> When natural or artificial silver sulphide is heated in an evacuated sealed tube for several days at a temp. of 350°–600° a certain amount of decomposition takes place. The small amount of silver formed seems to wander through the silver sulphide, appearing at the cooler end of the tube in the form of hair silver. A number of experiments which were made showed that neither silver-foil nor hair silver is attacked by sulphur vapour in a vacuum at 350°; the metal remained bright after forty-eight hours. Silver-foil heated alone in a vacuum for a long period at 450°–585° showed no trace of the growth of hair silver, but when silver foil and silver sulphide were heated together at 450° remarkable growths were obtained in a comparatively short time. To obtain these growths it is necessary for the silver and the silver sulphide to be actually in contact. Similar growths of copper were obtained by heating together copper and cuprous sulphide, but the process was much slower. When silver selenide or telluride was used in place of the sulphide, similar growths of silver were obtained, and hair copper was obtained to a certain extent with copper selenide and telluride. With gold, the best results were obtained when gold telluride containing silver was heated with silver-foil. After seven days' heating at 500°, growths of "moss" gold containing silver had appeared at the cooler end of the tube.

The phenomenon seems to be dependent on the breaking up of solid soln. of silver and silver sulphide. According to S. Kalischer, rolled silver is not crystalline, but it becomes so when heated to redness. A. H. W. Aten and L. M. Boerlage studied the rate of crystallization of silver in galvanic precipitation.

L. Vegard's **X-radiograms** of silver show that the crystal units are arranged as a simple face-centred cubic lattice with edge 4·060 A., and the smallest distance apart of the atoms 2·876 A. P. Sherrer gives $4·06\times10^{-8}$ cm. for the dimensions of the elementary cube. N. Gross, and H. Bohlin also made observations on the structure of crystals of silver. S. Nishikawa and G. Asahara examined the X-radiogram of silver which has been rolled, and found that the metal anneals itself spontaneously after three weeks, for, instead of giving an ill-defined structure with a symmetry related to the direction of rolling, distinct crystals appear. K. F. Slotte estimated the edge of the molecular cube of liquid and solid silver to be $6·6\times10^{-9}$ cm. M. Born and E. Bormann measured the mean **free-path** of silver atoms. W. L. Bragg showed that the radius of the at. spheres of silver in crystals of the metal is $0·177\mu\mu$, or 1·77 A. M. S. Saha made estimates of this magnitude. E. Beckmann and O. Liesche found that in boiling mercury silver is present as monatomic mols.

In the Arabian *Book of the Best Things for the Knowledge of Mineral Substances*, by Abu-r-Raihan, written towards the end of the tenth century,[3] the **specific gravity** of silver is stated to be 10·35, a value very close to that accepted at the present day. Another Arabian writer, Al-Khazini, in his *Book of the Balance of Wisdom*, written in the twelfth century, gives 10·30 for the value of this constant. A very large number of measurements of the sp. gr. of silver have been made since 1690, when R. Boyle[4] gave 11·091 for this constant. D. G. Fahrenheit (1726) found its value to be 10·481. A. Matthiessen failed to get constant results in his determinations of this constant, for his numbers varied from 10·424 to 10·511 at 132°. According to C. Karmarsch, the densest silver, of sp. gr. 10·566, is obtained by slowly cooling the metal from a molten state; when suddenly chilled by pouring the molten metal into cold water, the sp. gr. fell to 9·632; when cast into rods, 10·105; and when melted and then cooled in a crucible, the sp. gr. varied from 9·998 to 10·474. The results thus depend on the previous history of the metal. The sp. gr. of chilled cast silver, for instance, has been reported as low as 8·7, and of the slowly cooled silver, 9·4. G. Wertheim and others have shown that cold work greatly influences the sp. gr. as it does the mechanical and physical properties of metals—elasticity, e.m.f., thermal and electric conductivity, etc. F. C. A. H. Lantsberry found the sp. gr. of annealed silver to be 10·4475, and of cold-worked silver, 10·4410. G. Rose, and V. Kohlschütter and E. Eydmann found that at 18° silver precipitated from a soln. of the nitrate by ferrous sulphate had a sp. gr. of 10·56 to 10·62; silver reduced from silver oxide by hydrogen at 144°, 10·352; and after heating two hours at 160°, 10·490; silver reduced from the oxide by carbon monoxide, 10·113; silver reduced from silver chloride by zinc and sulphuric acid, 10·307; and silver reduced by aldehyde, when the grain-size is 250μ, 10·270. A. K. Christomanos found the sp. gr. of distilled silver to be 10·575; and G. W. A. Kahlbaum and co-workers found for the metal distilled in vacuo, a value 10·4923 (20°); and after compression at 10,000 atm., 10·5034 (20°). W. Spring found for annealed silver a sp. gr. 10·2696; for rolled silver, 10·2531; and for the metal which had been exposed to a great press., 10·2485. J. S. Stas obtained 10·4624 for the sp. gr. of the metal at 0°, and after compression and heating, the sp. gr. rose to 10·5023, but fell to 10·4894 when again heated to dull redness, and rose to 10·5104 when hammered. After re-heating to dull redness, and cooling in vacuo, the sp. gr. fell to 10·4977. J. S. Stas also found the sp. gr. of silver prepared in different ways ranged from 9·8688 to 10·5537, and he thought that the phenomenon was a secondary effect due to the occlusion of gases by the metal. It was assumed that the occlusion of gas diminished the sp. gr. The best representative value for the sp. gr. may be taken as 10·5. The **specific volume** of silver is therefore 0·0952; and the **atomic volume**, 10·3. According to W. C. Roberts and T. Wrightson, the sp. gr. of solid silver is 10·57, and of the liquid 9·46 to 9·51; according to A. Sieverts and J. Hagenacker, the sp. gr. of the solid at the m.p. is 10·0, and of the liquid 9·5, and at about 1120°, 9·453. According to T. M. Lowry, when silver is annealed at 100°, there is a contraction represented by an increase in sp. gr. of 0·0032 per cent.; at 180°, there is an expansion corresponding with a change of sp. gr. of 0·0020; and when annealed at a red heat there is a decrease in volume corresponding to an increase of sp. gr. of 0·0108. The annealing process thus involves three changes: a contraction at the lowest temp., and expansion at an intermediate temp., and a contraction at the highest temp. T. M. Lowry and R. G. Parker found that while the sp. gr. of silver *en masse* is 10·4960, that of the filings is 10·4786—*vide* allotropic silver and gold.

The **hardness** of silver on Mohs' scale varies between 2·5 and 3·0. Silver is harder than gold, and softer than copper. F. C. Calvert and R. Johnson[5] found the hardness of gold, silver, and copper to be in the ratio 4 : 5 : 7·2; the ratio on J. R. Rydberg's scale is 2·5 : 2·7 : 3·0; on S. Bottone's scale, 979 : 963 : 1364; and on F. Auerbach's scale, 97 : 91 : 95. E. A. Smith and H. Turner found Brinell's hardness of the cast and slowly cooled metal to be 38; C. A. Edwards gave 37·0. The increase in the hardness of cast sterling silver (7·5 per cent. copper) by progressive cold rolling:

Rolled to . .	—	0·500	0·365	0·250	0·125	0·076	0·042 in.
Brinell's hardness	60	135	145	157	170	177	183

A. Hanriot found that Brinell's hardness of silver increased from 19·0 to 36·0 after being subjected to a great hydrostatic press.—10,000 kgrms. per sq. mm. A. Kürth gave 29·3 for J. A. Brinell's hardness with a load of 400 kgrms. at 18°; and 27·1 at 200°. Z. Jeffries could detect no change in the microstructure of the compressed metal, and no substantial change in the physical properties. The hardness is increased by alloying the metal with, say, 10 per cent. of copper.

The **malleability** and **ductility** of silver are said to be exceeded only by gold. It is said that the metal may be hammered into leaves 0·00025 mm. or 0·00001 in. thick; and that a gram may be drawn into wire 1800 metres long, or that a grain may be drawn into wire 400 ft. long. The metal is hardened by hammering or rolling, but it recovers its malleability by annealing at a low red heat. G. Quincke's value for the **surface tension** at 1000°, $\sigma=782\cdot4$ dynes per cm., and corresponding value for the **capillary constant,** $a^2=15\cdot94$ sq. mm. T. Lohnstein computed rather larger values. A. Gradenwitz gave $\sigma=751$, and $a^2=14\cdot5$ sq. mm.; and S. W. Smith respectively 858 dynes per cm., and $a^2=18\cdot52$ sq. mm. I. Traube gave for the **internal pressure** of the solid, 161,900 megabars. The **velocity of sound** is conveniently taken as $26\cdot4\times10^4$ cm. per second. A. Masson[6] found 2605·2 metres per sec. for soft silver between 15° and 20°; and 2674·4 metres per sec. for hard silver at 10°. A bar of silver gives a characteristic clear sound when struck, but C. J. B. Karsten said the sound is rather dull, so that the so-called "silver tone" and "silver voice" are poetic expressions with meanings different from what is literally implied. W. C. Roberts-Austen found the coeff. of **diffusion** of silver in molten tin at 500° to be $k=4\cdot14$ per cm. per day. The **internal viscosity** of silver has been studied by C. E. Guye and co-workers from the logarithmic decrement of oscillating wires, and by M. Ishimoto, from tuning-forks and oscillating pendulums. K. Honda and S. Konno found the viscosity of hammered silver to be $2\cdot8\times10^8$ at 15°; and that of the metal annealed at 400°, $2\cdot24\times10^8$ at 15°. A. Einstein has calculated the wave-length of the elastic oscillations. A. Johnsen found the **plastic flow** of silver is diminished by cooling the metal in liquid air. O. Stern measured the **velocity of the molecules** of silver vapour, and showed that they are monatomic.

The fractional change in the volume caused by the application of unit press., *i.e.* the **compressibility,** of silver, is smaller than that of lead, tin, bismuth, aluminium, or zinc, and greater than that of copper, platinum, or palladium. According to T. W. Richards,[7] the compressibility coeff. of silver at 20° is $1\cdot01\times10^{-6}$ per megabar or 10^6 dynes per sq. cm. between 100 and 500 megabars. L. H. Adams and co-workers give $0\cdot97\times10^{-6}$, and they represent the change in vol. δv by a change of press. from p_0 to p by $\delta v=0\cdot000055+0\cdot000000968(p-p_0)$. The compressibility increases with a rise of temp., while the coeff. of expansion decreases with a rise of press. The greater the expansion with rise of temp. the greater the change in the compressibility. E. Grüneisen found the cubical compressibility of silver, at −191°, to be $0\cdot709\times10^{-6}$; at 16°, $0\cdot763\times10^{-6}$; at 134°, $0\cdot844\times10^{-6}$; and at 166°, $0\cdot86\times10^{-6}$. A. Mallock also found $0\cdot709\times10^{-6}$ at −190°; $0\cdot768\times10^{-6}$ at 17°; and $0\cdot820\times10^{-6}$ at 100°.

The coeff. of resistance of silver to extension, the so-called **modulus of elasticity** or **Young's modulus**—*vide* copper—was found by G. Wertheim[8] to be 7357 kgrms. per sq. mm. for drawn silver at 15°, and 7140 kgrms. per sq. mm. for the annealed metal also at 15°, and he gave 7274 and 6374 kgrms. per sq. mm. for the values at 100° and 200° respectively. W. Voigt represented Young's modulus by 7790 kgrms. per sq. mm. S. Katzenelsohn gave 7010 for drawn silver; and G. Angenheister, 7597 kgrm. per sq. mm. for cast silver; and other values have been obtained by

C. Schäfer, E. Grüneisen, A. Bock, etc. The best representative value at 15° may be taken as 7300 kgrms. per sq. mm. for the drawn metal, and 7140 kgrms. per sq. mm. for the annealed—when the extreme values range from 7010 to 8290 kgrms. per sq. mm. The modulus of elasticity gradually decreases as the temp. rises up to the m.p. A. Mallock estimated the ratio of Young's modulus at —273° to its value at 0° to be 1·37. According to W. Sutherland, the variation with temp. is linear and approximately in accord with the empirical relation indicated in connection with copper (*q.v.*), where K. R. Koch and C. Dannecker's Fig. 10 shows the steady and gradual fall of the modulus of elasticity with rise of temp. C. Schäfer gives 7·65 for the temp. coeff. or the percentage increase of Young's modulus in passing from 20° to —186°. C. Schäfer plotted the temp. coeff. and the m.p. of a number of elements, and found that there is some relation between the two constants.

G. Tammann gave 86 kgrms. per sq. cm. for the **elastic limit** of silver. An elastic body if subjected to a stress is deformed, and when the stress is removed, it wholly or partially recovers from the deformation. The recovery may take place immediately the stress is removed, or the recovery may proceed a certain way more or less rapidly and subsequently creep slowly back to its original state. Hence arises the so-called **elastic fatigue,** *elastische Nachwirkung*, etc. F. Rehkuh, and E. Scholz have studied this phenomenon with silver wires.

The ratio of the lateral contraction to the longitudinal extension of silver, or **Poisson's ratio,** is 0·363, according to C. Schäfer; and 0·380 to 0·407, according to G. Angenheister; A. Bock[9] found Poisson's ratio to be 0·337 at 20°; 0·352 at 50°; 0·372 at 100°; and 0·381 at 100°. C. Schäfer plotted the m.p. and Poisson's ratio for a number of elements, and showed that there is a close relation between them. The **volume elasticity,** cubic elasticity, or bulk modulus of silver is $10·9 \times 10^{11}$ dynes per sq. cm. The resistance to shearing, or the **rigidity** or **torsion or shear modulus** of silver, is given by C. Schäfer as 2467 kgrms. per sq. mm., W. Voigt gives 2960; M. Baumeister, 2650; G. F. C. Searle, 2816 for the hard-drawn metal. The mean value is 280×10^6 grms. per sq. cm. between 0° and 20°. When the maximum and minimum values are 331 and 257×10^6 grms. per sq. cm., the ratio of the value at 100° to that at absolute zero ranges from 0·956 to 0·962; and the corresponding ratio at 200° ranges from 0·858 to 0·898. W. Sutherland estimates the value of this constant to be 284×10^6 grms. per sq. cm. at absolute zero. G. Pisati gives for the rigidity of silver, n, at θ°, $n = n_0(1 - 0·000387\theta - 0·0_6 38\theta^2 - 0·0_8 11\theta^3)$ kgrm. per sq. mm., where $n_0 = 2566$, the value at 0°. F. Horton gives for the value of n at 15°, $2·67 \times 10^{11}$ dynes per sq. cm., and at θ°, $n = n_{15}\{1 - 0·00048(\theta - 15)\}$ dynes per sq. cm.

A. and C. R. Aikin found a wire 0·1 in. in diameter supported a weight of about 240 lbs. without breaking; this is eq. to about 13·64 tons per sq. in. of sectional area. Silver, said A. Baudrimont is tougher than copper, and not so tough as palladium; others say silver is tougher than gold, but not so tough as copper. A. le Chatelier gave for the **tensile strength** of cast silver 7·50 kgrms. per sq. mm.; 19·0 kgrms. per sq. mm. for the annealed, hammered, or rolled metal; and 35·0 kgrms. per sq. mm. for hard-drawn wire. A. Baudrimont[10] found the tensile strength of silver wire 1 sq. mm. in sectional area, at 0°, 100°, and 200° to be respectively 28·324, 23·266, and 18·577 kgrms. per sq. mm., or respectively 17·27, 14·19, and 11·33 tons per sq. in. G. Wertheim gave the results indicated in Table IV. J. Dewar

TABLE IV.—TENSILE STRENGTH OF SILVER WIRE.

(Kgrms. per sq. mm.)

Silver wire.	10° to 15°.		100°.	200°.
	Rupture slow.	Rupture sudden.		
Drawn . .	29·00	29·60	—	—
Annealed . .	16·02	16·40	14·00	14·00

found the breaking stress of a silver wire 0·098 in. in diameter to be 330 lbs. at 15° and 420 lbs. at —182°. When the cooled wires regain their former temp., no change in the breaking stress can be detected. G. T. and H. N. Beilby also found the tensile strength of silver to be increased by lowering the temp. such that the tensile strength increases from 25·7 units at 15°, to 34 units at —182°. F. A. and C. A. Lindemann found the tensile strength of a wire 0·0513 mm. thick to decrease from 64·0 kgrms. per sq. mm. at —252·6°; 53·9 kgrms. per sq. mm. at —192°; and 27·8 kgrms. per sq. mm. at 17°. They add that although the tenacity increases the metal becomes very brittle at the low temp. of liquid hydrogen. According to C. A. Mebius, heating by a current has no effect other than that due to a rise of temp. E. A. Smith and H. Turner found silver cast in sand bears a rather lower maximum stress than silver cast in iron moulds; the reverse is true for standard coinage silver—with 7·5 per cent. of copper. Their results are shown in Table V expressed in tons per sq. in.; the energy of rupture by the impact tests is expressed in kilogram-metres per sq. cm. J. Percy reported that the fractured surface of an ingot of silver showed a zone "consisting of a confused aggregate of imperfectly formed octahedral crystals while the rest of the *fracture* was largely fibrous or columnar."

TABLE V.—TENSILE AND COMPRESSION TESTS FOR SILVER.

		Silver alone.		Standard silver (7·5 per cent. copper).

Towards the end of the eighteenth century, A. L. Lavoisier and P. S. Laplace[11] measured the **coefficient of thermal expansion,** α, of cupelled silver between 0° and 100°, and found 0·000019074, a number which represents the increase per unit length per degree rise of temp. between the limits of temp. under observation. A. Matthiessen obtained $\alpha=0{\cdot}00001943$, between 0° and 100°, and he represented the vol. at θ° by $v=v_0(1+0{\cdot}00005246\theta+0{\cdot}000000405\theta^2)$, where v_0 denotes the vol. at 0°. H. Fizeau obtained $\alpha=0{\cdot}00001936$ between 0° and 100°. Hence the expansion from 0° to 100° is nearly 0·002, or $\frac{1}{500}$th of its length. H. le Chatelier obtained $\alpha=0{\cdot}0000205$ for the linear expansion up to 900°. W. Voigt found in the vicinity of 30°, the linear coeff. of expansion, α, to be $\alpha\times10^6=19{\cdot}25+0{\cdot}043(\theta-30)$. L. Holborn and A. L. Day gave for the length l of a bar of silver at θ° between 0° and 875° $l=l_0(1+0{\cdot}000018278\theta+0{\cdot}0_84793\theta^2)$, where its length at 0° is l_0. W. C. Roberts-Austen found 0·00003721 for the mean linear expansion between atm. temp. and the m.p. of the metal, and for the mean cubical expansion 0·00011164. F. Hennig found the linear expansion of a metre rod to be —3·527 between 0° and —191°; 4·574 between 16° and 250°; 10·040 between 16° and 750°; and 19·362 between 16° and 875°. E. Grüneisen studied the effect of press. on the linear coeff. of expansion. He showed that between —190° and 17° $\alpha=17{\cdot}12\times10^{-6}$ at one atm. press., and by raising the press. to 1000 kgrms. per sq. cm., the value fell to $17·03\times10^{-6}$. Similarly between 17° and 100°, and one atm. press., $\alpha=18·90\times10^{-6}$; and for 1000 kgrms. per sq. cm. press., $\alpha=18·67\times10^{-6}$. F. A. Lindemann found between 81·5° K. and 291·7° K., $\alpha=156\times10^{-6}$; between 82° K. and 90° K., $\alpha=132\times10^{-6}$; and between 80° K. and 20·4° K., $\alpha=98\times10^{-6}$. J. Disch made some observations at low temp.

K. Scheel gave for the expansion of silver in mm. per metre starting from 0° as zero:

	100°	200°	300°	400°	500°
Expansion	1·963	4·00	6·08	8·23	10·43

The **thermal conductivity** of silver for heat is greater than that of any other metal, and accordingly it is sometimes used as an arbitrary standard [12] 100. G. Wiedemann and R. Franz gave the order:

Ag	Cu	Au	Zn	Sn	Fe	Pt	Pb	Bi
100	73·6	53·2	19·0	14·5	11·6	8·4	8·1	1·8

The absolute conductivity, measured by H. F. Weber, at 0°, is 1·0960; this number represents the amount of heat in cals. conducted per sec. across two planes one cm. apart, and a sq. cm. sectional area, when the difference of temp. of the two surfaces of the planes is 1°. W. Jäger and H. Diesselhorst found 1·006 at 18°, and 0·9919 at 100°; and C. H. Lees, 0·974 at 18°, and 0·998 at —160°. For the thermal conducting capacity at 18°, W. Jäger and H. Diesselhorst found $a^2=1·74$, and at 100°, 1·67, where $a^2=K/DC$, when K is the thermal conductivity; D, the sp. gr.; and C, the sp. ht. They also found that if K_0 be the thermal conductivity at 0°, the conductivity K at θ° is $K=K_0(1+0·00017\theta)$. E. H. Hall has studied this subject. For G. Wiedemann and R. Franz's comparison of the electrical and thermal conductivities, *vide* copper. P. W. Bridgman measured the effect of compression on the thermal conductivity of silver, and found the effect decreases linearly with press.

In 1818, P. L. Dulong and A. T. Petit [13] measured the **specific heat** of silver and found it to be 0·0557 between 0° and 100°, and 0·0611 between 0° and 300°. The rise in the sp. ht. with rise of temp. may be regarded as evidence of a resistance offered by the metal to the raising of its temp. Other determinations have been made by H. Kopp, R. Bunsen, J. Pionchon, U. J. J. le Verrier, W. A. Tilden, T. S. Humpidge, etc. H. Schimpff gave 0·0557 for the sp. ht. at 0°; J. N. Brönsted gave 0·05535 between 0° and 19°; and H. Tomlinson 0·05684 between 0° and 100°. E. H. and E. Griffiths represented the sp. ht. C at θ° between 0° and 97·5° by $C=0·05560(1+0003396\theta—0·000000141\theta^2)$; or very approximately by $C=4·804A^{0·95}$, where A represents the at. wt. of the element. W. A. Tilden found the sp. ht. 0·0550 between —78° and 15°; 0·0576 between 15° and 350°; 0·0528 at 200°; and 0·0590° at 700°; U. J. J. le Verrier, 0·0565 between 0° and 260°; 0·075 between 260° and 660°; and 0·076 between 660° and 900°. He adds that the sp. ht. appears to undergo an abrupt change in the vicinity of 260°. J. Pionchon obtained 0·0748 for the solid at 800°, and for the liquid metal between the m.p. and 1100°, 0·0748. To summarize, the sp. ht. of silver above 0° may be taken as:

	0°	50°	100°	200°	400°	600°	961°
Sp. ht. .	0·0560	0·0560	0·0564	0·0571	0·0592	0·0655	0·0730

The sp. ht. falls rapidly as the temp. drops, *e.g.* J. Dewar found the sp. ht. at —223° to be 0·0242; T. W. Richards and F. G. Jackson found at —188°, 0·0511; H. Barschell, between —74° and —184°, 0 0492; U. Behn obtained 0·0544 for the sp. ht. between 18° and —79°; and 0·0496 between —79° and —186°. W. Nernst and F. A. Lindemann found 0·556 for the sp. ht. of silver at 0°; 0·03775 at —196°; and 0·01465 at —238°; and W. Nernst gives:

	0°	—40°	—73°	—189°	—209°	—238°	—253°
Sp. ht. .	0·0550	0·0546	0·0530	0·0410	0·0336	0·0146	0·0036

From the sp. ht. date, it follows that the **atomic heat** of silver rises from 0·39 at —253°

to 6·0 at 0°, and to 7·88 for the solid at the m.p. According to A. Eucken, the sp. ht. of the liquid at the m.p. 961° is 0·0748, and the at. ht. C_r is accordingly 8·07; and the at. ht. C_p of the solid at the m.p. is 8·20. E. Grüneisen measured the effect of press. on the sp. ht. of silver and found for silver $dC_p/C_p.dp=-0·00000038C_p$ kgrm. per sq. cm.

The **melting point** of silver was given by C. S. M. Pouillet[14] in 1832 as 538°, but in 1856 he gave 1000°. J. Prinsep gave 999°; L. B. G. de Morveau, 1033·71°—where the numbers to the right of the decimal point may be correct, but those to the left are about 71° too high. The reported values for this constant are indeed somewhat discordant and range from 954° to 1223°. This might have been anticipated (i) from the unsatisfactory methods of estimating temp. which were available to the early observers, and (ii) from the failure of the early workers to recognize the great influence of impurities on the result; and (iii) from the failure to recognize that silver oxide may be introduced as an impurity when the metal is melted in air—thus L. Holborn and A. L. Day (1900) found that silver melts at 961·5° when air is excluded, and at 955° if exposed to air; C. F. Heycock and F. H. Neville (1896) also found that the m.p. of silver was lowered by 10° or 17° by fusing the metal in an atm. of oxygen; and H. Callendar (1892) obtained a lowering of 6·4° under similar conditions. A. C. Becquerel found 960° for the m.p. of silver, and he ascertained that silver did not actually melt at the temp. of the evolution of the vapour of zinc boiling under ordinary atm. press., though it became so much softened at that temp. as to cause separate pieces of the metal, in contact with each other, to stick together. J. Violle, and A. Potilitzin gave 954°; A. D. van Riemsdijk, 1040°; J. F. Daniell first gave 1223° and later 915°; L. Holborn and W. Wien, 968°; D. Berthelot gave 962°; L. Holborn and A. L. Day, G. I. Petrenko, and E. Quercigh, 961·5°; C. W. Waidner and G. K. Burgess, 960 9°, and in an atm. of carbon monoxide, 960·0°; K. Friedrich and A. Leroux, 962°; H. Callendar, F. Wüst and co-workers, and N. Baar, 961°; W. C. Roberts-Austen and T. K. Rose, 969°; S. F. Schemtschuschny, 954°; G. Arrivaut, 950°; C. T. Heycock and F. H. Neville, 960·5°; S. W. Holman, R. R. Lawrence, and L. Barr, 960·5; A. L. Day and J. K. Clement, 958·3°±5°; A. L. Day and R. B. Sosman, 960°±0·7°; E. Tiede and E. Birnbräuer, 968°; C. W. Waidner and G. K. Burgess, 960·88°±0·16°; and the best representative value of the later determinations of the m.p. of silver is 960·5°; in agreement with L. I. Dana and P. D. Foote, and K. Scheel—W. Guertler and M. Pirani round off the number to 961°. J. Johnston estimated that the m.p. of silver is depressed 0·12° per atm. rise of press., and that under a press. of 14,000 atm. silver would melt at the ordinary temp.—excluding, of course, the appearance of new forms of silver at high press. R. Wright and R. C. Smith found that very finely divided silver shows signs of sintering far below its m.p. C. T. Heycock and F. H. Neville measured the lowering of the f.p. of tin, lead, and bismuth by the dissolution of a gram-atom of silver in approximately 100 gram-atoms of the metal. With cadmium as solvent there was a rise in the f.p.

R. Emden emphasized the fact that silver retains its mirror-like surface when melted in air; indeed, molten silver has a brighter lustre than when in the solid state. According to J. Violle, the **radiation of heat** from molten silver, at a temp. above its m.p., measured from its effect on the thermopile steadily falls with the temp. and then begins to rise again owing to undercooling; the radiation remains constant during the process of solidification, and he recommended this as a convenient secondary standard for spectro-photometric measurements, etc. When all the metal has solidified the radiation rises again because the solid metal at the m.p. has a greater radiating power than the molten metal.

W. A. Lampadius[15] noted the volatility of silver in 1839. J. L. Gay Lussac stated that the **volatility** of silver cannot be detected at temp. far exceeding its m.p. because purified silver can be cupelled without any appreciable loss, but W. A. Lampadius found that when heated in an open crucible at a white heat, it loses about one per cent. per hour even if the metal is covered with powdered charcoal. P. Berthier also found that when silver is heated in a porcelain oven, it loses about 0·5 of its weight, and that, under similar conditions, copper loses rather more. A. D. van Riemsdijk observed that when silver begins to volatilize to a sensible degree when heated in a slow current of hydrogen to a temp. not much above the m.p. of copper. E. Tiede and E. Birnbräuer found volatilization occurs at 850° in vacuo. C. M. Despretz also said that silver wire can be rapidly volatilized at a temp. produced by the passage of the current from 600 Bunsen cells. W. Borchers, and H. Moissan have studied the volatilization of silver in electric furnaces. H. St. C. Deville and H. Debray observed that when silver is heated in a lime crucible by means of the oxyhydrogen flame, it boils like mercury, and volatilizes as silver oxide which condenses as a pale yellow sublimate. C. F. Plattner, H. St. C. Deville and H. Debray, and L. Troost and P. Hautefeuille, and W. A. Ross brought evidence to show that the volatility of silver is due to the formation of a volatile oxide stable only at a high temp.—*vide* the spitting or spewing of silver. J. S. Stas distilled silver in considerable quantities by means of the oxyhydrogen flame, in a little apparatus made of quicklime. His apparatus for the *distillation of silver* is illustrated in Fig. 6. A block of marble 25 to 30 cms. long, 10 cms. wide, and 10 cms. high has a circular cavity *A*—3 cms. diameter and 2 cms. deep—in communication with another similar cavity *B* by means of an inclined channel *C*. The blowpipe flame is directed on to about 50 grms. of silver in the cavity *A*, and the vapour condenses in the cavity *B* to molten silver. Vessels of quartz can be used for the distillation of the metal in vacuo.

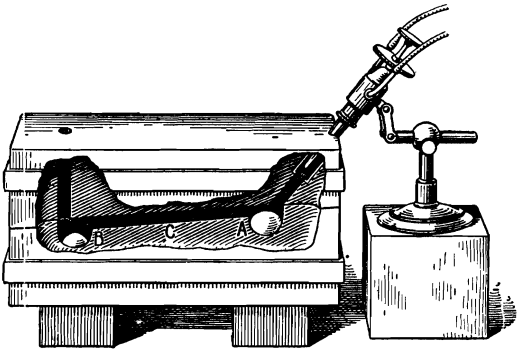

FIG. 6.—Apparatus for the Distillation of Silver.

According to A. Parkes, silver is easily volatilized when in connection with zinc or arsenic in a fused state, and he patented a process for separating silver from copper, copper regulus, etc., by heating the mixture in a reverberatory furnace, fitted with flues and chambers for collecting the volatile products, which were then to be cupelled for silver. The process has not been successful; F. J. Malaguti and J. Durocher heated a mixture of argentiferous blende and charcoal in a retort, and collected the zinc distillate which was found to contain only traces of silver. A. K. Christomanos studied the distillation of cupriferous silver. J. Napier, G. H. Makins, F. Elsner, J. W. Richards, etc., have made observations on the volatility of silver. T. Turner showed that volatilization can be detected in a stream of air at 700°, C. J. Hansen volatilized silver at 953° in vacuo; and H. von Wartenberg noted that the metal volatilizes more readily in an atm. of oxygen than in one of nitrogen. M. Knudsen found that the condensation of the vapour of silver on a clean glass or mica surface has a critical temp.—about 575°—below which the vapour is retained, and above which an appreciable fraction is repelled.

J. W. Richards estimated the **vapour pressure** of silver at different temp. to be:

	729°	913°	1169°	1500°	1867°	1977°	2040°
Vap. press. .	0·0002	0·013	0·779	26·35	300	548	760 mm.

H. von Wartenberg found the vap. press. at 1178° to be $1{\cdot}9\times10^{-4}$ atm.; at 1316°, $1{\cdot}8\times10^{-3}$ atm.; at 1435°, $5{\cdot}10\times10^{-3}$ atm.; and at 2100°, 1 atm.; a change of temp. of 6° alters the vap. press. about 9 per cent. He also ascertained that the **vapour density** corresponds with a one-atom molecule. O. Ruff and B. Bergdahl observed 102 mm. at 1660°; 116 mm. at 1680°; 200 mm. at 1758°; 300 mm. at 1810°; and 744 mm. at 1940°. J. A. M. van Liempt represented the vap. press. p

in atm. by $\log_{10} p=5{\cdot}93-13150T^{-1}$. Trouton's constant=27·15; A. Henglein compared the vap. press. formula of silver. The **boiling point** under 8 atm. press. is estimated to be 2747°; at 50 atm. press., 3298°; and at 162 atm. press., 3958°. F. Krafft and L. Bergfeld distilled silver in vacuo by exposing it to the green cathode light, and they found that under these conditions the metal evaporates at about 680°, and boils at about 1400°. C. J. Hansen gives for the b.p. of the metal 1660° at 103 mm.; 1780° at 263 mm.; and 2313° for the b.p. under normal press.; while H. C. Greenwood gives 1633° for the b.p. in vacuo, and 2313° at 760 mm.; and he later gave 1955° for the latter. H. von Wartenberg gave 2050° to 2100° for the b.p. of silver; O. Ruff and B. Bergdahl, and E. Tiede and E. Birnbräuer, 1950°; and J. A. M. van Liempt, 1944°.

According to J. Pionchon,[16] the **latent heat of fusion** of silver is 24·7 cals. per gram, or 2·7 Cals. per gram-atom. G. G. Person found 21·07 cals. per grm. F. Wüst and co-workers give 26·01 cals. J. W. Richards estimates the **latent heat of vaporization** to be 397 cals. per grm., or 43 Cals. per gram-atom. H. von Wartenberg found that the internal latent heat of evaporation, calculated from his observations of the vap. press., is 54·6 Cals. per gram-atom between 1178° and 1316°; 67·0 Cals. between 1316° and 1435°; and 59·7 Cals. between 1435° and 2100°. The mean value is 60·8 Cals. If the b.p. be 10° too low, the latent heat of vaporization would have to be raised 0·8 Cal. By means of the formula $4{\cdot}571 \log p=25-Q/T$, H. C. Greenwood has also calculated Q=55,800 cals. for the heat of vaporization per gram-atom, when the vap. press. at the absolute temp. T is p. J. A. M. van Liempt gave 60,200 cals. for the heat of vaporization at the b.p. G. G. Person gave 2280 cals. for the heat of sublimation. R. de Forcrand calculated Q=56·07 Cals. from Trouton's formula at the absolute temp. T=2228°. According to H. Buff, the **heat of thermal expansion** of silver is 2·378 cals. calculated from his relation $DC\alpha/\beta$, when D=10·3; C=0·0577; α=0·0001401; and β=0·0000573.

The **optical constants** of silver, namely the **refractive index** μ, and the **absorption index,** k, as well as the **extinction coefficient,** μk, have been defined in connection with the optical constants of copper; similar remarks apply to the **angle of principal incidence,** ϕ, and the **angle of principal azimuth,** ψ, of polarized light. A selection[17] of these constants is indicated in Table VI, along with the percentage **reflecting power,** R, in air, that is, the ratio of the intensity of the reflected ray to that of the incident ray for light of wave-length λ. J. Conroy, L. P. Wheeler, G. Quincke, and R. Sissingh have studied the reflecting power of silver in water, turpentine, or carbon tetrachloride. The index of refraction has been determined by A. Pflüger, L. R. Ingersoll, K. Försterling and co-workers, H. L. Barvir, etc. The angles of principal incidence and principal azimuth by A. Beer, P. Drude, J. C. Jamin,

TABLE VI.—OPTICAL CONSTANTS OF SILVER.

R. S. Minor, W. Voigt, A. L. Bernoulli, H. Knoblauch, K. Fösterling and V. Fréedericksz, C. Statescu, A. Galli and K. Försterling, etc. The index of absorption by A. L. Bernoulli, E. Hagen and H. Rubens, W. Wernicke, etc. The reflecting power has been determined by E. Hagen and H. Rubens, W. W. Coblenz, C. Zakrzewsky, etc. I. C. Gardner measured the reflection coeff. in Schumann's region of the spectrum. A. Kundt obtained $\mu=0{\cdot}27$ for the index of refraction of electrolytic silver for white light; and D. Shea $\mu=0{\cdot}27$ for $\lambda=431\mu\mu$; $\mu=0{\cdot}20$ for $\lambda=486\mu\mu$; $\mu=0{\cdot}25$ for $\lambda=656\mu\mu$. N. Galli and K. Försterling found the refraction and absorption indices for massive silver to be very different from those of silver films —*viz.* 12·2 and 7·42 for $\lambda=3{\cdot}00$ and $4{\cdot}50\mu\mu$ respectively. K. Schäfer studied the different values for silver for soln. of the salts on the assumption that the silver is ionized and also combined. The dispersion is small and it has been studied by A. Beer, J. C. Jamin, H. Rubens, A. Pflüger, W. Meier, W. Voigt, etc. F. Schön found the abnormal dispersion of the vapour is confined to the spectral lines of the principal series. J. H. Gladstone gave for the **refraction equivalent** of silver $(\mu-1)/D=0{\cdot}122$, and $A(\mu-1)D=13\ 2$, where A represents the at. wt. of the metal. J. Kanonnikoff calculated 12·6 for the refraction eq. from the values for the silver salts of the oxy-acids.

According to G. K. Burgess and R. G. Waltenberg, the **emissivity** of a mass of silver by the same standard as that employed for copper, is, for red light of wave-length $0{\cdot}65\mu$, 0·04 for the solid, 0·07 for the liquid; and for light of wave-length $0{\cdot}55\mu$, the emissivity of the solid is 0·35, and likewise also 0·35 for the liquid. There is no marked temp. coeff. between 900° and 2000°. The emissive power of heated silver has been studied by H. Rubens and E. Hagen, F. Henning, and C. M. Stubbs. H. Knoblauch has measured the polarization angle and refractive index of the heat rays. P. Desains studied the reflection of heat rays from the vapour of silver. J. Violle recommended the vapour of silver as a light standard. M. Faraday noted the effect of thin films of silver on polarized light; he prepared them by electrically deflagrating a thin silver wire in air or hydrogen. B. Pogany measured the **Faraday effect,** that is, the **rotation of the plane of polarization,** of films of silver.

The **photoelectric effect** with silver has been studied by G. Reboul, W. Ramsay and J. F. Spencer, K. Herrmann, E. Ladenburg, R. A. Millikan and G. Winchester, etc. As a rule, the more electropositive a metal the greater is its photoelectric activity—*vide* copper. W. Hallwachs found a photoelectric effect could be obtained by ultra-violet light which has passed through a silvered quartz plate; and O. Stuhlmann showed that the photoelectric effect produced by the emergent beam of ultra-violet light is greater than that of the incident beam, and this the more the thinner the metal film until it attains a constant value 1·07 times greater. W. Frese found that the photoelectric sensitiveness of silver is not affected by treatment with water or alcohol.

W. D. Bancroft and H. B. Weiser[18] reported:

> When silver nitrate is introduced into the flame, it first melts to a bead and then decomposes. If care be taken, a silver mirror can be obtained, along the edge of which there is precipitated a considerable quantity of black or bluish-black silver oxide. If the flame is too hot or if it contains too much salt, spots or specks of metallic silver and also grey, pulverulent silver are obtained instead of a mirror. Since there is a good deal of free silver in the flame when silver nitrate is added, and since silver vapour is blue, it is not impossible that the blue colour of the flame is due in part to the vapour of metallic silver.

The emission spark spectrum and the spectrum of the oxyhydrogen flame of silver was stated by W. N. Hartley to be very similar to that of copper, and to resemble in some respects that of gold and of platinum. The brightest or most prominent lines in the **emission spectrum** of silver in the electric arc in vacuo have a wave-length of 328·08 and $338{\cdot}30\mu\mu$ in the ultra-violet; 405·544 and $421{\cdot}21\mu\mu$ in the violet; $466{\cdot}87\mu\mu$ in the blue; and 520·925, 546·566, 547·172, and $562{\cdot}35\mu\mu$ in the green. C. C. Hutchins and E. L. Holden found that three lines 447·62, 466·80, and 487·43$\mu\mu$ are also present in the solar spectrum. The arc spectrum has been studied by F. J. Kasper, J. Frings, W. Happers, etc.; the spark spectra by J. Frings, F. L. Wagner, J. M. Eder, W. M. Hicks, etc. A. C. Becquerel observed two intense lines 771–772$\mu\mu$ and 825–829$\mu\mu$ in the ultra-red. The ultra-red spectrum of silver has been explored by H. M. Randall, H. Lehmann, J. M. Eder and E. Valenta, F. J. Kasper, L. and E. Bloch, etc. According to A. de Gramont, the 328·08 and the 338·30$\mu\mu$ lines in the ultra-violet are well defined in the spark spectrum of silver, and H. Könemann has explored the lines between 200 and 400$\mu\mu$. J. M. Eder, F. L. Wagner, R. A. Millikan, and W. Happers have studied the ultra-violet spark spectrum of silver; F. M. Walters the ultra-red spectrum. B. de la Roche studied the effect of reducing gases on the spectrum of silver.

The series spectra of silver have been studied by H. Kayser and C. Runge, L. Janicki, F. J. Kasper, H. Oellers, W. M. Hicks, etc. The lines in the spectrum of silver present similar relations as are presented by those of copper, and the two spectra are said to be homologous. The spectral lines of copper, silver, and gold appear to be built on the same general plan. The formulæ for the pairs of lines in the first series are: $\lambda\times10^8=30712\cdot4-130621^{n-2}-1093823^{n-4}$; $31633\cdot2-130621^{n-2}-1093823^{n-4}$, for $n=4$, 5, and 6 as shown in Fig. 7; there is a second associated series: $\lambda\times10^8=30696\cdot2-123788^{n-2}-394303^{n-4}$; $31617\cdot0-123788^{n-2}-394303^{n-4}$, for $n=4$ and 5, Fig. 7. The value for $n=3$ gives the smallest positive value for these series, and this would correspond with lines in the ultra-red. A. C. Becquerel observed two silver lines, 8250 and 7710$\mu\mu$, which may belong to the second of these sets, and E. P. Lewis gives the more accurate measurements, 8274·04 and 7688·4. Besides these lines there are pairs with $\lambda=5545\cdot86$ and 5276·4; $\lambda=4888\cdot46$ and 4678·04; and $\lambda=3383\cdot00$ and 3280·80. The last pair is the strongest in the whole spectrum. The available data on the series line spectra of silver have been reviewed by A. Fowler.

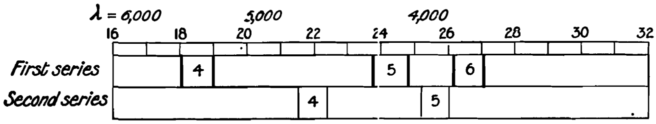

FIG. 7.—Series Spectra of Silver.

The colour of light transmitted through silver has already been discussed. G. D. Liveing and J. Dewar measured the **absorption spectrum** and found that a thin layer of silver deposited on quartz is transparent for rays between 335·0 and 307·0$\mu\mu$, and opaque on both sides of these limits. J. N. Lockyer and W. C. Roberts-Austen found a 60-cm. column of silver vapour gave a channelled spectrum without absorption in the red, but with complete absorption in the blue. The optical properties of films have been studied by V. Kohlschütter and E. Fischmann, L. Houllevigue, N. Galli and K. Försterling, etc.

The effect of *pressure* on the spectral lines of silver has been investigated by W. G. Duffield; the effect of *hydrogen*, by J. Meunier; and the effect of *magnetism*, by J. R. Rydberg; H. Konen, and H. Finger examined the feeble continuous spectrum of the condenser discharge between silver electrodes under *water*. A. de Gramont has studied the spark spectra obtained with argentiferous minerals. W. N. Hartley and H. W. Moss have determined the smallest quantities of elements needed for the appearance of the ultimate lines in the flame and spark spectra of silver, and other metals. W. Schuler found 0·0001 mgrm. of silver could be detected by means of the spark spectrum.

The production of **Röntgen rays** by silver cathode, the passage of these rays through silver plates, and the reflection of these rays from silver, have been the subject of many investigations.[19] E. Hjalmar, etc., studied the X-ray spectrum. According to W. H. Bragg, the stopping power s of a substance for the **α-rays** is approximately proportional to the at. wt. A. For gold, s=3·17. H. R. von Traubenberg found the range of the α-particles in silver to be 19·2×10^{-4} cm. According to J. Crowther, the coeff. of absorption μ for the **β-rays** is approximately proportional to the sp. gr. D, and for gold, μ/D=8·3. J. Chadwick measured the nuclear charge on the silver atom. M. N. Saha studied the **ionizing potential** of silver; and B. E. Moore, the excitation stages in the arc spectrum of that metal.

Silver is one of the best of conductors of electricity, and its conductivity is sometimes used as a standard of reference 100. H. F. Lenz's[20] values for the **electrical conductivity** are:

	Ag	Sn	Cu	Au	Zn	Fe	Pb
Electrical conductivity . .	100	73·6	73·3	58·5	22·6	10·7	10·3

As indicated in connection with copper, G. Wiedemann and R. Franz emphasized the close relation between the thermal and electrical conductivities of the metals. The different values published for the electrical conductivity at 0° range from 60·8×10^4 to 68·12×10^4 reciprocal ohms, and the best representative value is near 67·0×10^4 reciprocal ohms. The measurements of A. C. Becquerel, W. Siemens, A. Matthiessen, etc., have shown that the electrical conductivity of a hard-drawn silver wire is less than that of an annealed wire. A. C. Becquerel gave the relation 100 : 107; W. Siemens, 100 : 108·8; and A. Matthiessen, 100 : 110. W. H. Preece gave 1·609 ohms for the **electrical resistance**, R, of silver at 14°; and L. Weiller found that a silver wire, one mm. diameter, and one kilometre long, had a resistance of 19·37 ohms at 0° The effect of an increase of *temperature* is to augment the resistance and lower the conductivity. G. Niccolai's value for low temp., in ohms per cm. cube, are:

	0°	−50°	−76·8°	−100°	−150°	−200°	−252·8	−258·6°
Ohms . .	1·506	1·212	1·040	0·916	0·638	0·357	0·014	0·009

and E. F. Northrup's values for high temp. in microhms per c.c., are:

	100°	200°	400°	750°	960°	960°	1000°	1200°	1400°	1500°
R .	2·15	2·80	3·46	6·65	8·4	16·6	17·01	19·36	21·72	23·0
	Solid					Liquid				

A. Matthiessen and M. von Bose gave for the resistance, R, of silver, at θ° when the value at 0° is represented by R_0 is $R=R_0(1-0{\cdot}0038287\theta+0{\cdot}00000848\theta^2)$; J. Dewar and J. A. Fleming gave $R=R_0(1+0{\cdot}00377\theta)$, and P. W. Bridgman found the temp. coeff. between 0° and 100° to be 0·00407; L. Holborn, 0·00410 per degree between 0° and 100°; while W. Jäger and H. Diesselhorst found 0·00400 for silver 99·98 per cent. purity. According to H. K. Onnes, the ratio of the electrical resistance of silver at θ° and at 0° steadily falls as the temp. is reduced:

θ° . . .	0°	−103·7°	−195·1°	252·8°	−259·1°
R_θ/R_0 . .	1	0·581	0·197	0·009	0·007

so that the electrical resistance of silver probably vanishes towards absolute zero. A. L. Feild estimated the resistance of *amorphous silver* to be 5·29 micro-ohms per c.c. at 20°. P. W. Bridgman found the effect of *pressure* to be:

	0°	25°	50°	75°	100°
Resistance	1·0000	1·1011	1·2024	1·3044	1·4074
Press. coeff. 0 kgrm. . .	$-0{\cdot}0_5308$	$-0{\cdot}0_5363$	$-0{\cdot}0_5362$	$-0{\cdot}0_5359$	$-0{\cdot}0_5355$
Press. coeff. 12,000 krgms. .	$-0{\cdot}0_5308$	$-0{\cdot}0_5311$	$-0{\cdot}0_5313$	$-0{\cdot}0_5315$	$-0{\cdot}0_5318$

The press. coeff. at 0° is $-0{\cdot}0_5308$; E. Lisell found $-0{\cdot}0_535$ with a sample containing 0·08 per cent. copper and traces of carbon. E. Lax has studied the effect of *mechanical* stresses on the resistance of silver wires. S. Pienkowsky found the electrical resistance of silver is not changed by *illumination*. L. Grunmach and F. Weidert ascertained that the increased resistance of silver in a *magnetic field* is smaller than with bismuth, cadmium, or zinc, and greater than with gold, copper, tin, palladium, platinum, lead, or tantalum. According to S. Weber and E. Vosterhuis, a *thin film* of silver becomes conducting when it is over 6·5$\mu\mu$ in thickness. A. Sieverts found the resistance is increased by the *occlusion of hydrogen;* and G. Szivessy, that it is increased 0·3 to 0·6 per cent. by the *occlusion of oxygen.* F. Credner found that the electrical resistance of a silver wire at a constant temp. diminishes, and this the more rapidly the higher the temp.; at 400° the resistance rises again. V. Kohlschütter with E. Fischmann, and with A. Noll, has investigated the conductivity of thin films of silver under various conditions. P. W. Bridgman found that the electrical resistance of thin films of silver, for high current densities, is greater than corresponds with Ohm's law. A. L. Bernoulli showed that the great increase in the resistance of silver by small proportions of impurities cannot be explained by a decrease in the number of conductivity electrons.

S. Kyropoulos[21] showed that different parts of a piece of silver may have a different electric potential and thus exhibit different degrees of nobility. For instance, if a clean silver plate be scratched and immersed in a soln. of agar-agar containing potassium iodide and phenolphthalein, the scratches show up as black lines on a bright ground through the deposition of silver iodide on the less "noble" worked parts. According to C. E. Fawsitt, the **potential difference** of silver with a normal soln. of silver nitrate against a calomel electrode is 1·055 volt for brightly polished silver; 1·060 volt for the same silver annealed at a red heat; and 1·057 volt for annealed silver hammered until hard. Hence, annealed silver is more electropositive than hardened silver. He also measured the **electromotive force** of cells with hardened and annealed silver electrodes in soln. of silver nitrate. V. Kohlschütter and co-workers studied the potential of silver films produced in various ways. According to F. M. G. Johnson and N. T. M. Wilsmore, the potential difference of silver against a hydrogen electrode in 0·01N-, and 0·1N-$AgNO_3$ is —0·771 volt. I. M. Kolthoff gave —0·7887 volt. G. N. Lewis found the potential of the silver electrode against normal silver ion at 25° is —0·515 volt if that of the normal electrode be zero, or —1·079 volt if the normal electrode has a potential —0·560 volt at 18° or —0·564 volt at 25°. This agrees with the value found by A. A. Noyes and B. F. Brann. G. Magnanini found the difference of potential in volts between zinc in a normal soln. of sulphuric acid and silver immersed in the given soln. containing n mols per litre. $\frac{1}{2}n$-H_2SO_4, 1·213 volt; n-NaOH, 0·958 volt; n-KOH, 1·040 volt; $\frac{1}{2}n$-Na_2SO_4, 1·209 volt; n-$Na_2S_2O_3$, 0·648 volt; n-KNO_3, 1·057 volt; n-$NaNO_3$, 1·148 volt; $\frac{1}{2}n$-K_2CrO_4, 1·210 volt; $\frac{1}{2}n$-$K_2Cr_2O_7$, 1·324 volt; $\frac{1}{2}n$-K_2SO_4, 1·148 volt; $\frac{1}{2}n$-$(NH_4)_2SO_4$, 1·257 volt; $\frac{1}{4}n$-K_4FeCy_6, 0·878 volt; 0·167n-K_3FeCy_6, 1·249 volt; n-KCNS, 0·725 volt; n-$NaNO_3$, 1·15 volt; $\frac{1}{2}n$-$Sr(NO_3)_2$, 1·193 volt; $\frac{1}{8}n$-$Ba(NO_3)_2$, 1·215 volt; n-KNO_3, 1·150 volt; $\frac{1}{6}n$-$KClO_3$, 1·209 volt; 0·167n-$KBrO_3$, 1·208 volt; n-NH_4Cl, 1·017 volt; n-KF, 0·615 volt; n-NaCl, 1·013 volt; n-KBr, 0·824 volt; n-KCl, 1·076 volt; $\frac{1}{2}n$-Na_2SO_3, 1·037 volt; n-NaOBr with a quantity of bromine was used corresponding to NaOH=1, 0·997 volt; n-tartaric acid, 1·234 volt; $\frac{1}{2}n$-tartaric acid, 1·257 volt; $\frac{1}{2}n$-potassium sodium tartrate, 1·197 volt. U. Sborgi and A. Donati studied the potential of silver against various salt soln.; F. Jirsa, the effect of telluric acid on the depolarization of silver anodes; V. Kohlschütter and H. Stäzer, the anodic behaviour of silver in soln. of sodium sulphide; and G. Trümpler, the e.m.f. against the normal calomel electrode. P. Walden has made estimates of the **diameters and velocities of silver ions** in aq. and non-aq. solvents. W P. Davey gave 0·85 A. for the at. radius of silver in the iodide, and 1·18 A. for the radius in the chloride and bromide.

G. Carrara and L. d'Agostini found that with a normal soln. of silver nitrate and a normal calomel electrode (—0·56 volt) the potential is —1·055 volt, and with a 0·01N-soln., —0·977 volt; with 0·527N- and 0·1N-soln. of silver chlorate, the potential is —1·055 and —1·024 volt respectively; and with N-silver acetate, —0·991 volt. In the latter case, A. Jaques showed that the result is greatly influenced by the gases dissolved in the electrolyte, but not in soln. of silver nitrate or in soln. of lead nitrate or acetate. N. Isgarischeff found with an alkaline soln. of silver nitrate 0·910 volt. S. B. Christy found that in soln. of potassium cyanide the probable values are:

Per cent. KCy	6·5	0·65	0·065	0·0065	0·00065	0·000065	0·0000065	0
Volt . .	+0·340	+0·195	+0·055	−0·310	−0·420	−0·460	−0·495	−0·570

F. Förster found that in conc. soln. of potassium cyanide, the cathode potential behaves normally with increasing current density.

H. J. S. Sand investigated the changes of the cathode potential during the electrolysis of silver nitrate. F. M. G. Johnson and N. T. M. Wilsmore investigated the potential of silver against soln. of the nitrate and iodide in liquid ammonia. J. Neustadt and R. Abegg found that silver does not change its place in the electrochemical series against soln. of silver salts in water, methyl or ethyl alcohol, acetone, or pyridine. N. Isgarischeff, G. Carrara and L. d'Agostini, etc., studied soln. in methyl alcohol; L. Kahlenberg, soln. in methyl, ethyl, benzyl, or allyl alcohol, in glycol, glycerol, pyridine, or quinoline. P. Bechtereff, molten sodium hydroxide; O. Sackur, molten alkali chlorides; L. Poincaré, fused sodium nitrate; F. W. Küster and A. Thiel, soln. of mixed silver halides. The e.m.f. of silver in various combinations of galvanic cells has been also studied by W. Wolff, S. Lindeck, F. Exner and J. Tuma, G. Gore, C. R. A. Wright and C. Thompson, G. N. Lewis, R. Luther and F. Pokorny, F. M. G. Johnson and N. T. M. Wilsmore, A. Lapworth and J. R. Partington, P. Bechtereff, F. Haber, R. Beutner, etc.

The polarization of the silver electrode in different electrolytes has been studied by F. Streintz, E. Pirani, A. Oberbeck, M. le Blanc, G. Grube, R. Kremann and F. Noss, F. Haber and J. Zawadsky, etc. P. Bechtereff found silver becomes *passive* in molten sodium hydroxide and has the cathode polarization at 500° for current density 0·25, 0·63, and 1·89 amp. per sq. dm., the respective voltages 0·026, 0·083, and 0·377. It is less than for platinum, iron, or nickel, and is diminished by sodium peroxide. W. Winter has studied the electrolytic value action of silver anodes.

G. T. Beilby[22] found a **thermo-electric current** is produced by a thermo-couple with hardened and annealed silver wires. A. L. Bernoulli, and O. Sackur have studied the e.m.f. of *silver-copper* couples at different temp.:

	300°	550°	630°	675°	740°	775°	820°
Microvolts .	−14	−17	−10	0	+14	+20	+30

G. von Hevesy and E. Wolff of the *silver-nickel* couple:

	−80°−0°	0°−80°	0°−160°	0°−400°	0°−800°
Microvolts	22·1	23·7	26·9	20·0	35·0

J. Dewar and J. A. Fleming of the *silver-lead* couple:

	−205°	−105·8°	−6·5°	9·4°	24·2°	70·5°	100·1°
Microvolts .	43·4	−26·15	−2·05	+2·21	+6·73	+22·1	+33·2

W. Jäger and H. Diesselhorst, J. Dewar and J. A. Fleming, K. Noll, W. H. Steele have measured the e.m.f. of the *silver-platinum* couple. L. Holborn and A. L. Day's values are:

	−185°	100°	200°	400°	600°	800°	1000°
Microvolt .	−0·16	+0·74	+1·8	+4·5	+8·2	+13·2	+16·0

W. W. Coblentz found the *silver-bismuth* couple to have a thermo-e.m.f. of 89 microvolts per degree; N. A. Gesehus found the positive thermo-e.m.f. of silver is less than for antimony, cadmium, and zinc, and greater than for copper and brass. J. Monckman found the thermo-electric properties of silver were not influenced by the occlusion of oxygen. K. Noll found that for hardened and annealed silver, the *silver-mercury* couple had respectively an e.m.f. of +710·3 and +671·5 microvolts between 0° and 100°. E. Sedström, and H. Jahn have studied the Peltier effect for combinations of silver with various metals—*e.g.* Ag-Cd, and Ag-Zn. The thermoelectric force of silver against lead at atm. press. and $\theta°$ is $E=(2·556\theta+0·00432\theta^2)\times10^{-6}$ volts; the **Peltier effect** is $P=(2·556+0·00864\theta)(\theta+273)\times10^{-6}$ volts; and the **Thomson effect** $\sigma=0·00864(\theta+273)\times10^{-6}$ volts per degree. E. Lecher found that the Thomson effect between 123° and 525° could be represented by $(7·363+0·00887\theta)10^{-7}$ gram-cals. per coulomb. P. W. Bridgman observed the effect of press. between the compressed and uncompressed metal, and a selection of the results is indicated in Table VII. The Seebeck and Peltier effects are positive and increase regularly with press. and temp. The Thomson effect is positive and increases with rising press., and any constant press. is proportional to the absolute temp. E. Wagner also measured the effect of press. on the Seebeck effect. G. Borelius and F. Gunneson found the Thomson effect, in microvolts per degrees, to be 1·80 at 400° K., 1·31 at 300° K., 0·81 at 200° K., 0·55 at 150° K., 0·25 at 120° K., and —0·10 at 105° K. A. Cöhn and A. Lotz studied the **contact electricity** of silver against glass in vacuo.

TABLE VII.—THE EFFECT OF PRESSURE ON THE SEEBECK, PELTIER, AND THOMSON EFFECTS.

Temp.	Seebeck effect. Volts × 10⁶.			Peltier effect. Joules per coulomb × 10⁶.			Thomson effect. Joules per coulomb × 10⁶.		
	Press. in kgrms. per sq. cm.			Press. in kgrms. per sq. cm.			Press. in kgrms. per sq. cm.		
	2000	6000	12000	2000	6000	12000	2000	6000	12000
0°	+0·15	+0·48	+ 0·94	+3·9	+12·9	+25·3	+2·2	+4·1	+7·1
40°	0·66	2·00	3·91	5·6	16·6	32·1	2·5	4·7	8·1
60°	1·03	3·10	6·02	6·5	18·8	36·0	2·7	5·0	8·7
100°	1·87	5·49	10·56	8·4	23·3	44·2	3·0	5·6	9·7

A. Günther-Schulze[23] has found that silver exhibits the **electrolytic value** action with dil. hydrochloric, hydrobromic, or hydriodic acid. The formation of the electric arc, or sparking between silver poles, has been studied by F. J. Kasper, E. Täge, and D. Roschansky. The **disintegration** of the metal during sparking in vacuum tubes, etc., has been studied by W. Crookes,[24] H. B. Williams, V. Kohlschütter and T. Goldschmidt, etc. The tendency to disintegration is said to be greater with silver than with platinum, copper, nickel, iron, or aluminium; and to be smaller in air than in hydrogen. F. W. Aston found Crookes' dark space in vacuum tubes is thicker with silver than with aluminium, magnesium, iron, copper, zinc, tin, platinum, lead, carbon, or mercury. E. Weiss, and F. Ehrenheft have studied the character of the colloidal particles obtained by the disintegration of silver electrodes during sparking. W. G. Duffield, T. H. Burnham, and A. H. Davis studied the electric arc between silver electrodes; and V. L. Chrisler measured the potential gradient of the arc with silver electrodes.

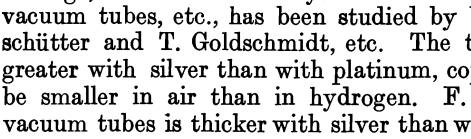

FIG. 8.—Magnetic Susceptibility of Copper, Silver, and Gold at different Temperatures.

P. Joubin[25] places silver among the magnetic metals, while it is usually regarded as diamagnetic, since it appeared in M. Faraday's list (1846) of diamagnetic metals: bismuth, antimony, . . . mercury, silver, copper—concerning which he said, "I cannot be sure that they are perfectly free, from magnetic metals." The **magnetic susceptibility** of silver has been determined by J. A. Fleming and J. Dewar, S. Meyer,

J. Königsberger, C. Chéneveau, etc. About 15°, the value is $-1{\cdot}3$ to $-1{\cdot}7\times10^{-6}$ volume units; and $-0{\cdot}2\times10^{-6}$ mass units. The magnetic susceptibility increases during the melting of the metal. M. Owen found a numerical increase. K. Honda found very little change, *e.g.* he obtained $-0{\cdot}19\times10^{-6}$ mass units at 18°, and $-0{\cdot}22\times10^{-6}$ mass units at 1100°. There is, however, a discontinuity at the m.p. as illustrated in Fig. 8. W. Gerlach and O. Stern demonstrated the magnetic moment of silver atoms.

§ 7. The Chemical Properties of Silver

Exposure to dry or moist **air** has no effect on silver if the air be free from extraneous constituents—ozone, hydrogen sulphide, etc.—which do attack the metal. Silver is not attacked by moist or dry **oxygen** at ordinary temp. and press., but J. L. Proust[1] early succeeded in oxidizing silver with the mouth-blowpipe. H. le Chatelier also found that at press. exceeding 15 atm., the metal is distinctly oxidized at about 300°; and, according to W. Manchot, silver is covered with a very thin film of oxide if it be heated to 200° in air. H. St. C. Deville and H. Debray, and L. Troost and P. Hautefeuille found that a mixture of silver oxide and silver is obtained when silver vapour, obtained by heating silver in the oxyhydrogen blowpipe, is rapidly cooled in air; the former also reported the presence of silver oxide in the condensed fumes from blast furnaces working *plomb argentifére.* H. von Wartenberg explained the more ready volatilization of silver in oxygen than in nitrogen by assuming the formation in oxygen of the more volatile silver oxide which can be detected in the condensed material. V. Kohlschütter and A. Noll found that silver disintegrated at the cathode in a tube containing oxygen or air at a low press., contains some silver oxide. It is also said that when silver is deflagrated by the electric discharge in air, the brown product which condenses from the vapour contains silver oxide. W. G. Duffield observed the formation of silver oxide by producing an electric light arc between silver electrodes. The oxide appeared as a black growth on a third cathode negatively charged to 50 volts and placed about 2 mm. above the horizontal arc.

It has long been known that when silver is melted in air, the metal is liable to spit and splutter during solidification. Suetonius, a Roman historian of the first century, referred to the blistered surface of silver, which has been melted in air, as *argentum pustulatum.* The cause of the **spitting of silver** was established by S. Lucas in 1819. He showed that the phenomenon was due to the absorption of oxygen when the molten metal is exposed to air, or to oxidizing substances like "some of the nitrates," and the subsequent evolution of the absorbed gas as the metal is quickly or slowly cooled. He stated that when silver, which has been melted in air so as to acquire oxygen, is left to cool gradually, for five minutes or longer, protuberances like miniature volcanic cones are thrown up here and there over the surface of the metal; if cooled rapidly, by being poured into water, the same phenomenon occurs, but the protuberances are smaller, and spread more equally over the surface. He collected a sample of the gas given off by the metal cooling under water, and John Dalton's analysis showed that it contained 86 or 87 per cent. of oxygen. In spite of precautions, some air must have been also collected with the oxygen. S. Lucas further ascertained that substances having a powerful affinity for oxygen, abstracted that gas from molten silver; for example, by spreading charcoal for a few moments on the surface of the metal, the whole of the oxygen was removed, and there was no emission of gas during the cooling—whether slowly or quickly conducted.

P. F. Chevillot showed that every gram of silver melted in air gave off, on solidification, 0·975 c.c. of oxygen; and J. L. Gay Lussac, that silver which had been melted under nitre gave off under the same conditions 22 times its volume of gas. H. Rose found that if silver be melted under a layer of potassium or sodium chloride, the metal solidifies with a bright surface, showing that oxygen had not been absorbed and afterwards emitted. If potassium or sodium nitrate be mixed with the saline covering later, spitting occurs. The silver obtained by the reduction of the chloride by fusion with sodium carbonate does not spit even though oxygen is evolved during the reduction: $4AgCl+2K_2CO_3=4Ag+4KCl+2CO_2+O_2$. The non-spitting of the silver is due to the evolution of the oxygen before the silver has melted. For the same reason, potassium chlorate does not cause spitting, while potassium chromate does; nor does silver spit when fused under a mixture of sodium chloride and manganese dioxide. A. Sieverts and J. Hagenacker measured the amount of oxygen absorbed by two grams of silver at different temp. and found:

Temp.	923°	973°	1024°	1075°	1125°
Oxygen occluded	0·56	21·35	20·56	19·39	18·49 c.c.

The volume of oxygen was here reduced to 0° and 760 mm. press. The results computed for the volume of oxygen absorbed per unit volume of silver are plotted in Fig. 9.

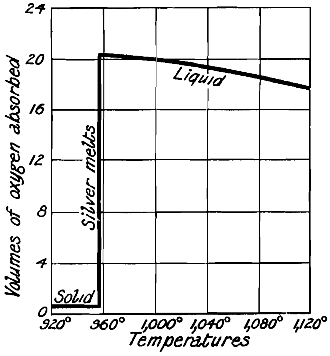

FIG. 9.—The Solubility of Oxygen in Silver.

J. W. Russell and A. Matthiessen, and C. T. Heycock and F. H. Neville found that hydrogen, nitrogen, carbon dioxide, and carbon monoxide do not cause spitting when bubbled through the molten silver; but the contrary is the case with oxygen and air. P. Hautefeuille and A. Perrey found that the metal spits if fused in an atm. of phosphorus vapour, and to a less extent in arsenic vapour. P. F. Chevillot found that silver with more than 15 per cent. of copper did not spit; J. L. Gay Lussac said that 5 per cent. of copper is effective, presumably because the copper unites with the oxygen which the silver absorbed. A. Levol found silver with one-third its weight of gold spits, but when the alloy has less silver than gold the phenomenon does not take place.

Not all the absorbed oxygen is given off on freezing; a little oxygen is retained by the solid, and it can be abstracted by heating the metal to 400° or 500° in vacuo. In this way B. Brauner obtained 0·347 c.c. of oxygen from 100 grms. of the metal heated a little over 450°. J. B. A. Dumas suggested that in J. S. Stas' at. wt. determinations. the silver must have contained occluded oxygen because the metal was melted with borax and nitre, but J. S. Stas always heated the silver to a dull redness before a weighing was made, and the greater part of the occluded oxygen would thus be expelled. J. S. Stas' results have been examined in the light of these facts by L. Meyer and K. Seubert, J. van der Plaats, etc.

From experiments on the action of oxygen on silver, made by C. F. Plattner, in 1856, he concluded that at ordinary temp. solid silver has very little affinity for oxygen, but at a moderately high temp. silver is oxidized by gaseous oxygen, and the silver oxide which is formed at that temp. is volatile, while at a lower temp. the oxide is resolved into silver and oxygen. He further added that the phenomenon of spitting is due, not as generally believed to the simple absorption of uncombined oxygen and its subsequent liberation, but rather to the formation of silver oxide at a high temp., and its soln. in molten silver like that of cuprous oxide in molten copper; and to the subsequent resolution at a lower temp. into its elements—silver and oxygen.

There are three possible cases. The oxygen absorbed by the silver may be chemically combined with the metal, or dissolved either as diatomic molecules, O_2, or monatomic molecules, O.

(1) If the gas be not chemically combined, and Henry's law of absorption be valid, the conc. of the dissolved oxygen will be proportional to the partial press. of this gas, provided the molecules have the same complexity in the liquid and gaseous states—*viz.* diatomic molecules. In that case, the partial press. of the free oxygen and the conc. C_{O_2} of the gas in soln. will be in equilibrium when $p=k_1C_{O_2}$, where k_1 is a constant. Consequently, if the oxygen be in the same mol. state in soln. and gas, the ratio p/C_{O_2} will be a constant. This is not the case, and the hypothesis is therefore invalid.

(2) Next suppose that the dissolved gas is in the atomic condition, $O_2\rightleftharpoons 2O$, by the law of mass action, $C_{O_2}=k_2C_O^2$; but Henry's law is valid for the dissolved

diatomic molecules of oxygen, $p=k_1C_{O_2}$, or $p=kC_O^2$, where k is a constant eq. to the product k_1k_2. Consequently if most of the dissolved oxygen is in the monatomic condition, its conc. C_O will be proportional to the square root of the press. of the oxygen gas, or $C_O=k\sqrt{p}$, or the ratio $\sqrt{p}/C_O$ is constant. This is what A. Sieverts and J. Hagenacker actually observed within the limits of experimental error. Let p denote the partial press. of the oxygen in mm. of mercury; and C the number of c.c. of oxygen reduced to normal temp. and press., absorbed by 10·87 grms. of silver at 1075°:

$p=$	1203	760	488	346	209	150	39
$C=$	26·91	21·01	17·02	14·53	11·75	10·09	4·75
$\sqrt{p}/C=$	1·29	1·31	1·30	1·28	1·23	1·21	1·31

The constancy of the ratio $\sqrt{p}/C$ is thus in agreement with the assumption that the dissolved gas is in the atomic condition; and the inconstancy of the ratio p/C is not in agreement with the assumption that the dissolved gas is in the same mol. state, O_2, as the gas.

(3) If the oxygen in the molten metal is mainly in the form of oxide, Ag_2O, the equilibrium relations in the molten silver are $Ag_2O=2Ag+O$; and $O_2\rightleftharpoons 2O$; and for the small amount of mol. oxygen in the soln., by Henry's law, $p=k_1C_{O_2}$ as before, exactly the same result is obtained, namely, $C_O=k\times\sqrt{p}$. Consequently, as F. G. Donnan and T. W. A. Shaw have emphasized, measurements of the partial press. of the oxygen will not distinguish between dissolved oxygen in the atomic condition and oxygen chemically combined with the silver as Ag_2O. According to the latter hypothesis, silver melted in air or oxygen is a dil. soln. of silver oxide, and is accordingly stable in spite of the great dissociation press. of the oxide. As the metal solidifies, the silver oxide, virtually insoluble in solid silver, is rejected from the soln., and dissociates explosively causing the mass to splutter. The experimental evidence does not here answer the question: Is the dissolved oxygen in soln. as silver oxide, Ag_2O, or as free atomic oxygen? F. G. Donnan and T. W. A. Shaw add:

> It is interesting to compare the solubilities of oxygen in molten copper, silver, and gold. In the case of copper the solid oxide Cu_2O can separate from the soln., since the dissociation press. of Cu_2O at the m.p. of copper is quite low. In the case of silver the solid phase Ag_2O cannot separate owing to its very great oxygen dissociation-press., although Ag_2O can probably exist in dil. soln. in molten silver. Finally, in the case of gold the affinity between this metal and oxygen has become so low that even a very dil. soln. of oxide of gold in molten gold would correspond to an oxygen press. many times greater than that of the atm. This comparison may perhaps lend some support to the view that the oxygen present in molten silver exists as dissolved silver monoxide.

According to T. Graham, silver can occlude 0·745 vol. of oxygen, which, "like the hydrogen in palladium, is permanently fixed in the metal at all temp. below an incipient red heat. It does not tarnish the bright metal surface of the silver, or produce any appearance suggestive of the oxidation of the metal." T. Graham found that a piece of silver wire absorbed 0·211 vol. of **hydrogen** at a red heat; G. P. Baxter, that fritted silver, reduced from the oxide, occluded very little hydrogen; G. Neumann and F. Streintz, and A. Sieverts and co-workers, that none was absorbd. M. Berthelot observed that silver heated to redness in a stream of hydrogen shows some signs of disintegration to dust. H. le Chatelier found that hydrogen is absorbed by silver at about 600°, and rejected about 30° from the m.p. The absorption of hydrogen by silver has also been studied by T. W. Richards, C. Chabrier, and H. T. Calvert. According to H. Hartley, during the absorption of gases and their catalytic combustion on a surface of silver, the metal acquires a negative charge. V. L. Chrisler, and W. Heald found that hydrogen is rapidly absorbed by a silver electrode when an electrical discharge passes through the attenuated gas. T. Graham also found a specimen of what he called "fritted silver" to occlude 0·938 vol. of hydrogen, 0·545 vol. of **carbon dioxide,** and 0·156 vol. of **carbon**

monoxide, but he remarks that this sample occluded hydrogen and carbon dioxide in larger proportions than former specimens he had examined. In another sample of silver he found 1·37 vols. of carbon dioxide, 0·20 vol. of **nitrogen,** and 0·04 vol. of carbon dioxide. P. A. Guye and F. E. E. Germann found hydrogen to be practically insoluble in silver, while carbon monoxide is appreciably soluble. A. Sieverts and M. Berthelot could detect no change when silver is heated in an atm. of nitrogen. A. Sieverts and E. Bergner found that **argon** is not absorbed by silver at 1120°. Red-hot silver is permeable to oxygen, but only traces of nitrogen, carbon dioxide, or carbon monoxide can pass through the metal. P. A. Guye, and G. P. Baxter and co-workers have measured the occlusion of gases by silver. The last-named found crude silver occluded 0·006 per cent. and refined silver 0·00063 per cent. under ordinary conditions. H. von Euler and A. H. Hedalius studied the adsorption of silver nitrate and potassium chloride from aq. soln. of these salts, by very finely divided silver.

C. Chabrier, and M. Berthelot [2] have discussed the possibility of forming a **silver hydride,** AgH. E. J. Bartlett and W. F. Rice added an excess of dil. hypophosphorous acid to a dil. soln. of silver nitrate, and obtained first a red and then a black soln. which could be filtered unchanged. The black soln. flocculated when allowed to stand a few minutes; the product was washed and dried to a constant weight at 60°. It has been suggested that the black residue is silver hydride because it loses from 0·53 to 0·96 per cent. when ignited—for silver hydride, AgH, the theoretical loss is 0·94 per cent. The alleged compound is not decomposed by water, and in the presence of hypophosphorous acid it gives no hydrogen. The evidence as to the individuality of the alleged hydride is very feeble. A. Sieverts and F. Lössner say that if the hypophosphorous acid is free from chlorine the precipitate is silver quite free from hydrogen.

C. F. Schönbein [3] showed that silver reacts with **ozone,** forming a peroxide, but only when the gas is moist; and, according to H. Thiele, dried ozone has no action on the dry metal. If warm silver be allowed to cool while a stream of ozone impinges on the surface of the metal, a black film of silver oxide is produced. The maximum effect is obtained between 240° and 220°; there is no action at 450°—*vide* ozone. According to R. J. Strutt, a single collision of an ozone molecule with silver suffices for its decomposition. Silver has a marked catalytic action on the decomposition of **hydrogen peroxide** (*q.v.*). O. P. Watts and N. D. Whipple studied the corrosion of silver by hydrochloric, perchloric, phosphoric, nitric, chromic, sulphuric, and acetic acids, by sodium hydroxide, and by a number of oxidizing agents—hydrogen peroxide; sodium arsenate and nitrate; ferric sulphate, and chloride; potassium dichromate, chlorate, permanganate, nitrate, bromide and iodide; and mercuric chloride.

Silver reduced by zinc from silver chloride retains water very tenaciously at 100°; and, according to A. Vogel,[4] the water is only completely expelled by heating the metal to 210°. At ordinary temp. **water** has no perceptible action on silver either *en masse* or in a finely-divided state. M. Traube-Mengarini and G. Scala, K. Kahle, G. P. Merrill, and G. van Dijk, have reported that silver is slightly soluble in hot water; and that the solubility is rather smaller than copper and greater than platinum. A. Leduc, T. W. Richards, E. Collins, and G. W. Heimrod, and K. E. Guthe, showed that properly washed silver does not change at room temp. by a prolonged digestion with water. W. Skey stated that when silver is immersed in distilled water for a few hours, its surface is so modified that it will not amalgamate immediately afterwards; the effect was not produced by spring water or by rain water. The affected metal is again susceptible to amalgamation after it has been in contact with rain or spring water, a soln. of ferrous sulphate, acetic acid, or after it has been heated to 260°. W. Skey assumed that in distilled water oxide of silver is formed, and in spring water and rain water the oxide is converted to chloride. The chloride is readily amalgamated by mercury, and he assumes that the oxide is not, although F. J. Malaguti and J. Durocher say that silver oxide is easily reduced by mercury. According to H. V. Regnault, when steam is passed over silver at a white heat, there is a notable disengagement of hydrogen; and, on subsequent cooling, the metal spits owing to the escape of the absorbed oxygen. In this experiment, H. St. C. Deville considers that the silver probably absorbed the oxygen gas from the products of the thermally decomposed steam.

H. Moissan[5] observed that **fluorine** attacks silver very slowly in the cold; at 100°, the action is faster; and at a red heat, the action takes place with incandescence. R. Cowper found that dry **chlorine** has scarcely any action on dry silver, but if moisture be present silver chloride is formed without incandescence; and, according to V. von Cordier, the reaction is quicker in light than in darkness. J. S. Stas noted that chlorine water acts similarly. H. Gautier and G. Charpy also showed the reaction between dried chlorine or bromine and silver is very slow. The attack with chlorine is faster than with **bromine.** According to G. Reboul, dried chlorine, bromine, or iodine vapour attacks a piece of silver foil more vigorously where it has been bent than in the parts of less curvature. When silver is heated with **iodine,** silver iodide is formed. J. H. Kastle said that the reaction between chlorine, bromine, or iodine and finely-divided silver is quantitative. A. Galecky and L. Bruner found that when a soln. of bromine or iodine in nitrobenzene, not completely dried, is electrolyzed between silver electrodes, silver halide forms on the anode, and silver is deposited on the cathode. C. C. Perkins noted that iodine is removed from aq. soln. by finely-divided silver. According to R. G. van Name and G. Edgar, the rates of dissolution of mercury, cadmium, zinc, silver, and copper in aq. soln. of iodine and potassium iodide are nearly the same at 25°. L. Bruner and E. Bekin found that silver is rapidly attacked by **iodine chloride,** ICl, while **iodine bromide** attacks silver very little. G. Tammann has studied the formation of surface films by exposing the metal to iodine vapour, and obtained similar results as with copper (*q.v.*).

C. W. Scheele, and J. L. Gay Lussac and L. J. Thénard[6] reported that aq. **hydrofluoric acid** does not act on silver. According to A. Jouniaux, dry hydrogen fluoride free from oxygen does not attack silver in light or darkness at ordinary temp. According to J. B. J. D. Boussingault, M. Berthelot, and A. Jouniaux, both **hydrogen chloride** and **hydrochloric acid** attack silver if air be simultaneously present. For the action of hydrogen chloride on silver, see silver chloride. According to J. L. Proust, when metallic silver is kept in hydrochloric acid, hydrogen is slowly evolved, and the reaction is more rapid if the acid be aerated. C. W. Scheele also showed that silver chloride is rapidly formed by the action of hydrochloric acid in the presence of various oxidizing substances such as manganese peroxide, arsenic acid, red lead, etc., and chlorine is at the same time evolved. N. W. Fischer also satisfied himself that silver does dissolve in hydrochloric acid and that the reaction is induced if another metal be present; indeed, M. Faraday and J. Stodart observed that in the analysis of their supposed alloy of silver and steel, the silver was attacked and dissolved by hydrochloric acid. G. Wetzlar, however, doubted whether the purified acid has any action on the purified metal. Silver derived by dissolving out the zinc from zinc-silver alloys by hydrochloric acid is stated by D. Palitsch to be an allotropic form of silver because it differs from ordinary silver in sp. gr., heat of soln. in mercury, and electrolytic potential. For the action of **hydrogen bromide** on silver, *vide* silver bromide; and for **hydrogen iodide,** *vide* silver iodide. M. Berthelot found silver is readily attacked by **hydrobromic acid** at ordinary temp., and the reaction is more marked than is the case with hydrochloric acid. **Hydriodic acid** is the most active of the halide acids. H. St. C. Deville and A. Potilitzin showed that the metal dissolves readily in the cold with the evolution of hydrogen, and when the acid is conc. the action is vigorous. The action continues until the liquid is sat. with silver iodide, and if the soln. be then heated the action is renewed. H. Danneel showed that the reactions in soln. are reversible.

According to K. A. Winkler,[7] silver easily decomposes **sodium chloride** at a red heat and with access of air, forming silver chloride, and this action is the more pronounced the more finely divided the silver. H. Rose melted silver under common salt, so that air could get only a very limited access, and until the salt had in great part volatilized; the residue contained much silver chloride, and it was not in the least alkaline. He assumed that the sodium of the salt is evolved as sodium oxide or hydroxide, and that this combines with the clay of the crucible and is so removed from the sphere of the reaction, for, at the temp. of the experiment, sodium hydroxide readily reduces silver chloride to silver. The greater the heating the greater the loss of metal by conversion into chloride. He found that with coins containing copper the conversion was considerably reduced, and he stated that "copper prevents the formation of silver chloride and the consequent loss of silver." H. Rose also said that C. F. Plattner roasted a mixture of finely-divided silver and common salt with the addition of a large excess of cupric or ferric oxide, and found no more silver chloride was formed than without such addition.

According to G. Wetzlar,[8] when silver is subject to an aq. soln. of sodium chloride with access of atm. air, silver chloride is formed, and the soln. acquires an alkaline reaction. H. St. C. Deville made a similar observation in 1859, for he found that silver dissolves with extreme rapidity though in small quantity in a conc. aq. soln. of sodium chloride, and the soln. turns red litmus blue owing to the formation of sodium hydroxide. In this way it is supposed that coins, etc., recovered from submerged wrecks, have been converted into silver chloride by long immersion in sea-water. Thus J. L. Proust found some silver piastres, recovered from a sunken Spanish ship after many years' immersion, had been almost wholly converted into chloride. Silver salt-cellars may become corroded by contact with table-salt, and in consequence such articles are sometimes gilded internally. J. Percy showed that "silver chloride is not formed when a soln. of sodium chloride is boiled in contact with silver, unless atm. oxygen has access."

Silver coins which have been long buried in the earth are almost always covered with a dark grey layer of soft silver chloride, *i.e.* horn silver, of varying thickness. If the silver contains a large proportion of copper, they show the green patina characteristic of bronzes. F. Rathgen, and A. Schertel say that there is a layer of silver subchloride, Ag_2Cl, between the surface layer of normal chloride and the metal, but this is probably a wrong inference. The outer layer of chloride can be removed by dissolution in ammonia-water, and a silver coin of Edward the Confessor's period is stated by J. Percy to have had the percentage composition:

Coin	AgCl	CuO	$3Cu(OH)_2.CuCl_2$	Sulphates
88·36	10·50	0·73	0·41	trace

There is usually a layer in immediate contact with the metal consisting of cupric oxide, silver sulphide, gold (if the silver is auriferous), etc. The following is A. H. Church's analysis of the granular layer from an ancient tomb in Cyprus:

Ag	Au	Cu	Pb	Sb	As	Bi
94·69	0·41	3·43	0·28	0·21	trace	trace

Both the analyses of A. H. Church, and R. Warington show that the composition of the unaltered ductile metal core is the same as that of the brittle granular layer; perhaps these facts are better expressed by saying that no difference in composition was revealed by the methods employed for the analysis. It was accordingly assumed that the change from the ductile to the brittle silver is purely physical, and is produced by "a molecular change, which in the course of ages had occurred throughout all the thinner parts of the piece of silver, but had left unchanged in the thickest part, a central fusiform core. A crypto-crystalline structure had been produced in the previously homogeneous alloy, which caused the peculiarly easy fracture of the metal." A. Schertel's explanation of the change is as follows:

> The layer of chloride of silver shows plainly that the water percolating through the clay, and containing chlorides in soln., first changed the copper into cupric chloride, and that this formed, with the silver, argentous and cuprous chlorides. The cuprous chloride

was then reconverted into cupric chloride, and again attacked the silver. The clay surrounding the metal kept the liquid in contact with it for a long time; so that, with but little copper, much silver was converted into chloride. The clay retained the chloride of silver like a filter, so that a thick incrustation was formed upon the vessels.

M. Berthelot added:

> Silver chloride is for the most part produced by the sodium chloride dissolved in subsoil water, which acts in conjunction with the oxygen and carbonic acid of the air: $4Ag+O_2+2(n+2)NaCl+CO=2(2AgCl.nNaCl)+2Na_2CO_3$; but this reaction differs from that which takes place in the case of copper in that it does not proceed continuously except in the presence of a considerable quantity of salt-water, as, for instance, in the sea. In museums, the alteration goes no further than corresponds with the minute quantity of sodium chloride contained in the object. On the other hand, in an earth which contains salts, the continued presence of water can bring about a more or less marked change.

E. von Bibra adopted a similar explanation, and assumed that the reddish colour sometimes seen on silver near a fresh fracture is produced by cuprous oxide. The outer layer is also coloured reddish-brown either from the adhesion of minute quantities of earth, or from the products of the action of light on the silver chloride. There is no need to assume with A. Schertel that the presence of copper is a vital necessity, because, as J. Percy remarks, silver chloride alone can be formed under the conditions stated—*viz.*, the presence of atm. oxygen, and dissolved chlorides. This explanation does not include the layer of unattacked metal which has lost its malleability and toughness. A. Schertel did succeed in making a rolled silver coin brittle by digesting it six months in a soln. of sodium chloride, but, in this particular case, the brittleness was due to the abstraction of copper from the metal.

C. J. B. Karsten,[9] and J. Percy found that, at a temp. between 12° and 20°, a soln. of **cupric chloride** alone reacts very slowly on silver: $CuCl_2+Ag=AgCl+CuCl$, but the action is very rapid in the presence of sodium chloride. M. C. Lea prepared a purple photo chloride (colloidal silver) by the action of metallic silver on a soln. of cupric chloride. C. J. B. Karsten also reported that an ammoniacal soln. of cupric chloride does not act on silver. According to G. Wetzlar, metallic silver slowly reduces an aq. soln. of **ferric chloride**: $FeCl_3+Ag=FeCl_2+AgCl$, and J. J. Berzelius utilized the reaction in determining the relative proportions of ferric and ferrous oxides in substances soluble in hydrochloric acid. At a certain stage in the reduction of ferric chloride by silver, G. Wetzlar noted the formation of what he regarded as black silver subchloride which, by prolonged immersion in the soln. of iron chloride, is converted into white silver chloride. According to A. Vogel, and M. C. Lea, silver reduces an aq. soln. of **mercuric chloride** to mercurous and silver chlorides: $Ag+HgCl_2=HgCl+AgCl$; C. Jones assumed a double salt, HgCl.AgCl, is formed. According to G. Campani, if the action of finely-divided silver is allowed to continue for some hours, mercury is formed: $2Ag+HgCl_2=2AgCl+Hg$. When a dry mixture of finely-divided silver and mercuric chloride is heated, mercurous chloride sublimes, and silver chloride remains. A. Colson, and J. N. Brönsted have studied the reducing action of silver on **mercurous chloride,** where the action is reversible.

According to A. Ditte, silver is attacked by aq. soln. of **potassium iodide** forming a layer of silver iodide on the metal, with conc. soln. of potassium iodide a double salt, $KI.AgI.\frac{1}{2}H_2O$, may be formed. A. Seyewetz found finely divided silver forms silver iodide when treated with a sat soln. of potassium iodide in *p*-benzoquinone; analogous results are obtained with a soln. of **potassium bromide.** G. Campani found that silver precipitates mercury completely from an aq. soln. of **mercuric iodide** and potassium iodide. According to A. J. Balard,[10] **chlorine monoxide** and **hypochlorous acid,** as well as aq. soln. of the **hypochlorites** with finely-divided silver form silver chloride, and give off oxygen. W. S. Hendrixson found silver is attacked by **chloric acid, bromic acid,** and **iodic acid** (*q.v.*) in accord with the equation: $6Ag+6HClO_3=AgCl+5AgClO_3+3H_2O$. C. Zenghelis found that silver foil is reduced by a soln. of **potassium chlorate.** O. P. Watts and N. D. Whipple investigated the action of **perchloric acid** on silver.

Silver is slowly attacked by contact with **sulphur** at ordinary temp. This is evidenced by rubbing a silver coin with a piece of sulphur, when a black stain of silver sulphide appears. Sulphur vapour reacts much more quickly, and W. Spring[11] reported that a mixture of sulphur and silver unite when compressed under high press. On the other hand, E. Obach found a soln. of sulphur in carbon disulphide to be almost without action on silver—*vide* silver sulphide. According to A. Orlowsky, the affinity of silver for sulphur is a little less than that of copper, but the affinity of selenium for silver is the greater. The affinity of silver for sulphur is also evidenced by its action on mercuric sulphide which, according to A. Colson, involves a reversible reaction. According to J. J. Berzelius, silver is blackened by the vapour of **selenium,** and the two elements unite when fused together; B. Brauner, and J. Margottet found similar remarks apply to the action of **tellurium** on silver. According to J. M. Cabell, purified and dried **hydrogen sulphide** does not attack silver at ordinary temp.; on the contrary, silver rapidly forms sulphide when the gas is admixed with air. The tarnish which silver acquires by exposure to the atm. contaminated with animal exhalations containing sulphur —possibly hydrogen sulphide—is due to the formation of a surface film of silver sulphide. The tarnish is most effectively removed by a dil. soln. of potassium cyanide. Not only does thoroughly dry hydrogen sulphide appear to be inert towards silver, but air or oxygen also appears to be necessary for the attack, because F. L. Hahn found that hydrogen sulphide may be bubbled through water in which silver has been placed, without blackening the metal. A trace of oxygen or hydrogen peroxide causes an immediate blackening. G. Reboul found that with a bent piece of silver, the attack by hydrogen sulphide is greatest where the curvature is greatest. Liquid hydrogen sulphide was found by E. Beckmann and P. Wäntig to have no action on silver. According to J. Percy, "the fading of some photographs, untoned by gold, is due to the transformation of silver or of a silver compound constituting the image into silver sulphide, which, in an extremely thin film, is yellowish-brown, just like incipient silver tarnish." M. Berthelot found hydrogen sulphide in the presence of silver decomposes at about 550°, forming silver sulphide. H. Pélabon has studied the reversible reaction : $2Ag+H_2S\rightleftharpoons Ag_2S+H_2$, at elevated temp. Silver is also attacked by **hydrogen selenide,** and the reversibility of the reaction, $2Ag+H_2Se\rightleftharpoons Ag_2Se+H_2$, has been studied by H. Pélabon.

E. Priwoznik found that silver is blackened by aq. soln. of the **alkali sulphides,** forming silver sulphide which dissolves in the excess. According to F. L. Hahn, air or oxygen is necessary for the attack on silver by alkali sulphides because, if air be vigorously excluded, silver may be boiled with a soln. of sodium sulphide without any blackening. A trace of oxygen or hydrogen peroxide causes an immediate blackening of the metal. A soln. of **ammonium polysulphide** acts on silver at ordinary temp., forming a bluish-grey film, which deepens with a more prolonged action, ultimately forming a crystalline crust of silver sulphide. G. Strüver has studied the action of the heavy **metal sulphides** on silver—hauerite, for example, forms a black layer of silver sulphide when placed in contact with the metal.

The so-called *oxydized silver* is silver whose surface has been rendered a lead-grey colour which is agreeably relieved by deeper tints in the depressed parts. The term is a misnomer in that sulphur, not oxygen, is the agent involved in its production. The effect is produced by immersing the articles in a hot soln. containing alkali sulphide until they acquire a sufficiently dark colour. They are afterwards brushed or wiped in the more prominent parts.

The spitting of silver which has been precipitated by iron sulphate has been attributed to the evolution of **sulphur dioxide** dissolved by the molten metal. W. Stahl[12] found that while sulphur dioxide is insoluble in the molten metal, yet, as J. Uhl has shown, when metallic silver is heated with dry sulphur dioxide, silver sulphide and sulphate are formed: $4Ag+2SO_2\rightleftharpoons Ag_2SO_4+Ag_2S$; or, if oxygen be present: $4Ag+2SO_2+2O_2\rightleftharpoons 2Ag_2SO_4$. Silver sulphate does not dissociate below 1080°, so that when gently melted, the fused sulphate floats on the surface as a slag. At higher temp., the sulphate dissociates, yielding sulphur dioxide and oxygen: $Ag_2SO_4=2Ag+SO_2+O_2$, and it is this oxygen which dissolves in the silver and causes the spitting.

Granulated silver dissolves readily in hot **sulphuric acid** with the evolution of sulphur dioxide—*vide* copper: $2Ag+2H_2SO_4=Ag_2SO_4+SO_2+2H_2O$, and the hot conc. acid can dissolve so much of the silver sulphate as to become a crystalline mass on cooling. The solvent action of sulphuric acid is utilized in the operation of parting gold from silver (*q.v.*). G. Wetzlar[13] said that "dil. sulphuric acid, when left in contact for any length of time with powdered silver, does not dissolve a trace of the metal"; and, according to E. Pannain, boiling sulphuric acid attacks pure silver only when the sp. gr. of the acid is not less than 1·710; a more dil. acid attacks silver only when the metal is impure; pure silver is insoluble in dil. sulphuric acid. E. Harbeck found that silver, as anode in a cell, dissolves in sulphuric acid of sp. gr. over 1·53 in the presence of iron, lead, tin, and copper. A. Vogel stated that finely-divided silver dissolves in conc. sulphuric acid without the evolution of sulphur dioxide. M. C. Lea found that finely-divided silver dissolves in sulphuric acid diluted with four or five times its volume of water. A. Vogel, A. Ditte, and P. Braham have also studied the dissolution of silver in sulphuric acid. W. S. Hendrixson observed that the continued action of the acid exerted no influence on the amount of silver dissolved, and he was able to show that dil. sulphuric acid alone is incapable of dissolving finely-divided silver, and that the seeming solvent action is due to the oxygen of the air dissolved in the acid, to the superficial oxidation of the silver, or to oxygen derived from some external source. According to E. Salkowsky, the solvent action of sulphuric acid on silver is facilitated if hydrogen peroxide be mixed with the acid. O. von der Pfordten reported that a soln. of potassium permanganate in dil. sulphuric acid dissolves silver in the presence of air; but C. Friedheim found the last limitation is not necessary. J. Keir, in 1790, augmented the solvent action of sulphuric acid on silver by mixing it with one-tenth its weight of potassium nitrate, and he recommended this solvent for stripping silver from silver-plated articles. It scarcely affects copper, lead, or iron. The sulphuric acid, of course, liberates nitric acid from the potassium nitrate so that the effect is eq. to a mixture of sulphuric and nitric acids. R. G. van Name and D. U. Hill found that when silver dissolves in a soln. of chromic acid containing sulphuric acid, the velocity of soln. depends on the physical state of the metal, which indicates that the rate of dissolution of the metal is not entirely dependent on the diffusion. The rates of dissolution of different metals tend to become more nearly equal as the conc. of the sulphuric acid increases, but with silver and cadmium the relative rates of dissolution diverge as the conc. of the sulphuric acid increases. E. Divers and T. Shimidzu found that finely-divided silver is rapidly dissolved by **pyrosulphuric acid** without the evolution of a gas, and when the soln. is poured into water, silver sulphate and sulphur dioxide are formed. H. Marshall found silver to be converted by **persulphuric acid** into a mixture of silver sulphate and peroxide. According to V. Lenher, silver is attacked by warm **selenic acid.** According to H. B. North, **sulphuryl chloride,** SO_2Cl_2, does not act on silver at 300°.

G. Wetzlar[14] ascertained that silver is slightly soluble, at ordinary temp., in an aq. soln. of **ferric sulphate,** and this the more when free sulphuric acid is present; and he added: "When the red soln. of ferric sulphate is heated, it dissolves silver and becomes green ferrous sulphate, but, on cooling, the silver is deposited, and the soln. acquires its original colour." The precipitation is never complete, and the more free acid the soln. contains, the more difficult the precipitation of the silver by ferrous sulphate, and if sufficient free acid be present, no silver is precipitated. Dil. sulphuric acid does not dissolve silver, but if a drop of ferric sulphate be present, an appreciable amount of silver will be dissolved in the course of an hour. The explanation of G. Wetzlar, 1828, reduces the process to a catalytic cycle:

> The ferric sulphate imparts oxygen to the silver and is thereby reduced to ferrous sulphate, but the latter immediately absorbs oxygen from the air and is brought back to its original state of ferric sulphate; and so these alternate reactions continue, the ferric sulphate acting as a vehicle for the transfer of oxygen from the air to the silver whereby silver oxide is produced, which combines with the sulphuric acid to form silver sulphate.

A. Vogel also found silver to dissolve readily in a boiling soln. of ferric sulphate, even though the soln. be made as neutral as possible by the addition of hydrated ferric oxide. F. Wöhler stated that a hot soln. of **ferrous sulphate** dissolves silver, which is subsequently precipitated as the soln. is cooled. Neither A. Vogel nor J. Percy could detect the least action when the metal is boiled with a soln. of ferrous sulphate, but if a trace of ferric sulphate be present, some silver will be dissolved by the boiling soln., and precipitated as metal when the soln. cools. M. C. Lea also found finely divided silver readily dissolves in a soln. of iron alum, *i.e.* **ferric ammonium sulphate.** K. Hopfgartner found that there is a state of equilibrium in the soln. $2Ag+Fe_2(SO_4)_3 \rightleftharpoons Ag_2SO_4+2FeSO_4$, or $Ag+Fe^{\cdot\cdot\cdot} \rightleftharpoons Ag^{\cdot}+Fe^{\cdot\cdot}$, such that $[Ag^{\cdot}][Fe^{\cdot\cdot}]=K[Fe^{\cdot\cdot\cdot}]$, where the symbols in brackets represent conc. The value of K is 0·004, and it alters a little in soln. of different conc., and when iron alum is used in place of ferric sulphate. The reaction has been studied by V. Kohlschütter and E. Eydmann, and by A. A. Noyes and B. F. Brann. K. Hopfgartner also recommended the reduction of an acidulated soln. of a known amount of ferric ammonium sulphate by silver and subsequently titrating the product with a soln. of potassium permanganate to be standardized. H. N. Stokes reported that silver dissolves in a hot soln. of **cupric sulphate,** and is deposited as the soln. cools.

According to E. C. Franklin and C. A. Kraus, silver is insoluble in liquid **ammonia.** M. C. Lea,[15] and C. Matignon and G. Desplantes found that finely-divided reduced silver is slightly soluble in aq. ammonia if air or oxygen be present, but if air or oxygen be excluded, it is probably insoluble. J. W. Turrentine found that when a very dil. soln. of silver in **hydrazoic acid** is electrolyzed with a silver anode, the anode efficiency exceeds 100 per cent. of the corrosion predicted by Faraday's law, and he explains the phenomenon by assuming that the metal dissolves or partially dissolves electrochemically at a valence lower than that usually ascribed to silver, forming compounds which are readily oxidized—he quotes the subhalides and suboxide in support of silver with a valence lower than unity. The phenomenon only occurs with very dil. soln., and if the electrolyte is stirred, the metal becomes passive.

The reports of the effects of nitrogen oxides on heated silver are not all consistent. According to W. Manchot, and A. Kurtenacker, **nitrous oxide** and **nitric oxide** are not changed, and, according to P. Sabatier and J. B. Senderens,[16] silver is not attacked by nitric oxide at any temp.; on the other hand, silver at a bright red heat decomposes the oxide of nitrogen completely, according to F. Epstein and R. Doht, and E. Calberla, and incompletely, according to H. Hermann. G. Reboul found that dil. **nitrogen trioxide,** N_2O_3, attacks a piece of bent silver most at the places of greatest curvature. W. Manchot found **nitrogen tetroxide,** NO_2, does not attack silver at 240°, but at room temp. the metal is coloured yellow. M. Oswald says that nitrogen tetroxide, N_2O_4, reacts with silver, forming silver nitrate and nitric oxide. Liquid nitrogen tetroxide was found by E. Divers and T. Shimidzu to convert finely-divided silver into silver nitrate and nitric oxide. J. J. Sudborough says that **nitrosyl chloride,** NOCl, produces on silver a thin superficial film of the chloride which protects the metal from further attack.

According to J. J. Berzelius,[17] when silver is suspended in pure **nitric acid,** and the liquid is viewed by transmitted light, the metal appears to dissolve without the evolution of gas, and the denser soln. of silver nitrate to fall in striæ from the surface of the silver. The soln. gradually acquires a greenish tinge, owing to the reduction of the nitric acid to nitrous acid; but as the liquid becomes warm, and occasionally quite abruptly, the evolution of gas begins. In his *Recherches sur* *l'acide nitrique*, N. A. E. Millon found that silver is not attacked by nitric acid of lower sp. gr. than 1·405, whose composition is represented by $4HNO_3+7H_2O$, so long as the temp. does not rise above 20°, and no soln. of silver nitrate is added. In pure conc. nitric acid, silver becomes coated with a grey or white film which protects the metal from further oxidization. J. W. Russell also showed that silver does not react with dil. nitric acid, because, when hydrogen is passed through silver nitrate, metallic silver is precipitated and nitric acid is formed. The amount of hydrogen absorbed is in excess of that required by the replacement of silver by hydrogen: $2AgNO_3+H_2=2HNO_3+2Ag$, because some nitrous acid is simultaneously formed: $2HNO_3+2H_2=2H_2O+2HNO_2$, and silver redissolves, forming silver nitrite when the passage of hydrogen is stopped. When silver dissolves in nitric acid, also, it does so as silver nitrite, not nitrate. This explanation of the action of nitric acid on silver is practically the same as that given by N. A. E. Millon to the dissolution of copper in nitric acid. These observations, coupled with those of V. H. Veley on the action of nitric acid on copper, show that the metal actively reacts with the acid only in the presence of nitrous acid, for the action of nitric acid on the metal is scarcely measurable unless, and until, a sensible quantity of nitrous acid is present. Silver cannot remain long in contact with nitric acid without reaction, but this is because the nitric acid is slowly dissociated into nitrous acid and oxygen, excepting perhaps when the acid is highly diluted. In any case, nitric acid of moderate conc. cannot be kept free from nitrous acid. Hence, nitric acid is considered to be the most important solvent for silver and, according to L. Marchlewsky, acid below one per cent. HNO_3 attacks the finely-divided metal. Neither E. Divers nor C. Montemartini could detect any signs of the formation of ammonia or hydroxylamine, but only nitric acid and nitrous acid. G. O. Higley and W. E. Davis used nitric acid varying from a sp. gr. 1·05 to 1·40. Neither nitrogen nor nitrous oxide was produced in any of the experiments; nitric peroxide is the principal reduction product with conc. acid, accounting for over 70 per cent. of the metal dissolved; the decrease of this gas and the complementary increase of nitric oxide as the acid is diluted is due to the decomposition of the nitric peroxide into nitric acid and nitric oxide by water.

According to V. H. Veley's hypothesis, the metal dissolves in the nitrous acid to form a nitrite and nitric oxide: $Ag+2HNO_2=AgNO_2+NO+H_2O$; the nitrite is then decomposed by the excess of nitric acid to reform nitrous acid: $AgNO_2+HNO_3=HNO_2+AgNO_3$. The nitric oxide formed by the reaction symbolized by the first of the equations reduces the nitric acid (or the nitrate) to produce a further quantity of nitrous acid: $HNO_3+2NO+H_2O=3HNO_2$. When the conc. of nitrous acid has reached its equilibrium value, the reverse reaction occurs: $3HNO_2=HNO_3+2NO+H_2O$, and nitric oxide is evolved from the liquid. E. Divers' hypothesis is that the silver reacts slowly with nitric acid, forming silver nitrite and nitrate: $2Ag+2HNO_3=H_2O+AgNO_2+AgNO_3$, and that the presence of nitrous acid catalyzes this reaction. The silver nitrite so formed reacts with the nitric acid to form nitrous acid: $AgNO_2+HNO_3=AgNO_3+HNO_2$, and the nitrous and nitric acids are consumed at the same rate by the reaction: $HNO_2+HNO_3+2Ag=2AgNO_2+H_2O$. In the former hypothesis silver nitrate is a secondary product of the reaction; in the latter hypothesis, part of the silver nitrate is a primary product—*vide* action of nitric acid on copper. A soln. of **cupric nitrate** was found by M. C. Lea to have no action on finely-divided silver. According to W. R. E. Hodgkinson and A. H. Coote, molten **ammonium nitrate** acts on silver if it is strongly heated; aq. soln. acts very slightly or not at all. W. R. E. Hodgkinson also found **aniline** and **toluidine nitrates** behave like ammonium nitrate.

In 1792, B. Pelletier[18] dropped **phosphorus** on silver heated to redness in a crucible, and found the metal instantly melted; he continued adding phosphorus until he believed the silver to be sat. The molten mass had a tranquil surface, but, on cooling, much phosphorus was emitted, and the surface became *toute mamelonnée* owing to the spitting of the silver as it rejected the phosphorus in soln.

It was estimated that the solid silver retained about 15 per cent. of phosphorus, and that it lost 10 per cent. in the act of solidification. J. Percy found a maximum of 0·293 per cent. to be retained by the solid metal. P. Hautefeuille and A. Perrey, and H. N. Warren confirmed these observations in a general way, and A. Granger found that silver at 400° absorbs phosphorus, which it rejects at about 500°, and takes up anew at 900°. O. Emmerling, A. Granger, and A. Schrötter prepared silver phosphides—AgP, Ag_2P_3, and AgP_2—by the action of phosphorus on the metal. A. Granger found that **phosphorus trichloride** is attacked by silver only at a high temp.; H. Goldschmidt, that **phosphorus pentachloride** reacts: $2Ag+PCl_5=2AgCl+PCl_3$; and B. Reinitzer and H. Goldschmidt, that **phosphoryl chloride** reacts at 250°, forming phosphorus trichloride, pyrophosphoryl tetrachloride, $P_2O_3Cl_4$; phosphorus pentoxide; silver chloride, phosphate, and pyrophosphate. O. P. Watts and N. D. Whipple studied the action of **phosphoric acid** on silver. J. J. Berzelius found that when **ammonium sodium hydrophosphate**, microcosmic salt, is fused with silver in an oxidizing flame, a yellow opalescent glass is formed.

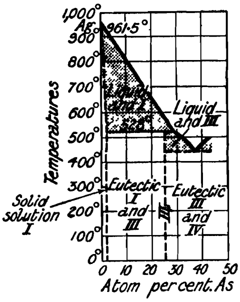

FIG. 10.—Freezing Point Curve of the Binary System Ag–As (K. Friedrich and A. Leroux).

T. Bergmann[19] found that silver takes up one-fourteenth of its weight of arsenic, and thereby becomes yellow and brittle. A. F. Gehlen heated a mixture of equal parts of powdered silver and **arsenic,** and obtained what he called a compact, brittle, steel-grey, crystalline mass with about 16 per cent. of arsenic—possibly Ag_4As. The two elements unite without incandescence. P. Berthier described a similar alloy. J. Percy likewise obtained an alloy with 18·54 per cent. of arsenic—possibly Ag_3As. P. Hautefeuille and A. Perrey noted that as in the case of phosphorus, the molten alloy of silver and arsenic spits in the act of solidification, owing to the rejection of arsenic by the cooling metal. K. Friedrich and A. Leroux studied the f.p. curves and found evidence of the formation of silver arsenide, Ag_3As. A portion of the curve is shown in Fig. 10, for alloys with up to about 40 per cent. of arsenic. I refers to the mixed crystals of arsenic in silver, III refers to the alloy Ag_3As; the portion to the right has not been explored. W. Spring prepared alloys by compressing mixtures of the powdered elements at 6500 atm. C. W. Scheele reported that **arsenic oxide** does not act on silver, but when the two elements are melted together, arsenious oxide sublimes, and silver arsenate, Ag_3AsO_4, is formed. A. F. Gehlen found **arsenious oxide** does not act on silver at a high temp. Alloys of silver and **antimony** are easily prepared. P. Berthier[20] said that each of the two elements has *beaucoup d'affinité pour l'autre et se combinent en toutes proportions.* Their whiteness increases as the proportion of antimony increases; they are always brittle, and a very small proportion of antimony suffices to impart that quality to silver. The alloys are very fusible, and wholly decomposed by cupellation or fusion with nitre; *l'argent reste pur.* P. A. von Bonsdorff says that about one-tenth per cent. of antimony remains obstinately united with the silver when the alloy is cupelled. H. Rose found that by repeatedly heating the alloy with ammonium chloride, the proportion of antimony is gradually diminished. Portions of the constitutional diagram were worked out by H. Gautier, and C. T. Heycock, and completed by G. I. Petrenko. The diagram is illustrated in Fig. 11. The break at 559° corresponds with 27·07 per cent. of antimony and represents

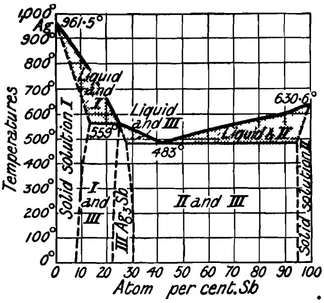

FIG. 11.—Freezing Point Curve of the Binary System Ag–Sb (G. I. Petrenko).

the formation of the antimonide, Ag_3Sb; the eutectic at 483° corresponds with nearly 45 per cent. of antimony. The areas bounded by the liquidus and solidus curves are shaded in the diagram. I refers to solid soln. of antimony in silver; and II of silver in antimony; while III refers to the antimonide, Ag_3Sb. G. Charpy studied the microstructure of the alloys; E. Maey, the sp. gr.; N. A. Puschin, the electrochemical behaviour; E. Elsässer, the electrical conductivity; and W. Haken, the thermo-electric force.

According to P. Berthier,[21] silver and **bismuth** easily fuse together, forming a brittle laminar alloy. A. Wright found homogeneous alloys can be obtained with all proportions of the two constituents. According to P. Berthier, silver is readily separated from the bismuth by cupellation. R. Schneider remarked that when impure bismuth—containing sulphur, arsenic, iron, nickel, cobalt, and silver—is fused and poured upon a cold plate, the globules of metal which are thrown up during solidification contain at least 99·5 per cent. of bismuth; and of the heavy metals, only silver remains in these globules, the copper remains with the mass. He suggests this property might be advantageously employed for a preliminary purification of bismuth. The f.p. curves have been determined by G. I. Petrenko, and C. T. Heycock and F. H. Neville. The curves are shown in Fig. 12. The curve is the simple V-type with a eutectic at 262° and 2·5 per cent. of silver. The sp. gr. of the alloys has been investigated by P. von Muschenbrock, A. Matthiessen and M. Holzmann, and E. Maey; the thermo-electric properties by A. Batelli; and the e.m.f. by W. N. Lacey. The e.m.f. of the alloys is greater than that of bismuth; and the alloys are all formed with the absorption of heat. According to C. M. Marx, an alloy of equal parts of the two elements does not expand on solidifying, but an expansion does occur when the proportion of bismuth is double that of silver. According to H. Moissan, silver does not alloy with **vanadium.**

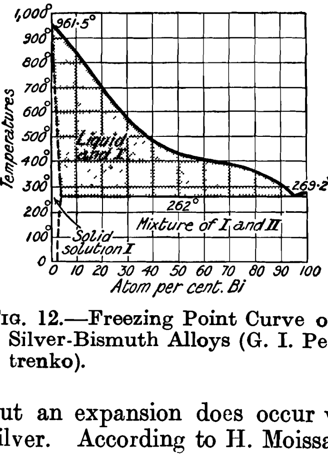

FIG. 12.—Freezing Point Curve of Silver-Bismuth Alloys (G. I. Petrenko).

In 1835, J. L. Gay Lussac [22] stated with respect to the action of **carbon** on silver:

> I have sought to detect the presence of mercury in silver, by heating in a small crucible in a muffle, a gram of it with lamp-black in order to avoid the vaporization of the silver; but I have been deceived in my attempt; after heating the mixture for 45 mins., the weight of the silver had sensibly increased—in one experiment the excess of weight had risen to more than 3 per cent.

There are several possible explanations of the increase in weight—*e.g.* the increase may have been due to the sulphur not uncommonly present in the lamp-black of commerce. J. Percy has shown that there is, indeed, not the least ground for here suspecting that silver can take up the smallest quantity of carbon under the circumstances. O. Ruff and B. Bergdahl found that molten silver dissolves a little carbon. M. Berthelot, and B. Reinitzer and H. Goldschmidt could detect very little evidence of a reaction between silver and **carbon monoxide**; when heated in a sealed tube, carbon monoxide was found by M. Berthelot to begin to react at 300°, some carbon is formed, and carbon dioxide is produced. M. Berthelot did not find any signs of the combination of **cyanogen** with silver at any observed temp. For the solvent action of soln. of the **alkali cyanides** on silver, *vide* gold. In conformity with others' observations, A. Brochet and J. Petit found silver is attacked by potassium cyanide soln. in the presence of air. According to A. Hébert, the **organic acids,** in general, have no action on silver, and, in accord with this, M. C. Lea found that **acetic acid** does not act on finely-divided silver, but if hydrogen peroxide be also present, E. Salkowsky found that the metal is attacked by the acid. O. P. Watts and N. D. Whipple also studied the action of acetic acid on silver. Silver was found by M. le Blanc and E. Plaschke,[23] and S. Foden to be not so active a catalytic agent as copper in the oxidation of, say, methyl alcohol vapour to formaldehyde. Silver is used with hydrogen for the reduction of nitro-compounds to the amines; and for the dechlorinization of certain organic compounds.

J. J. Berzelius stated that it is easy for a small proportion of **silicon** to unite with silver, when heated strongly in a crucible; and when the malleable button of alloy is digested with nitric acid, the silver dissolves leaving a residue of silica. J. Percy and C. Winkler did obtain a grey, brittle alloy, the former by fusing silver with sodium and potassium fluosilicates, and the latter by fusing a mixture of silica and silver under cryolite. H. Moissan found silicon readily dissolves in fused silver, and a part separates out in a crystalline state before freezing—*vide* silicon. H. Moissan and F. Siemens measured the solubility of silicon in silver at different temp. The results of G. Arrivaut's thermal study of the silicon-silver alloys is shown in Fig. 13. There are no compounds here revealed, and this agrees with J. Percy's observations. H. N. Warren, and G. J. L. de Chalmot alloyed the two elements, and F. Wöhler thought a compound was precipitated along with silver when silicon hydride is passed into a soln. of silver nitrate. E. Vigouroux noticed that when pulverulent silver is heated in the vapour of **silicon tetrachloride,** silver chloride is formed, but the silicon does not unite with the silver. H. Moissan found that when silver is fused at the high temp. of an electric furnace it dissolves **boron;** and also **boron carbide** which separates in crystals as the soln. cools. J. J. Berzelius says that a **borax** bead with a silver salt in an oxidizing flame becomes opalescent or milk-colour, and in the reducing flame, grey owing to the reduction of the silver. According to V. Kohlschütter, when the borax bead is heated and removed from the flame, it is at first clear, the characteristic coloration appearing suddenly during the cooling. J. Donau, however, obtained borax bead coloured yellow by dissolved silver. It is well known, too, that certain compounds of silver impart a yellow colour to **glass** when the two are heated in contact. R. Wynn and others have studied the coloration of glass by silver. According to E. Warburg's theory, the quantity of silver which diffuses in glass is proportional to the product of the sq. root of the time, the conductivity of the glass and the absolute temp. G. Schulze found this applied with molten silver chloride or bromide. J. S. Stas thought a yellow silver silicate was formed, but, as J. C. M. Garnett showed, the coloration is more probably due to the diffusion of extremely finely-divided metallic silver in the glass, just as the ruby-red colour of glass is due to finely-divided gold, and red colour of the Chinese rouge flambé glazes is probably due to finely-divided copper—*vide* colloidal copper, silver, and gold. The adsorption of silver ions from soln. of **silver sulphate or nitrate** by silver has been studied by H. von Euler.

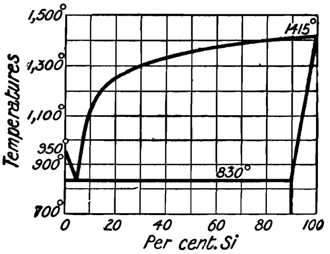

FIG. 13.—Fusion Curves of Alloys of Silver and Silicon.

According to M. C. Lea,[24] silver dissolves but slowly in a dil. soln. of **potassium permanganate.** W. Foster, and H. B. Giles have shown that a neutral soln. of potassium permanganate is reduced by silver. R. Kremann and F. Noss found a soln. of **chromic nitrate,** $Cr(NO_3)_3$, dissolves silver in the cell $Ag|Cr(NO_3)_3|C$, and this the more the higher the temp.; as the soln. approaches saturation, some nitrogen oxides are given off. According to J. M. Eder, a cold soln. of **potassium ferricyanide** forms silver and potassium ferricyanide when treated with silver; G. McP. Smith found that a boiling soln. gives a dark green precipitate, and some of the silver forms the double cyanide, $KAgCy_2$. O. Ruff and A. Heinzelmann found warm silver is slightly attacked by **uranium hexafluoride,** UF_6; and O. Ruff and F. W. Tschirch, that **osmium octofluoride,** OsU_8, forms silver fluoride, osmium, and a lower osmium fluoride. Silver readily alloys with the **metals,** and the silver alloys are discussed along with those of copper and gold. The alkali hydroxides can be fused in silver crucibles. According to W. Dittmar and D. Prentice,[25] the attack is more vigorous if the fusion be made in air than if air is excluded; and more vigorous with potassium hydroxide than with sodium hydroxide. W. L. Dudley found that molten **sodium peroxide** also rapidly attacks silver, and the grey product contains monoclinic prismatic crystals; it appears to be a mixture of silver with about 25 per cent. of silver oxide. N. N. Beketoff also found that a black body, thought to be *potassium argentate*, KOAg, is formed when **potassium tetroxide** is fused on a silver crucible. It is probably a mixture of silver and silver oxide. Silver is also stated to be less attacked than platinum when fused with **potassium nitrate** or hydroxide in air. A. Chodnew found that **potassium hydroxide** is coloured yellow when heated 10 mins. in a silver crucible, and when extracted with water there remains a black mixture of silver and silver oxide. O. P. Watts and N. D. Whipple studied the action of soln. of sodium hydroxide and of various salts on silver.

W. A. Lampadius heated a mixture of equal parts of silver and **barium oxide** with 10 per cent. of carbon and obtained a metal which disintegrated in air to silver and barium oxide. According to C. E. Wait, if silver be mixed with **manganese, barium,** or **lead dioxide,** or **lead monoxide,** and heated in an oxidizing atm. in a muffle, up to about 36 per cent. of the silver is oxidized to Ag_2O; on the other hand, no oxidation occurs with bismuth, zinc, calcium, or cupric oxides.

Reactions of analytical interest.—An aq. soln. of silver nitrate is (*q.v.*) generally taken to represent the behaviour of soln. of silver salts. This soln. gives a brown precipitate of silver oxide, Ag_2O, when treated with **potassium hydroxide.** The same result is obtained with sodium hydroxide. The precipitate is insoluble in excess of the precipitant, but is readily soluble in nitric acid and in aq. ammonia. If a dil. soln. of silver nitrate contains dextrine, gum arabic, cane sugar, starch, or the like, the brown oxide remains in suspension so that the intensity of the coloration is proportional to the amount of silver in soln. Hence, G. S. Whitby [26] utilized the reaction for the colorimetric determination of the metal. The colour is so sensitive that in 50 c.c. of soln. one part of silver can be detected in 25,000,000 parts of soln. T. G. Wormley detected one part of silver in 125,000 of liquid by the sodium hydroxide reaction, and F. Jackson, 1 in 8000. P. Jolibois, R. Bossuet, and M. Chevry found that with a mixed soln. of copper and silver nitrates, sodium hydroxide first precipitates the whole of the copper as cupric hydroxide before any of the silver is precipitated as silver hydroxide.

When aq. **ammonia** is gradually added drop by drop to a neutral soln. of silver nitrate, the first few drops give a white precipitate, which quickly changes to the brown oxide, Ag_2O. Most of the silver, however, remains in the soln. as silver ammino-nitrate, $Ag(NH_3)_nNO_3$, and the oxide is itself dissolved as silver ammino-hydroxide, $Ag(NO_3)_nOH$, by an excess of ammonia. According to F. Jackson, the ammonia reaction will detect one part of silver in 800 of liquid. White silver carbonate is precipitated when **sodium carbonate** is added to a soln. of a silver salt, the precipitate becomes yellow if boiled with the mother liquid, owing to a slight decomposition of the carbonate into oxide: $Ag_2CO_3 \rightarrow Ag_2O + CO_2$. F. Jackson found the reaction to be sensitive to one part of silver in 32,000 of liquid. The same precipitate is produced with **ammonium carbonate,** but it is soluble in excess of the precipitant. **Hydrochloric acid** or aq. soln. of the chlorides precipitate silver chloride from aq. soln. of the silver salts—excepting the thiosulphate. The precipitate is curdy from conc. soln., but from very dil. soln. it shows itself as a white or bluish-white opalescence. According to G. J. Mulder, the opalescence appears with one part of silver in 1,000,000 parts of liquid; P. Harting gives 1 in 378,000; C. H. Pfaff gives 1 in 189,000; and F. Jackson, 1 in 64,000 when hydrochloric acid of sp. gr. 1·035 is used for the test, and 1 in 32,000 when a soln. of sodium chloride (1·20) is employed. According to J. L. Lassaigne, a soln. containing one of one part of silver in 200,000 parts of liquid gives a very slight turbidity with hydrochloric acid or sodium chloride; with one in 400,000 soln. the opalescence is scarcely perceptible; and with one in 800,000 the opalescence appears in about 15 mins. The precipitated chloride is almost insoluble in nitric acid; it is slightly soluble in hydrochloric acid or in soln. of the alkali chlorides; it is readily soluble in aq. ammonia, and the chloride is re-precipitated when the ammoniacal soln. is neutralized with acid; it is readily soluble in a soln. of potassium cyanide; and, in the absence of an acid, it is readily soluble in a soln. of sodium thiosulphate, and the soln. when boiled does not precipitate silver sulphide. Potassium iodide gives a yellow curdy precipitate of silver iodide which is but sparingly soluble in ammonia, but readily soluble in soln. of potassium cyanide or sodium thiosulphate. According to P. Harting, one part of silver can be detected by the potassium iodide reaction in 47,250 parts of liquid, and F. Jackson gives one in 8000. J. S. Stas detected one part of silver as bromide when in 5,000,000 parts of water; and by suitably arranging the light, T. W. Richards detected one part of silver chloride in 30,000,000 parts of water. W. Böttger detected 0·00012 mgrm. of silver as chloride; and H. Behrens, 0·0001 mgrm. The solubilities of silver bromide, and iodide are respectively $0·3\times10^{-6}$, and $1·5\times10^{-3}$ grm. per litre; and the sensitivenesses are respectively $0·3\times10^{-6}$, and $0·34\times10^{-6}$. W. Biltz detected 0·0042 mgrm. of silver ultramicroscopically as chloride, and 0·00036 mgrm. as bromide. M. Gorsky obtained the Tyndall effect with 0·0002 mgrm. of silver bromide using an eq. of potassium bromide, and 0·00014 mgrm. with an excess of that salt; with 0·0001 mgrm. of silver iodide using an eq. of potassium iodide; and 0·00007 mgrm. with an excess of that salt.

The precipitation of grey metallic silver by boiling a mixed soln. of **ferrous sulphate** and silver nitrate has already been discussed; so also has the precipitation of silver from neutral soln. by means of **zinc.** Neutral, acid, or ammoniacal soln. of silver salts give a precipitate of black silver sulphide when treated with **hydrogen sulphide.** According to F. Jackson, the reaction is sensitive to one part of silver in 64,000 of soln. The precipitate is insoluble in aq. ammonia, alkali sulphides, or dil. potassium cyanide soln., but it is appreciably soluble in a conc. soln. of potassium cyanide, so that if a considerable amount of the last-named salt be present, hydrogen sulphide may give no precipitate at first, but with an excess of hydrogen sulphide a precipitate of silver sulphide is gradually formed. Black silver sulphide is readily soluble in a hot dil. soln. of nitric acid with the separation of sulphur, and the formation of silver nitrate. A reddish-brown precipitate of silver dichromate is obtained by adding a soln. of **potassium dichromate** to one of silver nitrate. The precipitate is soluble in ammonia; the same remarks apply to the brownish-red precipitate of silver chromate which is formed by adding a soln. of **potassium chromate** to one of silver nitrate. According to F. Jackson, this reaction is sensitive to one part of silver in 8000 parts of soln. Neutral soln. of silver salts give a yellow precipitate of silver phosphate when treated with **sodium phosphate:** $3AgNO_3+2Na_2HPO_4=3NaNO_3+NaH_2PO_4+Ag_3PO_4$. F. Jackson says the reaction is sensitive to one part of silver in 8000 of liquid. The precipitate is soluble in nitric acid and aq. ammonia. The phosphate is reprecipitated if the ammoniacal soln. be neutralized with acid. **Potassium arsenite** gives an egg-yellow precipitate, which P. Harting found to be perceptible with one part of silver in 6000 parts of liquid, and to reach its limits with 1 in 20,000. **Oxalic acid** precipitates a white pulverulent silver oxalate; **potassium thiocyanate,** white silver thiocyanate; **potassium ferrocyanide,** white silver ferrocyanide; **potassium ferricyanide,** reddish-brown silver ferricyanide; and **potassium iodate** or **potassium bromate,** respectively white silver iodate or bromate. **Hydrocyanic acid** or **potassium cyanide** precipitates white silver cyanide which is curdy in conc. soln., C. W. Scheele, its discoverer, said that it had the consistency of cheese; it dissolves in an excess of potassium cyanide.

The uses of silver.—The word *silver* not only refers to the pure unalloyed metal, but to the alloy of silver with one-half, one-third, or other proportional parts of copper.[27] The term *silver bullion* is applied to ingots and bars generally to silver in bulk, as distinguished from silver coin or plate. Silver with appreciable amounts of gold is called *doré silver.* The so-called *refined silver* usually contains from 99·75 to 99·9 per cent. of silver. Silver of a still higher degree of purity is called *fine silver.* Gold and silver are much used for ornaments, jewellery, coinage, etc. Fine silver is too soft to be sufficiently durable for coinage, and many other purposes; the pure metal is therefore alloyed with other hardening metals—usually copper. British coinage is very nearly 925 fine and contains 92·5 per cent. of silver, and 7·5 per cent. of another metal which is nearly always copper. This is the *standard silver* or *sterling silver* required by law for coinage and silver plate, so that sterling silver is 925 fine. This peculiar standard originated with the particular system of weights in use in the sixteenth century. From very early times, the fineness of silver coinage has been measured in terms of the division of the troy pound:

Pound.	Ounces.	Pennyweights (dwts.).	Grains.
1	12	240	5760
	1	20	480
		1	24

Consequently the so-called *standard* of sterling silver is 11 ozs. 2 dwts. or 5328 grains of silver, and 18 dwts. or 432 grains of the other metal. The English term standard is equivalent to the French *titre,* excepting that in France the unit of weight is the kgrm. or 1000 grms. British coin in France thus has the *titre* or standard 925. The chemist regards standard silver as an alloy of silver and copper; the bullion-dealer or assayer says that it is silver containing 18 dwts. of *alloy* per lb. troy. There are thus two meanings to the word alloy. The term *base metal* is also used synonymously with alloy when used in the last-named sense. S. Johnson, in his *Dictionary of the English Language* (London, 1805), said that "alloy or allay is derived by some from *à la loi,* according to law; by others from *allier,* to unite; perhaps from *allocare,* to put together."

Standard silver 925 fine was established for British silver coinage in the reign of Henry II., and it has so remained for 600 years, excepting a period of 20 years—from the end of the reign of Henry VIII. to the beginning of the reign of Elizabeth—when it was more or less debased. In the early accounts the standard of fineness is spoken of as the "old standard of England" or the "Easterling allay." The inhabitants of Eastern Germany in the twelfth and thirteenth centuries were called Easterlings, and their money was famous for its purity, and Henry II. imported some Easterling coiners to improve the quality of the debased British currency. Hence, said J. Stow,[28] "The money of England was called of the workers thereof, and so the Easterling pence took their name of the Easterlings, which did first make this money in England in the reign of Henry II." Hence arose the term *sterling* applied to the gold and silver.

A second legal standard introduced in 1696 allows 11 ozs. 10 dwts. of silver per pound troy, or 958·3 per thousand, but the alloy is seldom used because it is so much softer than sterling silver. It is known as *Britannia silver* because that stamped at Birmingham and Sheffield had a stamp with the figure of a woman commonly known as Britannia, instead of the lion passant stamp used for sterling silver. The same alloy stamped elsewhere had a stamp with a lion's head erased (*i.e.* without the body). The stamp includes also the initials of the maker; the heraldic representation of the assay office, and the year of assay by a letter which is changed every year. The payment of duty is represented by the Sovereign's head.[29] Most other countries use silver 900-fine for coinage, and foreign plate is usually 800 to 950 fine. The American dollar has 90 per cent. of silver. According to L. J. Chaudet,[30] the silver coin of France has 97 to 103 parts of copper in 1000 parts. The composition of the coins of the world is discussed in J. C. Nelkenbrecher's *Allgemeines Taschenbuch* (Berlin, 1858). J. A. Phillips found 5 to 8 per cent. of silver in some old Roman coins dated Claudius Sothicus, A.D. 268; and another Tacitus, A.D. 275. Silver ornaments made from standard silver can be heated in air to oxidize the copper near the surface of the metal, the resulting copper oxide is removed by digestion with sulphuric acid leaving a superficial layer of silver. The effect so produced is called *frosted silver.*

Objects made of base metals or their alloys—copper, brass, German silver, etc. —can be silvered or gilded to give them the appearance of having been made of the more precious metal. If the coating of precious metal be thin, they are said to be *silvered* or *gilded;* and if thick, *gold-plated* or *silver-plated.* Many small articles can be silvered directly by a simple immersion in a warm soln. of silver chloride in sodium sulphite, sodium thiosulphate, cream of tartar, etc. Glass can be silvered by precipitating the silver while the vessel is immersed in an alkaline soln. of silver in the presence of a suitable reducing agent—milk-sugar,[31] formaldehyde, etc.

V. Kohlschütter and T. Toropoff [32] obtained *black silver* by the action of organic reducing agents on silver soln., by the action of zinc, copper, and cadmium on dil. soln. of silver salts; and electrolytically from dil. soln. by the use of comparatively high current densities. Black silver is considered to be silver in a condition between the colloidal and the crystalline states, for it appears crystalline microscopically, but it behaves as a colloid towards electrolytes. Black silver cannot be preserved, for it speedily changes into grey or white crystalline silver. If the current be stopped during its preparation by electrolysis, it begins to pass over into grey crystalline silver, as evidenced by the change in colour, and the apparent shrinkage of the mass. However, no real volume change occurs in the passage from coherent massive silver, to silver black, and then to grey crystalline silver. The formation of black silver is attributed to the lack of crystal centres, so that each discharged ion finds itself more or less isolated, and consequently deposits as such, and does not attach itself to a crystal centre with the formation of the grey, crystalline silver. The sudden change to grey silver on breaking the current is explained as an electro-surface tension phenomenon. The black silver with very large surface takes up the form of smallest surface on stopping the current, but while the current is flowing and it is negatively polarized the electrostatic repulsions of the charged particles overcome the tendency to a surface diminution.

The silvering of glass mirrors.—Add ammonia drop by drop to a beaker containing a soln. of 5 grms. of silver nitrate in 9 c.c. of distilled water until the precipitate just redissolves; make the soln. up to 125 c.c. with distilled water; pour this soln. into a beaker containing 5 c.c. of a 4 per cent. soln. of formalin; and at once pour the mixture into a dish containing the glass to be silvered; and rock the dish up and down for about two minutes, when the silvering should be complete. If a muddy deposit is formed, insufficient formalin has been added; and if the process takes place too quickly, too much formalin was used. It is of the greatest importance that the glass to be silvered be scrupulously cleaned, say, by rinsing it first with a sulphuric acid soln. of potassium bichromate, then with water under a tap, and then with distilled water. Dry the glass by rubbing it with a clean linen cloth, and finally rub it with a little absolute alcohol, and soft linen handkerchief. The silvered mirror is rinsed with tap water, and then with distilled water. When dry, polish the mirror with a little of finest rouge on a very soft chamois leather pad.

According to V. Kohlschütter, the film on silvered mirrors is colloidal and amorphous, and it gradually passes into normal silver. L. Hamburger has studied the properties of thin metal films deposited under different conditions. V. Kohlschütter and co-workers have also studied the effect of various conditions on the form of precipitated silver. A. Silvermann and R. M. Howe studied the conditions for the production of silver mirrors.

In *silver plating* a plate of silver is laid on the smooth clean surface of a copper ingot, and the two metals are bound together with wire. A sat. soln. of borax is painted round the edges so that when the compounded metals are heated the borax will melt, and prevent access of air to the surface of the copper, since a film of copper oxide between the silver and the copper would prevent their adhesion. The two metals are sweated together by hammering or rolling just below the m.p. of silver. The compound mass is finely rolled until it has the desired thickness.[33] *Gold plating* is done in a similar manner. The *electroplating of silver* was discovered in 1840 by J. Wright, O. W. Barrett, and A. Parkes—*vide* copper. J. Wright soon afterwards developed a process in which a soln. of silver cyanide in potassium cyanide was used as electrolyte; and he obtained a thick coherent deposit of silver. This process was patented by G. R. and H. W. Elkington. To make the cyanide electrolyte: dissolve 10·75 grms. of silver nitrate in water, and carefully add a soln. of potassium cyanide so long as a precipitate forms—avoid an excess of the cyanide soln. Wash the precipitate by decantation, and add enough potassium cyanide soln. to dissolve the precipitate, and dilute the soln. to 500 c.c. The object to be silvered is connected with the cathode, and a silver plate is used as anode. For *electroplating gold* a similar process is employed, substituting gold in place of silver.

§ 8. The Atomic Weight and Valency of Silver

According to H. E. Roscoe and A. Harden,[1] in a notebook dated March, 1804, J. Dalton wrote 150 for the at. wt. of silver when that of oxygen is 5·5, and, later, in his *A New System of Chemical Philosophy* (Manchester, **2**. 352, 1810), he gave 100 for the at. wt. if oxygen be 7; if oxygen be 16, Dalton's number becomes virtually 228. In 1817, J. J. G. Meinecke estimated the at. wt. to be 108; and in 1826, L. Gmelin estimated the eq. wt. to have the same numerical value. J. J. Berzelius first adopted a value approximately four times that employed to-day, and later used half his former value, by making the at. wt. of silver 215·94 or 2×107·97—

with oxygen 16. Assuming as is done to-day that the at. wt. of silver approximates to 108, silver is univalent in the halides; possibly bivalent in the peroxide, Ag_2O_2, or AgO; and possibly tervalent in the perhalides, AgI_3. The at. wt. approximating 108, is in harmony with Avogadro's hypothesis; with Dulong and Petit's rule; with Mitscherlich's rule; and with Mendeléeff's periodic law—*vide* copper.

H. von Wartenberg found the mol. wt. of silver vapour, calculated from vapour density determinations, to be between 107 and 111. The highest value obtained was 145. This leaves little room for doubting that the mol. of silver vapour is monatomic. J. Wislicenus showed that white silver generally behaves as a univalent element, the alleged existence of the suboxide and of the subsalts of this element shows that there is a possibility that silver may act as a bivalent element. M. Traube assumed that silver is bivalent, and wrote silver chloride, Cl.Ag.Ag.Cl, *i.e.* Ag_2Cl_2. G. A. Barbieri supposed silver to be bivalent in the pernitrate, and in the pyridine complex with silver persulphate, $AgS_2O_8.4C_5H_5N$, as well as in the mixed crystals of this salt with cupric persulphate. R. Luther and F. Pokorny, and G. A. Barbieri, assumed that silver may also exist as a tervalent element, for example, in the sesquioxide, Ag_2O_3, and that it is bivalent in the dioxide, Ag_2O_2. E. Bose and K. Jellinek also believe in the existence of a bivalent silver.

A number of ratios involving various salts containing silver, chlorine, bromine, iodine, sodium, or potassium have been employed to furnish fundamental values for the at. wt. of these elements. The at. wt. of oxygen arbitrarily selected as 16 is the primary standard for the modern table of at. wt., and the relation of the at. wt. of silver to that of oxygen is one of the most important of the secondary standards, since only a few at. wt. can be conveniently related directly with the at. wt. of oxygen, while many are related with that of silver either directly, or through silver with that of chlorine, bromine, or iodine. Consequently, the determination of the at. wt. of silver is of special importance. The at. wt. of silver is not conveniently determined directly from the Ag : O ratio in silver oxide. A less direct relation between silver and oxygen is obtained by the analysis of the chlorates, bromates, and iodates, for the ratio RX : 3O, and when the ratio Ag : RX is known, there follows Ag : 3O. The transformation of, say, potassium chlorate into chloride is susceptible to so many sources of error, that it was a long time before the reaction could be manipulated to furnish values of an acceptable degree of precision. Better results have been obtained by the synthesis of silver nitrate from silver for the ratio: Ag : NO_3, since the relation of nitrogen to the primary standard, oxygen, has been directly determined with a high degree of precision. The subject has been discussed by L. Meyer and K. Seubert, F. W. Clarke, J. D. van der Plaats, B. Brauner, etc. P. A. Guye, and G. P. Baxter and L. W. Parsons have discussed the effect of errors due to the presence of occluded gases and an adherent pellicle of moisture on the at. wt. of silver; G. P. Baxter discussed the effect of solid impurities on the at. wt. determination.

Determination of the silver nitrate ratio.—F. Penny dissolved silver in nitric acid, evaporated the soln. to dryness, and weighed the product. He found for the ratio Ag : $AgNO_3$=100 : 157·4417; J. C. G. de Marignac obtained 100 : 157·4236; J. S. Stas obtained in three series of experiments numbers ranging from 100 : 157·474 to 100 : 157·486; and T. W. Richards and G. S. Forbes, 100 : 157·479. E. Turner and F. Penny measured the ratio $AgNO_3$: AgCl, and the former found 100 : 84·373, and the latter 100 : 84·3744. J. C. G. de Marignac found the ratio $AgNO_3$: KCl to be 100 : 43·858; and J. S. Stas, between 100 : 43·8697 and 100 : 43·8823.

The determination of the silver halide ratio.—Analyses of silver chloride were made by C. F. Wenzel, C. F. Bucholz, H. Davy, etc. Between 1811 and 1826, J. J. Berzelius synthesized silver chloride by dissolving silver in nitric acid, and precipitating silver chloride from the soln.; he obtained 83·7 per cent. of silver oxide and 18·7 per cent. of hydrochloric acid; and later 80·9034 and 19·0966. From his data involving two syntheses of silver chloride he got Ag : Cl =100 : 32·757; E. Turner repeated Berzelius' work and obtained 100 : 32·832;

F. Penny, 100 : 32·8363 ; and J. C. G. de Marignac, 100 : 32·839. In these experiments silver chloride was synthesized ; L. Maumené (1846) reduced silver chloride in hydrogen and obtained the ratio 100 : 32·7364. J. B. A. Dumas synthesized silver chloride and found 100 : 32·8755 ; and J. S. Stas synthesized silver chloride directly by heating silver in chlorine ; by passing hydrogen chloride into a soln. of silver nitrate ; and by adding hydrochloric acid to a soln. of silver nitrate he found 100 : 32·8445. T. W. Richards and R. C. Wells found J. S. Stas' result to be affected by errors due to the occlusion of oxygen and possibly also alkalies ; and they found that glass vessels were attacked by the soln. and changed in weight by the acids used in the operations. Hence, T. W. Richards and R. C. Wells worked in porcelain and quartz vessels, and, eliminating the occlusion errors, found the ratio Ag : Cl=100 : 32·8668.

The earlier analyses of silver bromide by A. J. Balard, J. von Leibig, J. J. Berzelius, and C. Löwig were made on preparations contaminated with chlorine ; and W. Wallace's specimens were contaminated with arsenic. J. C. G. de Marignac purified his bromine free from chlorine, precipitated silver bromide from a soln. of silver nitrate by potassium bromide, and obtained for the ratio Ag : Br=100 : 74·077 ; J. S. Stas precipitated silver bromide from a soln. of the sulphate and of the nitrate by hydrobromic acid. He obtained the ratio 100 : 74·084 ; O. W. Huntington analyzed silver bromide and found 100 : 74·071 ; T. W. Richards synthesized silver bromide and found 100 : 74·065 ; G. P. Baxter precipitated silver bromide from the nitrate with ammonium bromide, and fused the product in bromine vapour ; he found for the ratio Ag : Br, 100 : 74·0786. B. Brauner showed that some of J. S. Stas' processes resulted in his samples being contaminated with bromoform ; this made his results a little too high.

J. C. G. de Marignac precipitated silver iodide from a soln. of silver nitrate by means of potassium iodide and obtained for the ratio Ag : I, 100 : 117·5335 ; J. S. Stas precipitated the iodide with hydriodic acid, and synthesized silver iodide from known weights of iodine and silver ; he obtained 100 : 117·5344. J. C. G. de Marignac's and J. S. Stas' values of this ratio were based on a value for iodine which A. Ladenburg showed was about one-tenth of a unit too low ; and he obtained for the ratio Ag : I=100 : 117·552. A. Scott also obtained 100 : 117·6421 (vacuum weighings). P. Köthner and E. Aeuer avoided the error due to the occlusion of silver nitrate by silver iodide, when precipitated by adding hydriodic acid to a soln. of the nitrate ; they also synthesized the iodide by the action of iodine vapour on silver. The mean of the two sets is Ag : I=100 : 117·6413. G. P. Baxter precipitated silver iodide, from a soln. of the metal in nitric acid, by means of ammonium iodide in the presence of an excess of ammonia ; he found values for the ratio Ag : I varying from 100 : 117·6314 to 100 : 117·6585. G. Gallo obtained for this ratio 100 : 117·5770.

J. C. G. de Marignac measured the ratio Ag : KCl and found 100 : 69·062 (weighings in air). Between 1860 and 1882, J. S. Stas also made many series of determinations of this magnitude, and his values ranged from 100 : 69·1033 to 100 : 69·1230. T. W. Richards and E. H. Archibald found 100 : 69·1138 ; E. H. Archibald, 100 : 69·114 ; and T. W. Richards and A. Staehler, 100 : 69·1073. J. C. G. de Marignac found the ratio Ag : KBr to be 100 : 110·343 ; and Ag : KI, 100 : 153·6994. J. S. Stas found for Ag : KBr, 100 : 110·3463 ; G. Dean, 100 : 110·313 ; and T. W. Richards and E. Mueller, 100 : 110·3190.

T. J. Pelouze found for the ratio Ag : NaCl, 100 : 54·141 ; J. B. A. Dumas, 100 : 54·172 ; J. S. Stas, 100 : 54·2078 and 100 : 54·20625 ; and T. W. Richards and R. C. Wells, 100 : 54·1854. J. S. Stas also found for the ratio Ag : NaBr, 100 : 95·4383 to 100 : 95·4426 ; and with a correction for the presence of silica in the alkali bromide, 100 : 95·4376.

The methods employed for determining the ratios Ag : NH_4Cl and Ag : NH_4Br are similar to those employed for the corresponding ratio with sodium and potassium halides. J. T. Pelouze found for Ag : NH_4Cl, 100 : 49·5365 ; J. C. G. de Marignac, 100 : 49·523 ; and A. Scott, 100 : 37·3234 ; J. S. Stas' values ranged from 100 : 49·589 to 100 : 49·597. For the ratio NH_4Cl : AgCl, T. W. Richards, P. Köthner, and E. Tiede found 100 : 37·3217 0 ; and A. Scott, 100 : 37·3218. For the ratio Ag : NH_4Br, J. S. Stas obtained 100 : 90·8297 ; and A. Scott, 100 : 90·7944. J. J. Berzelius obtained for the ratio Ag : KCl, 100 : 51·997 ; J. C. G. de Marignac, 100 : 52·011 ; L. Maumemé, 100 : 51·878 ; T. W. Richards, and E. H. Archibald, 100 : 52·0215 ; A. Thiel, 100 : 51·999 ; E. H. Archibald, 100 : 52·024 ; and T. W. Richards and A. Staehler, 100 : 52·0118. V. Rose first determined the ratio AgCl : NaCl, and J. J. Berzelius found Ag : NaCl=100 : 40·883 ; W. Ramsay and E. Aston, 100 : 40·867 ; and T. W. Richards and R. C. Wells, 100 : 40·7797.

J. B. A. Dumas determined the ratio AgCl : AgBr to be 100 : 131·030, while G. P. Baxter found 100 : 131·0173. Similarly J. J. Berzelius found for the ratio AgCl : AgI, 100 : 163·326 ; J. B. A. Dumas, 100 : 163·733 ; A. Ladenburg, 100 : 163·8257 ; P. Köthner, and E. Aeuer, 100 : 163·8070 ; and G. P. Baxter, 100 : 163·8131.

There are many other determinations in which a chloride has been balanced against silver, and the silver halide produced, weighed. These results were obtained in the determination of the at. wt. of other elements. Thus, V. Lenher converted silver selenite into silver chloride, and reduced the latter to the metal by heating in hydrogen ; W. C. Ebaugh obtained similar results with silver arsenate ; T. W. Richards and E. H. Archibald, with cæsium chloride ; E. H. Archibald, rubidium chloride ; G. P. Baxter and F. B. Coffin, cobalt chloride ; G. P. Baxter and M. A. Hines, manganese chloride ; and G. P. Baxter and J. H. Wilson, with lead chloride. In another set of determinations the ratios RCl : Ag and RCl : AgCl (or the corresponding bromide) have been measured, and this permits a calculation of the ratio Ag : Cl. T. E. Thorpe's determination of the at. wt. of titanium ; T. E. Richards, barium ; T. W. Richards and H. G. Parker, magnesium ; G. P. Baxter, M. A. Hines, and H. L. Frevert, cadmium ; E. H. Archibald, platinum ; T. W. Richards and H. H. Willard, lithium ; T. E. Thorpe and A. G. Francis, strontium ; T. E. Thorpe and A. P. Laurie, gold ; T. W. Richards and A. S. Cushman, nickel ; T. W. Richards and G. P. Baxter, cobalt ; T. W. Richards and B. S. Merigold, uranium ; J. P. Cooke, antimony ; T. W. Richards and E. F. Rogers, zinc ; G. P. Baxter and A. Thiel, indium ; etc.

Determination of the chlorate, bromate, or iodate ratio.—From analyses of silver chlorate, J. C. G. de Marignac obtained for the ratio AgCl : 3O, 74·912 : 25·088 ; S. Stas, 74·920 : 25·180. J. S. Stas' analyses of silver bromate gave for the ratio AgBr : 3O, 79·651 : 20·349. Analyses of silver iodate made by N. A. E. Millon furnished the ratio AgI : 3O=82·953 ; 17·047 and J. S. Stas found 83·0253 : 16·9747. G. P. Baxter and G. S. Tilley found the ratio between iodine pentoxide and silver to be I_2O_5 : Ag=100 : 64·2229. The relations between silver and various compounds of carbon—organic acids, etc.—and between various sulphur or oxy-sulphur salts of silver—sulphide, sulphate, etc.—have been determined in connection with the at. wt. of carbon and sulphur. Similar remarks apply to many other elements.

The general result of the older determinations gave the value 107·93 for the at. wt. of silver. The determinations of J. S Stas furnished the same value 107·93, and W. Ostwald obtained from Stas' results 107·9376 with a probable error ±0·0037. The deviations from the mean were in general smaller than the probable error calculated from the individual determinations, and consequently he inferred that " none of the five methods employed by J. S. Stas had a constant error." On the mathematical side, the calculation neglected to provide for facts which chemists subsequently found to invalidate the conclusion. As a result, J. S. Stas' value is now regarded as being too high, and what is assumed to be the best representative value is rather less, *viz.* 107·883, when that of oxygen is 16. F. W. Clarke obtained 107·88±0·00029 as the best representative value calculated from twenty-nine values deducted from seventy-five different sets of determinations. The minimum was 107·666±0·029, and the maximum 108·094±0·0540. The modern value for the at. wt. is in close accord with 107·883 obtained by T. W. Richards and G. S. Forbes from the analysis of silver nitrate, and the result is but slightly affected by the small uncertainty in the at. wt. of nitrogen. The International Table for Atomic Weights for 1920 gives 107·88. The **atomic number** of silver is 47.

The electrochemical equivalent of silver.—Special attention has been paid[2] to the electrochemical eq. of silver because this method affords special facilities for an accurate determination, and for testing Faraday's law, "the quantity of a given metal deposited in an electrolytic cell, or dissolved in a battery cell when there is no local action, depends on the quantity of electricity that passes, and is independent of the time." The value for silver is taken as a basis for calculating the electrochemical eq. of many of the other elements. The reported numbers for the amount of silver deposited per sec. per ampère range from T. W. Richards, E. Collins, and G. W. Heimrod's 1·1172 mgrms. to H. Pellat and A. Potier's 1·1195 mgrms. The earlier determinations were often affected by errors due to the use of filter paper, and impurities—acid, alkali, colloidal matter, etc.—in the voltmeter. The best representative value of the older determinations is 1·1182 mgrms. per sec. per amp., and this makes the charge per ion to be 96540±10 coulombs; and for the more recent measurements, the best representative value is taken to be 1·1175 mgrms. per sec. per amp. This makes the eq. charge, per ion, to be 96580±10 coulombs. The method has also been applied to the determination of the amount of silver in a given quantity of a silver salt. Thus, W. L. Hardin dissolved silver in nitric acid, and the solid was evaporated, dried, and fused. The salt was then mixed with an excess of a soln. of potassium cyanide, and electrolyzed in a platinum dish. The results obtained gave for the ratio Ag : $AgNO_3$=100 : 157·484.

L. Naudin[3] reported some unpublished experiments by P. Schützenberger in which lead freed from silver was found to contain traces of silver after conversion to chloride by chlorine gas followed by reduction with hydrogen, and he claimed that repetitions of the experiment confirmed the result.

§ 9. Silver Suboxide, or Silver Quadrantoxide, or Silver Tetritoxide

The well-established oxides of silver are silver oxide or silver monoxide, Ag_2O; and silver peroxide, Ag_2O_2. Silver suboxide or quadrantoxide, Ag_4O, is not generally recognized, although there is a score of reports of its formation. Silver tritetratoxide, Ag_4O_3, and silver hemitrioxide or sesquioxide, Ag_2O_3, are largely based on reports by M. Berthelot, and are probably non-existent. When silver oxide is dissolved in aq. ammonia, and the pale brownish soln. is exposed to the air in an open vessel, a brilliant pellicle forms on its surface, which, when removed, is succeeded by another, and another, until most of the metal has been separated. This phenomenon was observed by C. L. Berthollet[1] in 1789, and he stated that its production is dependent on the abstraction of ammonia by the atm. M. Faraday analyzed the product, which is an oxide of silver, and said that "there is every reason to believe that its composition is eq. to that of silver monoxide, but containing about two-thirds the quantity of oxygen found in the common oxide," which makes its formula approximate Ag_3O. H. Vogel stated his belief that Faraday's oxide is a mixture of argentous and argentic oxides, and that the former resulted from the action of light. G. H. Bailey and G. J. Fowler repeated Faraday's experiment and obtained "suboctahedral masses of an iron-grey colour." It was always accompanied by a small quantity of fulminating silver which could not be separated, and by a yellow crystalline substance which appeared after exposing the first product to the air for some days. The analyses and properties agreed with the assumption that Faraday's suboxide is silver oxide modified by the presence of a small amount of fulminating silver.

In 1839, F. Wöhler[2] announced the formation of a silver suboxide having the composition, Ag_4O. He said that when silver oxalate, mellitate, or citrate is heated in a current of hydrogen to 100°, or thereabouts, mixtures of the free acid with yellow or brown sub-salts are formed, and half the oxygen is given off as water. He then extracted the free acid by washing the mixture with water until the runnings assumed a port wine-red colour; and found the residue in the case of silver citrate had a composition corresponding with that of silver subcitrate. When a soln. of the subcitrate is treated with potassium hydroxide, a black powder is obtained which he assumed without analysis to be a suboxide. From the repetition of F. Wöhler's experiments by S. B. Newbury, and of G. H. Bailey and G. J. Fowler, it appears (i) that considerable quantities of carbon dioxide are evolved during the preparation of the alleged sub-citrate owing to the decomposition of citric acid, so that the reaction is far more complex than F. Wöhler supposed; (ii) that the alleged subcitrate is not a chemical individual because when extracted with ether, it gives a tar-like mass containing much free citric acid; (iii) that the product is a complex mixture of itaconic and other organic acids, all reduction products of citric acid; (iv) that F. Wöhler interrupted the reduction of the citric acid at an arbitrarily selected stage where the less soluble products, by chance, happened to correspond with values approximating to the subcitrate; (v) that the port wine-red soln. of the alleged subcitrate is always turbid and grey by reflected light, and the coloration is due to finely divided silver and silver oxide. The conclusion is drawn that F. Wöhler's suboxide is "a mixture of metallic silver with silver oxide," probably, added W. Muthmann, in a more or less colloidal state.

F. Wöhler, and F. Rautenberg also concluded that a cold ammoniacal soln. of silver chromate, or a warm ammoniacal soln. of silver molybdate, or tungstate is reduced by hydrogen to the lower state of oxidation; but W. Muthmann has shown that it is more probable that the product of the reduction is rather a mixture of more or less colloidal silver with the ordinary silver salt. H. Rose[3] reported that a soln. of silver nitrate furnishes black silver suboxide when treated with an alkaline soln. of stannous chloride; but W. Pillitz showed that the precipitate is a mixture of silver and stannic hydroxide. R. Bunsen likewise obtained the alleged black silver suboxide by the action of an alkaline soln. of antimony trioxide on an ammoniacal soln. of silver nitrate, but W. Pillitz showed that the precipitate is a variable mixture of silver, silver oxide, and antimony. A. Sänger obtained what he regarded as silver suboxide by the action of phosphorous acid on silver nitrate in neutral or feeble ammoniacal soln. at ordinary temp.: $8AgNO_3+2H_3PO_3+H_2O+8NH_3=Ag_4O+Ag_4(PO_3)_2+8NH_4NO_3$. He added that the suboxide decomposes rapidly, particularly if the ammonia is in excess, or the soln. warm; the phosphite is then oxidized to phosphate. According to A. Sieverts, the reduction of ammoniacal soln. of silver salts, or of acidulated soln. of silver phosphate by phosphorous acid gives a black precipitate of silver, not silver suboxide. O. van der Pfordten, and C. F. Rammelsberg have studied this reaction. The former treated an alkali tartrate with silver nitrate and a little sodium hydroxide, and thought that a subsalt, probably subtartrate, is formed, which, with the further action of the alkali, gives a black precipitate of silver suboxide, and he later stated that the precipitate is silver subhydroxide—possibly Ag_4H_2O; but C. Friedheim showed that the precipitate is a mixture of silver, silver oxide, and organic impurities. M. Berthelot found that when pure silver foil is heated to 500° or 550° in dry air or in oxygen, or in a sealed tube, the metal loses its lustre and disintegrates to a yellowish-white powder assumed to be silver suboxide, Ag_4O. The action was said to begin at about 200°; and no such action is observed with steam, nitrogen, or carbon dioxide. He assumed that silver oxide, Ag_2O, was formed by the oxidation of silver, and that the loss in weight of the silver oxide was due to his sample containing moisture and carbon dioxide, or both, since it is quite difficult to keep silver oxide free from these impurities because they are both rapidly taken up from the air. Under the conditions of these experiments silver, silver oxide, silver suboxide, and oxygen could not all exist in the equilibrium. In the absence of the suboxide, the phase rule shows that equilibrium is possible between silver, silver oxide, and oxygen; while if silver oxide is present, the possible states of equilibrium are between oxygen and silver oxide and suboxide, and between silver suboxide, silver and oxygen. A. Guntz introduced enough potassium permanganate in a glass tube of known contents, to give at 358° a press. of 49 atm., and two side arms in the tube contained respectively silver and silver oxide. After heating three days at 358°, the silver oxide lost in weight 3·39 per cent.—theory for $4Ag_2O=2Ag_4O+O_2$ requires a loss of 3·44 per cent. The metallic silver gained in weight 3·88 per cent.—theory for $8Ag+O_2=2Ag_4O$ requires an increase of 3·67 per cent. The product in both cases was pale brown. G. N. Lewis could only obtain a mixture of silver and silver oxide, and obtained no evidence of the formation of the alleged suboxide.

Many other reactions have been reported to furnish silver suboxide but without an adequate examination of the nature of the product. F. Wöhler,[4] for instance, says that normal silver phosphate or arsenate is reduced by ferrous sulphate to a black powder which is a mixture of silver and silver suboxide; he also claimed to have made a similar product by boiling normal silver arsenite with a conc. aq. soln. of sodium hydroxide: $2Ag_3AsO_3=Ag_4O+2Ag+As_2O_5$. A. Geuther stated that black silver suboxide is formed when an aq. soln. of silver nitrate is treated with cuprous hydroxide; and H. Rose reported a similar product to be formed when an ammoniacal soln. of silver nitrate or sulphate is digested with ferrous, manganese, or cobaltous sulphate, A. Guntz prepared what he regarded as silver suboxide by the action of steam at 160° on silver subfluoride. F. Glaser reported the formation of silver suboxide when a stream of hydrogen is passed for 22 hrs. at about 34°, and the product does not change after another 15 hrs. action between 47° and 48°. E. Divers and T. Haga say that when a soln. of silver nitrate is treated with hydroxylamine, there is at first a black precipitate of silver suboxide. A. Leduc and M. Labrouste electrolyzed a clear soln. of silver oxide, obtained by the action of baryta on silver nitrate, between platinum electrodes at a press. of 10–12 volts, and noticed that a brown cloud is produced in the neighbourhood of the cathode, at the edges of which light filaments of silver are formed, while there is an abundant evolution of hydrogen. The brown cloud, it is said, "probably consists of silver suboxide." E. A. Schneider believes that the so-called colloidal silver, prepared from silver nitrate and ferrous citrate, is really silver suboxide, because with hydrochloric acid it forms silver chloride without the escape of hydrogen. Although the alleged silver suboxide is resolved by heat into oxygen and silver, E. Lenssen says that it may be stabilized by the presence of other oxides, so that it can exist at a high temp., for, he added, on melting in a crucible a precipitate of the silver, zinc, and iron sulphides mixed with nitre and sodium carbonate, he found an olive-green crust above the button of silver, and on this rested a lilac-coloured powder containing ferric oxide, zinc oxide, and silver suboxide. According to C. Weltzien, when clean silver foil is dipped into a neutral soln. of hydrogen peroxide, it first becomes covered with bubbles of oxygen, then with a greyish-white film of what he regards as hydrated silver suboxide, $Ag_4O.H_2O$. This oxide then dissolves, and a small quantity of a greyish-blue substance is precipitated;

when the soln. is exposed to the air, it becomes slightly turbid, and blue owing to the separation of finely-divided silver. Potassium hydroxide precipitates a brownish-black substance; and on evaporation a crystalline residue is formed from which water dissolves hydrated silver suboxide, and leaves translucent red crystals of silver.

This review shows that the evidence for the existence of alleged silver suboxide, Ag_4O, is very unsatisfactory. Where the reactions have been sceptically examined the conclusion is drawn that the suboxide is non-existent, and where they have been sympathetically examined, it is concluded that silver suboxide is a true chemical individual and its properties are described. It seems as if man cannot always balance evidence with a purely logical and unbiassed mind. Logic and temperament each plays its own part in forming his opinions or beliefs. Graphic formulæ have even been put forward. J. Wislicenus,[5] and M. Traube favour the assumption that the silver atom in the suboxide is bivalent; J. F. Heyes that the oxygen atom is quadrivalent:

$$\begin{matrix}Ag-Ag\\ Ag-Ag\end{matrix}\!>O$$

Silver atoms bivalent.

$$\begin{matrix}Ag\\ Ag\end{matrix}\!>O<\!\begin{matrix}Ag\\ Ag\end{matrix}$$

Oxygen atom quadrivalent.

§ 10. Silver Oxide

The formation of an oxide of silver when the metal is heated in air or oxygen has been discussed in connection with the action of the gases on the metal. H. le Chatelier[1] first showed that the oxidation of silver is probably a reaction of the balanced type: $2Ag_2O \rightleftharpoons 4Ag + O_2$, for he obtained a press. of 10 atm. by heating silver oxide in a closed tube at 300°; and at a press. of 15 atm. in a sealed tube at the same temp., he observed the oxidation of the silver. Hence he placed the decomposition press. of silver oxide between 10 and 15 atm. A. Guntz argued that the observed decomposition press. at 308° is not that of silver oxide, but of silver suboxide. He tried to show that silver oxide first decomposes: $4Ag_2O = 2Ag_4O + O_2$, and that the suboxide then decomposes until equilibrium is attained: $2Ag_4O = 8Ag + O_2$. G. N. Lewis found the equilibrium press. for decomposing silver oxide at 302° to be 20·5 atm.; at

325°, 32 atm.; and at 445°, 207 atm. In no case was there any sign of the formation of any silver suboxide; and the condition of equilibrium is that represented by the equation: $2Ag_2O \rightleftharpoons 4Ag + O_2$.

Silver oxide was obtained by H. Rose[2] by heating silver carbonate to 100°. L. Joulin said the decomposition is complete at 225°, but a little of the oxide is simultaneously decomposed. Silver oxide is usually prepared by precipitation from a soln. of the nitrate by means of potassium, sodium, calcium, or barium hydroxide. Care must be taken that these precipitants are free from carbonates and chlorides. According to H. Rose, the washed precipitate should be dried at a temp. between 60° and 70°, and not exceeding 80°. There is some difference of opinion as to the temp. at which the material can be dried without danger of decomposition. According to M. C. Lea, the product retains some water after 20 hrs. drying at 100°, and, with longer drying, some oxygen is lost even at that temp. A. Colson said the temp. can be carried to 200° without decomposing the silver oxide, while H. Rose says a little oxygen is given off at 100°. V. Kohlschütter and E. Eydmann recommended drying the product in vacuo over calcium oxide; W. G. Mixter recommended drying the precipitate two days between 200° and 220°, and an hour at 280°. E. H. Madsen said that only 0·13 per cent. of water is retained at 85°, but only at 280° is all the water lost; at this temp., however, some oxygen is lost. W. L. Hardin said that all his attempts to make pure silver oxide free from water proved unavailing.

W. Gregory, and F. Mohr made silver oxide by boiling freshly precipitated silver chloride with a soln. of potassium hydroxide of sp. gr. 1·25 to 1·30, until a washed sample dissolved completely in nitric acid; if the reaction should not be completed in ten minutes, the lye is poured off, and the product triturated in a mortar, and again boiled with new or the old lye. The product is then washed with boiling water, then with cold water, and lastly dried on the filter paper. J. S. Stas emphasized the difficulty of washing out the alkali from silver oxide prepared by this process.

Pure silver oxide has not been made. If a conc. soln. of silver nitrate is treated with a dil. soln. of sodium hydroxide and the precipitate be washed with water free from carbon dioxide, and dried, a dark brown oxide with a violet tinge is obtained containing between 1 and 2 per cent. of silver hydroxide, and probably traces of silver carbonate. Some reduction of the oxide always occurs because the moist precipitate gives a white silver chloride with hydrochloric acid, while the dried product gives a red-coloured chloride, the colour of which is deeper the higher the drying temp. The oxide also dissociates when the attempt is made to drive off all the moisture.

G. W. Morse[3] found that in the electrolysis of the best conductivity water between silver electrodes at 1·40–3·80 volts, with the electrodes 1 mm. apart, a faint brown cloud appears about the anode, and the liquid contains particles which exhibit the Brownian movement. From solubility observations, the particles are considered to be silver oxide. With higher voltages, the silver anode can be wholly converted into the oxide. F. Wöhler electrolyzed a soln. of potassium nitrate with a silver anode, silver oxide was formed, and remaining suspended in the electrolyte, coloured it brown. E. Müller and F. Spitzer also reported the anodic formation of silver oxide by the electrolysis of alkali cyanide or thiosulphate soln. of silver salts; J. S. Hughes and J. R. Withrow, by the electrolysis of silver nitrate which contained sulphuric acid or potassium fluoride, or perchloric acid with ammonia.

A. Lottermoser[4] prepared **colloidal solutions of silver oxide,** or hydroxide by mixing $\frac{1}{40}N$-soln. of silver nitrate and potassium hydroxide. C. Paal and F. Voos treated soln. of a silver protalbinate or lysalbinate with sodium hydroxide; L. Sensburg treated soln. of silver salts with aq. soln. of tannin or related products; and M. Kimura, and L. Wöhler heated silver to redness, and suddenly dipped it in cold water. According to V. Kohlschütter, the yellow coloration of the beads, obtained by fusing silver oxide or borax, is due to colloidal silver. V. Kohlschütter and

J. L. Tüscher prepared silver oxide dispersed in a gaseous medium by making the metal one electrode of an electric arc, and oxidizing the vapour.

H. Vogel added a soln. of 1·156 grms. purified sodium hydroxide in 20 grms. of water to a soln. containing a gram of silver nitrate in 15 grms. of water. He then added ammonia drop by drop until the precipitate dissolved. A violet skin of crystalline oxide forms on the surface of the liquid, and the crystals continue to form for a few weeks. W. Biltz and F. Zimmermann found that if the hydroxide of beryllium, aluminium, indium, zirconium, tin(ic), antimony, or bismuth be precipitated with ammonia, and thoroughly washed free from the precipitant, the product has no action on a $\frac{1}{10}N$-soln. of silver nitrate: but with some other hydroxides, silver oxide is formed and absorbed; thus, magnesium hydroxide is coloured brownish-yellow; zinc hydroxide pale brown; cadmium hydroxide brownish-yellow; and lead hydroxide, violet-brown. The formation of silver oxide by the oxidation of silver with the dioxides of the metals, potassium nitrate, etc., is discussed in connection with the metal.

H. Rose[5] said that the purest oxide he could prepare by precipitation was brown and that its colour readily darkens in sunlight. W. Gregory's product was bluish-black. The crystalline masses prepared by H. Vogel were in the form of 4- or 6-rayed stars, and the **crystals** appeared to belong to the cubic system, for he said that it forms "microscopic isotropic crystals which can be grown in small octahedra." According to W. P. Davey, the **X-radiogram** corresponds with the tetrahedral cubic lattice with the smallest distance apart of the atoms 2·03 A. According to R. W. G. Wyckoff, the crystals have the same structure as those of cuprous oxide—*i.e.* a face-centred cubic lattice—and the length of the side of unit cube 476×10^{-8} cms.

The **specific gravity** of the oxide is given by T. Herapath[6] as 7·143 (16·6°); by P. F. G. Boullay as 7·250; by C. J. B. Karsten, 8·2558; by L. Playfair and J. P. Joule, 7·147 (3·9°); and by H. G. F. Schröder as 7·521. The difference in the volume of two mols of silver oxide less four gram-atoms of silver is 20 c.c.

According to M. Berthelot, silver oxide is quite stable at ordinary temp. whether it be dry or moist. P. Berthier[7] states that silver oxide is *très fusible,* but this statement must be a mistake. The decomposition of the salt during its drying has already been discussed. In addition, H. Rose said that silver oxide begins to decompose and lose oxygen at 250°. According to T. Carnelly and J. Walker, there is a rapid loss of water and a small quantity of oxygen between 100° and 180°, while silver oxide with a small quantity of silver is comparatively stable between 180° and 270°; there is a rapid reduction of silver oxide to metallic silver between 270° and 300°; and the reduction is complete between 300° and 340°. K. Frenzel, S. Fritz, and V. Meyer showed that in a current of air, decomposition begins at 250°. As previously indicated, M. C. Lea found decomposition occurs between 100° and 165°. E. H. Madsen found that there is always some reduction during the drying at 85°–98°, for while the moist precipitate yields a white chloride when treated with hydrochloric acid, the dried salt gives a red chloride, where the colour is deeper the higher the temp. of drying. According to P. Berthier, silver oxide is more stable when it is associated, or in combination, with the oxides of other elements—*e.g.* lead, copper, and manganese—when it is not reducible to the metal by heat alone. L. Joulin found that at 250° the dissociation press. is very feeble, and G. N. Lewis found the decomposition of the oxide at 340° was very slow; at this temp. thermal decomposition of the silver oxide commences very slowly, but proceeds very much more quickly as time goes on. Thus,

Time from commencement .	10	13	14	16	18	20	21 hrs.
C.c. of oxygen per min. . .	0·017	0·037	0·055	0·25	2	1	0·28

The reaction thus steadily increased in velocity, and reached a maximum speed after about the eighteenth hour; the speed then steadily decreased as is typical of such reactions. The values obtained with silver, prepared in different ways, have a great influence on the speed of decomposition, and G. N. Lewis assumed that the *period of induction* in this reaction is due to the catalytic action of silver produced in the reaction—*autocatalysis* as the phenomenon is called. If silver is initially mixed with the silver oxide, the decomposition commences at once, and the speed increases with the amount of silver added.

If x denotes the fractional portion of the oxide which has been decomposed at the time t, x is proportional to the quantity of silver present at the time t; and $1-x$ is the fractional portion of the unchanged silver oxide. The velocity of the reaction was found to be proportional to the amount of silver oxide and silver present in the system, so that

$$\frac{dx}{dt}=kx(1-x)\text{; or }\log\frac{x}{1-x}=kt\text{; or }\frac{x}{1-x}=ekt$$

where k is a constant which G. N. Lewis found to be $k=4$. The integration is made on the assumption that zero time is calculated when the reaction has its greatest velocity, *i.e.* when $t=0$, $x=1-x$. Consequently, $dx/dt=kekt(1+ekt)^{-2}$.

Platinum and manganese dioxide act as catalytic agents, and stimulate the speed of decomposition of silver oxide. J. Kendall and F. J. Fuchs found that the addition of cupric oxide, manganese dioxide, ferric oxide, cerium dioxide, silica, and chromium trioxide to silver oxide, mercuric oxide, or barium peroxide increases in every case the rate of evolution of oxygen on heating and in most cases reduces the decomposition temp. The observed values of the **decomposition press.** of silver oxide are indicated above. F. G. Keyes and H. Hara found the press. in atm. are well represented by $\log_{10} p=-2859/T+6·2853$, the value at 25° calculated from the calorimetric data is 5×10^{-4}, where the heat of decomposition, Q, is related with the change in the vap. press., p, and temp., T, as represented by Clausius' equation, $dp/dT=QT(v-V)$, where v is the vol. of oxygen at $T°$ and press. p, and V is the total change in vol. of the solid system, *i.e.* the difference in vol. between 2 mols of silver oxide and 4 gram-atoms of silver. Q is the heat absorbed during the decomposition; if U denotes the internal energy, and $p(v-V)$ the work done during the change; then, if U varies with temp. T as $U=U_0-aT$, where a is the decrease in the thermal capacity of the system during the decomposition of 2 mols of silver oxide, Clausius' equation becomes $dp/dT=\{U_0-aT+p(v-V)\}/T(v-V)$. If V is not negligible but is a constant magnitude, integration furnishes:

$$\log\frac{p_1}{p_2}=\frac{U_0}{R}\left(\frac{1}{T_1}-\frac{1}{T_2}\right)+\frac{V}{R}\left(\frac{p_1}{T_1}-\frac{p_2}{T_2}\right)+\frac{R-c}{R}\log\frac{T_1{}^2}{T_2}$$

and with the observed dissociation press. the increase of internal energy accompanying the decomposition of 2 mols of silver oxide, U_0, is very nearly 13·6 Cals., and at room temp. about 12·8 Cals., so that the **heat of formation** of silver oxide, at room temp., exclusive of external work, is half this value, or 6·4 Cals. J. Thomsen calculated the heat of formation (2Ag, O) to be 5·9 Cals. from the observed heat of neutralization of silver oxide, and from the heat of the reaction between copper and silver nitrate; and M. Berthelot similarly obtained (2Ag, O), 7·0 Cals.; while W. G. Mixter gives 5·4 Cals. F. G. Keyes and H. Hara give for the external heat of the reaction $Q=6582p(v-20·7)/T$ cals. per mol of oxygen. The external and internal heats, $U=Q-pdv$, minimum values:

	25°	200°	300°	400°	500°	600°	700°	800°
Q . .	—	13083	13042	13046	13313	14071	14973	15349
U . .	12640	12142	11907	11712	11751	12204	12760	12840

H. von Wartenberg gives for the heat of formation in the gaseous state 9·8 Cals., calculated from a vap. press. of silver of $2·5\times10^{-3}$ mm., and a **vapour pressure** of silver oxide of $6·5\times10^{-3}$ at 1453°. The **heat of vaporization** is also calculated to be between $-90·6$ and -109 Cals. M. de K. Thompson calculated the **free energy** of formation to be 3·31 and also 3·9 Cals. (the total energy is 5·9 Cals.). J. Thomsen gives for the **heat of neutralization,** (Ag_2O, 2HClaq.), 42·38 Cals.; for (Ag_2O, H_2SO_4aq.), 14·49 Cals.; and for (Ag_2O, $2HNO_3$aq.), 10·88 Cals.

M. Berthelot gives (Ag_2O, $2HNO_3$aq.), 10·4 Cals.; for (Ag_2O, 2HBraq.), 51·2 Cals.; and for (Ag_2O, 2HIaq.), 64·2 Cals.

The colour of silver oxide gradually deepens when exposed to light, and at the same time H. Rose [8] found that the compound is decomposed with the evolution of oxygen. According to G. Wetzlar, also, the aq. soln. of silver oxide acquires a reddish colour when exposed to light. After exposure to light, the dry solid yields a red chloride when treated with hydrochloric acid.

The **potential** of $Ag_2O|Ag$ at 25° in a soln. of potassium hydroxide against a hydrogen electrode with the same electrolyte was found by R. Luther and F. Pokorny [9] to be 1·172 volts, and to be independent of the conc. of the electrolyte. P. Bechtereff found that the presence of silver oxide raises the e.m.f. of the $C|B_2O_{3\text{fused}}|Pt$ cell less than do the oxides of iron, cobalt, nickel, or copper, because it acts on the platinum electrode by the deposition of silver. A. Leduc and M. Labrouste also studied the electrolysis of an aq. soln. of silver oxide. According to G. Tammann, when ignited zinc oxide is left in a soln. of silver nitrate or sulphate in subdued light, it remains white for a whole day, but in bright light it quickly becomes grey, and, after a quarter of an hour, black. Lead oxide blackens in the same manner, even in subdued light, but less rapidly than in sunlight, and ferric oxide, bismuth oxide, antimonic oxide, and yellow mercuric oxide change in colour more slowly. The blackening is due to the deposition of silver oxide. An ionic exchange is said to take place at the surface of the oxide, controlled, probably, by the electric potentials of the reacting substances. The velocity of the reaction is said to depend on the tendency of the silver oxide to crystallize in the lattice form appropriate to the medium in which the deposition takes place.

Silver oxide is sparingly soluble in water. J. L. Proust,[10] and C. F. Bucholz noted that the aq. soln. has a metallic taste, and N. W. Fischer, and A. Vogel an alkaline reaction, for it turns red litmus blue, and turmeric brown like other strong bases, for, according to A. Bineau, the aq. soln. decomposes the metal halides and oxy-salts, setting free the base as oxide. According to A. Bineau, the **solubility** is such that 100 parts of water dissolve 33×10^{-3} parts of silver oxide; M. G. Levi gives $6·5\times10^{-3}$; R. Böttger, $2·14\times10^{-3}$ at 19·96; and $2·51\times10^{-3}$ at 24·94; R. Abegg and A. J. Cox, $2·1\times10^{-3}$ at 25°; A. A. Noyes and D. A. Kohr, $2·51\times10^{-3}$ at 25°. According to G. S. Whitby, the solubility of the oxide increases with time, becoming constant only after 14 days; at first it is $1·72\times10^{-3}$ at 20°, and in 14 days it increases to $2·15\times10^{-3}$. Silver oxide dissolves in an aq. soln. of *ammonia*, or *ammonium carbonate*; *sodium thiosulphate*; *sodium* or *potassium cyanide*; and the cyanides of the alkaline earths. It is not soluble in aq. soln. of *potassium*, *sodium*, or *barium hydroxide*. E. C. Franklin and C. A. Kraus found silver oxide to be insoluble in *liquid ammonia*; and M. Hamers, insoluble in pure and in sat. aq. soln. of *ethyl acetate* at 18°.

Cold silver oxide was found by A. Colson [11] to absorb hydrogen. According to F. Wöhler, and K. Frenzel, S. Fritz, and V. Meyer, silver oxide is reduced by **hydrogen** at 100°; while F. Glaser said that at 34° silver oxide is reduced to the suboxide, and at 63° to the metal, but the former statement needs revision. S. Hauser gave about 25° for the temp. of reduction. I. W. Fay and A. F. Seeker found that the reduction occurs at 0°, but more slowly. In a sealed tube at 0° fitted with a mercury gauge, the mercury had moved 14·9 mm. in one day; 18·3 mm. in 2 days; 39 mm. in 4 days; and 107 mm. in 12 days. A. Colson says that in the reaction between hydrogen and silver oxide, some metal is volatilized. According to V. Kohlschütter, the perfectly dry substances do not react; in presence of a trace of moisture, the reaction takes place even at the ordinary temp. The presence of larger quantities of water retards the change, which always begins at the points of contact of silver oxide and glass. If a little silver oxide dust is distributed over the walls of a flask, which is then filled with hydrogen nearly sat. with aq. vap., minute drops of water can be caused to condense round the silver oxide particles by cooling one side of the flask. The reduction takes place in these drops much more rapidly than in the dry particles, and, when the drops are evaporated, a film of silver is left on the glass. The film consists of colloidal silver; it does not conduct electricity at first, but soon passes into the ordinary form of the metal. When a suspension of silver oxide in pure water is reduced by hydrogen, the reaction takes place almost exclusively in the contact surface of glass and the soln., the solid oxide being unattacked; the reduced silver is obtained partly as a mirror and partly as a hydrosol. The rate of reduction of the silver oxide increases with the ratio (glass surface)/(vol. of soln.), whilst the ratio hydrosol/mirror diminishes. The nature of the hydrosol obtained depends on the kind of vessel used. Ordinary glass and quartz glass give yellowish-brown soln., Jena glass yields red, blue, or violet soln., whereas platinum gives no hydrosol, all the silver separating as a crystalline deposit on the platinum. The soln. contain dissolved silver hydroxide in addition to the colloidal silver.

According to M. Berthelot, the sesquioxide, Ag_4O_3, is formed when **ozone** acts on moist silver oxide, or on silver. L. J. Thénard[12] noted that there is a vigorous reaction between **hydrogen peroxide** and silver oxide resulting in the liberation of oxygen, and the separation of silver. T. Bayleigh said that more oxygen is given off than corresponds with the passage of the hydrogen peroxide to water, but M. Berthelot, and E. Mulder maintained that dil. hydrogen peroxide in contact with silver oxide only gives off an amount of oxygen corresponding with the catalytic reduction of the peroxide, the silver oxide is not decomposed. They believed that in the reduction the silver oxide first forms an unstable dioxide, Ag_2O_2, which acts as intermediate compound in the catalysis. A. von Bäyer and V. Villiger, however, observed that all the silver oxide is reduced to the metal if sufficient hydrogen peroxide is present; and M. Berthelot explained this by assuming that in the second phase of the reaction: $2Ag_2O+3H_2O_2=Ag_4O_3+O_2+3H_2O$, and that the oxide decomposes: $2Ag_4O_3=4Ag_2O+O_2$.

According to M. Berthelot, **silver tritetratoxide**, Ag_4O_3—sometimes called silver sesquioxide—is formed during the catalytic action of hydrogen peroxide on silver or silver oxide in hydrated black flecks, which decompose when the attempt is made to dry them. With dil. acids, the corresponding salt of silver is formed with the evolution of oxygen. The same oxide is said to be formed during the action of ozone on silver or on freshly precipitated silver oxide. He gives for the heat of formation (4Ag, 3O) 21 Cals. A. von Bäyer and V. Villiger maintained that M. Berthelot's alleged tetratritoxide does not exist, and that hydrogen dioxide with silver oxide produces metallic silver. The tetratritoxide may be a mixture of silver oxide and dioxide. E. R. Watson supposed it to be produced when ammonia acts on silver dioxide: $6Ag_2O_2+2NH_3=3Ag_4O_3+N_2+3H_2O$. G. Baborovsky and B. Kuzma assumed that silver peroxynitrate or peroxysulphate respectively obtained in the electrolysis of soln. of silver nitrate or sulphate with platinum electrodes is fundamentally silver tritetratoxide, Ag_4O_3.

J. S. Stas[13] found moist silver oxide is attacked by **chlorine,** forming a mixture of silver chloride, hypochlorite, and chlorate, and some hypochlorous acid; and A. J. Balard showed that **hypochlorous acid** reacts with silver oxide, forming silver chloride, oxygen, and a little chlorine. L. Bruner and J. Sahbill found that the electrical conductivity of a soln. of **bromine** in nitrobenzene is very much reduced by the addition of silver oxide owing to the formation of complexes. The action was studied by C. W. B. Normand and A. C. Cumming. A. Naquet reported that when **iodine,** suspended in water, is treated with silver oxide, silver iodide and iodic acid are formed. G. L. Fowler and J. Grant, and W. R. Hodgkinson and F. K. S. Lowndes found **potassium chlorate** is oxidized by silver oxide to the perchlorate and silver without the evolution of oxygen.

R. Böttger[14] found that when finely divided **sulphur** is triturated with silver oxide, the mixture inflames. A. Geuther reported that flowers of sulphur is oxidized by silver oxide and water, forming a little acid silver sulphate; and J. B. Senderens, by heating the mixture in a sealed tube, obtained silver sulphide and sulphate. A. Geuther also found that **sodium pentasulphide** and freshly precipitated silver oxide form sulphur, silver sulphide, sodium hydroxide, and a little silver sulphate but no dithionate. W. Vaubel, and A. Geuther also found that **sodium thiosulphate** reacts with silver oxide : $Ag_2O+Na_2S_2O_3=Ag_2S+Na_2SO_4$. R. Böttger found that ignition takes place when silver oxide is triturated with various metal sulphides—**auric sulphide,** black **antimony trisulphide,** and **mercuric sulphide** (realgar or orpiment)—or **selenium.** A. Vogel also boiled **lead sulphide** with silver oxide and water and so obtained lead oxide; **arsenic trisulphide** when similarly treated suffered no change A. Vogel found that **sulphur dioxide** reacts incompletely with warm silver oxide, forming silver and silver sulphate. It was found by H. B. North and A. M. Hageman that silver oxide in the cold does not attack **thionyl chloride,** but when heated in a sealed tube at 150°, a little silver chloride, etc., is formed.

S. Hauser[15] said that silver oxide is reduced by **ammonia** gas at room temp. Silver oxide is insoluble in liquid ammonia; but it is soluble in aq. ammonia or an aq. soln. of **ammonium carbonate**—*vide infra.* G. Bruni and G. Levi reported the formation of **silver diammino-oxide,** $Ag_2(NH_3)_2O$. P. Sabatier and J. B. Senderens found that **nitric oxide** decomposes silver oxide at 170°. When silver oxide is heated to redness with **ammonium chloride,** a mixture of silver and silver chloride is formed. According to H. Rose, a portion of the silver oxide is reduced to silver, and this is not altered by the ammonium chloride which converts the remainder of the oxide to silver chloride. An alkaline soln. of **hydroxylamine** is vigorously oxidized by silver oxide with the liberation of nitrous oxide, and the formation of a little hyponitrous acid, $H_2N_2O_2$. R. Böttger found that when amorphous **phosphorus** is triturated with silver oxide, the mixture inflames. A. Vogel oxidized **phosphorous acid** with silver oxide. G. Wetzlar found that when a soln. of **sodium phosphate** is shaken with silver oxide until the colour is not changed, the soln. becomes very alkaline, but retains some phosphoric acid.

P. Bechtereff found that the presence of silver oxide stimulates the oxidation of **carbon.** According to A. Colson,[16] **carbon monoxide** reduces silver oxide energetically at 10°, but at −21° there is very little reduction although sometimes the gas is absorbed or replaced by an equal vol. of carbon dioxide, with the formation of silver carbonate. I. W. Fay and A. F. Seeker found appreciable reduction occurs at 0°, and the reaction is more vigorous than with hydrogen. S. Hauser said that the reduction occurs at room temp. C. F. Schlagdenhauffen and M. Pagel found that carbon monoxide is completely converted to the dioxide in its passage over dry silver oxide at 60°. A. Colson found the velocity of the reaction varies with the previous history of the silver oxide. The reaction was also found to be influenced by its humidity. The gas dried by passing through conc. sulphuric acid begins to react at the temp. of a water-bath. K. Frenzel, S. Fritz, and V. Meyer found the heat liberated by the reaction when a current of carbon monoxide is passed over the oxide raised its temp. to 300°. H. Dejust observed that when carbon monoxide acts on dry silver oxide at the ordinary temp., a considerable amount of heat is developed and metallic silver is formed: $Ag_2O+CO=2Ag+CO_2+61{\cdot}2$ Cals. It is sometimes necessary to raise the temp. of the oxide to 40°–50° before the reaction sets in. The gas also acts slowly on the oxide suspended in water; metallic silver is deposited and a yellowish-brown soln. is formed which also deposits silver. The reaction takes place much more rapidly in ammoniacal soln.; the colourless soln. turns brown, then black, and deposits silver. H. Dejust suggests the possibility of utilizing this reaction for the determination of the amount of carbon monoxide in air. According to A. Gautier, moist silver oxide slowly absorbs carbon monoxide, forming silver subcarbonate, Ag_4CO_3, along with traces of formic and oxalic acids. N. W. Fischer found that freshly precipitated and moist silver oxide readily absorbs **carbon dioxide** from the atm., and G. N. Lewis shows the possibility of errors arising in analytical work owing to the absorption of moisture and carbon dioxide by silver oxide exposed to the air. G. Wetzlar observed that an aq. soln. of silver oxide is rendered turbid by the passage of a little carbon dioxide, but the soln. becomes clear with the passage of more carbon dioxide. The property possessed by moist silver oxide of giving up its oxygen at a low temp. is utilized in organic chemistry—*e.g.* for the transformation of organic bromides and chlorides into alcohols. According to L. Vanino, **formaldehyde** reacts with silver oxide in the presence of sodium hydroxide forming sodium formate: $Ag_2O+NaOH+CH_2O=2Ag+H_2O+HCOONa$, while, according to H. Wieland, dry formaldehyde is reduced to carbon dioxide; dry **acetaldehyde** does not react, but in the presence of moisture, the reaction is vigorous; **chloral** reacts very slowly if at all; **chloral hydrate** is readily oxidized. H. Vogel oxidized **lactose**; M. A. Gordon, **hydroquinone**; etc. A. Michael and A. Murphy observed that **carbon tetrachloride** reacts at 250°, while a soln. of chlorine in carbon tetrachloride reacts at ordinary temp., forming carbonyl chloride, $COCl_2$. The chlorine acts as a catalytic agent.

According to N. W. Fischer,[17] and H. Rose, silver oxide freed from all traces of silver salts—more especially the carbonate—and suspended in water, is completely reduced by the **metals** copper, zinc, cadmium, lead, and tin, while iron, cobalt, nickel, or the other metals which precipitate silver from soln. of the silver salts, are without action. F. J. Malaguti and J. Durocher found silver oxide is readily reduced by mercury and the resulting silver forms an amalgam. C. Winkler found that when a mixture of silver oxide and magnesium is heated in a sealed tube, the reaction proceeds with explosive violence. According to N. W. Fischer, an ammoniacal soln. of silver oxide is rapidly reduced by zinc, copper, and arsenic; more slowly by cadmium, mercury, tellurium, and lead; to a slight extent by manganese and antimony; and not at all by bismuth, tin, iron, and nickel, etc.

On account of its relative solubility, H. Rose found that silver is completely exchanged by the metals: beryllium, aluminium, chromium, gold, iron, cobalt, copper, zinc, bismuth, and mercury; and the replacement is only partial with salts of yttrium, manganese, nickel, cadmium, and lead; and but slight with the salts of calcium and magnesium—the halogen salts excepted. According to J. Persoz, also, boiling aq. soln. of cobalt, nickel, cerium, cadmium, magnesium, or copper dissolve silver oxide with the separation of the corresponding metal oxide. P. Sabatier has shown that with nitrate of copper, the silver is mixed with a basic cupric nitrate—similarly also with the sulphate, chlorate, and thiosulphate. D. Vitali found silver oxide completely decomposes mercurous, mercuric, ferrous, ferric, and cupric nitrates and auric and platinic chlorides; almost completely decomposes cobalt and nickel nitrates; partially decomposes cadmium, manganese, zinc, and aluminium sulphates; and very incompletely decomposes magnesium and calcium sulphates. Stannous chloride, when hot, gives a violet coloration; and a soln. of mercurous chloride, when boiled with silver oxide, gives a green mixture of mercuric oxide and silver subchloride. When chromic hydroxide is boiled in alkaline soln. with an alkali hydroxide and silver oxide, D. Meneghini found the corresponding alkali chromate is formed.

According to G. Wetzlar, and J. Percy, if at ordinary temp. moist silver oxide is added to an aq. soln. of sodium and potassium chlorides, so long as a white precipitate is formed, a soln. of the alkali hydroxide is obtained. The action, however, is not complete; while if the soln. be boiled the reaction reverses and silver oxide is formed as in the preparation of silver oxide by W. Gregory's and F. Mohr's processes (*q.v.*). Similar reactions occur with the alkaline earth chlorides. According to H. Rose, the reaction is complete with magnesium chloride in the cold. The bromides and iodides behave similarly. A. Kusminsky has studied the action of silver oxide on lithium chloride, bromide, and iodide. The alkali hydrocarbonates are converted into carbonates; alkali sulphates are not changed; and aq. soln. of the alkali nitrates dissolve some silver oxide. H. Rose also found calcium nitrate dissolves silver oxide copiously, but not a soln. of barium nitrate; and soln. of magnesium nitrate and sulphate are not changed, although A. Kormilitzine found the former is very slowly changed.

§ 11. Silver Hydroxide and Silver Ammino-Hydroxide

H. Rose [1] attempted to make **silver hydroxide,** $AgOH$, by the action of lime water on a soln. of silver nitrate, but the product was virtually free from water when dried at 100°; and it contained no hydroxide. It has often been assumed that the moist precipitate, obtained by the action of the hydroxides of the alkaline earths on soln. of silver salts, is silver oxide; thus T. Carnelly and J. Walker say that the product is stable up to 100°, but that it rapidly loses oxygen and water between 100° and 180°. D. Lance found that possibly silver hydroxide, or else silver oxide, is precipitated by heating soln. of the oxide or carbonate in amines, or mixed soln. of the amines and ammonia. J. D. Bruce has shown that dil. eq. soln. of silver nitrate and potassium hydroxide in 90 per cent. alcohol, at ordinary temp., give a granular brown precipitate of silver oxide; but at a low temp., say —45°; the precipitate is almost white, but it soon becomes coloured, and at —40° it is pale brown. The aq. soln. of silver oxide is assumed to contain silver hydroxide. According to V. Kohlschütter, the electrical conductivity of these soln. at 25° is:

$N\times10^4$ . . .	2·0	2·2	2·4	3·0	3·2	4·0	4·8	6·4
$k\times10^6$ . . .	25·8	27·9	29·3	34·0	39·25	49·6	57·8	73·0

From the electrical conductivity of the soln. containing a mol of the hydroxide in 1783 to 14,264 litres, M. G. Levi calculated the ionization constant to be $1\cdot15\times10^{-4}$, indicating silver hydroxide to be a stronger base than ammonium hydroxide. The degrees of ionization: $AgOH \rightleftharpoons Ag^{\cdot}+OH'$ are respectively 38·7 and 72·2 per cent. W. Biltz and F. Zimmermann estimate the ionic solubility to be between $2\cdot2\times10^{-4}$ and $3\cdot02\times10^{-4}$ mols per litre. S. Glixelli studied the electroösmosis of colloidal silver hydroxide.

According to A. Reychler, if a conc. aq. soln. of silver monammino-nitrate be dialyzed into water, white needles, whose composition, after washing with alcohol and ether, and drying at a low temp., approximates to *silver monammino-hydroxide*, are formed. The salt supposed to be silver monammino-nitrate is, however, but a mixture of silver nitrate and diammino-nitrate. J. Kunckel, in his *Vollstandiges Laboratorium chymicum* (Berlin, 1767), described how *fulmen præcipitatum* is obtained as a precipitate by adding *sal volatile urinæ* to a soln. of a silver salt; this product was later called *fulminating silver—Knallsilber* or *l'argent fulminant.* About twenty years later, C. L. Berthollet [2] prepared it by treating precipitated silver oxide with conc. aq. ammonia. The action was accompanied by a noise like that which attends the slaking of lime with water, and after 12 hrs. the film formed on the surface was dissolved by adding fresh aq. ammonia, the clear liquid decanted, and the fulminating silver, which collected at the bottom of the vessel, was dried in separate small portions, on pieces of filter paper. M. Faraday cautiously boiled precipitated silver oxide with an aq. soln. of potassium hydroxide and ammonia. The function of the potassium hydroxide is to remove any carbon dioxide which may have been absorbed by the silver oxide and would otherwise prevent the soln. of the oxide in the aq. ammonia. Another process which has been recommended is to add gradually purified potassium hydroxide to a soln. of silver chloride in conc. ammonia, until no effervescence occurs, when more alkali is added. The black turbid liquid is diluted with water, filtered, and the resulting black powder is washed on the filter and dried, in small portions at a time. Crystals of fulminating silver are also reported to have been obtained by J. L. Proust, B. Higgins, C. L. Berthollet, and J. L. Gay Lussac, as indicated below, by exposing colourless ammoniacal soln. of silver oxide to the air; in addition, F. Raschig by warming this same soln. on a water-bath, or by heating it with alcohol.

The term *fulminating silver* is also applied to ***silver fulminate*** prepared in 1798 by L. Brugnatelli, by pouring a soln. of one part of silver in 10 parts of nitric acid of sp. gr. 1·36 into 20 parts of 85–90 per cent. alcohol. It separates from the soln. in fine needles, and is regarded as the silver salt, $Ag_2C_2N_2O_2$, of fulminic acid, $H_2C_2N_2O_2$, which has not been isolated. The mercury and silver salts are employed in filling percussion caps.

Fulminating silver appears either as a black powder, or in black opaque crystals with a metallic lustre. B. Higgins, and M. H. Klaproth and F. Wolff assumed the crystals are pure fulminating silver, and the black powder a mixture of fulminating silver, metallic silver, and possibly Faraday's suboxide. Dry fulminating silver is instantly decomposed by slight disturbing causes—percussion, friction, heat, etc.; the decomposition is attended by a violent explosion which usually shatters the containing vessel. Thus, F. Raschig says that a drop of water falling directly on the moist product is attended by an explosion. The products of the decomposition are said to be silver, water, and nitrogen. The moist oxide is not so liable to explode as when dry. The composition of fulminating silver is unknown. It may be *silver nitride*, Ag_3N, or *silver imide*, Ag_2NH. F. Raschig's analyses corresponded in one case with Ag_3N; and in two cases with Ag_2NH. He also observed that fulminating silver is slowly soluble in aq. ammonia; sulphuric acid converts it into silver and ammonium sulphates; and it dissolves in aq. soln. of potassium cyanide without the evolution of gas: $Ag_3N+3KCy+3H_2O=3AgCy+3KOH+NH_3$.

Many of the compounds of silver are dissolved by aqua ammonia, and, in some cases, powerfully detonating and dangerous substances are formed. For example, A. Stock tried to accelerate the dissolution of silver oxide in dil. aq. ammonia by warming, and a vigorous explosion resulted; C. Matignon, also, found an ammoniacal soln. of silver oxide exploded after standing 24 hrs., possibly owing to the drying of fulminating silver on the walls of the glass vessel. A. Sieverts has also emphasized the danger of violent explosions incurred in working with ammoniacal silver soln. Even clear soln., said he, may give rise to explosions.

According to M. Faraday, precipitated silver oxide dissolves completely in aq. ammonia, forming a pale brown soln. On the contrary, J. L. Gay Lussac said that there is always some residue which does not dissolve and which is identical with the so-called fulminating silver; but N. W. Fischer showed that the freshly precipitated oxide dissolves completely, while the dried oxide dissolves only partially.

W. R. Whitney and A. C. Melcher found that the solubility of silver oxide, expressed in C_{Ag} gram-atoms of silver per litre, in aq. ammonia soln., expressed in C_{NH_3} mols of ammonia per litre, at 25°, is

C_{NH_3}	0·214	0·469	0·720	0·827	0·899	0·999	1·522
C_{Ag}	0·0654	0·140	0·225	0·248	0·278	0·299	0·470
Ratio	3·272	3·361	3·196	3·336	3·237	3·344	3·235

So that the solubility in aq. ammonia at 25° is almost exactly proportional to the conc. of the latter between the investigated limits where the ratio $C_{NH_3}' \div C_{Ag}$ is virtually constant. The ratio of the solubility eq. to the ammonia conc. is nearly as 1 : 3·31 at 25°; and 2·53 at 0°. The solubility of silver oxide is thus much greater at 0° than it is at 25°, and the reverse is true for the solubility of the oxide in water. H. von Euler has also measured the solubility of silver oxide in methylamine and in ethylamine.

When the ammoniacal soln. of silver oxide is exposed to the air, or, according to J. L. Proust, when a soln. of silver chloride in aq. ammonia is exposed to the air, or still more readily by the application of heat, black opaque crystals of fulminating silver are deposited. These crystals were found by B. Higgins, M. H. Klaproth and F. Wolff to detonate violently with the slightest disturbance, even that which is produced by agitating the mother liquid in which they are being produced; *au contraire*, according to M. Faraday, the crystals which form at the surface of the soln. are silver suboxide (*q.v.*), while if the soln. be boiled for a few moments, the liquid becomes highly coloured, nitrogen is given off, and a black curdy precipitate of fulminating silver is formed which leaves the liquid colourless; when the colourless liquid is again heated, it is blackened, gives off nitrogen, and deposits a precipitate of silver oxide, not fulminating silver. Other crops of oxide may be obtained by repeating the operation. The liberation of nitrogen therefore does not belong exclusively to the formation of fulminating silver, but seems rather to depend on the production of oxide. When the soln. of silver oxide in ammonia is kept for three months in a closed vessel, oxygen gas is evolved, and the soln. deposits a layer of metallic silver, but no fulminating silver. The soln. gives white precipitates when treated with potassium hydroxide, ether, or alcohol; the precipitates soon change colour, and, after drying, detonate both by heat and by friction. M. Berthelot found that when the ammoniacal soln. is treated with hydrogen peroxide, crystalline silver is precipitated, and oxygen is liberated. N. W. Fischer found that when the soln. is treated with alkali phosphates, chromates, or chlorides, if too much ammonia be not present, the corresponding salt of silver is precipitated. Lead and copper reduce silver from the soln., tin and iron do not. A. Oppenheim found that phosphorus precipitated metallic silver from the boiling soln.; and H. Dejust found that carbon monoxide produced an analogous result.

G. Bruni and G. Levi prepared **silver diammino-oxide,** $Ag_2O.2NH_3$. Many investigations on the physical properties of ammoniacal soln. of the silver compounds point to the conclusion that the silver of these compounds exists in soln. as a complex cation, $Ag(NH_3)_2^{\cdot}$, and in the case of soln. of the oxide, as **silver diammino-hydroxide,** $Ag(NH_3)_2OH$, or $AgOH.2NH_3$. For example, A. Reychler[3] showed that the f.p. of silver nitrate or sulphate soln. is almost unaffected by the addition of ammonia until 2 mols have been added, when subsequent additions produce the normal lowering. D. Konowaloff, and W. Gaus found that the addition of silver chloride or nitrate to a soln. of ammonia reduced the partial press. of ammonia to a value equal to that of a soln. of ammonia of a conc. less by 2 mols of NH_3 per gram-atom of silver added. M. Berthelot and M. Delépine proved that on mixing dil. soln. of ammonia and of silver nitrate, no heat effect occurs with the addition of an excess of either component beyond that required for the ratio : Ag : $2NH_3$. G. Bodländer and R. Fittig investigated the solubility relations of silver chloride or bromide in aq. ammonia containing either potassium chloride or silver nitrate, and assuming the mass law is applicable, it follows that the silver is present almost exclusively as the cation $Ag(NH_3)_2^{\cdot}$; and this conclusion was confirmed by e.m.f. measurements of conc. cells with silver electrodes and soln. containing the same conc. of silver nitrate or chloride, and different conc. of ammonia. The dissociation constant, K, for the breaking up of the complex ion $Ag(NH_3)_2$ into the components $[Ag^{\cdot}][NH_3]_2=K[Ag(NH_3)_2^{\cdot}]$ was found to be small. $K=6{\cdot}88\times10^{-8}$; H. von Euler found $K=4{\cdot}1\times10^{-8}$; and A. A. Noyes and D. A. Kohr found $K=7{\cdot}0\times10^{-8}$. W. Bonsdorff found that the strength of silver, cadmium, copper, nickel, and zinc ammino-hydroxides decreases in the order named, and that silver ammino-hydroxide is the strongest base of the series, being more strongly ionized than barium hydroxide, while zinc ammino-hydroxide is a very weak base. H. von Euler made similar investigations with methylamine and ethylamine soln., and found for the former $K=2{\cdot}45\times10^{-7}$, indicating that the methylamine complex $Ag(NH_2CH_3)_2$ is five times less stable than the ammonia complex $Ag(NH_3)_2OH$. W. R. Whitney and A. C. Melcher studied the transport of the ion $Ag_n(NH_3)_{2n}$ into neutral soln. of sodium salts; they found the f.p. of ammonia soln. is not affected by the dissolution of the silver oxide; that the eq. conductivity changes so slowly with dilution as to show that the complex salt is completely ionized; and the greater solubility of silver oxide in aq. ammonia at 0° than at 25°, corresponds with the smaller tendency of the complex ion to dissociate into its components at the lower temp.

§ 12. Silver Dioxide; or Silver Peroxide

According to C. F. Schönbein,[1] and J. C. G. de Marignac, ozone acts on silver, producing a black **silver peroxide.** A. Volta says that the action occurs only when moisture is present; no action occurs if ozone and metal be thoroughly dried. The reaction has been studied by W. Manchot and W. Kampschultze, and H. Thiele—*vide* ozone. J. Schiel says that silver oxide likewise yields silver peroxide when exposed to the action of ozone. H. Erdmann found a soln. of ozone in liquid oxygen immediately blackens the inside of a silver vessel; the coloration clears off rapidly at ordinary temp. It is assumed to be due to the formation of a silver peroxide. A. Mailfert obtained bluish-black silver peroxide by the action of ozone on a soln. of silver nitrate or sulphate; the product with the last-named soln. is the more stable. The peroxidation of silver chloride or cyanide is slow. E. Salkowsky noted that in the presence of a small amount of alkali hydroxide, a little hydrogen dioxide gives a black precipitate which becomes grey when more hydrogen dioxide is added. The precipitate is considered to be a mixture of silver and silver oxide. According to H. Marshall, a mixture of potassium persulphate, or, according to L. Cramer, ammonium persulphate and silver nitrate, first forms silver persulphate, $Ag_2S_2O_8$, and this immediately decomposes producing black silver peroxide: $Ag_2S_2O_8+2H_2O=Ag_2O_2+2H_2SO_4$. M. G. Levi, E. Migliorini, and G. Ercolini represented the reaction: $2Ag+K_2S_2O_8+H_2O \rightarrow Ag_2O+K_2SO_4+H_2SO_4$, followed by $Ag_2O+H_2SO_4=H_2O+Ag_2SO_4$. From the anodic decomposition curves of soln. of silver nitrate and sulphate, M. Bose concluded that the oxide is Ag_2O_2. G. I. Higson regarded it as a mixture of peroxide and sulphate. N. Tarugi concluded that the product is the silver salt of Caro's acid: Ag_2SO_5; and P. C. Austin concluded that it is a mixture of silver peroxide and persulphate. The following method of preparation is given by P. C. Austin:

> Ten grams of silver nitrate dissolved in 100 c.c. of distilled water were added to a soln. of 30 grms. of potassium persulphate in a litre of water, at the ordinary temp., in a large separating funnel, the mixture being thoroughly shaken. The formation of the black precipitate, although not immediate, quickly followed. Owing to the difficulty of filtering such a soln., since the persulphate attacks filter paper, it was kept for about an hour, by which time the bulk of the precipitate had settled and could be drawn off. It was immediately shaken with distilled water, washed three or four times by decantation, and finally filtered and washed again. It was then spread out on a watch-glass and dried in a vacuum desiccator over sulphuric acid. The drying was found to require several days. An analysis of the product showed that it contained 21 per cent. of silver persulphate; 77 per cent. of silver peroxide; and 2·5 per cent. of water.

H. Marshall and J. K. H. Inglis represent the reaction in terms of the ionic hypothesis: $2Ag^{\cdot}+S_2O_8 \rightleftharpoons 2Ag^{\cdot\cdot}+2SO_4$. When the conc. of the silver salt and silver peroxide is small in comparison with that of the persulphate, the speed of the peroxidation may be represented by an equation characteristic of a unimolecular reaction, and therefore $dC/dt=kC$, where C denotes the conc. of the persulphate. In the absence of oxidizable substances, hydrolysis may occur with the formation of peroxyhydroxide, oxide, or a basic salt. Ammonia may be oxidized to a nitrate: $4Ag_2O_2+NH_4^{\cdot}+6H^{\cdot}=8Ag^{\cdot}+NO_3'+5H_2O$. The reaction with ammonium persulphate is eight times as fast at 50° as at 25°; and it is almost proportional to the conc. of the silver salt. Neutral salts retard the reaction, acids accelerate it—possibly in virtue of the consecutive reaction $2Ag_2O_2+4H^{\cdot}=4Ag^{\cdot}+O_2+2H_2O$. G. A. Barbieri found that silver oxide in alkaline soln. is partially peroxidized by potassium permanganate—more rapidly hot than cold—in accord with the reversible action: $Ag_2O+2KMnO_4+2NaOH \rightleftharpoons Ag_2O_2+K_2MnO_4+Na_2MnO_4+H_2O$. E. Mulder, and E. R. Watson obtained it by heating silver peroxynitrate or peroxysulphate with water. According to R. Luther and F. Pokorny, when silver is oxidized in alkaline soln., say N-NaOH, with a small current-density, silver oxide, Ag_2O, is at first formed quantitatively and reversibly; on further oxidation, it is changed quantitatively and reversibly to a higher oxide, Ag_2O_2. The change $Ag \rightarrow Ag_2O$ takes place at 1·72 volts (taking the hydrogen electrode as zero), the change $Ag_2O \rightarrow Ag_2O_2$ at 1·40 volts, both at 25°, and no higher peroxide could be obtained in alkaline soln. G. Grube obtained silver peroxide in the electrolysis of alkaline soln. of potassium ferro- and ferri-cyanides with a silver anode; G. W. Morse in the electrolysis of water with a press. exceeding 1·40 volts; and F. Wöhler, by the electrolysis of sulphuric acid or a soln. of sodium sulphate with a silver anode. *Vide* silver peroxynitrate.

According to G. A. Barbieri, a soln. of silver peroxide in conc. nitric acid does not reduce lead dioxide, manganese dioxide or potassium permanganate; nor does it give rise to hydrogen peroxide, and hence A. Piccini would regard it as a higher oxide of silver, but not a true peroxide. This view is confirmed by the observation that when silver oxide is treated with permanganate in alkaline soln., it undergoes partial oxidation to Ag_2O_2 by the reversible reaction just indicated. The oxide Ag_2O_2 is a weaker base than Ag_2O, and its soln. in conc. nitric acid is supposed to contain argentic nitrate $Ag(NO_3)_2$, which is stable only in the presence of a large excess of nitric acid with which it forms a complex salt. Argentous nitrate, $AgNO_3$, dissolved in conc. nitric acid, acts as if it were a reducing agent towards lead dioxide and bismuth tetroxide presumably because the argentous nitrate is oxidized to argentic nitrate. The oxidizability of silver salts in nitric acid soln. is supposed to explain the accelerating influence they exert upon certain oxidation processes.

The formula Ag_2O_2 is usually taken to represent silver peroxide, but G. A. Barbieri used the formula AgO; and J. F. Heyes assumed that graphically the formula is Ag.O.O.Ag, or if oxygen be tetravalent, $Ag_2 : O : O$. According to E. R. Watson, silver peroxide is a greyish-black powder, of sp. gr. 7·44, and it can be heated to 100° without decomposition, but it decomposes at higher temp. into its elements; P. C. Austin's product exploded at 110°. F. Streintz measured the electrical conductivity of silver dioxide. C. F. Schönbein and E. R. Watson found that the peroxide dissolved in conc. nitric acid to a dark brown liquid which was stable or decomposed very slowly in the cold, but gave off oxygen when heated and the soln. was decolorized; when the nitric acid soln. was diluted with water the silver peroxide was re-precipitated; the peroxide is scarcely affected by cold dil. nitric acid:

The brown soln. of silver peroxide in conc. nitric acid is assumed by G. A. Barbieri to contain *silver dinitrate*, $Ag(NO_3)_2$, with silver bivalent. The salt is readily hydrolyzed, and stable only in the presence of an excess of nitrate ions; he also showed that a 1 per cent. soln. of silver nitrate in nitric acid of sp. gr. 1·4 is oxidized at −10° by lead dioxide and more rapidly by bismuth tetroxide, Bi_2O_4, to form silver dinitrate. E. R. Watson writes the formula $Ag_4(NO_3)_8$.

E. R. Watson found the peroxide dissolves in hot. dil. sulphuric acid, giving off oxygen, and forming silver sulphate; M. Traube likewise found it to dissolve in sulphuric acid with the formation of silver sulphate. E. C. Franklin and C. A. Kraus found silver peroxide is insoluble in liquid ammonia. E. R. Watson assumed the reaction with aq. ammonia is represented by the equation: $6Ag_2O_2+2NH_3=3Ag_4O_3+N_2+3H_2O$. E. Mulder found silver peroxide catalytically decomposes hydrogen peroxide. L. Cramer, and E. Salkowsky, studied the action of silver peroxide on gum arabic, gelatine, etc. R. Kempf found silver peroxide to be an energetic oxidizing agent for organic substances; and it completely oxidizes ammonia to nitrogen very quickly.

M. Berthelot[2] assumed that *silver sesquioxide*, Ag_2O_3, is formed as an intermediate product in the catalytic action of silver on hydrogen peroxide; and A. Loduc and M. Labrouste assumed that it is formed as a black dust on the silver anode, without the evolution of gas, during the electrolysis of a clear, freshly prepared soln. of silver oxide. R. Luther and F. Pokorny believe that F. Wöhler's peroxide, and E. Mulder's peroxynitrate (*q.v.*), are essentially silver sesquioxide, with more or less absorbed silver salts. These products were obtained with acid electrolytes; $2Ag \rightarrow Ag_2O_3$; if the electrolyte be alkaline, silver peroxide is formed: $Ag_2O_3 \rightarrow Ag_2O_2$ at 1·57 volts. In acid soln., the sesquioxide is decomposed directly into silver by electrolytic reduction; and conversely silver can be oxidized directly to the sesquioxide.

§ 13. Silver Fluoride

A. Guntz prepared what he regarded as **silver subfluoride,** Ag_2F, by electrolyzing a sat. soln. of silver fluoride with silver electrodes and a strong current. If the liquid is allowed to become hot, silver is not deposited, but bronze plates are deposited at the cathode. These crystals, though mixed with some silver fluoride, contain less fluorine than normal silver fluoride. In dil. soln. with 6 volts and 2 amps., or with 24 volts and 5 amps. whereby the soln. is heated, or in conc. soln. with 6 volts and 5 amps., L. Vanino and P. Sachs[1] obtained silver deposits alone, but, says A. Guntz, a dil. soln. at all temp. furnishes silver alone, a conc. soln. over 50° is needed for the formation of silver subfluoride, and, adds K. Eisenreich, when $8N$-soln. of silver fluoride are used the anode no longer dissolves, but becomes coated with silver subfluoride, Ag_2F. K. Eisenreich also observed the formation of silver subfluoride when the light from a mercury quartz lamp acts on soln. of silver fluoride. A. Guntz also found that if finely-divided silver be heated with a warm soln. of silver fluoride in a sealed tube, the liquid becomes yellow above 50°, and if the temp. does not exceed 90°, all the silver is converted into a crystalline powder resembling brass filings. H. Moissan also made the same salt by leaving silver foil in contact with an aq. soln. of silver fluoride. L. Wöhler and G. Rodewald prepare silver subfluoride in the following manner:

> A soln. of 5 grms. of silver nitrate in 250 c.c. of water with slight excess of ammonia is treated with 2 or 3 c.c. of formalin with constant stirring. The metal is precipitated when the liquid is allowed to stand at the room temp.; it is washed cold, by decantation, and pressed between filter paper—about 3 grms. of silver are so obtained. Again, 17 grms. of silver nitrate in 100 c.c. of water is treated in the cold with sodium carbonate; in this way, the formation of sparingly soluble oxides is prevented. The precipitated carbonate is washed, and then dissolved in hydrofluoric acid, and the soln. conc. on a water-bath and filtered. The resulting liquid contains the eq. of about 4 grms. of silver, and it is mixed with the pressed silver previously prepared, and evaporated on a water-bath with constant stirring until the bronze-green crystals of silver fluoride and the yellowish-brown crust of silver fluoride begin to form The liquid is filtered by suction through a filter tube, closed with a stopper fitted with a calcium chloride tube, and washed 4 or 5 times with 1 to 2 c.c. of absolute alcohol, then with absolute ether. The thin surface layer of solid is rejected, and the compound is dried in vacuo over sulphuric acid for a couple of hours, and then preserved in a sealed tube.

The octahedral crystals are a golden-yellow colour, and unlike the other silver halides, the crystals are not sensitive to direct light; a press. of 20,000 atm. is without influence. The crystals are decomposed by water with the development of heat: $AgF+Aq.=3\cdot4$ Cals.; and $Ag_2F+Aq.=AgF_{aq.}+Ag+2\cdot73$ Cals.; $2Ag_{aq.}+F_{gas}=Ag_2F_{solid}+26\cdot3$ Cals.; not $24\cdot9$ Cals. as A. Guntz stated, and therefore $Ag_{aq.}+AgF_{aq.}=Ag_2F_{solid}-0\cdot7$ Cal. The crystals do not alter in dry air, but in moist air they decompose. A little water continues decomposing the salt until the soln. contains 64·5 per cent. of silver fluoride. With sodium chloride, it is decomposed into silver and silver chloride and fluoride. L. Vanino and P. Sachs have expressed the opinion that the alleged silver subfluoride is a mixture of normal silver fluoride with silver or silver oxide in varying proportions, claiming that (i) under the microscope the former appears as a transparent mass, in which the latter is scattered in black spots; (ii) after treatment with water, the ratio of soluble to insoluble silver is as 1 : 4 to 1 : 5, whereas silver fluoride requires a ratio 1 : 1; and (iii) the total silver in the alleged subfluoride varies in quantity. According to L. Wöhler and G. Rodewald, silver fluoride is very easily decomposed by water, and the influence of atm. moisture is the source of the difficulties which are found in accepting the evidence of the individuality of this product. If a little silver fluoride be placed on a filter paper supported on a clay triangle, over a glass dish with a few drops of water, and all be covered by a bell-jar, decomposition is evident after the elapse of 5 minutes, and all is completely decomposed in 25 minutes: $Ag_2F=Ag+AgF$. The transition point in an atm. of nitrogen or carbon monoxide for $Ag_2F\rightleftharpoons AgF+Ag$ is 90°, above this temp. the reaction passes as symbolized from left to right; and below 90°, from right to left. This reaction represents the case of a solid dissociating into two other solids; the decolorization which attends the transformation is completed in a few minutes at 110°–115°; the transition temp. in contact with a sat. soln. of silver fluoride also occurs at 90°. Unlike silver fluoride, silver subfluoride is insoluble in absolute alcohol and in absolute ether. It is virtually insoluble in acetone and xylene, while pyridine decomposes it into silver and silver fluoride.

The preparation of silver fluoride.—H. Moissan[2] showed in 1891 that metallic silver is but slowly attacked in the cold by fluorine gas; at 100° the attack is faster; and at a red heat, the two elements react with incandescence. J. L. Gay Lussac and L. J. Thénard reported in 1811 that silver is not attacked by hydrofluoric acid, and that silver fluoride is obtained when a soln. of silver oxide or carbonate in hydrofluoric acid is evaporated to dryness. J. J. Berzelius, and G. Gore prepared silver fluoride in this manner, but H. Moissan pointed out that the product always contains some reduced silver and silver oxide. He therefore recommended dissolving freshly precipitated silver carbonate in silicon-free hydrofluoric acid, and evaporating the liquid over a free flame until crystallization begins, and continuing the evaporation to dryness on a sand-bath with constant stirring. The black pulverulent mass is dissolved in water, filtered, and evaporated in darkness in a platinum dish, in vacuo, over conc. sulphuric acid. Dark brown crystals of the anhydrous salt form as a crust on the surface, while octahedral crystals of the hydrated salt form on the bottom of the dish. Good yields are obtained if the hydrofluoric acid is pure, and glass vessels are not employed since glass is attacked.

According to E. Frémy, the neutral or slightly alkaline soln. gives on evaporation in vacuo either small yellow cubes or colourless tetragonal pyramids of **hydrated silver fluoride,** $AgF.H_2O$. J. C. G. de Marignac gives the axial ratio $a : c=1 : 1{\cdot}1366$ for $AgF.H_2O$. The particular form of the crystals depends on the temp. According to A. and A. A. Guntz, on evaporating in a vacuum at 10° a neutral soln. containing 120 grms. of silver fluoride in 100 grms. of water and suitably seeding the liquid, colourless, transparent crystals of **tetrahydrated silver fluoride,** $AgF.4H_2O$, m.p. 18·5°, were obtained, having at 13° a heat of soln.—4·93 cals. Below 18·5° this is the only hydrate stable in neutral soln. A soln. containing 170 grms. of silver fluoride allowed to crystallize between 18° and 38° gives deliquescent prisms of **dihydrated silver fluoride,** $AgF.2H_2O$, m.p. 42°, decomposing to the anhydrous fluoride. Its heat of soln. is —1·5 cals. at 10°. The presence of hydrofluoric acid lowers the transition temp. of $AgF, 4H_2O$ to $AgF, 2H_2O$, 5·5 per cent. of acid lowering it to 0°. On evaporating a neutral, sat. soln. of silver fluoride at 26°–36°, hard, highly refractive, slightly yellow, deliquescent crystals are obtained of a monohydrate, $AgF.H_2O$. The heat of soln. of this hydrate is +0·85 cal. at 10°. By repeating this crystallization at the ordinary temp. there is formed round each nucleus of the monohydrate, voluminous, colourless rosettes of a hydrate, $2AgF.5H_2O$. Both the latter forms are unstable in the presence of crystals of $AgF.2H_2O$, giving this hydrate and anhydrous silver fluoride; if the conc. aq. soln. be allowed to stand some time colourless prismatic crystals of dihydrated silver fluoride, $AgF.2H_2O$, appear. The hydrates are very deliquescent, and all of them lose all their combined water in vacuo. According to E. Frémy, if the hydrated salt be dried in vacuo, the whole of the water and some hydrofluoric acid is evolved, and the remaining yellow amorphous mass is contaminated with some oxyfluoride. A. and A. A. Guntz prepared the salt by evaporating a soln. of silver with 5 per cent. of hydrofluoric acid in vacuo. L. Pfaundler showed that by heating the hydrated salt to 327°, it loses about 0·5 per cent. of fluorine as hydrogen fluoride; and if heated in a covered crucible to its m.p. some hydrofluoric acid also escapes with the water, and no more is lost if the fluoride be heated up to 960°.

The properties of silver fluoride.—Silver fluoride forms a yellow or yellowish-brown mass. The various reports as to the colour of silver fluoride are not very consistent; the pure salt is probably colourless and the observed colours are due to admixtures of very small quantities of, possibly, colloidal silver, or silver oxide. The brown colour, say L. Vanino and P. Sachs,[3] is due to the presence of silver oxide. The amorphous powder, which is yellow at 0°, becomes orange at 25°. Ruby-red cubes are obtained, according to A. and A. A. Guntz, by evaporating a soln. of silver fluoride in 5 per cent. hydrofluoric acid in vacuo. According to G. Gore, its sp. gr. is 5·852 (15·5°); and, according to H. Moissan, it melts at 435°, forming a black liquid which, according to O. Unverdorben, solidifies to a black horn-like mass when rapidly cooled, and a crystalline mass with slow cooling. The horn-like variety cannot be powdered by pulverization, but, says L. Pfaundler, it can be cut with the scissors. The molten fluoride attacks silver crucibles, and slightly attacks platinum. The heat of formation from its elements is, according to M. Guntz, $Ag_{solid}+F_{gas}=AgF_{solid}+25{\cdot}6$ Cals.; $Ag_2O+2HF_{gas}=2AgF+H_2O_{liq.}+32{\cdot}8$ Cals. Further, $AgF+2H_2O=AgF.2H_2O+4{\cdot}9$ Cals.; $AgCl+HF=12{\cdot}9$ Cals.; and for $\frac{1}{2}Ag_2SO_4+HF=9{\cdot}2$ Cals. The heat of hydration: $AgF+2H_2O=4{\cdot}9$ Cals.; and the heat of soln. of dihydrated silver fluoride in a large quantity of water at 10° is 1·5 Cals., while for the anhydrous salt at 16°, the heat of soln. is +4·3 Cals. The molten salt conducts electricity like a metal without the development of a gas. According to L. Vanino and P. Sachs, the metallic conductivity is due to the presence of metallic silver formed during the melting of the salt. Silver fluoride is readily soluble in water—100 grms. of soln. at 15·5° has 64·8 grms. of salt, and the sp. gr. is 2·61. The great increase in the solubility of silver fluoride which L. Wöhler and G. Rodewald observed at about 50°, is probably due to the transition from the hydrate $AgF.2H_2O$ to the anhydrous salt. The aq. soln. has a neutral reaction. The comparatively high solubility of silver fluoride is in marked contrast with the low solubilities of the other three silver halides. Silver oxide dissolves in a soln. of silver fluoride probably forming complex ions, *viz.* $[Ag_2OH]^{\cdot}$, together with the F'-ions. L. Pfaundler also noted the apparent formation of **silver oxyfluoride,** $AgF.AgOH$, by the evaporation of neutral aq. soln., or by melting the salt in imperfectly dried vessels. These oxyfluorides are probably mixtures of silver fluoride with some oxidized salt. Under-cooled soln. are readily formed, and on electrolysis, silver is deposited on the cathode, and oxygen is evolved at the anode. S. Tanatar obtained what he regarded as **silver peroxyfluoride,** $4Ag_3O_4.3AgF$, by the electrolysis of an aq. soln. of the fluoride; it decomposes when heated with the evolution of oxygen, and, when digested with water on a water-bath, and washed with hot water, furnishes another peroxyfluoride, $2Ag_3O_4.AgF$.

The electrical conductivities of aq. soln. of silver fluoride have been determined by R. Abegg and C. Immerwahr. For 1·21*N*-soln. the conductivity at 18° is $\lambda=0{\cdot}0539$, and α, the ionization, 53 per cent.; for 0·211*N*-soln., $\lambda=0{\cdot}0812$, and α, 80 per cent.; and for 0·0121*N*-soln., $\lambda=0{\cdot}0955$, $\alpha=94$ per cent. The numbers are very close to the corresponding values for silver nitrate. The calculated value of λ_∞ is 0·0116, but for very dil. soln.—0·00516*N*- to 0·000516*N*-—the conductivity is greater; this is taken to mean that the solute is hydrolyzed. A. Heydweiller gives the sp. gr. at 18° (water at 18° unity) for 0·1001*N*-soln., 1·01280; 0·2010*N*-, 1·02566; 0·4034*N*-, 1·05067; 0·8044*N*-, 1·10018; 1·584*N*-, 1·19604; and 3·136*N*-, 1·38206. He also gives the indices of refraction of soln. at 18° for sodium light for 0·1*N*-soln., $\mu=1{\cdot}33465$; dispersion for H_γ and $H_\alpha=1{\cdot}035$; *N*-soln., $\mu=1{\cdot}34583$, dispersion, 0·942; and for 3*N*-soln., μ=1·36703, dispersion, 0·844. Silver fluoride, says G. Gore, does not dissolve in alcohol. According to E. Paterno and M. Cingolani, aq. soln. of silver fluoride are bactericides, and under the trade name *tachyol* they recommend it for disinfecting drinking water and, according to L. Pigorini, very dil. soln. exercise a toxic action on fish.

G. Gore reported that dry silver fluoride is not altered in dry air on exposure to light. Under the influence of the light from a mercury quartz lamp. soln. of silver fluoride are decomposed with the formation of silver subfluoride and silver peroxide. When fused, silver fluoride is attacked by moist air with the formation of silver; the vapour of water also reduces it at a dull red heat, $4AgF+2H_2O=4Ag+4HF+O_2$. This reaction is taken to explain how silver fluoride prepared under ordinary conditions is contaminated with metallic silver. If hydrated silver fluoride, $AgF.H_2O$, be dried in a vacuo or in a stream of dry air at ordinary press. until the salt becomes yellow, the residue contains silver oxyfluoride, AgF.AgOH. **Silver hydrofluoride** is formed when a soln. of silver fluoride in hydrofluoric acid is cooled. The crystals have the composition of silver trihydrofluoride, AgF.3HF, or H_3AgF_4, and they readily dissociate in air. G. Gore, and E. Frémy also noted the formation of acid fluorides, the latter by crystallization of a soln. of silver fluoride, in an excess of hydrofluoric acid; the former by the action of the gas on the dry fused salt at 13°. Hydrogen in the cold acts neither on the dry salt nor on aq. soln. in darkness or in light; but at a red heat, the fluoride is completely reduced. Many investigators—E. Frémy, H. Davy, G. Aimé, and C. J. and T. Knox—have attempted to prepare fluorine gas by the action of chlorine on silver fluoride. G. Gore found that between 15° and 110°, chlorine superficially attacks the fluoride very slowly, forming, in platinum or gold vessels, double salts of the chloride of these metals with silver fluoride—*e.g.* $PtCl_4.AgF$; with a graphite vessel, carbon fluoride is formed; vessels of glass, cryolite, or fluorite are attacked by molten silver fluoride. In soln., oxygen is evolved: $16AgF+8Cl_2+8H_2O=14AgCl+2AgClO_3+16HF+O_2$. Bromine acts like chlorine, and the action of iodine has been studied by L. Pfaundler, H. Kammerer, and G. Gore—iodine pentachloride is formed. Dry hydrogen chloride also decomposes silver fluoride at a red heat; bromic or iodic acid gives a precipitate of silver bromate or iodate, but chloric acid has no action. Nitrosyl chloride, NOCl, was found by O. Ruff and K. Stäuber to form nitrosyl fluoride, NOF, at 200°–250°. G. Gore and H. Moissan have shown that the vapour of sulphur chloride gives sulphur fluoride and silver chloride and sulphide; phosphorus pentachloride gives silver chloride and phosphorus pentafluoride; and phosphorus trichloride, phosphorus trifluoride; phosphorus oxychloride gives phosphorus oxyfluoride; the carbon chlorides at a red heat give silver chloride and carbon fluoride; silicon chloride gives silicon fluoride; boron trichloride gives boron trifluoride; sulphur at a red heat gives silver sulphide and sulphur fluoride; sulphur dioxide has no action. Fused silver fluoride at a red heat does not attack carbon, but it reacts explosively at ordinary temp. when triturated with boron—the mixture becomes incandescent. L. Pfaundler says silver fluoride has no action on boron. Silicon also reacts violently with silver fluoride, forming silicon fluoride, and silver; if the reaction takes place in a soln. of silver fluoride, the precipitated silver is crystalline. Silica and boric oxide reduce silver fluoride at a red heat. When heated in a current of coal gas silver fluoride gives silver, hydrofluoric acid, and carbon tetrafluoride; with carbon disulphide, silver sulphide and carbon tetrafluoride are formed; cyanogen reduces solid silver fluoride at a dark red heat, and a soln. of that salt is reduced by the same gas cold. Hydrogen cyanide behaves similarly. When triturated with calcium hydride, the mass becomes incandescent, forming silver and calcium fluoride. F. Valentiner and A. Schwarz found iodoform to be converted into fluoroform and silver iodide, or, according to M. Meslens, into a double compound, AgF.AgI. G. Gore analyzed silver fluoride by heating a known weight with an excess of lime: $4AgF+2CaO=2CaF_2+4Ag+O_2$. According to G. Gore, dry silver fluoride absorbs 844 vols. of ammonia, hence the product very nearly corresponds with **silver**

amminofluoride, $AgF.NH_3$. E. C. Franklin and C. A. Kraus found silver fluoride to be slightly soluble in liquid ammonia. G. Bruni and G. Levi prepared the silver ammino-fluoride, $AgF.2NH_3.2H_2O$ or $2AgF.4NH_3.5H_2O$. Molten silver fluoride is decomposed by ammonia gas. B. Grützner obtained white needle-like crystals of **hydrated diammonium argentofluoride,** $2NH_4F.AgF.H_2O$, or $(NH_4)_2AgF_3.H_2O$, by cooling a soln. of freshly precipitated and moist silver oxide in a cold conc. aq. soln. of ammonium fluoride. E. Böhm, in his *Zur Kenntnis der Fluoride* (Giessen, 1906), also described the preparation of colourless needles of the complex salt $15NH_4F.AgF.4H_2O$.

§ 14. Silver Chloride

Small quantities of silver chloride occur in nature as *horn silver*, *chlorargyrite*, *cerargyrite*, or *kerargyrite*—from κέρας, horn—in various parts of the world notably in Chili and Peru; it has been reported in Nicaragua, Honduras, Norway, Alsace, Cornwall, Brittany, Freiberg, etc.[1] An earthy variety at Andreasburg (Harz) is called *Buttermilcherz*. It usually occurs in veins of clay slate, accompanying other silver ores; and also associated with iron and copper ores, calcite, barite, etc.

There can be little doubt that silver chloride was known in the time of Pliny for, in his *Historiæ naturalis* (**33**, 25), he refers to operations in which this compound must have been formed. Geber also, in his *Summa perfectionis magisterii*, describes its *color mirabilis*. W. Fabricius, in his *De rebus metallicis* (Tiguri, 1565), refers to the colour, translucency, and fusibility of the mineral horn silver, but there is nothing about the change of this compound in light. O. Croll, in his *Basilica chymica* (Frankfort, 1609), described the preparation of silver chloride. A. Libavius stated that the resulting chloride weighed less than the silver used in its formation, but both R. Boyle and J. Kunckel contradicted this assertion. The latter, in his *Vollstandiges laboratorium chymicum* (Berlin, 1716), said that "in ☽ cornea, 12 loth of ☽ retain from common salt, 4 loth of terra and salt," otherwise expressed: 12 parts of silver form 16 parts of common salt, a result which is very close to the best determinations of to-day. A. Libavius describes, in his *Alchemia* (Frankofurti, 1585), how he precipitated silver chloride by adding a soln. of salt to one of a silver salt; and "Basil Valentine" said the same thing: "common salt precipitates ☽." J. B. Porta, in his *Magia naturalis* (Naples, 1549), mentions the fusibility of this compound. Mediæval chemists called the precipitated silver chloride *lac argenti;* the fused product was called *luna cornea* or *horn silver.* J. R. Glauber, in his *Furnis nova philosophicis* (Amstelodami, 1648), refers to its solubility in ammonia. R. Boyle specially commented on the blackening of white silver chloride by exposure to the air; and in his *Experiments and observations on colours* (London, 1663), he said:

> Having dissolved good silver in *aqua fortis,* and precipitated it with spirit of salt, upon first decanting the liquor, the remaining matter was purely white; but, after it had lain awhile uncovered, the part of it that lay contiguous to the air, not only lost its whiteness, but appeared of a very dark, and almost blackish colour; but if the part that was contiguous to the air were gently taken off, the subjacent part of the same mass would appear very white; till that also having continued a while exposed to the air would likewise degenerate.

R. Boyle attributed the darkening to the presence of air; it required almost another century to find that light alone produces the effects observed by R. Boyle. J. H. Schulze [2] is regarded as the discoverer of the sensitiveness of silver salts to light, for, in a paper entitled: *Scotophorus pro phosphore inventus seu experimentum curiosum de effectu radiorum solarium,* he specially states that when a soln. of silver in nitric acid is treated with chalk, the precipitate is darkened on the side exposed to light, and he proved that this effect is produced by light, but not by heat. C. W. Scheele, also in his essay *Aëris atque ignis examen chemicum* (Upsala, 1777), further commented upon the darkening of silver chloride in light; and by exposing paper impregnated with silver chloride to different parts of the spectrum, he further proved that this compound is blackened far more quickly by the violet rays than by the other coloured rays, and he attributed the phenomenon to the greater readiness with which the violet rays parted with their phlogiston.

Dry hydrogen chloride produces varying colours from violet-red to violet-black when it is passed over silver fluoride, and, according to A. Guntz,[3] some **silver subchloride,** Ag_2Cl, is formed, but the transformation is incomplete; on the other hand, silver subfluoride is completely transformed into the subchloride by the action of silicon or carbon tetrachloride, or phosphorus trichloride. The violet product blackens in a few days without losing any appreciable amount of chlorine. H. Vogel also prepared it by the action of silver nitrate on cuprous chloride. The heat of the reaction is $2Ag+Cl=Ag_2Cl+29{\cdot}7$ Cals., while the reaction $Ag+Cl=AgCl+29{\cdot}2$ Cals. A similar difference is observed in the case of the two fluorides. It also follows that the hypothetical reaction: $2AgCl=Ag_2Cl+Cl$, absorbs 28·7 Cals. Silver subchloride is decomposed by heat into silver chloride and silver; dil. nitric acid has no action, but the conc. acid, especially if warm, gives silver chloride, $AgCl$, and a mixture of different colours. A soln. of potassium cyanide rapidly dissolves the subchloride, forming silver and silver cyanide: $Ag_2Cl+KCy=Ag+AgCy+KCl$. E. von Bibra reported the formation of a black powder of *silver tritetritachloride,* Ag_4Cl_3, by the action of hydrochloric acid upon silver subcitrate obtained by heating silver citrate to 100° in a stream of hydrogen until its weight was constant—7 to 8 hrs. According to S. B. Newbury, the supposed silver subcitrate is a mixture of metallic silver and unchanged silver citrate, and E. von Bibra's product is thought to be a mixture of silver chloride and silver.

The preparation of silver chloride.—Silver is slowly converted into the chloride when exposed to the action of chlorine gas or chlorine water. If chlorine gas be passed into a bottle loosely packed with silver foil, when the air is displaced, and the bottle is closed, the silver is quickly converted into chloride without shrinkage or changing its form. J. S. Stas [4] prepared this salt by passing purified chlorine over the purified metal heated in a tube of hard glass. R. Cowper, and V. von Cordier showed that if the reagents be quite dry, there is no reaction. The reaction is faster in light than in darkness. Chlorine gas precipitates silver chloride from soln. of silver salts with the formation of some silver hypochlorite which decomposes immediately into silver chlorate and chloride. C. Weltzien [5] found with silver nitrate, five-sixths of the silver was precipitated as chloride, and one-sixth formed a soluble chlorate. Free chlorine, said J. J. Berzelius, displaces bromine or iodine from warm silver bromide or iodide respectively. L. Bruner and E. Bekier found iodine chloride, ICl, transforms metallic silver or silver iodide into the chloride. Dry hydrogen chloride converts silver into hydrogen and silver chloride, and conversely, silver chloride with hydrogen form silver and hydrogen chloride. J. B. J. D. Boussingault showed that the reaction is reversible—Fig. 8, Cap. XVIII. According to A. Potilitzin, the reaction between silver and hydrogen chloride begins at 150°, and, according to A. Jouniaux, at 400°. If the gas be dried R. E. Hughes found very little action. J. L. Proust found that silver chloride is superficially attacked by hydrochloric acid and a small proportion dissolves, while M. C. Lea says the metal is not attacked by an acid of specific gravity 1·20. N. W. Fischer showed that if air acts simultaneously with the acid (sp. gr. 1·20) much silver is dissolved in, say, eight days, and the addition of water precipitates silver chloride from the soln. C. W. Scheele, and F. T. Sonneschmid also showed that the attack is much hastened if oxidizing agents—arsenious acid, manganese dioxide, or copper sulphate or chloride—be present. Silver oxide forms silver chloride when treated with hydrochloric acid, and G. Wetzlar found that soln. of the alkali chlorides convert silver oxide into silver chloride and alkali hydroxide. Hydrochloric acid also converts soluble silver salts and many insoluble silver salts into silver chloride, but not so with silver iodide or bromide. The usual method of preparation is to add hydrochloric acid or a soln. of sodium chloride to a soln. of silver nitrate, and well wash the precipitate away from violet light. If a few drops of a chloride be added to an ammoniacal soln. of silver nitrate, G. Carlo found that silver chloride free from ammonia is precipitated. B. Finzi also found that the precipitation of silver chloride by adding mercuric chloride to a soln. of a silver salt is not quantitative; a part of the silver remains in soln., as a complex silver-mercury salt.

The velocity of formation of silver chloride, when soln. of silver nitrate and sodium, potassium or ammonium chloride are allowed to mix by diffusion, has been investigated by K. Jablczynsky, B. L. Vanzetti, O. Scarpa, L. Rolla, and T. Paul; while T. W. Richards and R. C. Wells have shown how difficult it is to precipitate silver chloride without the occlusion of other substances which cannot be removed by washing. W. L. Hardin recommends for the preparation of highly purified silver chloride what is virtually the following process:

> Purified silver is dissolved in hot dil. nitric acid, and the soln. evaporated to dryness, fused, and heated until nitrogen oxides commence to be evolved. The cold mass is dissolved in the smallest possible quantity of water, and allowed to stand 24 hrs. The soln. is then filtered through a double filter paper, and diluted with 30 times its volume of water. An excess of hydrochloric acid is added, and the precipitate after it has settled is washed by decantation first with dil. hydrochloric acid, and then with water. The precipitate is collected on a Buchner funnel, dried, finely powdered, and digested three days with aqua regia. The product is then thoroughly washed by decantation and dried.

According to H. Rose, silver is converted into chloride by the action of sodium chloride at a red heat, and this the more rapidly, the finer the state of subdivision of the metal. According to C. F. Plattner, the reaction is not hastened by the addition of ferric or cupric oxide; but, according to H. Rose, manganese dioxide does accelerate the reaction. The action of sodium chloride on a mixture of silver and gold is the basis of the so-called cementation process for the separation of these metals. Soln. of sodium chloride, exposed to air, slowly attack silver, forming silver chloride and sodium hydroxide, and J. L. Proust found that after some years' exposure to sea water, some silver coins were transformed into chloride. A. J. Balard found gaseous chlorine monoxide, or aq. soln. of hypochlorous acid, or the hypochlorites, transform silver into chloride; phosphorus pentachloride, says H. Goldschmidt, reacts $PCl_5+2Ag=2AgCl+PCl_3$. When silver sulphide is heated in chlorine gas or roasted with sodium chloride, silver chloride is formed. With a soln. of cupric chloride, mixed with sodium chloride, silver and cuprous chlorides are formed which remain in soln.; lead chloride forms lead sulphide and silver chloride. C. W. B. Normand and A. C. Cumming found silver thiocyanate to be incompletely converted into chloride by hydrogen chloride—ammonia, and sulphuric, and hydrocyanic acids were simultaneously formed. J. Kablukoff found the alkali halides convert molten silver nitrate almost completely into silver halide. Carbon tetrachloride reacts with silver at 250°, and a soln. of chlorine in carbon tetrachloride at ordinary temp. forms silver and carbonyl chlorides.

Colloidal silver chloride.—According to R. Ruer,[6] if a $0{\cdot}002N$-HCl be treated with $0{\cdot}1N$-$AgNO_3$, no precipitate is formed, but a bluish opalescence appears; after standing half an hour, the soln. is turbid; and in 24 hrs. a precipitate has settled on the bottom of the vessel. A. Lottermoser and E. von Meyer obtained colloidal silver chloride by the action of a soluble chloride on colloidal silver. C. Paal and F. Voss made it by first precipitating colloidal silver oxide by mixing soln. of sodium hydroxide and silver nitrate, then treating the product with an alkali chloride soln.

Properties of silver chloride.—Precipitated silver chloride, dried at 100°, is a white, flocculent, or curdy, non-crystalline, anhydrous solid. F. Kuhlmann[7] prepared an imitation of horn silver by filling a flask quite full with a soln. of silver nitrate, and closing the flask with a porous stopper, and placing the whole under hydrochloric acid. Masses of horn silver are slowly formed about the stopper. H. Debray obtained crystals of silver chloride by repeatedly heating and boiling silver chloride with a conc. soln. of silver nitrate or mercuric nitrate. According to P. Growth, the **crystals** are hexakisoctahedra, A. P. H. Trivelli and S. E. Sheppard say dyakisdodecahedra, belonging to the cubic system. The slow evaporation of the ammoniacal soln. in darkness furnishes white octahedral crystals. A. Ditte obtained the crystals by slowly cooling the soln. of the salt in hydrochloric acid. K. Haushofer, O. Lehmann, A. Streng, and H. Behrens studied the crystals of silver chloride. W. Reinders studied the precipitation of silver chloride in the presence of protective colloids. He showed that silver chloride crystallizing in the presence of various colloids—*e.g.* colloidal silver, gelatine, albumen, casein, etc. —has the capacity of taking up and homogeneously distributing these colloids in the crystals; with gelatine the effect was noticeable with conc. as low as a mgrm. of gelatine in 10 litres of water. P. Debye and P. Scherrer, A. W. Hull, and R. B. Wilsey have studied the **X-radiogram** of silver chloride. The lattice presents the simple cubic arrangement with a cube edge 2·78 A., and the distance of the nearest atomic centres 2·78 A.

The **specific gravity** determined by C. J. B. Karsten[8] is 5·501 before fusion; 5·5671 after blackening in sunlight; and after fusion, 5·4582. G. F. Rodwell gave 5·505 (0°). The sp. gr. of the salt which has been fused ranges from J. L. Proust's 5·4548 to H. G. F. Schröder's 5·594. F. Mohr says the sp. gr. is the same after precipitation, after standing in the mother liquid for some time, and after heating to 100°. According to G. F. Rodwell, its sp. gr. steadily increases from its fusion point down to —60°. G. F. Rodwell gave the sp. gr. of the molten salt as 4·919 at 451°; and G. Quincke, 5·4. The mean of I. Domekyo's values for native silver chloride, horn silver, is 5·37. P. Walden, and F. A. Henglein studied the mol. vol. of the silver halides.

The values reported for the **melting point** range from G. F. Rodwell's[9] 450° to W. Ramsay and N. Eumorfopoulos' 460°. The best representative value is 455°. Before melting, the salt is yellow, after melting it forms a transparent viscid orange-yellow liquid, and when cooled, forms a colourless translucent horn-like mass. H. Stolzenberg and M. E. Huth have studied the formation of anisotropic liquids or liquid crystals during the freezing of molten silver chloride. C. Sandonnini found that the f.p. curves of mixtures of lithium and silver chlorides give mixed crystals of two kinds with a gap between 16 and 50 gram-mol. per cent. of silver chloride; with sodium and silver chlorides, C. Sandonnini and P. C. Aureggi found that there is a continuous variation in the f.p. from silver chloride to sodium chloride, showing that an unbroken series of mixed crystals of the two salts is formed without a minimum in the freezing curves. E. Jänecke has followed the whole course of the "unmixing" of the mixed crystals when the molten mixtures are cooled. The crystals under the microscope appear to be homogeneous, and those crystals with up to 11 per cent. of silver chloride, as in the mineral *huantajayite*, dissolve in water, leaving a curdy residue. S. F. Schemtschuschny found silver and potassium chlorides form a typical V-curve with the eutectic at 306°, and 60 gram-mols. per cent. of silver chloride; a similar curve is obtained with silver and rubidium chlorides, and C. Sandonnini and P. C. Aureggi give the eutectic at 251° with 60 gram-mols. per cent. of silver chloride. H. Stolzenberg and M. E. Huth have obtained liquid crystals of silver chloride during the cooling of fused silver chloride. According to I. Kablukoff, and G. Scarpa, there is a eutectic with mixtures of silver nitrate and chloride at 160° with 75 to 90 gram-mols. per cent. of silver nitrate. Silver chloride which has been fused forms a waxy or horn-like translucent mass, and when in thin flexible and transparent plates, which appear colourless although *en masse*, the colour is yellowish-grey. According to A. and C. R. Aikin, the fused chloride has been turned in a lathe, and ornaments have been made from it.

T. W. Richards and G. Jones'[10] value for the **compressibility** of silver chloride between 100 and 500 megabars is 0·00000222 megabar per sq. cm.; or 0·00000218 kilogrm. per sq. cm.; or 0·00000225 atm. per sq. cm.; and the mol. compressibility is 0·000057 megabar per cm. N. Kurnakoff and S. F. Schemtschuschny's value for the *Fliessdruck*, that is, the press. required to make precipitated silver chloride flow through a small opening is 65·2 kilogrms. per sq. mm.; for precipitated and compressed silver chloride, 34·7; and for precipitated silver chloride, 17·2. G. Quincke's value for the **surface tension** of molten silver chloride is $\sigma=\frac{1}{2}a^2Dg$ dynes per cm., where a is the difference in cms. between the height of the plane corresponding with the upper surface of the liquid and the plane of greatest diameter, g the acceleration of gravity, 980·6; and D, the sp. gr. of the liquid; but D=5·3, and a=0·286, accordingly σ=210 dynes per cm. A. Gradenwitz found σ=212·7; and for the specific cohesion a^2, 8·18 sq. mm. A. Colson has investigated the **diffusion** of solid silver chloride into solid sodium chloride.

H. Fizeau's[11] value for the **coefficient of linear expansion** is 0·000032938; and for the mol. cubical expansion, 0·00255. The **heat of fusion** of silver chloride is 4·4 Cals. according to O. H. Weber. The **specific heat** C_p of silver chloride which has been fused is 0·0911 between 15° and 98° (H. V. Regnault), and 0·0978 between 160° and 380° (O. Ehrhardt). J. N. Brönsted gives 0·08775 between 0° and 19°; and the corresponding **molecular heat,** 12·58 Cals. The mol. ht. rises with the temp.; thus A. Magnus gives 13·01±0·06 from 15° to 100° 13·60±0·01 from 16° to 250°; and 13·72±0·02 from 16° to 300°. A. Eucken likewise found the mol. ht. falls to 11·81 at —65·5°, and to 10·34 at —157°. W. Nernst gives for the mol. ht. 2·98 at —249·5°; 4·79 at —240·2°; 7·25 at —227·4°; and 9·79 at —187·7°. W. Nernst and F. Schwers give 2·78 at —250·5°, and 9·82 at —181·6°. Silver chloride commences to volatilize at about 260°, and at a red-heat the loss by volatilization is appreciable. At a rather higher temp. it volatilizes as a dense white vapour. F. J. Malaguti and J. Durocher say that "silver chloride *per se* requires a very high temp. for its volatilization, and it volatilizes very slowly in a closed vessel on account of the low press. of its vapour." The **vapour pressure** of silver chloride at 1000° is less than 5 mm., and at 1150° it is nearly 15 mm. It is less volatile than lead chloride. **Vapour density** determinations by A. Scott, and by H. Biltz and V. Meyer, show that at 1735° the vapour density is 5·698; the theoretical value for AgCl is 4·965, and accordingly some molecules of Ag_2Cl_2 still exist undissociated at this temp.

According to M. Berthelot,[12] the **heat of formation** is Ag+Cl=AgCl (amorphous or crystalline), 29·2 Cals.; or 114 kilojoules per mol; $Ag_2O+2HCl_{aq.}$=41·8 Cals.; J. Thomsen's value for the heat of formation from its elements is 29·38 Cals. M. de K. Thompson found the **free energy** of formation with gaseous chlorine to be

25,600 cals., the **total energy,** 28,900 cals. The heat of formation calculated by J. N. Brönsted and F. Halla from the e.m.f. of the element HgCl|AgCl is 29·939 Cals. U. Fischer gives 30·1 Cals. between 15° and 159°, and H. Braune and F. Koref, 30·410 Cals. For the formation of silver chloride from fused silver nitrate and potassium chloride, J. Kablukoff gives 14·51 Cals. M. Berthelot tried if the heats of dissolution of the different forms of silver chloride in potassium cyanide show any differences outside the range of the errors of experiment, but with negative results.

A. de Gramont says that kerargyrite is electrically non-conducting. W. Kohlrausch[13] found the **electrical conductivity** of silver chloride at 20° to be less than 0·0000035 and to increase with a rise of temp. C. Tubandt and E. Lorenz also found it to gradually rise up to the m.p., when an abrupt increase occurs ; there is no sign of a change corresponding with the formation of liquid crystals. The data are :

	250°	350°	450°	455°	457°	550°	600
Conductivity .	0·00030	0·0065	0·112	melts	3·764	4·05	4·1

C. Tubandt said that the current in solid crystals of silver chloride is carried entirely by the positive silver ion; the velocity of the ion close to the m.p. was $0{\cdot}03\times10^{-3}$ cms. per sec. C. Sandonnini gives the electrical conductivity of fused silver chloride at its m.p. 455° as 3·654 reciprocal ohms, and he investigated the electrical conductivities of fused mixtures of silver and thallous chlorides. J. C. Ghosh also measured the conductivity and calculated the **ionization,** α, of fused silver chloride at different temp. He found at 523° $\alpha=0{\cdot}26$, and at 723°, $\alpha=92{\cdot}92$ per cent. L. Grätz showed that under a press. of 4000 atm. the electrical resistance decreases between 0·002 and 0·001 per cent. of its initial value, and a rise of temp. between 220° and 230° produces a similar result. The degree of ionization of silver chloride at 461° is $1{\cdot}25\times10^{-3}$. E. Becquerel found that when a substance is used for the two poles of a voltameter containing an electrolyte, there is a difference of potential when one plate is in darkness and the other plate is illuminated. H. Luggin studied the effect with silver halides. S. Arrhenius has studied the effect of light on the electrical conductivity of silver chloride. C. Tubandt studied the conductivity of the crystalline solid. G. Trümpler measured the e.m.f. of silver chloride against the normal calomel electrode. S. Meyer gave $-0{\cdot}28\times10^{-6}$ units of mass at 17° for the **magnetic susceptibility** of silver chloride ; no discontinuity was observed, by T. Ishiwara, when silver chloride is melted.

G. C. Schmidt obtained a marked **photoelectric effect** with silver chloride, bromide, and iodide. According to G. Dima, the order of magnitude is 200 : 430 : 750. C. Schell noticed that while silver iodide is a poor conductor of electricity in darkness, it becomes a much better conductor when illuminated ; that rays of wave-length $0{\cdot}4226\mu$, $0{\cdot}3222\mu$, and $0{\cdot}2712\mu$ are most active in changing the conductivity ; and that the absorption coeff. for photoelectrically active rays is 13,000 ; W. Wilson found 15,000. W. Wilson studied the photoelectric effect with silver iodide, and found this salt is ten times as active as an aluminium plate when illuminated by an arc light. The effect with violet light is 8 to 10 per cent. more than with ultra-violet light. W. Wilson explained this by the assumption that violet light causes the molecules to emit electrons of higher speed, and these are less easily liberated by an applied e.m.f., and so the conductivity suffers less change. The photoelectric effect of silver chloride, says G. Dima, is smaller than with silver bromide or silver iodide ; in arbitrary units, under the influence of ultra-violet light, the respective ratio is 1 : 2·15 : 3·75. H. Jackson found purified silver chloride in a high vacuum was apparently unaffected by daylight, but it glowed with a green phosphorescence in the cathode rays. The silver chloride was darkened by the exposure, and the darkening was greatest where the glow was brightest.

P. Dutoit and G. von Weisse found the potential of silver chloride against $\frac{1}{10}N$-silver nitrate is 0·226 volt at 25°, and M. Katayama found the e.m.f. of the cell

Ag|AgCl|Cl to be 1·130+0·0006(20−θ) volts at a temp. θ between 15° and 195°; and for the cell Ag|AgCl|$PbCl_2$|Pb, 0·480+0·0001(60−θ) volt between 23° and 121°. A. de Cloizeaux[14] found the **index of refraction** of native silver chloride for Na-light to be μ=2·071. L. Wernicke gives for λ=431, μ=2·135; λ=486, μ=2·101; and λ=656, μ=2·0473. J. A. Wilkinson observed that the salt has a green fluorescence. H. Hertenstein noted that the spark spectrum is very like that of the metal with some lines missing. T. W. Richards and R. C. Wells have measured the opacity of suspensions of silver chloride in water; and C. Wissinger, the absorption spectrum. S. Procopiu found that a liquid with suspended particles of silver chloride depolarized polarized light.

The **solubility** of silver chloride in *water* is very small. C. H. Pfaff[15] found the insolubility of silver chloride to be so great that water containing one part of hydrochloric acid in 113,000,000 parts of water is rendered turbid by the addition of silver nitrate, but the action is almost insensible with 1 in 227,000,000. G. J. Mulder, however, claimed that silver can be so detected in water containing at ordinary temp. one part of silver in 1,000,000 parts of water, but not in water with half that proportion of silver in soln. *Vide* analytical reactions of silver. According to C. Hoitsema, one part of silver chloride produces an appreciable turbidity in 3,000,000 to 5,000,000 parts of water. W. Böttger found the specific conductivity of aq. soln. at 100° to be $56{\cdot}7\times10^{-6}$ reciprocal ohms, and for infinite dilution, 373 reciprocal ohms; from this, he calculates the solubility to be $15{\cdot}2\times10^{-5}$ mols, or 0·0218 grm. per litre at 100°. From R. Abegg and A. J. Cox's value 0·015 volt for the cell Ag|AgCl against $\frac{1}{10}N$-KCl, H. M. Goodwin calculated $1{\cdot}25\times10^{-5}$ at 25°, and A. Thiel, $1{\cdot}41\times10^{-5}$. Collecting together the different data for the solubility of powdered amorphous silver chloride expressed in grams per litre:

	2°	10°	18°	25°	34°	42°	100°
AgCl .	0·00076	0·00096	0·00156	0·00191	0·00303	0·00303	0·0218

The solubility depends to some extent on the grain-size; J. S. Stas found that freshly precipitated curdy silver chloride is more soluble than the powdered form. The larger grains are less soluble than the small ones, and therefore increase in size at the cost of the small ones. The heat of soln. Q, or negatively, the heat of precipitation, calculated from the solubilities S_1 and S_2 at temp. T_1 and T_2 calculated from $\log S_1-\log S_2=\frac{1}{2}Q(T_1{}^{-1}-T_2{}^{-1})/R$, is −16 Cals., and J. Thomsen's value, found calorimetrically, is −15·8 Cals.

In estimating silver by J. L. Gay Lussac's method, in which a soln. of silver nitrate is titrated with a soln. of an alkali chloride, a point is reached at which a slight precipitate is produced by the addition of a drop either of the alkali chloride or of the silver nitrate soln., indicating the presence of either free silver nitrate or alkali chloride in a state of equilibrium, either of which is precipitated by the other. This is sometimes called *Mulder's neutral point* after G. J. Mulder's study of the reaction in his *De essayeer-methode van het zilver scheikundig onderzocht* (Utrecht, 1857), where the phenomenon was attributed to the presence of alkali nitrate; but J. S. Stas showed that alkali nitrate is not the cause which determines the soln. of the silver chloride; rather is it due to the solubility of silver chloride in the soln. and to the reduction of the solubility by the addition of an excess of either silver nitrate or of a little sodium chloride. The use of an alkali bromide or iodide obviates the difficulty which arises owing to the solubility of silver chloride, because silver bromide or iodide is so much less soluble in cold water than the chloride. J. P. Cooke says that 0·1 grm. of silver nitrate per litre makes silver chloride quite insoluble in water, while the addition of some *hydrochloric acid* lowers the solubility one half. According to C. St. Pierre, a soln. of silver nitrate is added drop by drop to conc. hydrochloric acid, and the whole is rapidly stirred, the silver chloride which is first formed dissolves so rapidly that its formation can be perceived only with difficulty; the proportion of silver chloride thus dissolved may exceed 0·5 per cent. of the weight of acid employed. When water is added, the soln. becomes turbid. The turbidity at first increases with the quantity of water added; but all the silver chloride cannot be precipitated by adding water.

The solubility of silver chloride in water is depressed when chlorine or silver ions are present in the soln. Since the solubility of silver chloride is approximately 10^{-5} mols per litre and the ionization is then complete, the solubility product is 10^{-10}, and therefore an excess of the ions of either chlorine or silver reduces the solubility very much. For instance, if the conc. of either of these ions be 10^{-3}, the solubility falls from 10^{-5} to 10^{-7} mols per litre. In many cases, however, complexes appear to be formed. A. A. Noyes and W. C. Bray[16] suggested the complex ion is $AgCl_2'$; G. Bodländer, $AgCl_4'''$. G. S. Forbes, however, obtained a little evidence of the formation of the complex ions $AgCl_3''$, $AgCl_4'''$, and possibly of $AgCl_5''''$, but not of $AgCl_2'$, in his study of silver chloride in soln. of various chlorides. With conc. *hydrochloric acid*, E. H. E. Reinsch showed that one part of silver nitrate in 15,000 parts of water becomes turbid when a little hydrochloric acid is added, and the turbidity clears up when more acid is present. Again, G. S. Whitby found that at 21°, 1 per cent. HCl dissolves 0·0002 grm. per litre; 5 per cent. acid, 0·0033 grm. per litre; and 10 per cent. acid, 0·0555 grm. per litre. C. St. Pierre also showed that while 100 grms. of conc. hydrochloric acid dissolve 0·5 grm. per litre, 100 c.c. of the same acid diluted with twice its weight of water, dissolve only 0·167 grm. of silver chloride. A. Vogel stated that with 100 c.c. of cold hydrochloric acid of sp. gr. 1·165, alone or diluted with:

Water . . .	0	100	200	300	500 c.c.
Silver chloride . .	0·298	0·056	0·018	0·0089	0·0035 grm. per 100 c.c.

Boiling hydrochloric acid diluted with its own vol. of water dissolved, under similar conditions, 0·56 grm. of silver chloride. O. L. Erdmann found that a hot mixture of alcohol and hydrochloric acid dissolves silver chloride, part of which separates out on cooling. E. H. Riesenfeld and H. Feld electrolyzed soln. of silver chloride in 35 per cent. hydrochloric acid, and they found that silver migrates to the anode as a complex **hydrochloroargentic acid,** $HAgCl_2$. This conclusion is in agreement with G. S. Forbes and H. I. Cole's work on the solubility of silver chloride in hydrochloric acid, and also in soln. of the chlorides of sodium, ammonium, potassium, rubidium, calcium, strontium, and barium.

According to N. A. E. Millon and A. Commaille, silver chloride is not soluble in aq. soln. of *calcium or zinc chloride;* but this statement has not been confirmed by A. Vogel, H. C. Hahn, or G. S. Forbes, who investigated the solubility of this salt in aq. soln. of *sodium potassium, ammonium, barium, strontium, calcium,* and *magnesium chlorides.* The solubility of silver chloride is very nearly proportional to the conc. of the dissolved chloride through considerable ranges, and is nearly doubled in passing from 0° to 25°. On the basis of the theory of the solubility product, G. S. Forbes calculated that silver chloride ought to be most insoluble in $\frac{1}{100}N$-soln. of the given chloride. H. C. Hahn says a sat. soln. of calcium chloride dissolves at 0°, 2·825 grms. of silver chloride per litre, and at 100°, 8·147 grms., while in magnesium chloride soln. the solubility is even greater. H. Debray, and J. Formâne say that the presence of mercuric chloride does not favour the solubility of silver chloride. A. Sauer says the presence of ferric chloride favours the solubility of silver chloride, while H. C. Hahn found a sat. soln. of *ferric chloride* at 24·5° dissolves 0·006 grm. of silver chloride per 100 grms. of soln.; *ferrous chloride,* 0·169 grm.; *cupric chloride,* 0·053 grm.; *manganese chloride,* 0·013 grm.; *zinc chloride,* 0·0134 grm.; a 27·32 per cent. soln. of *barium chloride,* 0·057 grm.; 41·26 per cent. of *calcium chloride,* 0·571 grm.; 36·35 per cent. *magnesium chloride,* 0·531 grm.; 2 per cent. *ammonium chloride,* 0·3397 grm.; 24·95 per cent. *potassium chloride,* 0·0776 grm. (19·6°); 25·95 per cent. *sodium chloride,* 0·105 grm. The solubility of silver chloride in soln. of sodium and potassium chloride at 15° show per 100 grms. of soln.—10 grms. KCl, 0·000 grm. AgCl; 20 KCl grms., 0·020 grm. AgCl; 25 grms. KCl, 0·084 grm. AgCl; and with 10 grms. NaCl, 0·0025 grm. AgCl;

21·98 grms. NaCl, 0·0439 grm. AgCl; and with 26·31 grms. NaCl, 0·127 grm. AgCl. A. C. and A. E. Becquerel found a litre of a sat. soln. of sodium chloride at ordinary temp. dissolved 0·807 grm. of silver chloride. J. Percy found the rate of dissolution of the salt in a cold sat. aq. soln. of calcium chloride to be, per 100 c.c.:

	2	5	10	21	60 days.
Grm. silver chloride .	0·0538	0·0576	0·0753	0·1134	0·1426

According to P. A. Guye, the solubility of silver chloride in soln. of *potassium chlorate* is 0·0018 grm. per litre. G. J. Mulder says that the solubility of silver chloride in *nitric acid* of sp. gr. 1·3 is not greater than it is in the dil. acid—hot or cold, conc. or dil., but according to C. St. Pierre, when nitric acid is distilled with a small quantity of pulverulent silver chloride, the salt gradually dissolves. This is not a case of simple soln. because silver nitrate crystallizes from the cooling liquid. According to C. van Rossem, the solubility is not perceptibly influenced by $\frac{1}{10}N$-soln. of *sodium or ammonium nitrate;* silver chloride is also slightly soluble in cold aq. soln. of sodium, potassium, calcium, magnesium, or ammonium nitrates, and more so in warm soln., inasmuch as "hot soln. which are perfectly clear become strongly clouded as they cool." He also showed that between 15° and 20°, a soln. containing 0·393 grm. of sodium nitrate dissolved 0·00096 grm. of silver chloride per 100 grms. of soln. and with 0·787 and 2·787 grms. of sodium nitrate respectively 0·00133 and 0·00253 grm. of silver nitrate. A conc. soln. of *silver nitrate,* at 25°, was found by G. S. Forbes to give a faint turbidity with 0·00003 grm.-eq. or 0·001 grm. of chlorine per litre. This is but one-tenth the solubility of silver chloride in a $2N$-soln. of alkali chloride. W. Böttger also found the solubility of silver chloride in $\frac{1}{50}N$-silver nitrate to be $0·15\times10^{-7}$. E. Reichert claims to have obtained what he thought to be a compound of silver chloride and nitrate, $AgCl.AgNO_3$. F.p. curves of silver chloride and nitrate have been examined by I. Kablukoff, and by G. Scarpa. There is a eutectic with 75 gram-mol. per cent. of silver nitrate at 160°. H. W. F. Wackenroder (1842), and J. von Liebig (1851) noticed that the silver halides dissolve comparatively easily in cold soln. of mercuric nitrate, and more so in hot soln.; while J. S. Stas measured some of the solubilities. J. T. Hewitt found that silver chloride suspended in nitric acid is dissolved when mercuric oxide is added. B. H. Buttle and J. T. Hewitt say the amount of silver in soln. rises from 0·00684 to 0·0187 gram-atom per litre as the conc. of the *mercuric nitrate* rises from 0·025 to 0·250 mol per litre. With a sufficiently great excess of mercuric nitrate, the addition of hydrochloric acid or silver nitrate results in the separation of an eq. amount of silver chloride. If the conc. of the nitric acid rises from 0·30 to 0·70 mol per litre, the amount of silver remaining in soln. falls from 0·00924 to 0·00862 gram-atom per litre. H. Morse found evidence of the formation of complexes of mercuric nitrate and silver chloride in the soln. R. Luther explains the phenomenon by assuming that when mercuric nitrate is added to the completely ionized soln. of silver chloride, some chlorine ions are discharged, by the formation, according to J. T. Hewitt, of a $HgCl^{\cdot}$-ion; and more silver chloride dissolves in order to preserve a constant solubility product for this salt. B. Finzi, and J. Barnes have studied the effect of mercuric salts on the solubility of silver chloride. A hot sat. soln. of silver chloride in one of mercuric nitrate deposits brilliant yellowish-white crystals of silver chloride on cooling. The addition of an excess of hydrochloric acid, sodium, or ammonium chloride, or nitric acid, precipitates all the silver as chloride; sodium acetate acts in a similar manner, forming mercuric acetate and sodium nitrate. Silver chloride precipitated with a small quantity of mercurous chloride, is stated by J. Spiller not to be blackened by light.

G. J. Mulder found silver chloride to be insoluble in dil. or conc. cold *sulphuric acid,* but it is decomposed by the boiling acid; and he also found silver chloride is not dissolved by cold or hot *sulphurous acid.* J. von Liebig, and H. Debray have studied the effect of *alkali acetates* on the solubility of silver chloride. E. Valenta found the solubility in *ammonium thiosulphate* soln. at 20°, to be per 100 grms.;

in soln. containing 1 : 100$(NH_4)_2S_2O_3$, 1·32 grms. AgCl ; with 1 : 10$(NH_4)_2S_2O_3$, 3·92 grms. AgCl. Again, with *sodium thiosulphate* soln. at 20°, the solubility per 100 grms. of soln. containing 1 : 100$Na_2S_2O_3$, 0·40 grm. AgCl ; 100$Na_2S_2O_3$, 2·00 grms. AgCl ; 10 : 100$Na_2S_2O_3$, 4·10 grms. AgCl ; and 20 : 100$Na_2S_2O_3$, 6·10 grms. AgCl ; T. W. Richards and H. B. Faber found a soln. with 200 grms. of sodium thiosulphate in litre at 35° dissolves 9·08 grms. of silver chloride per 100 grms. of soln. R. Luther and A. Leubner attributed the augmented solubility to the formation of complexes. A. Rosenheim and S. Steinhäuser isolated the complex $4(NH_4)_2S_2O_3.NH_4Cl.AgCl$. Similar remarks apply to the augmented solubility of silver chloride in *sodium sulphite* soln., where E. Valetta showed that soln. with conc. 10 : 100 and 20 : 100 Na_2SO_3 respectively dissolve 0·44 and 0·95 grm. of silver chloride per 100 grms. of soln. E. Valenta also showed that a 5 : 100 soln. of *potassium cyanide,* at 25°, dissolves 2·75 grms. of silver chloride. Thiocyanates also augment the solubility of silver chloride. Thus, 5 : 100, 10 : 100, and 15 : 100 soln. of *ammonium thiocyanate,* at 20°, dissolve respectively 0·08, 0·54, and 2·88 grms. of silver chloride per 100 grms. of soln. With soln. of conc. 10 : 100, at 25°, the solubility with *potassium thiocyanate* is 0·11 grm. of silver chloride ; *calcium thiocyanate,* $Ca(SCy)_2$, 0·15 grm. ; *barium thiocyanate,* $Ba(SCy)_2$, 0·20 grm. ; $Al(SCy)_3$, 2·02 grms. ; *thiocarbamide,* 0·83 grm. ; and *thiosinamine,* 3·90 grms. G. J. Mulder found silver chloride to be perceptibly soluble in a warm aq. soln. of *tartaric acid,* and to a less extent in a cold soln. N. G. Chatterji and N. R. Dhar observed no signs of peptization when silver chloride is treated with a conc. soln. of *cane sugar.*

M. Faraday (1818), and E. C. Franklin and C. A. Kraus (1898)[17] reported that silver chloride is slightly soluble in *liquid ammonia ;* but it is very soluble in *aqueous ammonia* as was noted by J. R. Glauber in 1648. Many observations have been made on the phenomenon since that time. If an ammoniacal soln. of silver chloride is boiled, J. L. Proust showed that fulminating silver is deposited, but if slowly evaporated at a gentle heat, silver chloride may be deposited in cubes or octahedra, or in pearly scales. The silver chloride is precipitated from the ammoniacal silver chloride soln. by neutralizing the ammonia with an acid ; and P. Berthier showed that hydrogen sulphide or alkali sulphides precipitate silver sulphide from the ammoniacal soln. by neutralizing the ammonia with an acid , and when boiled with ammonium sulphate finely divided silver is precipitated. N. W. Fischer found that zinc and copper rapidly reduce grey spongy silver ; lead reduces the silver slowly and completely ; cadmium and antimony act slowly and incompletely ; and tin, iron, bismuth, and mercury are without action. G. Bodländer found an ammoniacal soln. of lead acetate precipitates lead chloride from an ammoniacal soln. of silver chloride. An ammoniacal soln. of silver chloride or bromide when heated with iodic acid up to nearly 200° gives a deposit of silver iodide and an evolution of a small amount of gas. It is supposed that the iodic acid oxidizes the ammonia, forming nitrogen, water, and ammonium iodide : $NH_4IO_3+2NH_3=NH_4I+3H_2O+N_2$, a reaction verified by heating the iodic acid with ammonia in a sealed tube ; no bromic or chloric acid is formed if silver bromide or chloride be also present. The ammonium iodide so formed reacts with the less soluble silver chloride or bromide giving silver iodide. Bromic acid acts similarly.

According to R. Jarry, at 0°, 100 grms. of the soln. hold :

NH_3 . .	1·45	5·60	11·77	28·16	30·19	34·56	37·48 grms.
AgCl . .	0·49	3·44	4·68	6·59	7·25	4·77	3·90 ,,

When the soln. in a confined space is evacuated, at 0°, the manometer remains constant at 268 mm., and 10 to 15 c.c. of the soln. can give off more than 500 c.c. of ammonia without the press. changing. If evacuated further, the manometer falls to 15 mm. If an allowance be made for the water vapour, the partial press. of the ammonia in the two cases are 263 mm. and 12 mm. respectively ; these are the dissociation press. of the compounds $AgCl.3NH_3$ and $2AgCl.3NH_3$ respectively. There are also two breaks in the solubility curves of silver chloride in aq. ammonia which correspond with these two compounds as solid phases. G. Bodländer and R. Fittig's work on the solubility of silver chloride in aq. ammonia led to the inference that other ammino compounds are present—e.g. $AgCl.2NH_3$. J. Straub represents the relation between the silver [Ag] and the ammonia $[NH_3]$ in soln. by $[Ag]=0{\cdot}0218[NH_3]^2+0{\cdot}0550[NH_3]$.

M. Faraday noted in 1818 that when silver chloride is exposed to ammonia gas, a considerable proportion is absorbed, and the solid swells considerably and finally crumbles to powder. He also noted that when a conc. soln. of silver chloride in aq. ammonia is allowed to stand for some weeks it furnishes colourless transparent crystals. R. Jarry also obtained similar crystals by cooling to 0° a soln. of ammonia sat. with silver chloride at 20°. B. Gossner used an analogous mode of preparation. R. Kane also obtained these crystals by treating the soln. with alcohol. The product obtained by these different processes is **silver sesquiammino-chloride,** $2AgCl.3NH_3$. F. Isambert found this compound is also produced when silver chloride is exposed to a stream of ammonia at 20°. When exposed to air the crystals become opaque, ammonia is evolved, and silver chloride remains. Both F. Isambert and A. Horstmann have measured the dissociation press. at different temp.

6°	10°	20°	47°	58·5°	69·0°	71·5°	103°
22·0	28·2	52·6	268	528	786	946	4880 mm.

According to W. Biltz, the dissociation temp. for one atm. is 68°; the compound melts at 103°, and F. Isambert's value for the heat of formation is 11·58 Cals. per mol of ammonia. W. Biltz and W. Stollenwerk also found evidence of silver monammino-chloride, $Ag(NH_3)Cl$, above 30°, the sesquiammine and the monammine form mixed crystals. The vap. press. p of the sesquiammine is given by $\log p=-14{\cdot}57T+1{\cdot}75\log T-0{\cdot}0015T+3{\cdot}3$, where the heat of formation Q is 10·52 Cals.; likewise for the monammine, $Q=11{\cdot}11$ Cals., and the vap. press. p is given by $\log p=-Q/4{\cdot}57T+1{\cdot}75\log T-0{\cdot}0015T+3{\cdot}3$.

F. Isambert found that when the temp. of silver chloride is between 0° and 20°, a current of ammonia gas produces **silver triammino-chloride,** $AgCl.3NH_3$. A. Terreil prepared what he thought to be *silver diammino-chloride*, $AgCl.2NH_3$, by heating in a sealed tube on a water-bath silver chloride sat. with ammonia gas or with conc. aqua ammonia; on cooling, crystals of the salt in question separate out. The crystals may prove to be the partially dissociated triammino-salt. W. Biltz found the dissociation temp. of the triammino-salt to be 20° at one atm. press.; the dissociation press. are:

0·1°	0·6°	16·6°	28·8°	32·4°	34·2°	54°	57°
273	505	598·5	1355	1596	1713	4641	4880 mm.

Consequently, if silver chloride be placed in an excess of aqua ammonia at a press. of 760 mm., the compound $AgCl.3NH_3$ will be formed below 20° nearly; $2AgCl.3NH_3$ between 20° and 65° nearly; and above 65° silver chloride alone will exist. W. Biltz and W. Stollenwerk found the heat of formation $Q=9{\cdot}16$ Cals., and the vap. press., p, is given by $\log p=-Q/4{\cdot}57T+1{\cdot}75\log T-0{\cdot}0025T+3{\cdot}3$.

Soln. of ammonium chloride at 15°, containing 10, 19·23, and 28·45 grms. of *ammonium chloride*, dissolve respectively 0·0050, 0·0577, and 0·340 grm. of silver chloride per 100 grms. of soln. The solubility of silver chloride in soln. with 26·31 grms. of ammonium chloride per 100 grms. of soln. rises from 0·276 at 15° to 1·053 at 110°. A. Vogel found that a hot sat. soln. of ammonium chloride dissolves silver chloride, and, as the soln. cools, it deposits needles of silver chloride; silver chloride is also precipitated if water be added to the soln. P. T. Austen [18] found that an ammoniacal soln. of silver chloride can be acidified by hydrochloric acid without precipitation of silver chloride, and he assumes the soln. contains *ammonium silver chloride.* G. S. Forbes also studied the solubility of silver chloride in aq. soln. of ammonium chloride, and the formation of the complex salt. A soln. of *ammonium carbonate* (1 : 10) dissolves 0·05 grm. of silver chloride per 100 grms. of solvent.

Silver chloride is virtually insoluble in *ethyl alcohol*, and, according to G. Bodländer, J. Neustadt found the solubility in *methyl alchohol* to be $1·95 \times 10^{-13}$, and in ethyl alcohol, $1·8 \times 10^{-14}$. B. Wuth, and H. Euler have investigated the solubility of silver chloride in *methylamine* and in *ethylamine*. The salt is almost insoluble in *ether*. F. Mylius and G. Hüttner could find no sign of the extraction of any silver chloride by treating aq. or hydrochloric acid soln. with this menstruum. F. Bezold says it is insoluble in *methyl acetate*, and M. Hamers, in *ethyl acetate*. According to L. Kahlenberg and W. J. Wittich, the solubility in *pyridine* falls from 5·35 grms. per 100 grms. of pyridine at 0° to 0·12 grm. at 110°; between −1° and −22°, the solid phase is $AgCl.C_5H_5N$; and between −22° and −57°, $AgCl.2C_5H_5N$.

Chemical properties of silver chloride.—D. Tommasi[19] says that silver chloride is reduced by **hydrogen** under a high press. or at an elevated temp. The equilibrium reaction, $2Ag+2HCl \rightleftharpoons 2AgCl+H_2$, has been previously discussed, and A. Jouniaux's values for the equilibrium constant $K[HCl]^2=[H_2]$ are 0·1164 at 526°; 0·08912 at 605°; and 0·05728 at 705°. According to A. Jouniaux, silver chloride is reduced in **sunlight** at ordinary temp., and with time, the reaction is complete. H. Schulze observed no change when silver chloride is heated in oxygen, but A. Mailfert found it to be slowly peroxidized by **ozone.**

H. Rose[20] reported that when **phosphorus** is heated with silver chloride it forms phosphorus trichloride and silver; while at 400°, A. Granger obtained silver diphosphide. H. Rose also found that silver chloride is easily reduced by **phosphine,** forming phosphorus, silver, and hydrogen chloride. Silver chloride is not reduced when heated with **carbon,** but on charcoal in the blowpipe flame it is reduced to the metal. J. Thallwitz found an intimate mixture of silver chloride, charcoal, and sodium peroxide spontaneously inflamed in a short time, and produced a regulus of silver. According to F. Göbel, **carbon monoxide** reacts with silver chloride, forming phosgene, $COCl_2$, but neither A. G. Bloxam nor C. Stammer could confirm this: carbon monoxide does not reduce red-hot silver chloride. N. D. Costeanu did not detect any action when *carbon dioxide* is passed over silver chloride at 835° and 1000°.

E. Filhol and J. B. Senderens[21] say that silver chloride is not changed when boiled with **sulphur**; but P. Berthier states that a small proportion of silver chloride is decomposed when it is heated with sulphur, forming what he called a soft greyish-black *sulfo-chlorure*. C. F. Wenzel found that when silver chloride is heated with **mercuric sulphide,** silver sulphide and mercuric chloride are formed; A. Levallois obtained an analogous result with lead sulphide in a sealed tube at 160°.

F. J. Malaguti and J. Durocher made an elaborate study of the action of different metal sulphides and arsenides on silver chloride. They found that silver chloride is directly decomposed, at ordinary temp., by contact with various metallic sulphides when no liquid other than water is present. Thus by triturating a mixture of *cadmium sulphide* and silver chloride with water, the yellow sulphide becomes first bistre-coloured, and finally black; on filtering, cadmium chloride is found in the filtrate. With some sulphides the action is very slow—*e.g.* with copper pyrites the reaction is inappreciable in less than a month. *Stannic sulphide* becomes black, and the filtrate contains some free hydrochloric acid. *Cuprous sulphide*, according to C. J. B. Karsten, is converted by an ammoniacal soln. of silver chloride into copper chloride, and sulphide, and metallic silver: $2AgCl+Cu_2S=2Ag+CuCl_2+CuS$; F. J. Malaguti and J. Durocher represent the reaction: $4AgCl+Cu_2S=2Ag+Ag_2S+2CuCl_2$, and added: The reaction is as precise and almost as prompt as between two eq. proportions of liquid substances; but C. J. B. Karsten found no reaction occurs with cuprous sulphide and a soln. of silver chloride in sodium chloride. He also found *zinc sulphide* in the presence of aq. ammonia reacts with silver chloride, forming silver sulphide, but in the presence of an aq. soln. of sodium chloride, the reaction is retarded. F. J. Malaguti and J. Durocher represent the reaction with zinc blende in the presence of aq. ammonia: $2AgCl+ZnS=Ag_2S+ZnCl_2$. No silver is found in the filtrate because silver sulphide is not soluble in that menstruum. C. J. B. Karsten stated that *lead sulphide* has as little action as *bismuth sulphide* on silver chloride whether aq. ammonia or a soln. of sodium chloride be the solvent. F. J. Malaguti and J. Durocher found that a soln. of silver chloride in ammonia water or in a soln. of sodium thiosulphate reacts: $2AgCl+PbS=PbCl_2+Ag_2S$; *mercuric sulphide* also reacts in a similar manner: $2AgCl+HgS=HgCl_2+Ag_2S$.

Representing what F. J. Malaguti and J. Durocher call the decomposing faculty of various sulphides, etc., on silver chloride by the number of parts by weight of silver chloride decomposed in 18 hrs. by 100 parts of the sulphide, etc., when 0·2 grm. of the sulphide, etc., is treated with 7 c.c. of an ammoniacal soln. of silver chloride containing 0·002 grm. of the salt per c.c., they obtained for the decomposing faculty of artificial galena, 5; Heulgoat galena, 5; galena very rich in silver from Freiberg, 7; seleniferous galena, with curved faces, from Beresow, 8; antimonial galena, with slightly curved faces, from Saint-Mandé, 10; arsenical galena, with the solid angles and the edges of the cube truncated, from Saxony, 13; seleniferous galena from Fahlun, 13; crystallized blende from Saxony, 1; sulphide of zinc, prepared in the dry way, 3; very pure blende from Königsberg, 3; cadmiferous blende from Prizbram, 4; fibrous blende from Pontpéan, 5; lamellar blende from Pontpéan, 5; black artificial blende, obtained by sublimation, 10; artificial sulpide of cadmium, 14; cubical iron-pyrites, 0·25; white or prismatic pyrites, 0·50; white globular pyrites, 1; sulphide of cobalt, prepared in the dry way, 6; sulphide of nickel, prepared in the dry way, 8; sulphide of bismuth, prepared in the dry way, 3·50; protosulphide of tin, prepared in the dry way, 0·33; bisulphide of tin, or mosaic gold, 31; sulphide of antimony, 0·002; sulphide of molybdenum, 0·001; native cinnabar, 0; sulphide of copper (cuprous sulphide) artificially prepared, 337; copper-pyrites of unknown locality, 10; bornite or purple copper-ore, $3Cu_2S+Fe_2S_2$, from Sweden, 10; bornite, of a lilac tint, from Tunaberg, 180; cupro-nickeliferous pyrites from Espedal in Norway, 2; stromeyerite, $AgS+Cu_2S(Ag_2S+Cu_2S)$, 3·25; compact bournonite, 11; smaltine, 170; kupfer-nickel, 470; mispickel, forming a fibrous mass, 0·5; crystallized mispickel from Utö, 17·5; and nickel-glance from Schneeberg, 440.

They found three types of reaction: (i) double decomposition: $MS+2AgCl=Ag_2S+MCl_2$; (ii) reduction: $MS_2+2AgCl=Ag_2S+MS+Cl_2$; (iii) double decomposition and reduction: $M_2S+4AgCl=2Ag+Ag_2S+2MCl_2$. The general conclusion is that the decomposing faculty of the sulphides may be modified by the state of purity, the density, the composition, the mol. state, the cohesion, the structure of the substance, and the crystalline form, even by modifications in crystals belonging to the *same* system of crystallization.

The metals which give hydrogen when treated with hydrochloric acid reduce silver chloride to metallic silver; **zinc** is frequently used for this purpose, and it does its work equally well in contact with silver chloride, or in a soln. of the chloride in aqua ammonia. K. Seubert and A. Schmidt [22] found silver chloride to be reduced by heating it dry with **magnesium.** According to N. W. Fischer, the metals zinc, **cadmium, mercury, copper, iron, arsenic, antimony, bismuth, lead,** and **tin** when shaken with silver chloride suspended in water, or, better, in dil. hydrochloric or sulphuric acid, precipitate the silver, but they do not do so under alcohol or ether. D. Tommasi, U. Antoni and G. Turi, and J. Schnauss found copper and mercury reduce ammoniacal soln. of silver chloride. E. Vigouroux also reduced silver chloride by means of aluminium; and R. Escales found that if powdered **aluminium** be mixed with silver chloride, the reaction once started proceeds with explosive violence unless an excess of aluminium be present. According to F. T. Sonneschmid, the presence of sodium chloride is necessary for the reduction with mercury. According to J. N. Brönsted, the heat of the reaction with mercury is $AgCl+Hg=HgCl+Ag+1·4$ Cals., and with lead, 11 Cals. D. Tommasi says that **sodium amalgam** does not reduce silver chloride. J. H. Gladstone and A. Tribe found that a plate of silver dipping in molten silver chloride becomes covered with crystals of silver. A soln. of **ferrous sulphate** was found by R. Keir, H. Rose, G. Wetzlar, and J. Seymour not to reduce silver chloride in light or in darkness; as R. Keir puts it "luna cornea is not decomposed by martial vitriol." J. Seymour also found that **stannous chloride** does not reduce silver chloride, but **alkali stannite** soln. do. According to G. Skutari, silver chloride is reduced by **sodium hyposulphite,** $Na_2SO_2+2AgCl=2Ag+2NaCl+SO_2$, and the same result is obtained if the silver chloride is in soln. in aq. ammonia or potassium cyanide. A. Vogel showed that cold **sulphurous acid** does not reduce silver chloride, but the salt becomes grey if this acid be warm; A. Geuther and P. Berthier found that boiling **alkali sulphite** in presence of ammonium chloride reduces silver chloride to metal. A. Rosenheim and S. Steinhäuser found cold soln. of the **alkali bisulphites** dissolve silver chloride, and, after standing a little while, deposit metallic silver. P. Jannasch found a hot soln. of **hydroxylamine hydrochloride** and sodium hydroxide dissolves the silver halides. E. Riegler found silver chloride to be reduced to the metal by **hydrazine sulphate** in alkaline soln.—nitrogen is at the same time evolved. According to F. Mawrow and G. Mollow, **hypophosphorous acid** reduces silver chloride slowly; and, according to M. C. Lea, a dil. soln. of **sodium hypophosphite** produces no visible effect with silver halides, but it brings these substances into the same condition as they exist in the latent photographic image; conc. soln. of the hypophosphite colour the silver halides purple-brown. J. Seymour says sodium hypophosphite reduces silver chloride to the metal. G. B. Bonino found **potassium ferrocyanide** converts silver chloride into insoluble potassium silver ferrocyanide, AgK_3FeCy_6—silver bromide or iodide is not affected.

A. Vogel, and A. Sauer noted that cold **sulphuric acid** has no action on silver chloride; hot sulphuric acid dissolves some silver chloride and deposits it again on cooling; boiling sulphuric acid forms silver sulphate and hydrochloric acid. Native silver chloride is, however, attacked but slowly even by the boiling acid. G. J. Mulder found that if dil. sulphuric acid be distilled in darkness over silver chloride some hydrochloric acid will be found in the distillate. T. E. Thorpe, and C. S. Pierre noted that with **nitric acid** some silver nitrate is formed.

H. Moissan found that **fluorine** displaced the chlorine in silver chloride. J. J. Berzelius says that molten silver chloride absorbs chlorine gas and gives it up on cooling. The action of the other halogens on silver chloride has been much discussed. The heats of formation are AgCl, 29·44 Cals.; AgBr, 23·0 Cals.; and AgI, 14·66 Cals. Consequently, the formation of silver bromide or iodide by the action of the proper halogen on silver chloride should be an endothermal process, and therefore, by M. Berthelot's *le principe du travail maximum,* should not occur. P. Julius, however, showed that the chlorine can be completely displaced by bromine or iodine at a red heat if the action be prolonged. This, said M. Berthelot, is because the heats of formation of the silver halides are not the same at high as they are at ordinary temp. According to P. Julius,[23] air charged with **bromine** vapour converts silver chloride into bromide; but, says A. Potilitzin, at ordinary temp. the exchange is very slow. According to M. Berthelot, if silver chloride be suspended in water, it readily takes up bromine, which can be removed by the passage of a current of air. According to P. Julius, **iodine** vapour, and, according to N. N. Beketoff, a soln. of iodine in chloroform, slowly converts silver chloride into the iodide. According to C. Löwig, silver chloride is slightly soluble in hydrobromic acid, forming some silver bromide; and, according to H. St. C. Deville, hydriodic acid forms hydrochloric acid and silver iodide. Both reactions are exothermal, but conversely, hydrochloric acid displaces bromine from silver bromide. M. Berthelot tried to explain this by his principle of maximum work by supposing that hydrochloric acid forms *un chlorhydrate de chlorure d'argent.* The action of the metal bromides and iodides on silver chloride has been studied by F. Field, A. Potilitzin, and M. Berthelot. Further, A. Colson covered silver chloride with an alkali chloride, and he found that the latter diffused into the former when the mass was heated to a temp. below the m.p. of either; thus presenting an example of the diffusion of a solid. H. Baubigny found **iodic acid** at 200° produces silver iodide, and **ammonium iodate** and ammonia form ammonium iodide, which then reacts with silver chloride, forming the iodide. According to G. Mazzaron (1898), silver chloride gives chlorine, not chromyl chloride, when treated with potassium dichromate and sulphuric acid. F. W. O. de Coninck showed that **iodoform** converts silver chloride into chloroform and silver iodide. A. Mailfert found that **ozone** acts but slowly on silver chloride.

According to P. Berthier,[24] silver chloride dissolves in all proportions in fused **lead oxide,** and when galena is added to the mixture, the silver chloride is all reduced to the metal by the lead set free in the reaction: $2PbO+PbS=SO_2+3Pb$. F. J. Malaguti and J. Durocher found cuprous oxide exerts no appreciable action on silver chloride in water at 100°, but if some alum, ferrous sulphate, or cupric sulphate is present, the silver chloride is reduced; but the action is less energetic than it is with iron or copper with or without these salts. P. Berthier found that boric acid decomposes silver chloride only when heated in the presence of water vapour. P. Berthier stated that fused borax or siliceous fluxes dissolve silver chloride, forming an opalescent mass—it is doubtful if this mixture is a true soln.

G. Wetzlar [25] first reported the formation of **sodium silver chloride.** A boiling conc. soln. of sodium chloride dissolves silver chloride, and on cooling deposits cubic crystals of the double salt; the same salt was made by adding silver nitrate to a boiling soln. of sodium chloride until some silver chloride remained undissolved. His analyses were too indecisive as to the composition of the double salt to be "worth communicating." He found that the double salt could exist only in a very conc. soln. of sodium chloride, and was decomposed by a more dil. soln. as well as by water into silver chloride which separates in numerous voluminous flocks, and the alkali chloride which remains in soln. The crystals of the double salt were stated to be unaffected by exposure to the most intense sunlight, and not to be reduced by adding ferrous sulphate to the soln. of sodium chloride containing the double salt. He also found that potassium, calcium, and other "electropositive metallic" chlorides combined with silver producing analogous double compounds. A. C. Becquerel prepared octahedra and tetrahedra of double salts of silver chloride with potassium and sodium chlorides by the method he employed for sodium cuprous chloride. The soln. have been examined by O. Sackur, F. Cornu, and G. S. Forbes, and, as already indicated, the crystalline solid is probably a solid soln., although complexes do exist in soln. J. B. J. D. Boussingault prepared a crystalline mass by cooling a soln. of silver chloride in fused sodium chloride. The mass is decomposed by water, and is coloured violet by exposure to light. As already indicated, the work of F. Cornu, W. Botta, and C. Sandonnini shows that fused mixtures of sodium and silver chlorides furnish a continuous series of mixed crystals. G. Tammann showed that when the mixed crystals are treated with water, the sodium chloride is completely extracted when the proportion of silver chloride falls below 0·625, but not when it exceeds 0·75.

As previously indicated, C. Sandonnini's thermal study of *lithium chloride* and silver chloride showed that two types of mixed crystals are produced with a gap between 16 and 60 mols per cent. of silver chloride. S. F. Schemtschuschny did not obtain evidence of a compound of silver chloride and *potassium chloride* on the f.p. curve. O. Sackur, and G. S. Forbes obtained evidence of the formation of complexes in soln. of silver chloride in potassium chloride soln. C. Sandonnini and P. C. Aureggi in their thermal analysis of mixtures of *rubidium chloride* and silver chloride obtained a V-eutectic curve at 253° with 60 mols per cent. of silver chloride; there was no definite indication of a compound. H. L. Wells and H. L. Wheeler obtained rhombic crystals of **cæsium silver chloride,** $2CsCl.AgCl$, with axial ratios $a:b:c=0·971:1:0·244$, by saturating a very conc. soln. of cæsium chloride with silver chloride; a compound of the composition $CsCl.AgCl$ was obtained by C. Sandonnini and G. Scarpa in the f.p. curve of mixtures of the component salts. E. H. Ducloux also studied this salt. G. Poma and G. Gabbi found that silver chloride and *cuprous chloride* are completely miscible in the molten state, but in the solid state, P. de Cesaris found a gap between 7 and 10 and between 12 and 92 mols per cent. of cuprous chloride. According to C. Sandonnini, the m.p. curve falls from the m.p. of silver chloride to a eutectic at 260°

with 54·6 mols per cent. of cuprous chloride and then rises to the m.p. of cuprous chloride. According to G. Poma and G. Gabbi, the m.p. curve falls from the m.p. of cuprous chloride to 250° with 56 mols per cent. of silver chloride, and then rises to the m.p. of silver chloride.

§ 15. Action of Light on Silver Halides

When silver chloride is exposed to light, it darkens, assumes a violet tint, which passes into brown, and finally turns black. This fact was made known by C. Gesner[1] in his *De omni rerum fossilium genere* (Tiguri, 1565), for he recorded that horn silver darkens when exposed to light; R. Boyle (1660) noted that horn silver blackens in air; and G. Suckow specially studied the action of light on chemical compounds—*vide* introduction to silver chloride. *Chlorine is evolved when white silver chloride is blackened in light.* If white silver chloride under water in a closed flask be exposed to sunlight, G. Wetzlar[2] noted that the contents of the flask furnished chlorine. This continues time after time, the amount becoming smaller and smaller until at last what little chlorine is given off is converted into hydrochloric acid and oxygen. Even then, the innermost part of the white silver chloride remains unchanged. The loss of weight which occurs is small—N. W. Fischer found 0·1473 per cent.; G. J. Mulder, 0·155 per cent.; R. Hitchcock, 8·57 per cent.; and A. Richardson, 8 per cent.; while E. von Bibra found no perceptible loss after five weeks' exposure; D. Tommasi could detect virtually no loss of chlorine; P. P. Koch and F. Schrader that with the light from an arc filtered through 80 cms. of a one per cent. soln. of cupric sulphate, the silver halides do not change more than 1 to 2 per cent. in weight. According to E. Sonstadt, some hydrogen peroxide is formed; and, according to W. R. Hodgkinson, ozone is formed.

P. P. Koch and F. Schrader also showed that if silver bromide is definitely darkened by a light of 3200 candle metre seconds, in 5 seconds, in the same time silver chloride is darkened by light of 940 candle metre seconds. Ten minutes' illumination of silver iodide by the same light only gave a weak greyish-black coloration.

According to C. F. A. Morren, chlorine water restores the white colour of blackened silver chloride so that the chlorine liberated during the blackening of silver chloride sets up a back reaction. Silver chloride, when sealed in a glass tube with chlorine water remains white so long as free chlorine is present, but it becomes brown when the chlorine has been all converted into hydrochloric acid. The white colour is restored when the tube with the brown chloride is placed in diffused daylight or in darkness. G. Wetzlar found the blackening is slower under a soln. of sodium or potassium chloride than under water. E. von Bibra says that white silver chloride is not blackened under aq. soln. of cupric or ferric chloride; nor, according to H. W. Vogel, is it blackened under mercuric chloride soln., but it is blackened under acetic acid, and the mineral acids. C. W. Scheele said that white silver chloride is not blackened under nitric acid, but F. Guthrie, G. Wetzlar, and

E. von Bibra said that it is blackened under dil. or conc. nitric acid, and G. C. Wittstein stated that under nitric acid of sp. gr. 1·23, it is coloured pale violet by two days' exposure to daylight: and dark violet by an hour's exposure to sunlight; while under nitric acid of sp. gr. 1·4 it remains white in diffused daylight, and is coloured pale violet by an hour's exposure and dark violet by 4 hours' exposure to sunlight. G. Wetzlar also found the white chloride to be discoloured under hydrochloric acid; while H. W. Vogel, and E. von Bibra found the blackening to be delayed under conc. sulphuric acid; H. Vogel noticed only a faint discoloration under aqua regia; and, according to G. Wetzlar, it is not blackened under a soln. of ferrous sulphate. H. Rose, and E. von Bibra found silver chloride is not blackened when mixed with mercurous chloride; and F. Field states that silver chloride crystallized from an aq. soln. of mercuric nitrate remains unchanged, and also if it is exposed in a moist condition to sunlight. J. J. Pohl found silver chloride, prepared at 60°–80°, and kept at this temp. in the liquid, is not blackened after many days' exposure to light; and the darkened silver chloride becomes paler when heated, but it does not become white. H. B. Baker found white silver chloride under dried benzene is blackened on exposure to light, and, according to M. C. Lea, also under carbon tetrachloride, but, according to H. B. Baker, not if the solvent be thoroughly dried and air be excluded. N. W. Fischer found the white chloride to be discoloured under alcohol, ether, and nut oil.

White silver chloride is not discoloured in darkness at temp. below 100°. Although G. J. Mulder[3] stated that white silver chloride gradually turns grey when submerged in water, and protected from light. E. von Bibra could not detect the slightest discoloration when the chloride was kept for 8 days with light completely excluded, but when the temp. exceeded 100°, the chloride was soon discoloured. According to T. J. Seebeck,[4] *the presence of moisture is necessary for the discoloration of white chloride in light*, for it is not decolorized in vacuo over sulphuric acid, and R. E. Hughes exposed thoroughly dried silver chloride to intense sunlight without discoloration, but directly ordinary (moist) air was introduced, the discoloration occurred. T. J. Seebeck also found that covering the white chloride with alcohol protected it from blackening for some time. According to J. J. Ackworth, silver chloride becomes insensitive to light if heated to 220°; this M. C. Lea attributes to the need for heating the chloride to this temp. to make sure the moisture is all removed, and not to the existence of a variety insensitive to light.

The early observers on the darkening of silver chloride in light assumed that the result is a simple decomposition of silver chloride into metallic silver[5] and chlorine, but the fact that the darkening occurs under conc. nitric acid, or other solvents of silver, ousts the hypothesis that the darkening is due to the liberation of metallic silver. To get over this difficulty F. Guthrie supposed that the metallic silver which separates is in a special mol. or passive state.

In 1814, N. W. Fischer[6] suggested that the darkening is due to the partial decomposition of silver chloride, resulting in the production of a subchloride; and A. Riche assigned to the supposed subchloride the formula Ag_3Cl_2. M. C. Lea[7] suggested that a compound of silver chloride and subchloride, $AgCl.nAg_2Cl$, is formed.

J. J. Berzelius[8] stated that the blackened silver chloride is not attacked by nitric acid, but R. Hitchcock says that an amount of silver passes into soln. which is eq. to the chlorine which has been developed. H. B. Baker whitened the black chloride by boiling it with hydrochloric acid. C. F. Berthollet says that the blackened chloride dissolves without residue in aqua ammonia, but E. Mitscherlich and others have shown that a little changed chloride remains undissolved. M. C. Lea found that when the blackened chloride is digested with a soln. of sodium thiosulphate, a little metallic silver remains undissolved. H. B. Baker states that blackened silver chloride dissolved in a conc. neutral soln. of potassium chloride, and the resulting soln. has an alkaline reaction.

According to H. W. Vogel,[9] the dark product is an oxychloride identical with the black product obtained by L. Wöhler by the action of hydrochloric acid on silver suboxide; and if E. von Bibra's observation be correctly interpreted that the silver chloride suffers no appreciable change in weight although chlorine is lost, it would follow that the escape of chlorine is compensated by the absorption of some other substance. R. Hunt stated that the presence of oxygen is necessary for the blackening, and his demonstration that the decomposing chloride absorbs or combines with oxygen is as follows: Some pure chloride of silver was arranged in a bent tube closed at one end, and the other end immersed in a bottle of distilled water. In this state the chloride was exposed for many days to the action of sunshine, during which time it was frequently shaken, for the purpose of exposing the whole of the powder to its influence. As the chloride darkened the water rose into the tube, and it gave a precipitate of chloride of silver on the addition of the nitrate, thus appearing to prove the substitution of oxygen for chlorine under the agency of solar radiation. It was quite evident that some absorption of atm. air had taken place. R. Hunt's proof is not conclusive, but H. B. Baker repeated the experiment taking extreme precautions to ensure thorough desiccation, and he came to a similar conclusion. H. B. Baker showed that the blackening which occurs when white silver chloride under dried benzene is exposed to light, is not the normal type of blackening because the product is metallic silver removable by treatment with nitric acid. H. B. Baker suggested that an oxychloride with the ultimate composition Ag_2ClO is formed, which when kept in the dark absorbs more oxygen, forming a white oxychloride. W. R. Hodgkinson supposed the oxychloride is Ag_4OCl_2, that is, AgCl.Ag.O.Ag.AgCl. M. C. Lea says the blackening cannot be due to the formation of an oxychloride because it occurs under naphtha where oxygen and moisture are excluded. The phenomenon may be here related with that observed by H. B. Baker with benzene. E. von Bibra supposed that the blackening is due to change of white silver chloride into a dark-coloured silver chloride in a different molecular or allotropic state.

As previously indicated, C. W. Scheele showed that violet light is more effective than light from the other parts of the spectrum in darkening silver chloride, and J. Senebier, in his *Mémoires physico-chimiques sur l'influence de la lumière solaire pour modifier les êtres des trois règnes de la nature* (Genève, 1782), states that when horn silver in a darkened room is exposed to light of various colours, the times required for darkening are as follows:

Violet.	Purple.	Blue.	Green.	Yellow.	Orange.	Red.
15	25	29	37	330	720	1200 secs.

There is nothing to show if the intensity of these different-coloured lights was the same. R. Bunsen and H. E. Roscoe found that the amount of silver chloride decomposed in a given time is not proportional to the intensity of the incident light, but diminishes with time. By exposing a thin layer of silver chloride to light, the initial colour is violet-red, which changes to black. The black product is soluble in dil. nitric acid. Three layers have been distinguished in a film of insolated silver chloride—(i) black metallic silver; (ii) red silver chloride; and (iii) white unaltered chloride. Coloured silver chloride was obtained chemically by G. Wetzlar by the action of soln. of ferric, cupric, or mercuric chloride, for a short time on metallic silver. The following illustrative experiment is due to G. Staats:

> A plate of polished silver was immersed for 10 minutes in a 5 per cent. soln. of ferric chloride, by which the metal became covered with a slate-coloured film. The metal was then placed under a frame with strips of red, green, orange, and blue glass, and exposed to a bright light. The colours were reproduced on the metal plate.

The coloured products obtained by the action of light on silver chloride can be obtained by chemical processes. For example, J. Cavalier passed a stream of dry chlorine in darkness through an ammoniacal soln. of silver chloride, and obtained first a turbidity, and finally a black precipitate. Both E. von Bibra and F. P. Dulk believed that J. Cavalier's black product is not identical with the black product obtained by the action of light on silver chloride. M. C. Lea called the coloured derivatives of the silver halides *photo-salts*—*e.g.* photochloride, photobromide, and photoiodide :

> Of the three haloids, the chlorine salt is the most interesting, because of its relations to heliochromy ; it is also the most stable of the three compounds and exhibits perhaps a finer variety of coloration, though the bromide and iodide are also obtainable in very beautiful tints. The chloride shows all the warm shades from white to black through the following gradations : white, pale flesh colour, pale pink, rose colour, copper colour, red purple, dark chocolate, black. These compounds are obtained in an endless variety of ways : by chloridizing metallic silver ; by acting on the normal chloride with reducing agents ; by partly reducing silver oxide or silver carbonate by heat and treating with HCl ; by forming suboxide or a sub-salt of silver and treating with HCl followed by nitric acid ; by acting on subchloride with nitric acid or an alkaline hypochlorite, etc. ; by attacking almost any soluble salt of silver with ferrous, manganous, or chromous oxide, etc., followed by HCl ; by reducing silver citrate by hydrogen and treating it with HCl ; by treating a soluble silver salt or almost any silver soln. with potash or soda and almost any reducing agent, cane sugar, milk sugar, glucose, dextrine, aldehyde, alcohol, etc., and supersaturating with HCl ; there is no easily oxidizable organic substance that I have tried that has failed to give this reaction. Also almost any salt of silver exposed to light, treated with HCl, and then with hot strong nitric acid, yields it. Almost any of these classes represents a long range of reactions, each susceptible of endless variation. In fact, the more the matter is studied, the more extended the range of reactions is found to be that give rise to the formation of this substance. To show how slight an influence will lead to the production of red chloride instead of white ; if freshly precipitated argentic oxide is mixed for a few minutes with starch or tragacanth paste and is then treated with HCl, the result is not white, but pink silver chloride.

M. C. Lea seems to regard the photohalides as adsorption compounds of silver halide and subhalide. He says that just as alumina unites with certain colouring matters to form *lakes*, so may the silver halides unite with a certain proportion of its own subsalt, which by the union quite loses its characteristic instability and forms a compound of great permanence. All varieties of photochloride are destroyed by a prolonged treatment with hot conc. nitric acid, but in some cases it may require 25 hours' boiling to convert it into the white chloride ; the photochloride, also, may even resist boiling aqua regia for a time. Exposure to light changes the brighter shades to purple or purple-black. Black specimens at 100°, in a drying oven, become purple or chocolate ; a grey variety may become pink. R. Lorenz and K. Hiege also attribute the darkening of silver chloride or bromide to the formation of ultra-microscopic particles of silver, so small that the crystals appear optically clear even if coloured violet. If the slightly darkened crystals be removed from light and heated to 350°, the darkening continues, but if heated without previous illumination, there is no darkening. The latent photographic image, on this hypothesis, is a complex containing colloidal silver. F. Weigert and W. Schöller say that silver chloride in an emulsion is of itself not sensitive to light, but that the colloidal metallic silver which is present in small proportions as an impurity, is the only substance present which is sensitive to light.

The photohalides, says L. Cramer, are normal halides coloured by colloidal silver, and those obtained by chemical processes are quite similar in their properties to those prepared by the action of light on the normal halides. The different colours correspond with the differences in the grain size of the colloidal silver. A. P. H. Trivelli like M. C. Lea regards the photohalides as normal halides coloured with the subhalides not metallic silver. Either hypothesis can be defended, but not the one to the exclusion of the other. The colloidal silver hypothesis is the simpler and is therefore preferred. L. Schaum and H. Lang studied the relation between the colour of the photohalide and the colloidal character of the adsorbed silver.

Photography.—A celluloid sheet or a glass plate is coated on one side with a film of collodion or gelatine containing, say, silver bromide in suspension, and dried, so as to form a *photographic plate.* The plate is placed in the camera, and momentarily *exposed* by focusing the image of the object to be photographed on to the plate. The silver bromide is affected in some way so that the most intense change occurs where the light is brightest, while the change is less intense in the shadows. No visible change is apparent until the plate is *developed.* The plate is developed by treating it with a reducing agent—ferrous sulphate, pyrogallol, or some special developer. The developer continues the change started by the light, but is without action on the unexposed parts of the plate. As a result, finely-divided silver is deposited on the parts of the plate illuminated by the light reflected from the object. The deposit is thickest where the light was most intense. Hence, the dark parts of the object appear lightest on the plate, and the light parts dark. The image is thus the reverse of the object, and the plate is accordingly called a *negative.* The silver salt which has not been affected by the light nor by the developer is now removed, and the image thus *fixed* on the plate by immersing the plate in a soln. of sodium thiosulphate. The plate is then washed and dried. A *print* is made by laying the negative upon sensitized paper—that is, paper prepared in a similar way to the negative—so that the light must pass through the negative before striking the paper. The negative absorbs the light in proportion to the thickness of the deposit of silver, so that the print has the same shading as the object. The paper is then treated with a soln. of sodium thiosulphate to fix the image. The print may be *toned* by immersing it in a soln. of gold chloride so that some of the silver is replaced by gold ; this gives the print a warm reddish tone ; if a platinum salt be used instead of gold, a steel-grey tone is produced. The image on the print will be the reverse of that on the negative, and will therefore correspond with the object. Hence the print may be called the *positive.*

It will be evident that although no visible change is apparent in the film of a photographic plate which has been exposed, the light must have produced a marked difference in the film on the exposed and unexposed portions of the plate because of effects subsequently produced by the developer. It is usual to say that the light has produced a **latent image** during the exposure. There can be no question, said R. Namais, that one of the most marvellous things in photography is the formation of the latent image. The latent image is destroyed by a great number of reagents —*e.g.* soln. of nitric acid ; the halogens ; cupric, mercuric, ferric, or auric chloride ; hydrochloric acid ; hydrobromic acid ; potassium persulphate, permanganate, or ferricyanide ; and by chromic acid—which attack the exposed more than the unexposed silver bromide. On the contrary, a soln. of sodium thiosulphate attacks the unexposed more rapidly than the exposed silver bromide, so also do soln. of ammonia, potassium cyanide, and ammonium bromide. The photographic developers in common use are able to reduce to metallic silver the so-called latent image, and yet do not reduce the silver halide which has not been modified by exposure to light.

The latent image may gradually disappear by a process which is regarded as a reversal of the effect produced by the exposure to light, and it seems as if a reversible reaction is involved. L. Baekeland calls this phenomenon *photo-retrogression.* In the so-called daguerreotype process the latent image persists a few hours ; in some more modern process the latent image persists for years. Photo-retrogression is noticed more with under- than with over-exposed plates.

C. F. Brush has shown that there is a period of induction in the formation of the latent image :

> Photographic action is slow in starting, involving considerable light energy which leaves no permanent record. If exposure is stopped at this stage, the starting action relapses almost wholly within a few minutes and is lost to further exposure. Once started, however, action increases rapidly to full activity and then remains substantially constant during further exposure. A relapse of sensitiveness follows exposure and is very marked at the end of a few hours. Photographic action, when fully excited, *continues many minutes after exposure,* gradually dying out. With the adopted period of exposure, this after action amounts to something like eight or ten per cent. of the whole. Within an hour or two after action has ceased, relapse sets in and amounts to about four per cent. in the first thirty hours, fully half of which occurs within the first four hours.

The reaction which is involved in the production of the latent image and in the photo-retrogression has been the subject of many hypotheses.

1. *The assumption that the halide is oxidized.*—J. von Tugolessoff assumed that the latent image is an oxidation product. He supposes that the silver salt is first oxidized to a higher valency, and subsequently decomposed into a subhalide or to

metallic silver. He attempted to demonstrate an increase in weight during the production of the latent image, when an unstable oxyhalide of silver is formed, say AgBr.O.AgBr, but L. Cramer was unable to establish the accuracy of J. von Tugolessoff's experiments on the oxidation of silver bromide by dil. soln. of hydrogen peroxide, sodium nitrite, etc., and he tried to show that oxygen is not necessary for the development of the latent image.

2. *The assumption that the halide suffers a physical modification.*—In this hypothesis it is assumed that the silver salt undergoes a physical change when the latent image is produced whereby the silver bromide remains silver bromide, but the nature of the combination into aggregates is modified. The product is then invested with the properties known to be possessed by the latent image, and the phenomenon is fully explained. For example, the silver halide after exposure to light is more prone to dissociation, and yields more quickly when reducing agents are present. R. Namais and C. Jones assume that the silver halide is polymerized by light and depolymerized during the photo-retrogression. F. Hurter and V. C. Driffield make the converse assumption, depolymerization in light, polymerization in darkness.

3. *The assumption that the halide forms a nucleus of silver.*—The old assumption that the latent image is due to the reduction of the halide to metallic silver has been revived by W. Ostwald, and R. Abegg in the assumption that the formation of the latent image is due to the precipitation of an infinitesimally small quantity of metallic silver which, acting as a germ or a nucleus, facilitates the reduction of the surrounding silver bromide. The latent image, however, shows none of the reactions of metallic silver, nor does it show the electrical potential of metallic silver; the hypothesis cannot be reconciled with the facts of development or of solarization in which longer exposure means more silver produced though the amount approaches a limit; more silver means a more rapid reduction of silver bromide, and not a less rapid reduction. L. Cramer has also shown that the latent image does not behave like a mixture of silver bromide and metallic silver. C. Jones found the behaviour of aqua ammonia also does not favour this hypothesis; and S. E. Sheppard and C. E. K. Mees found the hypothesis fails to account for the resistance of the latent image to oxidizing soln. of such potential as to destroy the metal silver.

4. *The assumption that a subhalide is formed.*—This hypothesis was suggested by C. Choiselat and M. Ratel in 1843 to explain the latent daguerreotype image. Taking the case of silver bromide, it is assumed that this salt decomposes into free bromine and silver sub-bromide, Ag_2Br, thus: $4AgBr \rightleftharpoons 2Ag_2Br + Br_2$. The bromine is presumably temporarily dissolved by the decomposed or undecomposed grain of silver bromide. The system is in equilibrium when the vap. press. of the bromine has reached a certain value. When the silver sub-bromide is exposed to the action of bromine gas in darkness, silver bromide, AgBr, is formed. The amount of silver bromide decomposed, for equilibrium, depends upon the intensity of the light. If bromine be removed from the sphere of the reaction, by, say, mixing the silver salt with a suitable organic compound which " binds " the bromine, the reaction proceeds to an end. The photochemical decomposition of silver bromide has been studied by R. Schwarz and H. Stock. Some early experiments by R. Luther pointed to the existence of definite compounds Ag_2Br or Ag_2Cl. He placed a weighed amount of powdered silver in a $\frac{1}{10}N$-soln. of hydrochloric acid; added measured amounts of chlorine water; and, after shaking the vessel to bring about equilibrium, he placed a platinum electrode in the soln. and measured the potential against a silver-plated platinum electrode in $\frac{1}{10}N$-hydrochloric acid containing an excess of silver halide. These measurements were made after each addition of chlorine water, and sharp breaks were observed corresponding with the composition Ag_2Cl and AgCl; but subsequent experiments by E. Baur, by F. Heyer, and by H. Weisz have failed to confirm R. Luther's measurements because R. Luther did not measure the equilibrium conc. W. Reinders also failed to find satisfactory evidence of the existence of any stable compound of silver chloride at high or at low temp. The reactions of the latent image are not consistent with the existence of one compound, whatever

it be, and accordingly A. P. H. Trivelli gets over the difficulty by postulating the existence of four intermediate compounds with specific colours: $5AgCl \rightarrow Ag_5Cl_4$ (green)$\rightarrow Ag_5Cl_3$ (blue)$\rightarrow Ag_5Cl_2$ (yellow)$\rightarrow Ag_5Cl_1$ (red)$\rightarrow 5Ag$, but since there is no evidence of the existence of the alleged compounds, the hypothesis has not made much headway.

5. *The assumption that the latent image is a solid solution.*—Since the latent image is not a reduction product of silver halide—a definite subhalide, or free metallic silver—following M. C. Lea's suggestion, the latent image is considered to be a phase of variable composition with silver bromide as the end term. These solid soln. have been prepared by L. Cremer and by W. Reinders, and their properties are in harmony with observations. There is no means of distinguishing whether the latent image consists of a solid soln. of silver bromide and metallic silver, or silver bromide and silver subhalide; but the former hypothesis is simpler and fits in with the parallelism between the colours of the photohalides and those of colloidal silver. The arguments against the latent image being a reduction product are directed against the existence of free metallic silver or a definite free subhalide; they are invalid when directed against the solid soln. hypothesis. The properties of silver or a hypothetical subhalide absorbed in solid soln. by a large mass of silver bromide to form a phase of variable composition are quite different from the properties of a mixture. In the latent image, says C. Jones, " the amount of silver bromide which is decomposed must be exceedingly minute, small beyond imagination. The amount decomposed might be increased many thousand times before the product of decomposition would have accumulated in sufficient quantity for direct recognition," and the energy which is available during an ordinary exposure is quite inadequate to produce a material decomposition of silver bromide on the plate. F. Hurter and V. C. Driffield show that if all the energy available in a standard candle burning 0·0021 grm. per second be 0·016 Cal. per 100 sq. cms. of surface, a 10 seconds' exposure would then yield 0·16 cal. per 100 sq. cms. The amount of silver 0·0265 grm. which can be obtained by this exposure on the developed plate actually requires 5·6· cals. Hence, only 2·9 per cent. of the energy could be derived from the burning candle if all were converted into radiant energy; but, as a matter of fact, only a small fraction of the available heat is really converted into radiant energy. W. D. Bancroft adds that these difficulties, though very real, vanish entirely with the solid soln. theory because the difference in the energy content of the decomposed and undecomposed silver bromide can be theoretically made as small as we please; practically, the difference which can be detected depends upon the sensitiveness of the developer. The bromine set free by light is probably temporarily adsorbed on or in the grains of silver bromide, or on the parts of the silver bromide not exposed to light. This bromine may also pass into the air or it may react with gelatine, but if the conditions are favourable it may react with the silver in solid soln., and give the phenomenon of photo-retrogression. Hence, during photo-retrogression the latent image reacts with the halogen which comes mainly from the bromine adsorbed by the silver bromide; a small inappreciable amount may come from the decomposition of the gelatino-bromide of the film. In illustration, M. C. Lea showed how silver iodide may adsorb iodine, and how the silver halides generally can take up by adsorption many other foreign substances. For example, a dil. alcoholic soln. of iodine is quickly decolorized by silver iodide.

The so-called solarization, or reversal of the photographic image whereby the negative becomes positive, is primarily due to the silver halide and is independent of the nature of the associated materials it has obtained as a result of a prolonged exposure; by the antagonistic action of light of different colours; by an exposure to white light followed by treatment with an oxidizing soln. and subsequent exposure; by using white light during development; by very slowly developing an under-exposed plate; by very short and intense exposures followed by a short exposure to diffused light; by exposure to cathode rays followed by sunlight, etc. The latent image which gives rise to a negative under normal development consists of silver bromide with an excess of from 0·002 to 0·1 per cent. of silver; when the excess rises above 0·1 per cent. a positive results. M. C. Lea obtained effects simulating the latent image by the action of acids, press. or heat—*e.g.* characters were drawn on bromide paper by means of a glass rod dipped into sulphuric acid (1 : 2), the acid was washed away with water containing a trace of ammonia. When the plate was developed, brown marks appeared on a white surface. The effect, however, is not like the normal latent image, but is due to the removal of gelatine from the grains of silver bromide.

In 1801, J. W. Ritter found that silver chloride which had been darkened by the violet rays of the spectrum became lighter or bleached when exposed to the yellow and infra-red rays. This was attributed to the deoxidizing action of the less refrangible rays (at the red end), and the reducing action of the more refrangible rays (at the violet end). Analogous observations were made by W. H. Wollaston in 1804, by T. J. Seebeck in 1810, by J. Herschel in 1840, and by J. W. Draper. If an under-exposed iodized silver photographic plate or printing-out paper be exposed to yellow or red light, the opposite effect occurs, for the action started by the violet light is continued, hence E. Becquerel (1840) called the violet rays the *rayons excitateurs*, and the yellow and red rays the *rayons continuateurs*. Further investigations have shown that each colour of the spectrum can exert an oxidizing or a reducing effect which is determined by the nature of the substance sensitive to light. J. M. Eder adds:

> Although the oxidizing action of the red rays cannot be sharply distinguished from the reducing action of the violet rays, in the majority of cases yet examined, red light has in general an oxidizing action on metallic compounds, while violet light usually has a reducing action. A case in which red light can act as a reducing agent on metallic compounds is especially noticeable in the photography of the spectrum using silver salts and developing the picture. Violet and blue light have the most effect on compounds of the metalloids, for instance, on hydrogen and chlorine mixtures, on nitric acid, on sulphurous acid, on hydriodic acid, etc. (Hydrogen sulphide, however, is decomposed more rapidly by red light.) The action of light is partly a reducing one, depending on the nature of the substance in question. On organic compounds (especially the colourless ones) violet light usually has the strongest oxidizing action; dyes are oxidized most strongly by those rays which are absorbed. In all cases, however, the chemical action of coloured light comes under the law that those rays are the most effective which are markedly adsorbed by the light-sensitive substances.

T. von Grotthus showed that only those rays of light which are absorbed can produce chemical action, and that the action of a ray of light is analogous to that of a galvanic cell. The similarity in the products obtained by the action of light on sensitive substances, and those obtained by electrolysis, is taken to confirm the hypothesis as to the justness of the analogy between the action of a ray of light and of a galvanic cell. The electromotive force of light is low, and therefore the decomposition voltage of a substance must be low if it is to be susceptible to the action of light; if otherwise, the light sensitive substance must be admixed with something conventionally called a *depolarizer* which will lower its decomposition voltage. Hence, adds H. W. Vogel, the compounds of the metals which are sensitive to light are divided into two classes—those which are decomposed by the action of light alone, and those which are decomposed only in the presence of a substance which combines with one of the decomposition products. The sensitiveness of all substances to light is augmented by a suitable depolarizer. For example, silver nitrate can react with silver iodide, and consequently silver iodide is more sensitive to light in the presence of this agent. Similarly with silver bromide in place of the iodide, but with the chloride, the effect is not so marked. The decomposition of chlorine or bromine water in light, as previously indicated, is accelerated in the presence of tartaric or citric acid, and both acids are likewise attacked by the halogen. In some cases the depolarizer changes the sensitiveness of the system towards certain rays. These depolarizers are called optical sensitizers. In 1873, H. W. Vogel showed that a photographic silver bromide plate, stained yellow with the chemically inert aniline red, gave a maximum sensitiveness in the green not present when the aniline dye is absent. H. W. Vogel further showed that there is a relation between the sensitiveness of a silver bromide plate for certain wave-lengths and the absorption bands of the admixed dye. H. W. Vogel's results with silver chloride alone, and with silver chloride and coralline are indicated in Fig. 14. H. W. Vogel added: In order to make silver bromide sensitive to any desired colour, or to increase its existing sensitiveness for certain colours, it is necessary only to add a substance which will promote the decomposition of silver bromide, and which absorbs the rays in question, letting the others pass.

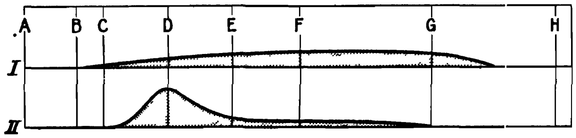

FIG. 14.—Action of different parts of the Spectrum on I. Silver Chloride alone ; II. Silver Chloride with Coralline.

T. Wedgwood [10] is considered to have been the first to obtain light-pictures. In 1802 he gave an account of a method of copying paintings and obtaining profiles of leaves by allowing light to pass through a more or less transparent object on the white paper or leather which had been moistened with nitrate of silver. H. Davy also repeated these experiments and succeeded in preparing pictures of small objects which had been magnified by the solar microscope. About 1814, these pictures were not permanent in light and had to be examined by candle-ilght. J. N. Nièpce tried to obtain permanent light pictures ; and about 1826 L. J. M. Daguerre was independently working in the same direction. J. N. Nièpce is now credited with having been the first to produce permanent photographs in a camera obscura. He coated a metallic surface with a layer of asphaltum, and exposed it to light in a camera for a whole day. The exposure rendered the asphaltum insoluble in Dippel's bone oil, while the soluble parts were removed by the oil. The pictures were lacking in detail. The metal if desired could be etched with acid. The parts protected by the insolated asphaltum were not affected by the acid. L. J. M. Daguerre was the first to employ silver iodide as a light-sensitive substance. In 1829 the two investigators joined forces in order as they said to develop " the discovery made by J. N. Nièpce and improved by L. J. M. Daguerre." In L. J. M. Daguerre's process, the vapour of iodine is allowed to act an a well-polished surface of silver as so to form a film of silver iodide. The film of iodide is then exposed to light in the camera obscura. In a short time the light produces an action which is not visible on the plate, but which develops when the plate is exposed to the action of mercury vapour. The portions of the iodide not affected by light were removed by a hot soln. of sodium chloride. J. Herschel's discovery of the better solvent action of sodium thiosulphate in 1819 was later utilized by L. J. M. Daguerre. This process is called the *Daguerreotype process.* In 1839 F. Talbot obtained negatives by a process which was improved in 1841. Paper coated with a film of silver nitrate was exposed in the camera, and the invisible image developed with a soln. of silver nitrate in acetic and gallic acids. The negative was soaked in white wax to make it transparent, and a positive prepared by placing the waxed negative on paper moistened with silver chloride and exposed to light. This procedure was called the *Talbot process* or the *calotype process.* In 1851, T. S. Archer used a transparent film of iodized collodion spread on glass as a photographic plate instead of W. H. F. Talbot's iodized paper. As a result, greater precision in the reproduction of detail was attained. The results were still further surpassed by the modern dry plate process in which a glass plate coated with an emulsion of silver bromide in gelatin—possibly also with a little silver iodide—is employed as the photographic plate.

§ 16. Silver Bromide

Silver bromide occurs in nature in cubes or octahedral crystals of *bromite* or *bromargyrite* of sp. gr. 5·8 to 6·0, and hardness 1 to $1\frac{1}{2}$. It is usually associated with silver chloride in Chili, Mexico, Honduras, etc., forming the so-called mineral *embolite*—*ἐμβόλιον*, an intermediate—in which the ratio Cl : Br varies indefinitely. The yellow and deep green varieties usually contain the largest proportion of bromine. From I. Domeyko's and P. Yorke's analyses of samples from Chili, embolite contains from 51 to 81 per cent. of the chloride and 18 to 49 per cent. of the bromide. A. Breithaupt [1] called the varieties of embolite with the larger proportion of bromine *megabromite*, and those with the smaller proportion *microbromite*. Silver bromide can be made by the action of bromine on silver, which, according to H. Gautier and G. Charpy,[2] is very slow, and which, according to V. von Cordier, progresses more rapidly in darkness than in light because of the decomposition of the resulting silver bromide. M. Berthelot says that silver is readily attacked by hydrobromic acid at ordinary temp., and A. Jouniaux has studied the equilibrium conditions in the reversible reaction, $2Ag+2HBr \rightleftharpoons 2AgBr+H_2$, which represents phenomena similar to those observed in the corresponding reaction between hydrogen chloride and silver. Bromine also forms silver bromide when it acts on silver chloride or iodide. A. Potilitzin, and T. S. Humpidge have shown that the reaction is very slow with silver chloride. The thermochemistry of the process has been discussed in connection with silver chloride. P. Julius observed that the reaction is complete when bromine vapour is passed over the molten halide; and that more rapidly with silver iodide than silver chloride. When silver chloride or some other sparingly soluble salt of silver—not the iodide—is warmed with a soln of potassium bromide, it is converted into silver bromide, $AgCl+KBr=AgBr+KCl$; if both silver bromide and chloride are present as solid phase, the system might be expected to be in equilibrium when the ratio KCl : KBr is equal to the ratio of the solubility product of the silver chloride and bromide; but there is a complication owing to the formation of a solid soln. of silver chloride and bromide, and the ratio of the chlorine and bromine ions in the soln. is dependent on the ratio of AgCl : AgBr in the precipitate, as was shown by F. W. Küster. The ratio [AgBr]/[AgCl] : [KBr]/[KCl] between soln. and precipitate undergoes very little change. A. Thiel also showed that in a series of mixed soln.

of silver bromide and chloride, in equilibrium with a normal soln. of potassium chloride and bromide, the change of potential steadily increases as the proportion of silver bromide increases. Silver bromate was found by C. Löwig to be decomposed into the bromide and oxygen.

As A. J. Balard first showed, silver bromide separates as a white curdy precipitate when a soln. of a silver salt is treated with hydrobromic acid or a soluble bromide. In his work on the at. wt. of bromine, G. P. Baxter prepared silver bromide in the following manner :

> Purified silver was dissolved in purified nitric acid, dil. with an equal volume of water, and heated until free from nitrous acid and the oxides of nitrogen. The soln. was still further diluted to a conc. of about a quarter normal and added slowly, with constant agitation, to a dil. soln. of an excess of purified ammonium bromide in a glass-stoppered precipitating flask, and the whole violently shaken to promote coagulation. By adding the silver soln. to the bromide, the occlusion of silver nitrate was almost wholly prevented. After standing about 24 hrs., the flask was again shaken, and allowed to stand until the supernatant liquid was clear. The precipitate was washed on a Gooch's crucible and dried for several hours at 130°, and finally for about 14 hrs. at 180°.

J. S. Stas tried to distinguish six different forms of silver bromide : (i) The white flocculent precipitate obtained by precipitation with an excess of silver salt ; (ii) the yellow flocculent precipitate obtained with an excess of hydrobromic acid or soluble bromide ; (iii) the pulverulent yellow salt obtained when the preceding product is agitated with water ; (iv) the yellowish-white product obtained by boiling the flocculent bromide with water ; (v) the white product obtained when the yellowish-white salt is boiled a long time ; and (vi) the yellow crystalline or fused salt. He showed that some of these forms have different solubilities, and different sensibilities to light. The precipitate with an excess of potassium bromide appears yellow owing to the adsorption of a little potassium bromide, which forms a yellow solid soln. When the flocculent precipitate is allowed to stand for some time, or when heated in boiling water, it forms a pulverulent mass—the action presumably depends on the smaller grain dissolving and reprecipitating on the larger less soluble grains. B. L. Vanzetti says that potassium bromide diffuses into soln. of silver nitrate as rapidly as potassium chloride or iodide ; and K. Jablczynsky, that the precipitate of silver bromide is formed twice as slowly as silver chloride. According to W. Böttger, a turbidity appears in a soln. containing $0{\cdot}3\times10^{-6}$ mol of silver bromide per litre ; and, according to L. Rolla, with potassium or sodium bromide and silver nitrate, with between 4 or 5×10^{-7} mol per litre. For the preparation of **colloidal silver bromide,** see the analogous colloidal silver chloride.

A. C. Becquerel[3] obtained **crystals** of silver bromide by heating a mixture of hydrobromic acid and silver in a sealed tube. C. Löwig obtained octahedral crystals by evaporating a soln. of silver bromide in hydrobromic acid ; and H. Debray by cooling a warm soln. of the chloride in mercuric nitrate. A. P. H. Trivelli and S. E. Sheppard prepared crystals of silver bromide by allowing a mixture of aq. ammonia and silver bromide to stand in a bottle, with frequent shaking, at 20° for about a week. The ammoniacal soln. was then allowed to crystallize (i) by dilution with water, (ii) by evaporating off excess of ammonia, (iii) by cooling the soln. Crystals of an ammino-complex are yellow, those of silver bromide are white. V. Bellach described tetrahedral forms; E. Baur, and J. V. Elsden hexagonal forms; F. W. T. Krohn, cubic crystals which crystallize as hexagons; and F. F. Renwick, both hexagonal and cubic forms. P. Groth placed silver bromide in the hexakisoctahedral class of the cubic system; and A. P. H. Trivelli and S. E. Sheppard, in the dyakisdodecahedral class because of the occurrence of pentagonal dodecahedra as in the case of stannic iodide, ferric disulphide, cobalt sulphoarsenide, cæsia-alum, and trimethylammonia-alum. The evidence of the existence of a metastable hexagonal form is not sufficient to establish the dimorphism of silver bromide. G. I. Higson could find no evidence of the polarization of light by the crystals. The phenomenon, say A. P. H. Trivelli and

S. E. Sheppard, may be due to reflection and not to anisotropism. E. Banks, V. Bellach, P. P. Koch and V. du Prel, G. I. Higson, L. Cramer, and F. W. T. Krohn showed that much of the silver bromide in emulsions used for sensitive photographic plates is crystalline. For the adsorption of gelatine during the crystallization of silver bromide in the presence of the protective colloid gelatine, see silver chloride. A. P. H. Trivelli and S. E. Sheppard studied the **corrosion figures** of silver bromide by aq. ammonia. A. Thiel showed that there is a continuous change of potential with mixtures of silver chloride and bromide in agreement with the formation of solid soln. of the two salts in all proportions. The **X-radiogram** of silver bromide has been studied by P. Debye and P. Scherrer, A. W. Hull, and R. B. Wilsey. The lattice is a simple cube with sides 2·89 A., and the distance of the nearest atomic centres, 2·89 A. The **specific gravity** of silver bromide is 6·245 (0°) according to G. F. Rodwell;[4] 6·215 (17°); according to F. W. Clarke the sp. gr. of the salt which has been fused is 6·473 (25°); and according to G. P. Baxter and M. A. Hines, 6·479. H. G. F. Schröder gave numbers ranging from 6·32 to 6·49. The sp. gr. of the molten salt at 427° is 5·595. G. Quincke gives 6·2. P. Walden, and F. A. Henglein studied the mol. vol.

T. W. Richards and G. Jones'[5] value for the **compressibility** of silver bromide is 0·00000259 megabar per sq. cm. or 0·00000262 atm., or 0·00000254 kilogram per sq. cm. between 100 and 500 megabars, and the mol. compressibility is 0·000075. According to J. E. Meyers and F. Braun, if subjected to a press. of 3000–50,000 atm. precipitated silver bromide in layers 3–4 mm. thick gradually becomes translucent. The *Fliessdruck*—that is, the press. required to make silver bromide flow through a small opening—is, according to N. Kurnakoff and S. F. Schemtschuschny, 18·6 kilograms per sq. mm. G. Quincke's value for the **surface tension** of molten silver bromide is 120 dynes per cm. when the sp. gr. is 6·2, and the **specific cohesion** $a^2=4$ sq. mm.

Silver bromide melts to a reddish liquid which on cooling forms a yellow horny translucent mass. The reported values for the **melting point** range from C. Sandonnini's[6] 419°, to K. Mönkemeyer's 422°, and to T. Carnelley's 434° ± 2°. According to K. Mönkemeyer, for a mixture of silver chloride, melting at 451°, and silver bromide, melting at 422°, containing about 65 mols per cent. of silver bromide, the m.p. is 413°. As O. Lehmann showed, the two salts form mixed crystals and the f.p. curve corresponds with H. W. B. Roozeboom's Type III curve. The results are in harmony with C. Sandonnini's observations on the electrical conductivity of mixtures of the two salts. The mixed crystals correspond with the mineral *embolite.* N. Kurnakoff and S. F. Schemtschuschny measured the **hardness,** and also the press. required to make the mixed crystals flow. According to H. Stolzenberg and M. E. Huth, the pale greenish-yellow crystalline solid is anisotropic and at 259° forms greenish-orange liquid crystals which are isotropic, and at 398° forms an orange-red liquid, but C. Tubandt and E. Lorenz could detect no sign of the alleged transformation point at 259° by the electrical conductivity method.

According to J. H. van't Hoff, silver bromide dissociates at 60° in vacuo in the sense of the equation: $2AgBr \rightleftharpoons 2Ag+Br_2$, until the press. of the bromine vapour reaches the very minute press. $2·9\times10^{-53}$ mm. The value for silver chloride is $5·4\times10^{-73}$ mm. H. V. Regnault's value for the **specific heat** of fused silver bromide is $Cp=0·0739$ between 15° and 98°. According to G. F. Rodwell, the salt steadily contracts from its fusion temp. down to —60°, when it attains its maximum sp. gr. H. Fizeau's value for the linear coeff. of expansion is 0·0000347, the mol. cubical expansion 0·00302.

J. Thomsen's value for the **heat of formation** from its elements, $Ag+Br_{liq.}=AgBr_{cryst.}+23·7$ Cals.; or 20·7 to 23·7 Cals.; or 398 kilojoules. According to M. Berthelot,[7] the heat of transformation AgBr (precipitated) to AgBr (crystalline) is 3·4 Cals. per mol. M. Berthelot also gives $Ag_2O+2HBr_{aq.}=AgBr+44·6$ Cals. to 51·2 Cals. The heat of precipitation in dil. soln. is 20·2 Cals. according to J. Thomsen. M. de K. Thompson found the **free energy of formation** of silver bromide—halogen liquid—is 23,000 cals., and the **total energy** of formation 23,400 cals.

W. Kohlrausch[8] found the **electrical conductivity** of silver bromide at 20° to be 0·35$\times10^{-5}$ reciprocal ohms, and K. Arndt and A. Gessler give for the conductivity at

150°	250°	350°	410°	418°	419°	500°	600°
0·00008	0·0044	0·11	0·722	melts	2·767	2 94	3·10

There is therefore a sharp break at the m.p.; and below the f.p. the conductivity rapidly decreases. C. Tubandt said that the current is carried entirely by the positive silver ion which, at 422°, has the velocity 0·15$\times10^{-3}$ cm. per sec. C. Sandonnini found the conductivity of fused silver bromide at its m.p. 422° to be 2·920 reciprocal ohms, and he investigated the electrical conductivities of fused mixtures of silver chloride and bromide. C. Tubandt studied the conductivity of the crystalline solid. J. C. Ghosh measured the conductivity, and calculated the **ionization,** α, of fused silver bromide at different temp., and found $\alpha=0·089$ per cent. at 473°, and 63·72 per cent. at 673°. L. Graetz has studied the influence of press., and S. Arrhenius that of light on the electrical conductivity of silver bromide. P. Dutoit and G. von Wiesse's value for the potential against 0·1N-$AgNO_3$ at 25° is 0·296 volt; M. Katayama's value for the e.m.f. of the cell Ag | AgCl | AgBr | Ag is zero, and for the cell Ag | AgBr | $PbBr_2$ | Pb is 0·342 $+0·00025(20-\theta)$ volts between 20° and 145°, and $AgBr+\frac{1}{2}Pb=\frac{1}{2}PbBr_2+Ag+9·6$ Cals. J. A. Wilkinson[9] reported that the salt has a bluish-violet fluorescence. For the **photoelectric effect,** see silver chloride. W. Wernicke gives for the **index of refraction,** for $\lambda=431$, $\mu=2·360$; $\lambda=486$, $\mu=2·303$; and $\lambda=656$, $\mu=2·2336$. S. Meyer[10] gave $-0·26\times10^{-6}$ mass units for the **magnetic susceptibility** of silver bromide at 19°; and no discontinuity was observed by T. Ishiwara when silver bromide was melted.

Silver bromide is less soluble in water than silver chloride; according to F. Kohlrausch's calculation[11] from the electrical conductivity data, a litre of water at 21° dissolves 0·000107 grm. of silver bromide, or 0·00058 milligram-eq. I. M. Kolthoff gave 4·1$\times10^{-13}$ for the solubility product at 18°. According to A. E. Hill's calculation from the equilibrium condition $AgSCy+KBr\rightleftharpoons AgBr+KSCy$, a litre of water at 25° dissolves between 6·6$\times10^{-7}$ and 8·1$\times10^{-7}$ mols per litre when the solubility of silver chloride is 0·000016, and that of silver thiocyanate 0·735. According to A. F. Holleman, the effect of grain size on the solubility of the different forms of silver bromide has been discussed by J. S. Stas; and the electrical conductivities of soln. of silver bromide by F. Kohlrausch and F. Rose. According to W. Böttger, all three silver halides in sat. aq. soln. are completely ionized. C. Löwig noticed that silver bromide dissolves in conc. *hydrobromic and hydrochloric acids*—a mol of hydrogen bromide in conc. aq. soln. dissolves nearly a mol of silver bromide. The latter salt separates on dilution with water, and crystals of silver bromide are obtained on evaporation. According to M. Berthelot, the soln. contains a *bromhydrate de bromure d'argent;* with hydrochloric acid an analogous chlorohydrate is formed. Silver bromide also dissolves in soln. of alkali bromides forming double salts.

Silver bromide dissolves in soln. of *sodium thiosulphate.*[12] According to T. W. Richards and H. B. Faber, 5 c.c. of a soln. containing 100, 200, 300, 400 grms. of crystalline sodium thiosulphate per litre at 35° dissolve respectively 0·118, 0·224, 0·341, and 0·613 grm. of silver as silver bromide. E. Valenta found 100 grms. of sodium thiosulphate soln., at 25°, contain

Per cent. $Na_2S_2O_3$ . .	1	5	10	15	20
Grms. of AgBr . .	0·35	1·90	3·50	4·20	5·80

E. Valenta says that the solvent power of *ammonium thiosulphate* is nearly the same as for the sodium salt, but A. and L. Lumière and A. Seyewetz say that the action of the ammonium salt is the faster. A. Rosenheim and S. Steinhäuser isolated tetragonal crystals of $4(NH_4)_2S_2O_3.NH_4Br.AgBr$, analogous with those obtained with silver chloride. E. Valenta also found that 100 grms. of a 1 : 10 soln. of *potassium, calcium*, or *barium thiosulphate*, at 25°, dissolves 0·73, 0·03, or 0·02 grm. respectively of silver bromide; 100 grms. of 1 : 10 and 1 : 5 soln. of *sodium sulphite* dissolve respectively 0·04 and 0·08 grm. of silver bromide at 25°; 100 grms. of 1 : 20 soln. of *potassium cyanide* dissolves 6·55 grms. of silver bromide; and 100 grms. of 1 : 20, 1 : 10, and 1 : 6⅔ soln. of *ammonium thiocyanate* at 20° dissolve respectively 0·21, 2·04, and 5·30 grms. of silver bromide. K. Hellwig finds the solubility of silver bromide in soln. of *silver nitrate* is smaller than that of silver iodide. P. Kremers, H. Risse, and K. Hellwig obtained products which they thought to be compounds of silver bromide and nitrate. The needle-like crystals obtained by cooling a hot soln. of freshly precipitated silver bromide in one of conc. silver nitrate, have a composition corresponding with $AgBr.AgNO_3$. I. Kablukoff, and G. Scarpa have investigated the f.p. curve of mixtures of silver nitrate and bromide and found a eutectic with 75 gram-mol. per cent. of silver nitrate at 155°. H. W. F. Wackenroder also found soln. of *mercuric nitrate* readily dissolve silver bromide.

According to E. C. Franklin and C. A. Kraus, silver bromide is soluble in liquid ammonia,[13] and according to R. Jarry, and A. Joannis and M. Croizier, at —30° a white compound **silver triammino-bromide,** $AgBr.3NH_3$, can be obtained which, between 3·5° and 4·0°, passes into the sesquiammine $2AgBr.3NH_3$. R. Jarry also says the triammine is formed in aq. soln. if the water is sat. under a press. corresponding with the dissociation press. of the salt, namely—

−23°	−18°	−8°	0°	3·5°	8°	14°	20°	23°
140	195	360	605	745	920	1310	1820	2140 mm.
